Inversion Amalgam Chronopotentiometry

V.I.Bakanov and M.S.Zakharov

The review deals with the theoretical principles of the method of inversion amalgam chronopotentiometry. The transition times and the potential-time relations for the electrochemical dissolution of amalgams under galvanostatic conditions are analysed and the applications of the method in electroanalytical practise, in the study of the kinetics of electrode processes and adsorption, in the determination of the numbers of electrons involved in the reaction and diffusion coefficients, and in the study of complex formation, corrosion of amalgams, etc. are examined in detail. The fundamentals of the theory of electrode processes complicated by preceding, subsequent, and simultaneous chemical reactions are described. The possibilities and advantages of the method of amalgam chronopotentiometry in relation to other electrochemical procedures are indicated.
The bibliography includes 86 references.

CONTENTS

I. INTRODUCTION

One of the promising methods for the determination of low concentrations of elements and for the investigation of the kinetics of electrode processes on amalgams is that of inversion amalgam chronopotentiometry (MIAC). The studies carried out hitherto have shown that this method is distinguished by the simplicity of the apparatus employed and of the mathematical treatment of the physicochemical relations. The latter factor makes it irreplaceable in the investigation of the chemical reactions accompanying the electrode process. The linear chronopotentiometric plot has already been used widely for these purposes, but the number of studies on the applications of inversion amalgam chronopotentiometry in the investigation of the kinetics of electrode processes and for the determination of microconcentrations of elements is still small. This is probably due to the novelty of the method (the first studies by this method were published in 1966) and the lack of a review dealing with the method.

II. THE METHOD OF INVERSION AMALGAM CHRONOPOTENTIOMETRY

The method of inversion amalgam chronopotentiometry (or simply amalgam potentiometry) is a variety of the galvanostatic method, the fundamental principles of which have been described[1,2]. In this method analysis of the transition times and of the shape of the potential-time curve yields information about the presence of the depolariser in the amalgam and the physicochemical characteristics of the electrode process are determined.

The galvanostatic method was used for the first time to investigate the electrochemical dissolution of amalgams by Zbinden[3]. He demonstrated the possibility of determining copper at concentrations down to 10^{-8} M in the electrochemical dissolution of copper amalgam. The stepwise variation of the current and chemical dissolution on open circuit were used by Bruckenstein and Nagai[4] to determine thallium and lead at concentrations of 2×10^{-7} M. They obtained the amalgam at a rotating platinum electrode.

The method of inversion amalgam chronopotentiometry, which is essentially a new electrochemical procedure, has been put forward in a number of investigations[5-9]. Three stages must be distinguished in this method.

1. Preliminary electrolysis. The metal in the solution is concentrated in the mercury electrode at a specified potential with formation of an amalgam or a sparingly soluble deposit.
2. Period without stirring. After pre-electrolysis, the solution is allowed to stand for 30–60 s; the flux from the electrode then becomes virtually zero[10].
3. Electrochemical dissolution of the metal from the amalgam when a direct current is passed through the electrode. Under these conditions, the pen recorder draws the curve (chronopotentiogram) characterising the time variation of the electrode potential (Fig. 1).

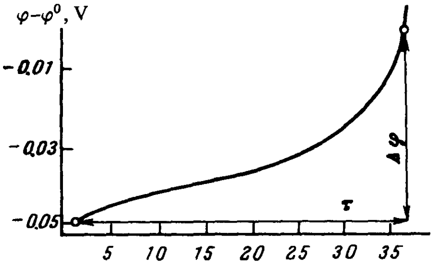

Figure 1. Theoretical chronopotentiometric curve.

If the electrochemical dissolution takes place in a stirred electrolyte, the system is allowed to stand until the attainment of the equilibrium (more precisely the initial) potential of the amalgam. The electrochemical-concentration and the solution-at-rest stages have been examined[10,11]. According to these investigations[10,11], a uniform distribution of the metal throughout the bulk of the electrode is observed towards the end of the second stage. This conclusion played an appreciable role in the formulation of the initial condition in the theory of inversion amalgam voltamperometry.

The usual circuit for galvanostatic measurements is assembled for recording chronopotentiometric curves in MIAC[1,2]. Two types of electrodes are used in the method: a mercury film electrode (stationary or rotating) and a stationary spherical mercury electrode consisting of a mercury drop with a radius not exceeding 0.1 cm. The mercury film electrode consists of a film of mercury between 4 and 20 μm thick deposited on a polished surface of the end-face of a silver wire 1–2 mm in diameter. The silver wire is pressed into a Teflon cylinder ($d \simeq$ 8 mm). A hermetically sealed three-electrode cell is used for the experiments. When a rotating disc electrode is employed, provision is made for a system regulating the rate of rotation (stepwise or continuous)[12]. The rates of rotation of the electrode employed usually do not exceed 10 000 rev min^{-1}.

III. THEORY OF THE METHOD IN THE ABSENCE OF KINETIC COMPLICATIONS

1. Expressions for the Transition Time

Suppose that a simple first-order electrochemical reaction

$$\mathrm{M(Hg)} \rightleftarrows \mathrm{M}^{z+} + ze$$

takes place at the electrode. We assume that there is an excess of an indifferent electrolyte in the solution, that the ψ_1 potential is negligibly small and independent of the cell potential, that there is no specific adsorption of the starting materials and products, and that the oxidised form of the electrochemically active substance is soluble in the electrolyte solution. We shall bear in mind that the reduced form of the electrochemically active substance diffuses under the conditions of restricted diffusion, i.e. during the measurement of the curve the diffusion layer extends throughout the entire volume of the electrode. The diffusion of the ions formed during the electrochemical dissolution of the amalgam from the surface of the electrode will occur under the conditions of a semi-infinite volume[13]. This is valid for $L_X \geqslant \sqrt{D_0 \tau}$, where L_X is the distance from the electrode surface to the wall of the electrolytic cell, D_0 the diffusion coefficient of the ions in solution, and τ the transition time. This condition is almost always fulfilled with the exception of thin-layer electrolysers.

In the electrochemical dissolution of the amalgam at a constant current density i the equations for the distribution of the concentration of the metal atoms are of the following form:

$$c^s_{\mathrm{R,f}} = c^0_R - j_R\left[v_R + \frac{1}{3} - 2\sum_{n=1}^{\infty}\frac{\exp(-\mu_n^2 v_R)}{\mu_n^2}\right], \tag{1}$$

on the surface of the mercury film electrode[5,14], where $\mu_n = n\pi$, $n = 1, 2, 3, \ldots$, $v_\mathrm{R} = D_\mathrm{R}t/l^2$, and t the time;

$$c^s_{\mathrm{R,s}} = c^0_R - j_R\left[3v_R + \frac{1}{5} - 2\sum_{n=1}^{\infty}\frac{\exp(-\bar{\mu}_n^2 v_R)}{\bar{\mu}_n^2}\right], \tag{2}$$

on the surface of a spherical mercury electrode[9], where $\bar{\mu}_n$ are the roots of the transcendental equation $\tan\bar{\mu}_n = \bar{\mu}_n$. In Eqns. (1) and (2) $j_\mathrm{R} = q_\mathrm{R}y_0/D_\mathrm{R}$, $q_\mathrm{R} = i/zF$, q_R is the flux from the electrode, z the number of electrons participating in the electrode process, F the Faraday, c^0_B the initial concentration of the metal in the amalgam, y_0 the characteristic dimension of the electrode ($y_0 = l$ for the mercury film electrode and $y_0 = r_0$ for the spherical electrode), and D_R the diffusion coefficient of metal atoms in mercury.

Eqns. (1) and (2) have been analysed in detail in a number of reports[14-16]. For large values of t, the exponential terms in these equations may be neglected. The following equations are valid (to within at most 1%)

for the mercury film electrode with $v_R \geqslant 0.35$ (when $D_R = 10^{-5}$ cm^2 s^{-1} and $l \leqslant 10^{-3}$ cm, we then have $t \geqslant 0.035$ s) and for the spherical electrode with $v_R \geqslant 0.14$ (when $r_0 \leqslant 5 \times 10^{-2}$ cm and $D_R = 10^{-5}$ cm^2 s^{-1}, we then have $t \geqslant 35$ s):

$$c^s_{\mathrm{R,f}} = c^0_R - j_R\left(v_R + \frac{1}{3}\right) \tag{3}$$

and

$$c^s_{\mathrm{R,s}} = c^0_R - j_R\left(3v_R + \frac{1}{5}\right). \tag{4}$$

When $v_R \geqslant 34$ (when $D_R = 10^{-5}$ cm^2 s^{-1} and $l \leqslant 10^{-3}$ cm, we have $t \geqslant 3.4$ s), Eqn. (3) reduces to

$$c^s_{\mathrm{R,f}} = c^0_R - j_R v_R. \tag{5}$$

Since the time required to record chronopotentiograms is usually greater than 5 s, Eqn. (5) may be used.

The expression for the transition time τ is determined by the condition $c_R(1, v'_R) = 0$, where $v'_R = D_R\tau/y_0^2$. From Eqns. (3), (4), and (5), we obtain for the film electrode

$$\tau = \frac{zFlc^0_R}{i} - \frac{l^2}{3D_R}, \tag{6}$$

$$\tau = \frac{zFlc^0_R}{i}, \tag{7}$$

and for the spherical electrode

$$\tau = \frac{zFlc^0_R}{3i} - \frac{r_0^2}{15D_R}. \tag{8}$$

Analysis[14-16] of Eqns. (6)–(8) leads to the following conclusions: (1) the transition time for electrodes of both types is directly proportional to the concentration of the metal in the amalgam c^0_R (this relation is used in electroanalytical practise); (2) according to Eqn. (7), the product $i\tau$ is independent of current density and is proportional to the amount of metal in the amalgam; (3) the independence of $i\tau$ of current density constitutes a criterion of the absence of a preceding chemical stage; (4) Eqn. (8) may be used to find the diffusion coefficient of the metal atoms in the amalgam; (5) the form of the relation between τ and i makes it possible to investigate the adsorption of surface-active substances on the electrode.

Table 1. The transition times in inversion amalgam chronopotentiometry with film (τ_1) and spherical (τ_2) electrodes and in chronopotentiometry under the conditions of linear semi-infinite diffusion (τ_3) ($z = 2$, $l = 10^{-3}$ cm, $r_0 = 0.06$ cm, $D_R = 10^{-5}$ cm^2 s^{-1}; the degree of concentration of the metal in the mercury film electrode was assumed to be 1000*).

$10^{-7}c^0_O$, g-ion cm^{-3}	$10^{-5}i$, A cm^{-2}	τ_1, s	τ_2, s	τ_3, s	$\frac{\tau_1}{\tau_2}$	$\frac{\tau_1}{\tau_3}$
1	4	480	6	1.6	80	300
2	2	960	12	6.4	80	150
4	1	1920	24	25.6	80	75

* The degree of concentration of the metal in the mercury film electrode usually exceeds this value[14].

The expressions for the transition time in amalgam chronopotentiometry differ from those in the usual chronopotentiometry[1] (under the conditions of semi-infinite diffusion). Table 1 lists the calculated values of τ for chronopotentiometry under the conditions of restricted linear and spherical diffusion (amalgam chronopotentiometry) and semi-infinite linear diffusion. Evidently, other conditions being equal, the transition time in amalgam chronopotentiometry is much longer than in direct chronopotentiometry (under the conditions of semi-infinite diffusion), the difference decreasing with increasing concentration or with decreasing current density. Table 1 demonstrates the clear advantages of the mercury film electrode (in relation to analytical practise).

2. Equations of Chronopotentiometric Curves

For a reversible electrode process, the equation of the chronopotentiometric curve is (in terms of the diffusion overvoltage–time variables)[14-17]

$$\eta_d = \frac{2{,}3\,RT}{zF} L_O, \tag{9}$$

where

$$L^f_O = \lg[v'_R/(v'_R - v_R)]\,(1 + 2j_0v_0^{1/2}/\pi^{1/2}c^0_O)$$

for the mercury film electrode ($v'_R \geqslant 3.4$), T is the absolute temperature, c^0_O the initial concentration of the metal ions in solution and

$$j_0 = \frac{il}{zFD_0};\; v_0 = \frac{D_0t}{l^2}.$$

For the spherical mercury electrode ($v'_R \geqslant 0.14$), we have

$$L^s_O = \lg\frac{(3v'_R + 0{,}2)}{3(v'_R - v_R)}\left[1 + \frac{j_0}{c^0_O}(1 - \exp v_0 \cdot \operatorname{erfc} v_0^{1/2})\right].$$

The plot of η_d against L_O is a straight line with a slope of $2.3RT/zF$. This serves as a criterion of the reversibility of the electrode process[17]; agreement between the theoretical and experimental values shows that the electrode process is reversible.

At high overvoltages ($\eta \gg RT/zF$) the irreversible electrochemical reaction $M(Hg) \rightarrow M^{Z+} + ze^-$ takes place and the equation of the chronopotentiometric curve simplifies greatly[14-17]:

$$\eta_{ir} = \frac{2{,}3\,RT}{\beta zF}\left(\lg\frac{i}{i_0} - L_{ir}\right), \tag{10}$$

where

$$L^f_{ir} = \lg\frac{v'_R - v_R}{v'_R} \text{ and } L^s_{ir} = \lg\frac{3(v'_R - v_R)}{(3v'_R + 0{,}2)}.$$

Hence the slope of the plot of η_{ir} against L_{ir} is βz; the exchange current density i_0 and hence the rate constant for the electrode process k_S may be found from the initial overvoltages taking into account the relation

$$k_S = \frac{i_0}{zF\,(c^0_O)^\beta\,(c^0_R)^\alpha}, \tag{11}$$

where α and β are the transfer coefficients for the cathodic and anodic processes respectively.

The main factors which determine the applicability of Eqns. (9) and (10) are the exchange current density, the overvoltage, and the transition time[14]. With decrease of i and η and with increase of τ, the processes shift towards reversibility and conversely.

A numerical estimate yields

$$4 \cdot 10^{-2} \geqslant k_S \geqslant 4 \cdot 10^{-5}. \tag{12}$$

The intermediate values of k_S correspond to a quasireversible (quasidiffusional) electrode process. A more detailed analysis of chronopotentiometric curves has been given elsewhere[14-17].

Some problems of amalgam chronopotentiometry at a mercury film electrode have also been examined by Igolinskii and Igolinskaya[18] and at a spherical mercury electrode by Galus[19] and Baranski[20].

All the above equations were obtained without taking into account the influence of the structure of the electrical double layer. In order to allow for the electrical double layer[21], the quantity ψ_1 must be introduced into the fundamental equation of electrochemical kinetics. If it is assumed that the electrode potential is distributed over the series-connected capacitances of the dense (C) and diffuse (C_d) components of the double layer and that the capacitance is independent of potential in the range of values of the latter corresponding to the chronopotentiometric curve, then

$$\psi_1 = \frac{C}{C_d}(\varphi - \varphi_0), \tag{13}$$

where φ_0 is the zero-charge potential.

The method of cyclic chronopotentiometry[1] (with current reversal), which makes it possible to investigate both the anodic and cathodic processes, is convenient for the study of the kinetics of electrode processes. The theory of amalgam chronopotentiometry with current reversal has been discussed[22,23]. The equations were derived on the assumption that the direction of the current is reversed at the instant of attainment of the transition time and that the current density is not equal to that in the cell before reversal. If a reduction process takes place after an oxidation process, then analysis of the theoretical relations gives rise to the following expression, which is simplest when the current densities for the forward and reverse processes are equal:

$$\tau = \frac{4}{3}\tau_1, \tag{14}$$

where τ_1 is the transition time of the oxidation process.

The characteristic points[23] on the cathodic branch of the chronopotentiometric curve in amalgam chronopotentiometry for a mercury film electrode are $\tau/4$ and 1.0716τ.

An interesting variety of the method of amalgam chronopotentiometry has been proposed[24-26], namely amalgam chronopotentiometry with a programmed current. Cases have been examined where the current was specified in the form of linear, exponential, and sinusoidal functions. The sinusoidal form of the specified current may find the greatest number of practical applications (under these conditions, the error in the determination of the transition time is fully excluded).

3. The Influence of the Charging of the Electrical Double Layer in Amalgam Chronopotentiometry

In the chronopotentiometric method a proportion of the charge supplied to the electrode is required to charge the electrical double layer (e.d.l.), which results in a discrepancy between the experimental and theoretical (obtained without allowance for the charging of the electrical double layer) relations[1]. Using the method of integral equations, de Vries[27] analysed theoretically the influence of the charging of the e.d.l. on chronopotentiometric curves for the electrochemical dissolution of amalgams from a mercury film electrode on the hypothesis that a diffusion-controlled process takes place at the electrode and that the e.d.l. capacitance is independent of the potential.

Using the Huber method, he solved the integral equation. The theoretical φ–t curves, calculated for certain values of K_C and h (see below), are presented in Fig. 2, while Table 2 lists the calculated shifts of the chronopotentiometric curves ($\Delta\varphi_{\tau/4}$) with and without allowance for the charging of e.d.l. Here $K_C = (RT/zF)C_d[c_R^0(\pi D_R\tau_\infty)^{1/2}]^{-1}$ is a parameter characterising the distortion of the chronopotentiometric curve, $h = l^2/D_R\tau$, $\lambda = t/\tau_\infty$, and τ_∞ is the transition time under the conditions of semi-infinite diffusion without allowance for the charging of e.d.l.

Table 2 shows that the error in the determination of the transition time is less than 4% for $h > 0.3$. This value of h characterises the applicability of the Delahay-Mattax method[1], which has been used here to determine the transition time. With decrease of h, the error in the determination of the transition time increases and the distorting influence of the e.d.l. capacitance becomes more appreciable (Fig. 2); the Delahay-Mattax method becomes unsuitable under these conditions. Fig. 2 shows that, with increase of the e.d.l. capacitance, the chronopotentiometric curves shift along the potential axis with a simultaneous change in the slope of the initial and final sections of the curve, the two being equal.

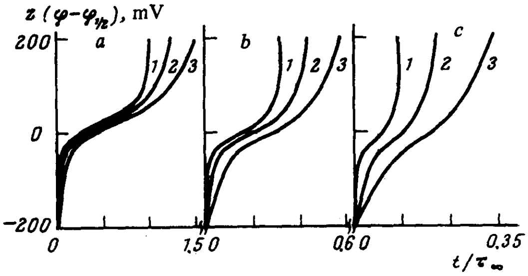

Figure 2. Theoretical φ–t curves for a mercury film electrode calculated taking into account the charging of the electrical double layer for different values of K_C [1) 0; 2) 0.003; 3) 0.0075] and three values of h [a) $h = \infty$; b) $h = 0.1$; c) $h = 0.01$].

De Vries[27] analysed in detail the case where $h \to 0$ (the case of thin films and large values of τ). The Delahay-Mattax graphical method may be applied in the potential range −200 – +200 mV subject to the condition that a horizontal line, parallel to the time axis, divides the distance between the initial and final sections of the curve in proportions of 0.382 : 0.618. The error in the measurement of the transition time under these conditions is not more than ±4% for $K_C \leqslant 0.01$ and $h \leqslant 0.1$.

The order of magnitude of the error due to the charging of the e.d.l. can be estimated approximately by Hirst's method[1]:

$$\frac{Q_C}{Q_\varphi}=\frac{C_d\Delta\varphi}{i\tau}, \tag{15}$$

where $\Delta\varphi(V)$ is the width of the chronopotentiogram. Evidently the error is smaller the higher the current density and the concentration of the electrochemically active substance. For example, when $C_d = 20\ \mu F\ cm^{-2}$, $\Delta\varphi = 0.1 V$, $D_R = 10^{-5}\ cm^2\ s^{-1}$, $z = 2$, and $c_R^0 = 10^{-6}$ g-atom cm^{-3}, the current density should not exceed 0.1 A cm^{-2} for a permissible error of 1%.

Table 2. The results of the calculation of the influence of the charging of the electrical double layer on the characteristics of the chronopotentiometric curves ($\Delta\varphi_{T/4}$ is the shift of the chronopotentiometric curve).

	$z\,(\Delta\varphi_{\tau/4})$, mV			Error in the determination of λ, %	
hK_c	0	0.003	0.0075	0.003	0.0075
	0	−1.7	−2.6	−1.7	1.9
$h=3$	−0.6	−2.4	−3.0	0	2.4
$h=1$	−5.6	−7.3	−7.9	0.5	3.5
$h=0.3$	−14.4	−15.8	−16.3	1.5	5.6

IV. APPLICATIONS OF THE METHOD OF AMALGAM CHRONOPOTENTIOMETRY

1. Oxidation of a Multicomponent Amalgam

If the chronopotentiometric half-wave potentials differ appreciably, several steps are observed on the potential–time curve. The system of equations describing the distribution of the concentrations of the elements at the surface of the mercury film electrode is[14-16,28-30]

$$\sum_{k=1}^{m} c_{R,k}^{S}=\sum_{k=1}^{m}\left\{c_{R,k}^{0}-j_{R,k}\left[v_{R,k}+\frac{1}{3}-2S_1(v_{R,k})\right]\right\}. \tag{16}$$

We shall consider the electrochemical oxidation of a two-component amalgam, where the following reactions take place at the electrode:

$$M_1(\mathrm{Hg})\rightarrow M_1^{z_1+}+z_1e,$$
$$M_2(\mathrm{Hg})\rightarrow M_2^{z_2+}+z_2e.$$

The metal M_2 is oxidised at more positive potentials. When the transition time τ_1 is reached, M_2 begins to react, while M_1 continues to diffuse to the electrode surface, where it is oxidised simultaneously with M_2. If M_1 is fully oxidised during the time τ_1, then it has no influence on the transition time of M_2.

The fraction of the residual metal M_1 in the amalgam after the time τ_1 may be found from the formula[14,29]

$$p=\frac{il}{z_1Fc_R^0D_R}. \tag{17}$$

It follows from Eqn. (17) that the fraction of the residual metal in the mercury film increases with increasing film thickness and polarising current density. We shall estimate p for the following conditions: $i = 2\times10^{-4}$ A cm^{-2}, $l = 2\times10^{-3}$ cm, $S = 6\times10^{-2}\ cm^2$, $D_R = 10^{-5}\ cm^2\ s^{-1}$, and $c_R^0 = 2\times10^{-6}$ g-atom cm^{-3}, whereupon $p = 0.04$. Under the above conditions, $\tau = 5$ s. Usually $\tau > 5$ s and $l < 2\times10^{-3}$ cm and p is then less than 0.01.

Consequently when the curves are drawn by a pen recorder during the transition time, almost the entire metal dissolves from the mercury film. The constancy of $i\tau$ over a wide range of variation of the polarising current (from 7.5×10^{-7} to 1.4×10^{-5} A) has been demonstrated experimentally[14] in relation to the oxidation of cadmium (1 M KCl), lead (1 M KNO_3), and indium (0.5 M $HClO_4$) amalgams. This implies that, under the conditions of amalgam chronopotentiometry, the metal emerges almost completely from the mercury film.

Using the method of additive functions, Pnev and Zakharov[30] arrived at the following expression when they considered the oxidation of a two-component amalgam:

$$\tau_2-\frac{2l^2}{D_R}\left[S_1(\tau_1+\tau_2)-S_1(\tau_1)\right]=\frac{z_2Flc_{R,2}^0}{i}, \tag{18}$$

where

$$S_1(\tau_1+\tau_2)=\sum_{n=1}^{\infty}\frac{\exp\left[-\mu_n^2\left(v_{R_1}+v_{R_2}\right)\right]}{\mu_n^2};$$
$$S_1(\tau_1)=\sum_{n=1}^{\infty}\frac{\exp\left(-\mu_n^2v_{R_1}\right)}{\mu_n^2}.$$

It follows from the last equation that, for a fairly large value τ_1 (for $v_R' \geqslant 0.35$), when the sums $S_1(\tau_1+\tau_2)$ and $S_1(\tau_1)$ may be neglected, the transition time for the oxidation of the succeeding element (M_2) is independent of the transition time for the oxidation of the previous element (M_1). For spherical diffusion, this conclusion is valid when $v_R' \geqslant 0.14$ (see above). The theoretical results obtained have been confirmed for the oxidation of thallium and lead amalgams in the presence of zinc and for a thallium amalgam in the presence of cadmium[14,28].

Table 3. Data for the determination of the number of electrons involved in the reaction by amalgam chronopotentiometry.

Element	$10^3 i\tau_{exp}$, C	$10^3 i\tau_{theor}$, C	z_{exp}	z_{theor}
Pb	2.65	2.80	1.9	2
Cd	2.87	2.92	2.0	2
In	2.02	2.2	2.8	3

Under the conditions of semi-infinite diffusion, the mutual influence of the elements is observed when they are present jointly in solution, which hinders their accurate quantitative determination[1].

2. Determination of the Number of Electrons Involved in the Electrode Reaction

Using Eqn. (7), it is possible to determine the number of electrons z and to reach appropriate conclusions concerning the mechanism of the electrode reaction. This method has been used in the determination of the number of electrons involved in the electrochemical oxidation of lead (1 M KNO_3), cadmium (1 M KCl), and indium (0.5 M $HClO_4$) amalgams[14]. The observed values of z agree with the theoretical values (Table 3). The determination of the number of electrons from the chronopotentiometric curve is discussed below.

3. Determination of the Diffusion Coefficients of Metal Atoms in Mercury

As stated above, the diffusion coefficients of metal atoms in mercury can be found by analysing Eqn. (8)†.

According to Eqn. (8), the plot of τ against $1/i$ is a straight line, which makes an intercept $r_0^2/15D_R$ on the τ axis. Knowing r_0, it is possible to calculate the diffusion coefficient of metal atoms in mercury.

4. Investigation of the Kinetics of the Ionisation of Amalgams. The Use of the Rotating Disc Electrode

Eqns. (9) and (10) have been used[17] to investigate the electrochemical dissolution of thallium, lead, bismuth, and indium amalgams at a mercury film electrode. It was established that the electrochemical oxidation of thallium, bismuth, and lead amalgams in the corresponding supporting electrolytes (Table 4) is reversible, while that of indium and bismuth amalgams in perchloric acid solutions is irreversible (Table 5).

Table 4. The results of the study of the electrochemical dissolution of thallium, lead, and bismuth amalgams at a stationary mercury film electrode and a rotating mercury disc electrode (n_{rev} = 1200 rev min^{-1}) at 293 K.

Amalgam	Supporting electrolyte	φ^0, V	2.3 RT/zF, V		
			experimental values		Theoretical values
			stationary electrode	disc electrode

Bi	1 M HNO_3	−0.008	0.020	0.0215	0.0194

Table 5. The results of the study of the kinetics of the electrochemical oxidation of bismuth and indium amalgams at a stationary mercury film electrode.

Amalgam	Supporting electrolyte	$10^5 c_O^0$, M	$10^5 i$, A	τ, s	$\frac{2.3RT}{\beta zF}$, V	βz	$10^4 i_0$, A cm^{-2}	k_S, cm s^{-1}
In	2 M $HClO_4$	1,0	0.9	20.0	0.0277	2.1	0.9	$4\cdot10^{-5}$
Bi	1 M $HClO_4$	1.0	1.3	25.0	0.0233	2.49	1.83	$2\cdot10^{-4}$

Kinetic studies can be carried out very conveniently at a rotating electrode[12], whereby it is possible to take into account exactly concentration polarisation. The rotating disc electrode has been used in inversion amalgam chronopotentiometry to investigate the kinetics of the electrochemical dissolution of amalgams[31]. It has been stated[32,33] that amalgam chronopotentiometry with a rotating disc electrode is distinguished by the simplicity of the interpretation of the results. If the treatment is based on the general kinetic discharge–ionisation equation[21], then the equation of the chronopotentiometric curve for the electrochemical dissolution of the metal from the amalgam on the rotating disc electrode is

$$\eta = \frac{2{,}3\,RT}{\beta zF}\left(\lg\frac{i}{i_0} - L_{\text{k}}\right), \tag{19}$$

where

$$L_{\text{k}} = \lg\left[\frac{v'_R - v_R}{v'_R} - \left(1 + \frac{j_0}{c_O^0}\right)e^{-\frac{zF}{RT}\eta}\right] \tag{20}$$

is the thickness of the boundary diffusion layer on the rotating disc, $j_0 = i\delta/zFD_O$, $\delta = 0.642\,D_O^{1/3}\nu^{1/6}n_{\text{rev}}^{-1/2}$), and n_{rev} the rate of rotation of the electrode (rev s^{-1}).

At fairly high overvoltages (but not such that an irreversible electrode process can occur), the η – L_{k} curve becomes a straight line with a slope of 2.3 $RT/\beta zF$ (Fig. 3). Evidently, with increase of the rate of rotation of the electrode (with decrease of the parameter j_0/c_O^0), the curve is transformed into a straight line at lower overvoltages. The limiting case corresponds to $j_0/c_O^0 \ll 1$. This factor makes it possible to simplify the analysis of chronopotentiometric curves. Hence the advantage of amalgam chronopotentiometry using a rotating disc electrode is evident.

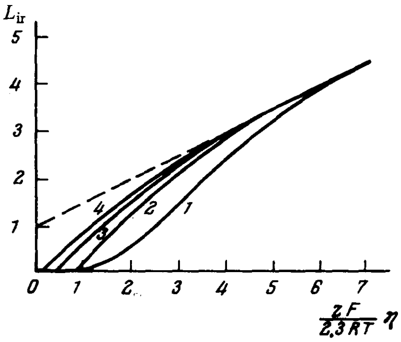

Figure 3. Variation of η with L_{ir} for a rotating mercury disc electrode corresponding to different values of j_0/c_O^0: 2) 4; 3) 1; 4) ≪ 1; β = 0.5. Curve *1* has been plotted for a stationary mercury film electrode.

For diffusion-controlled processes, the equation of the chronopotentiometric curve is

$$\eta_{\text{d}} = \frac{2.3\,RT}{zF}\left[\lg\left(1 + \frac{j_0}{c_O^0}\right) + L_O\right], \tag{21}$$

where

$$L_O = \lg\frac{\tau}{\tau - t}.$$

---

† In view of the small thickness of the mercury film electrode, the analogous Eqn. (6) is difficult to use for these purposes.

It follows from this equation that the plot of η_d against L_O is a straight line with a slope of $2.3RT/zF$. It is appropriate here to compare the equation obtained with the analogous equation [Eqn. (9)] for a stationary mercury film electrode; the evident simplicity of Eqn. (21) can be easily seen. Analysis of Eqn. (21) shows that an increase of the rate of rotation of the electrode leads to a shift of the chronopotentiometric curves towards negative potentials, the maximum shift being observed when $j_0/c_O^0 \ll 1$.

Studies at a rotating mercury disc electrode showed that the electrochemical dissolution processes for thallium and lead amalgams (in 1 M KNO_3 as the supporting electrolyte) and bismuth amalgam (in 1 M HNO_3 as the supporting electrolyte) are diffusion-controlled (Table 4). The study of the ionisation of cadmium and zinc amalgams in the appropriate supporting electrolytes at a rotating disc electrode showed that the electrochemical dissolution of these metals from the amalgams is determined by mixed kinetics (Table 6). The kinetic parameters found by the method of amalgam chronopotentiometry agree with the literature[34-38].

Table 6. The results of the study of the kinetics of the electrochemical oxidation of zinc and cadmium amalgams at a rotating mercury disc electrode ($i = 1.2 \times 10^{-4}$ A cm^{-2}, $n_{rev} = 1200$ rev min^{-1}).

Amalgam	Supporting electrolyte	$10^4 c_0^0$, M	$\frac{2.3RT}{\beta zF}$, V	βz	$10^4 i_{0_2}$, A cm^{-2}	k_S, cm s^{-1}	
						experimental data	literature data
Zn	1 *M* KNO_3	1.0	0.050	1.16	1.1	$3.2 \cdot 10^{-3}$	$3.5 \cdot 10^{-3}$ [36,37]
Cd	1 *M* Na_2SO_4	0.1	0.040	1.45	1.2	$1.1 \cdot 10^{-2}$	$2.6 \cdot 10^{-2}$ [38] (0.5 *M* Na_2SO_4)

It is noteworthy that the methods used in the literature[35-38] are more complex as regards apparatus and the interpretation of the results than in amalgam chronopotentiometry.

5. Analytical Scope of the Method

Using Eqn. (15), we shall estimate theoretically the minimum concentration which can be determined by the method of amalgam chronopotentiometry. When the error introduced by the capacitance current is $m\%$, we have[28,39]

$$c^0_{O,\min} = \frac{10^5 SC_d\Delta\varphi}{mzF\gamma V}\ (\text{mole litre}^{-1}), \tag{22}$$

for the film electrode and

$$c^0_{O,\min} = \frac{1{,}26 \cdot 10^6 r_0^2 C_d\Delta\varphi}{mzF\gamma V}\ (\text{mole litre}^{-1}), \tag{23}$$

for the spherical electrode, where γ is the coefficient of consumption of the solution[40,41] and V the volume of the solution analysed.

After recalculation for a sample g (in grams), we have

$$a_{\min} = \frac{AV}{10\ g} c^0_{O,\min}, \tag{24}$$

where A is the atomic weight of the element to be determined and $a_{\min}$ the minimum impurity content which can be determined.

Numerical estimates yielded $c^{0f}_{o,\min} = 6.5 \times 10^{-9}$ M, $a^f_{\min} = 6.5 \times 10^{-8}\%$, $c^{0s}_{o,\min} = 6.7 \times 10^{-9}$ M, and $a^s_{\min} = 6.7 \times 10^{-8}\%$ for the following experimental conditions: $g = 1$ g, $A = 100$, $V = 1$ ml, $\gamma = 0.63$, $C_d = 20$ μF cm^{-2}, $D_R = 2 \times 10^{-5}$ cm^2 s^{-1}, $z = 2$, $m = 5\%$, $r_0 = 4 \times 10^{-2}$ cm, $\Delta\varphi = 0.080$ V (for lead) and $S = 0.025$ cm^2 (for the film electrode). These calculations have been confirmed by experimental data obtained in studies[6,7] where lead, copper, and zinc were determined at molar concentrations of $10^{-9}n$ ($n = 4$–8).

In the analysis of multicomponent amalgams a superposition of chronopotentiograms is possible (when the equilibrium potentials of the amalgams are similar). The problem therefore arises of the resolving capacity of the method. The resolving capacity may be[28] characterised approximately by the quantity $\Delta\varphi$ (Fig. 1). The lower the value of $\Delta\varphi$ the greater the number of elements which may be determined from a single chronopotentiogram. It has been shown theoretically[28] that, for reversible processes, $\Delta\varphi$ decreases with decrease of the concentration of the depolariser ions in solution and, for irreversible processes, $\Delta\varphi$ is independent of c_O^0 (Fig. 4). Experimental investigation of the electrochemical oxidation of lead and thallium amalgams in 1 M KNO_3 supporting electrolytes (reversible processes) and zinc amalgam in 1 M KNO_3 (irreversible process) confirmed the theoretical conclusions (Fig. 4). $\Delta\varphi$ is independent of the thickness of the mercury film, which is very convenient in analytical studies (there is then no need for an accurate determination of the film thickness, which may vary during the experiments).

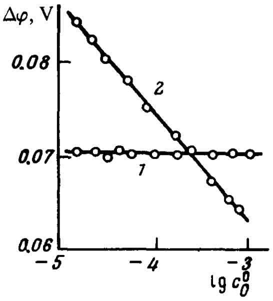

Figure 4. The influence of the depolariser concentration in solution on $\Delta\varphi$ for the electrochemical oxidation of zinc (curve *1*) and lead (curve *2*) amalgams.

The minimum value of $\Delta\varphi$ has been estimated[28] for bivalent elements, amounting to about 44 mV. For comparison, we may point out that the width of the polarographic wave for a dropping mercury electrode is about 72 mV and the width of the anodic peak in the method of amalgam polarography with accumulation is about 60 mV.

The possibility of the simultaneous determination of different elements with adequate resolution and accuracy makes the method of amalgam chronopotentiometry of potential value in analytical practise. The simplicity of the shape of the chronopotentiometric curve permits the application of the method in schemes for the automatic monitoring of continuously varying concentrations of chemical elements[42–44]. A model of a digital chronopotentiograph has been constructed for the analysis of traces of elements by amalgam chronopotentiometry[43]. Other possible designs for chronopotentiometric apparatus have been described[45–47].

The use of a rotating mercury disc electrode yields more clear-cut chronopotentiograms (Fig. 5). This is achieved as a result of the alteration of the shape of the curve (the S-shaped curve at a stationary electrode is replaced by the "logarithmic" curve at a rotating disc electrode).

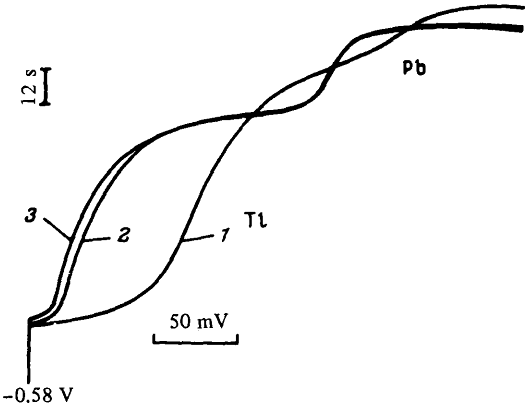

Figure 5. Chronopotentiometric curves for the ionisation of a thallium–lead amalgam at stationary (curve *1*) and rotating disc electrodes (curves *2* and *3*) for rates of rotation of 1200 and 3400 rev min^{-1} respectively.

6. Oxidation of Amalgams in the Presence of Oxygen

The interaction of the oxygen dissolved in the solution being analysed with amalgams makes a definite contribution to the dissolution of metals in the absence of a current[48]. Doronin and Kabanova[49] used the reaction of thallium amalgam with dissolved oxygen for the chronopotentiometric determination of both thallium and oxygen. The reduction of oxygen at a thallium amalgam in the absence of a current but in the presence of thallium ions in solution has been investigated[49,50].

The joint chronopotentiometric determination of thallium and oxygen is possible under certain conditions[49]. In the determination of oxygen the concentration of thallium in the amalgam should not be high, so that the rate of its dissolution in the reaction with oxygen can be measured. Preliminary electrolysis in the determination of oxygen yields the thallium amalgam and the concentration of oxygen is then found from the chronopotentiogram for the decomposition of the amalgam by the oxygen diffusion flux with the solution stirred in a specific manner. When the ratio of the concentrations of thallium and oxygen in solution is 10 : 1, oxygen can be determined at a concentration of 3×10^{-7} M or less.[49] Evidently the minimum concentration of oxygen which can be estimated is limited by the concentration of oxidants in solution, which may oxidise the metal in the amalgam to the ionic state. The possibility of determining traces of oxygen in gases or solutions by the chronopotentiometric method has also been pointed out[51].

Buffle et al.[48] examined theoretically the oxidation of metals in amalgams under chronopotentiometric conditions in the absence of a current. The following reaction then takes place at the electrode:

$$M(\mathrm{Hg}) + \frac{z}{2n}\mathrm{O}_2 \rightarrow \mathrm{M}^{z+} + \frac{z}{n}\mathrm{O}^{n-} + \mathrm{Hg}.$$

The reduction of oxygen to water (O^{2-}) or hydrogen peroxide (O^-) depends on the nature of the metal[52,53] and the experimental conditions[50].

The equations of chronopotentiometric curves have been derived under the following conditions: (1) the expression for the spreading of concentration in the mercury drop in the presence of oxygen obeys Shain's equation[54]; (2) the flux of metal to the surface of the electrode is proportional to the flux of oxygen with the sign reversed and with the proportionality coefficient $z/2n$; (3) the chemical reaction between oxygen and the amalgam is assumed to be rapid compared with diffusion, so that one can put $c^S_{O_2} = 0$; (4) the solution is stirred vigorously and the flux of oxygen (q_{O_2}) to the electrode via a diffusion layer having a thickness δ_{O_2} is

$$q_{O_2} = \frac{zD_{O_2}c^0_{O_2}}{\delta_{O_2}}. \tag{25}$$

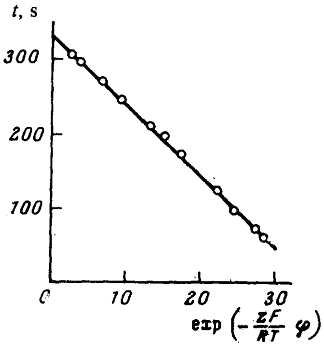

Figure 6. Relation between *t* and the potential in the electrochemical dissolution of a lead amalgam.

The equation of the chronopotentiometric curve (on the assumption that a reversible electrode process takes place) is[48]

$$\varphi = \varphi^0 + \frac{RT}{nF}\ln\left(zc^0_{O_2}\frac{D_{O_2}}{D_0}\right) - \frac{RT}{nF}\ln\left(c_R - \frac{3zc^0_{O_2}D_{O_2}t}{\delta_{O_2}r_0} - \frac{zc^0_{O_2}r_0D_{O_2}}{5D_R\delta_{O_2}} + \frac{2zc^0_{O_2}r_0}{D_R\delta_{O_2}}D_{O_2}S_{\mathrm{sph}}\right), \tag{26}$$

where

$$S_{\mathrm{sph}} = \sum_{n=1}^{\infty}\frac{\exp(-\bar{\mu}^2_n v_R)}{\bar{\mu}^2_n}.$$

Eqn. (26) was tested experimentally[43] in the oxidation of zinc, lead, and cadmium amalgams. The results of the test for lead amalgam are presented in Fig. 6 in terms of a plot of t against $\exp(-zF\varphi/RT)$. Similar results were obtained for zinc and cadmium amalgams. The value of δ_{O_2} was calculated from the slope of the plot (Fig. 6). For $D_{Pb^{2+}} = 8.3 \times 10^{-6}$ cm^2 s^{-1}, $r_0 = 0.038$ cm, and $\varphi^0 = -0.120$ V, $\delta_{O_2} = 7.5 \times 10^{-4}$ cm was obtained, which agrees approximately with the literature ($\delta_{O_2} \simeq 10^{-3}$ cm).[55]

The expression for the transition time subject to the condition $v'_R \geqslant 0.14$ is

$$\tau = \frac{\delta_{O_2} r_0 c_R^0}{3 z c_{O_2}^0 D_{O_2}} - \frac{r_0^2}{15 D_R}. \tag{27}$$

Hence it follows that the transition time is inversely proportional to the O_2 content in solution. This relation has been used[48] to determine the content of oxygen in an acetate buffer (pH 4.7). The concentration obtained $c_{O_2}^0 = 8.23 \times 10^{-7}$ M corresponds to the solubility of O_2 in the test solution.

Thus, using the reaction of dissolved oxygen with amalgams, the method of amalgam chronopotentiometry can be applied for the determination of oxygen in gases or solutions.

7. The Study of Adsorption on Mercury

The simplicity of the chronopotentiometric method in the study of the adsorption of various substances on mercury has been increasingly frequently emphasised in the literature[56-58]. A planar mercury electrode is suitable for such purposes. When the substance in the form of a sparingly soluble compound or metal deposit is adsorbed on the surface of a mercury film, the transition time characterising the complete exhaustion of both the adsorbed and non-adsorbed depolariser is described by the equation

$$\tau = \frac{zFlc_R^0}{i} + \frac{zF\Gamma}{i}, \tag{28}$$

where Γ is the amount of adsorbed substance (mole cm^{-2}).

If the electrochemically active substance is insoluble in mercury (but is adsorbed on the surface of the electrode), Eqn. (28) reduces to

$$\tau_{\text{ads}} = \frac{zF\Gamma}{i} \tag{29}$$

Using the values of τ_{ads}, it is possible to plot the adsorption isotherm. Ershler et al.[56] and Herman and Blount[59] analysed in detail various models for adsorption on mercury electrodes and the transition times. According to Herman and Blount[59], the method of chronopotentiometry with current reversal, whereby it is possible to investigate adsorption phenomena in both anodic and cathodic processes, is suitable for the study of adsorption.

8. Other Possible Applications of the Method and Some of Its Modifications

The method of amalgam chronopotentiometry can be used to determine the solubilities of sparingly soluble metals in mercury[17]. The essential feature of one of the modifications is as follows. A preliminary electrolysis is carried out for various concentrations of the element (whose solubility in solution is to be determined) during a period which is always the same and chronopotentiograms are recorded in each case. The transition time increases with increase in concentration up to a limit and then remains unchanged. This limiting transition time corresponds to the solubility of the metal in mercury. The above method yields correct results only when the solid phase formed dissolves at an infinitesimally low rate.

The above method can also be used to investigate chemical processes[60] which complicate the electrode process involving the dissolution of the amalgam (the formation of intermetallic compounds, complex formation). This problem is discussed in greater detail in the next section.

Using the method of the rotating disc electrode, it is possible to investigate the corrosion of amalgams under chronopotentiometric conditions.

An interesting version of amalgam chronopotentiometry—chronopotentiometry in the absence of a current or chronopotentiometry with a specified resistance—has been proposed[61-64]. In this method the electrochemical dissolution of the amalgam is measured with the aid of additional resistances introduced into the circuit.

Amalgam chronopotentiometry in a two-sided thin-film system has been examined[65]. The author[65] showed that the theoretical relations obtained by Christensen and Anson[66] for one-sided thin-film systems can be used in conjunction with this version of the method.

V. THEORY OF THE METHOD WHEN THE ELECTRODE PROCESS IS COMPLICATED BY CHEMICAL REACTIONS

In many cases electrode processes take place in several stages. In order to understand the mechanisms of the electrode process and particularly for a correct interpretation of experimental results, it is necessary to know the characteristics of chemical reactions at the surface of the electrode and the relations governing them.

The electrochemical dissolution of the amalgam may be complicated by chemical reactions occurring in the amalgam or in the solution. Certain metals are known to form with one another intermetallic compounds soluble in mercury[67]. In the electrochemical dissolution of such an amalgam the electrode process is complicated by the dissociation of the compound in the amalgam. If the metal ions formed on electrochemical dissolution of the amalgam react chemically with the components of the electrolyte or are involved in complex formation, the electrode process is complicated by the subsequent chemical reaction. The theory of inversion amalgam chronopotentiometry with kinetic complications has been largely described[14-16]. It is assumed that, in the presence of an excess of an indifferent electrolyte in solution, there are no adsorption effects, and that the electrolyte solution is not stirred.

1. Preceding Chemical Reactions

If the electrochemical dissolution of the amalgam is preceded by a chemical reaction (dissociation of the intermetallic compound), the electrode process can be represented schematically as follows[68,69]:

$$\mathrm{Y\,(Hg)} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{M(Hg)} \;+\; n\mathrm{M_1\,(Hg)} \xrightarrow{ze} \mathrm{M}^{z+},$$

where Y is the intermetallic compound soluble in mercury and M and M_1 are the metal atoms into which the substance Y dissociates. It is postulated that Y and M_1 are not oxidised at the potential of the electrochemical oxidation of M.

The expression for the distribution of the metal concentration at the surface of an electrode of any shape, subject to the condition $D_R = I_Y = D$, is

$$c_R^S = \frac{c_R^0 - j(S_1 + K_pS_2)}{1 + K_p}. \tag{30}$$

We have for the mercury film electrode ($v_R \geqslant 0.34$)

$$S_1 = v_R + \frac{1}{3}, \tag{31}$$

$$S_2 = \frac{1}{\sqrt{K}\tanh\sqrt{K}} - \frac{e^{-Kv_R}}{K}, \tag{32}$$

and for the spherical mercury electrode ($v_R \geqslant 0.14$)

$$S_1 = v_R + \frac{1}{15}, \tag{33}$$

$$S_2 = \frac{1}{3\sqrt{K}\coth\sqrt{K} - 1} - \frac{e^{-Kv_R}}{K}, \tag{34}$$

where $K = \lambda_1 + \lambda_2$, $\lambda_1 = K_1y^2/D$, $\lambda_2 = K_2y^2/D$, and K_p is the equilibrium constant for the chemical reaction. Hence we have the following expression for the transition time subject to the condition $c_R^S = 0$:

$$v'_K = v'_R - K_pS_2(v'_K), \tag{35}$$

where v'_R corresponds to the transition time in the limiting case where the chemical reaction is fast:

$$v'_R = \frac{c_R^0}{j} - \frac{1}{3};\; v'_K = \frac{D\tau}{l^2}.$$

It follows from Eqn. (35) that the kinetic effect may be observed[69] under the condition

$$K_pS_2(v'_K) \geqslant 0.1\, v'_K. \tag{36}$$

According to Eqn. (35), when account is taken of Eqn. (32) or (34), the plot of the relation is linear with the slope at low current densities

$$\frac{K_p}{\sqrt{K}\tanh\sqrt{K}}$$

for the mercury film electrode and

$$\frac{K_p}{3\sqrt{K}\coth\sqrt{K} - 1}$$

for the spherical mercury electrode. The value of K may be calculated from these relations when K_p is known. Since v'_K is proportional to concentration for constant j, the linear plot of v'_K against concentration may be extrapolated to $v'_K = 0$. S_2 may be determined from the intercept on the ordinate axis and K_p and K can then be calculated.

In order to derive the equations of chronopotentiometric curves, it is necessary to substitute in the kinetic equation the expressions for c_R^S and c_O^S. The formula for the distribution of the concentration c_O^S has been published[1]. The equations of chronopotentiograms are simpler[68,69] when $D_O = D_R$:

$$\varphi = \varphi_{1/2} - \frac{RT}{zF}\ln\frac{c_R^0 - jS_1 + K_pS_2}{(1 + K_p)\,c_O^S} \tag{37}$$

for reversible electrode processes, and

$$\varphi = \varphi^0 + \frac{RT}{\beta zF}\ln\frac{q}{k_S} - \frac{RT}{\beta zF}\ln\frac{c_R^0 - j(S_1 + K_rS_2)}{1 + K_p} \tag{38}$$

for irreversible electrode processes. The quantity $jK_pS_2/(1 + K_p)$ introduces a correction for the kinetic effect. Since $jK_pS_2/(1 + K_p) > 0$, the chronopotentiometric curve should shift towards positive potentials when there is a preceding chemical reaction.

2. Subsequent Chemical Reactions

The influence of the chemical reaction which follows electron transfer is manifested in processes with a reversible electrochemical stage. In irreversible processes the subsequent chemical reaction cannot have any influence on the kinetics of the electrode process. Therefore the occurrence of the subsequent chemical reaction can affect only the distribution of the metal concentration in solution. For the mechanism under consideration,

$$M(Hg) \overset{ze^-}{\rightleftarrows} M^{z+} + N \underset{k_2}{\overset{k_1}{\rightleftarrows}} Y,$$

where M is the metal in the amalgam, M^{Z+} the metal ions formed on electrochemical dissolution of the amalgam and then reacting with the excess of the substance N, and Y the substance formed as a result of the chemical reaction (Y is not reduced or oxidised in the potential range where M is oxidised), the equation of the chronopotentiometric curve corresponding to reversible electrode processes at a mercury film electrode is (subject to the conditions $v_R \geqslant 0.34$ and $D_I = D_O = D$)[14,70]

$$\varphi = \varphi_{1/2} - \frac{RT}{zF}\ln(v' - v) + \frac{RT}{zF}\ln P(v), \tag{39}$$

where

$$P(v) = \frac{1}{1 + K_p}\left(\frac{2v^{1/2}}{\pi^{1/2}} + \frac{K_p\,\mathrm{erf}\sqrt{Kv}}{\sqrt{K}}\right). \tag{40}$$

For a fairly long transition time (low current density), the second term in Eqn. (40) becomes negligibly small compared with the first. Under these conditions, K_p may be calculated from the chronopotentiometric half-wave potential (the case of a stable equilibrium in the chemical reaction).

Using Eqn. (40), it is then possible to calculate K and hence k_1 and k_2.

The quantity $K_p\,\mathrm{erf}\sqrt{Kv}/\sqrt{K}$ introduces a correction for the kinetic effect. Since it is positive, in the subsequent chemical reaction the chronopotentiometric curve shifts towards negative potentials:

$$\Delta\varphi_{\tau/2} = \varphi_{\tau/2,K} - \varphi_{\tau/2} = \frac{RT}{zF}\ln\frac{1}{1 + K_p}\left(1 + \frac{\pi^{1/2}K_p}{\sqrt{2Kv'}}\,\mathrm{erf}\sqrt{\frac{Kv'}{2}}\right) \tag{41}$$

or in the limiting case (low current densities) we have

$$-\Delta\varphi_{\tau/2} = \frac{RT}{zF}\ln(1 + K_p). \tag{42}$$

Thus the shift of the chronopotentiometric half-wave potential, in which the current density becomes constant, does not change on further decrease of current density. Under this condition, it is fairly easy to calculate the equilibrium constant K_p.

At high current densities (low values of τ) the kinetic effect is vanishingly small and in this case Eqn. (39) assumes the form corresponding to the absence of kinetic complications.

For an irreversible chemical reaction, which occurs, for example, in the formation of many complexes, the equation of the chronopotentiogram simplifies[70]:

$$\varphi = \varphi_{1/2} - \frac{RT}{zF}\ln(v' - v) + \frac{RT}{zF}\ln\frac{\mathrm{erf}\sqrt{k_1v}}{\sqrt{k_1}}. \tag{43}$$

If the rate of the chemical reaction is fairly high, we obtain the following expression from Eqn. (43) when $\sqrt{k_1 v} \geqslant 3$:

$$\varphi = \varphi_{1/2} - \frac{RT}{zF}\ln(v' - v) - \frac{RT}{2\,zF}\ln k_1, \tag{44}$$

i.e. the electrode process becomes irreversible. k_1 may be determined by Eqn. (44) from the chronopotentiometric half-wave potential.

By analysing the $\varphi - t$ curves, Bakanov[14] derived the following criterion of the irreversibility of the electrode process followed by a chemical reaction:

$$k_f \ll \frac{v'\sqrt{k_1}}{\operatorname{erf}\sqrt{k_1 v'}}. \tag{45}$$

Thus, when the rate constant for the chemical reaction k_1 is greater than k_f (k_f is the formal rate constant for the cathodic process), the electrode process becomes irreversible. This conclusion is consistent with the above hypothesis that the process is irreversible.

The equations of chronopotentiometric curves for a spherical mercury electrode are more complex. They have been analysed in detail together with a quasireversible electrode process for electrodes of both types[14,70].

Table 7. Criteria for the determination of kinetic mechanisms.

Kinetic mechanism	Logarithmic time function	Slope of linear section*	$i\tau$	$\Delta\varphi_{\tau/2,\,K}$
1) $M(Hg) \rightleftarrows M^{z+} + ze$	$\frac{\tau}{\tau - t}\left(1 + \frac{2qt^{1/2}}{\pi^{1/2}D_o^{1/2}C_o^0}\right)$	$\frac{RT}{zF}$	const	0
2) $M(Hg) \rightarrow M^{z+} + ze$	$\frac{\tau}{\tau - t}$	$\frac{RT}{\beta zF}$	const	0
3) $Y(Hg) \underset{k_2}{\overset{k_1}{\rightleftarrows}} M + nM_1 \rightleftarrows M^{z+} + ze$	$\frac{v' - v + K_p(S_2' - S_1)}{\frac{c_0^0}{j} + \frac{2}{\pi^{1/2}}v^{1/2}}$	$\frac{RT}{zF}$	f (*i*)	>0
4) $Y(Hg) \underset{k_2}{\overset{k_1}{\rightleftarrows}} M + nM_1 \rightarrow M^{z+} + ze$	$v' - v + K_p(S_2' - S_2)$	$\frac{RT}{\beta zF}$	f (*i*)	>0
5) $M(Hg) \rightleftarrows M^{z+} + ze + N \underset{k_2}{\overset{k_1}{\rightleftarrows}} Y$	$\frac{S(v)}{v' - v}$	$\frac{RT}{zF}$	const	<0
6) $M(Hg) \rightleftarrows M^{z+} + ze + N \xrightarrow{k_1} Y$	$\frac{\operatorname{erf}\sqrt{k_1 v}}{v' - v}$	$\frac{RT}{zF}$	const	<0

---

* The slope of the linear section is found from the time variation of the overvoltage.

3. Criteria for the Determination of Kinetic Complications in Amalgam Chronopotentiometry

Analysis of the transition times and of the time variation of the potential makes it possible to determine the kinetic mechanisms of electrode processes. If the electrochemical amalgam dissolution stage is preceded by a chemical stage, the quantity $i\tau$ depends on the current density and the kinetic parameters may be determined from the transition times. Indeed, we can put Eqn. (35) in the form

$$v_R' = \frac{c_R^0}{j} - K_p S_2(v_R') - b, \tag{46}$$

where $b = 1/3$ for the mercury film electrode and $b = 1/15$ for the spherical mercury electrode. It follows from Eqn. (46) that

$$jv_R' = c_R^0 - j\,[K_p S_2(v_R') + b], \tag{47}$$

whence it is seen that the product jv_R' depends on the current density; for short transition times, this relation is non-linear.

When the amalgam ionisation stage is followed by a chemical reaction and the preceding stage is merely diffusion in the amalgam, the product $i\tau$ is independent of current density, as in the absence of chemical reactions. Therefore in such cases the potential–time curves must be analysed in order to obtain kinetic data. The following criteria for the determination of kinetic mechanisms may be suggested: (1) a linear relation between the logarithm of the corresponding time function and potential; (2) dependence of the product $i\tau$ on current density; (3) a change in the half-wave potential of the chronopotentiometric curve $\Delta\varphi_{\tau/2}$ in the presence of kinetic complications. Table 7 illustrates the application of these criteria to certain electrode processes occurring in the electrochemical dissolution of amalgams at a mercury film electrode. All the relations indicated in Table 7 were analysed above in detail.

4. Application of Amalgam Chronopotentiometry in the Study of Complexes Formed During the Electrochemical Dissolution of Amalgams

The problems of inversion amalgam chronopotentiometry in relation to electrode processes complicated by complex formation have been examined[14,15,71-74]. If a reversible process takes place at the electrode with formation of equilibrium complexes in the presence of an excess of the ligand, then the composition and stability constant of the complex are determined from the dependence of the shift of the chronopotentiometric half-wave potential on ligand concentration[14]. The shift of the half-wave potential is described by the following equation on the assumption that the ligand concentrations at the electrode surface and in the bulk of the electrolyte are the same[75]

$$\Delta\varphi_{\tau/2,k} = -\frac{RT}{zF}\ln\sum_{n=0}^{p} K_n (c_X)^n, \tag{48}$$

where K_n is the stability constant of the nth complex and c_X is the ligand concentration.

Since the dependence of $\varphi_{\tau/2,k}$ on $\lg c_X$ is similar to that in the polarographic method, Eqn. (48) can be analysed by the method of de Ford and Hume[76].

When only one type of complex is present in solution, Eqn. (48) reduces to

$$\Delta\varphi_{\tau/2,k} = -\frac{RT}{zF}\ln K_n - \frac{nRT}{zF}\ln c_X. \tag{49}$$

According to this expression, the dependence of the chronopotentiometric half-wave potential on the logarithm of ligand concentration should be linear; the coordination number n may be determined from the slope of this relation and the stability constant K_n may be found from the intercept on the ordinate axis, where $c_X = 0$.

Complex formation in the presence of concentration polarisation with respect to the ligand has been examined[74]. As in the presence of an excess of the ligand, the quantity $\Delta\varphi_{\tau/2,k}$ is in this case defined by Eqn. (49).

Bakanov[14] and Bakanov and Zakharov[71] tested the theoretical conclusions in relation to the hydroxo- and chloro-complexes formed in the electrochemical oxidation of lead and cadmium amalgams respectively. The ionic strength of the solution was kept constant and equal to unity by varying the concentration of KNO_3. The concentration of lead ions in solution was 1×10^{-4} M. The experiments were performed at a mercury film electrode. It was established that in 1 M KOH as the supporting electrolyte lead forms the complex $Pb(OH)_3^-$. The slope of the relation between $\Delta\varphi_{\tau/2,k}$ and c_{OH^-} proved to be 85.5 mV. $\lg K_n = 12.55$ was found from the intercept on the ordinate axis. The results agree well with those obtained in other studies[77-79]. Lingane[80] obtained $\lg K_n = 12.8$ and $n = 3$ at an ionic strength of 0.1.

In the electrochemical dissolution of a cadmium amalgam in 1 M ($KCl + KNO_3$) as the supporting electrolyte the complexes $CdCl^+$ and $CdCl_2$ are formed in succession[14]. Their stability constants were found to be 21.5 and 60.7 respectively, in good agreement with other results[79,80].

The method of amalgam chronopotentiometry has been applied[15,72] in the study of the kinetics of the electrochemical dissolution of the amalgam with participation of complex ions. The following mechanism was proposed:

$$z_R M(Hg) + p_2 X \rightarrow z_O MX_{p_2} + ze$$

with the subsequent attainment of the equilibrium

$$z_O MX_{p_2}^{(p_2 m-z)-} + (p - p_2)\, X^{m-} \rightleftarrows z_O MX_p^{(pm-z)-},$$

where P is the composition of the complex predominating in the solution, p_2 the composition of the intermediate complex formed directly in the electrochemical dissolution of the amalgam, z_O and z_R are the orders of the electrochemical reaction with respect to the oxidant and reductant respectively, and X is the ligand.

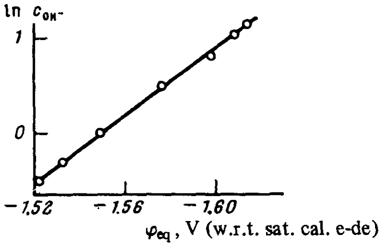

Figure 7. The dependence of the equilibrium potential of a zinc amalgam on OH^- concentration.

The general case has been analysed[15] on the hypothesis that a quasireversible electrode process takes place with subsequent complex formation. It was shown that the composition of the intermediate complex p_2 and the order of the electrochemical reaction may be determined from the exchange current density by means of the following relations:

$$\frac{\partial \ln i_O}{\partial \ln c_R^0} = \alpha z_R - \beta; \quad \frac{\partial \ln i_O}{\partial \ln c_O^0} = \beta z_O - \alpha: \qquad (50)$$
$$\frac{\partial \ln i_O}{\partial \ln c_X} = p_2 - \beta p.$$

The conclusions reached were tested in relation to the formation of zinc hydroxide and tartrate complexes formed in the electrochemical dissolution of a zinc amalgam[72]. The ionic strength was maintained at 3 by adding NaCl solution. The zinc hydroxide complexes were studied in a solution having the composition x M KOH + $(3 - x)$ M NaCl. To determine the composition of the complex predominating in solution, a study was made of the dependence of the equilibrium potential on the concentration of OH^- ions for a constant zinc concentration in solution and in the amalgam (Fig. 7). The slope of this relation pRT/zF proved to be 0.057, whence $p = 4$ ($z = 2$), in agreement with Vetter's data[81]. The values of i_O, z_R, and βz were determined from a plot of η against L_{ir} (Fig. 8): $i_O^0 = (1.75 \pm 0.3) \times 10^{-2}$; $\beta z = 0.48 \pm 0.02$; $z_R = 0.89 \simeq 1.0$. Here i_O^0 is the standard exchange current density. Using Fig. 7 and Eqns. (50), the composition of the complex $p_2 = 0.96 \simeq 1$ was determined. On the basis of the results, the ionisation of zinc amalgam can be represented as follows:

$$Zn(Hg) + OH^- \rightarrow Zn(OH)^+ + 2e + Hg,$$
$$Zn(OH)^+ + 3\,OH^- \rightleftarrows [Zn(OH)_4]^{2-}.$$

The conclusions reached agree well with the literature data[81].

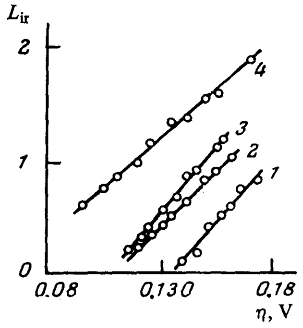

Figure 8. Variation of L_{ir} with $\eta_{Zn(Hg),Zn^{2+}}$ at different zinc amalgam concentrations (g-atom litre^{-1}): 1) 6.1×10^{-3}; 2) 1.3×10^{-2}; 3) 3.6×10^{-2}; 4) 5×10^{-2}.

Similar studies on zinc tartrate complexes showed that, in agreement with the literature[82], the complex Zn(tart) predominates in solution. It was established that $z_R = 1.0$, $\beta = 0.49 \pm 0.02$, $i_O^0 = (2.55 \pm 0.33) \times 10^{-2}$, and $p_2 = 0.13$. The value of p_0 obtained leads to the conclusion that mainly hydrated zinc ions are involved in the ionisation of the amalgam.

The results quoted above have shown that the method of amalgam chronopotentiometry can be used to investigate complex formation.

5. Simultaneous Chemical Reactions in Amalgam Chronopotentiometry

When several electrochemically active substances whose standard potentials differ appreciably are present jointly in solution, a simultaneous amalgam oxidation reaction may occur. Chemical oxidation of the amalgam in the presence of oxygen has been investigated[7,83,84].

A quantitative treatment of this phenomenon for the spherical mercury electrode was described for the first time by Barański and Galus[85]. The authors began with the following mechanism:

$$M_1\,(Hg) \rightleftarrows M_1^{z_1+} + z_1e$$
$$z_2M_1\,(Hg) + z_1Ox_2 \rightarrow z_2M_1^{z_1+} + z_1R_2,$$

where Ox_2 is the oxidised form of the reactant (it may consist either of the ions of a metal more electropositive than M_1 or of traces of dissolved oxygen) and R_2 is the reduced form of the reactant.

The electrode reaction is assumed to be reversible. If the rate of the chemical reaction is limited by the diffusion of Ox_2, the expression for the concentration can be obtained from the equation of Fick's Second Law. The quantitative treatment of the influence of the simultaneous chemical reaction on the electrode process involving the electrochemical dissolution of the amalgam was based by the authors[85] on the equality

$$i_0 = i + i_c,$$

where i_0 is the overall current in the circuit, i the electrode reaction current, and i_C the amalgam chemical oxidation current. The results of the study are expressed as the ratios of the transition times:

$$\frac{\tau_0}{\tau} = \frac{15\,D_{R_1}\tau_0}{15\,D_{R_1}\tau_0 + r_0^2} - \frac{6\,D_2^{1/2}z_2c_2^0}{\pi^{1/2}z_1r_0c_{R_1}^0}\tau_0^{1/2} - \frac{3\,z_2D_2c_2^0}{z_1r_0^2c_{R_1}^0}\tau_0, \qquad (51)$$

where τ_0 is the experimental transition time, τ the transition time in the absence of a chemical reaction, and c_2^O the initial concentration of Ox_2.

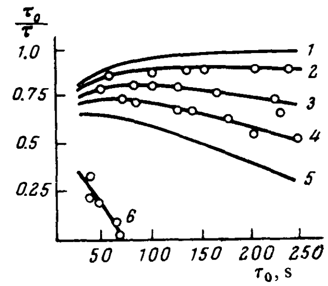

Figure 9. Theoretical $\tau_0/\tau - \tau_0$ relations for different values of $c_2^0/c_{R_1}^0$: 1) 0; 2) 0.013; 3) 0.04; 4) 0.067; 5) 0.1; 6) 0.33. The circles represent experimental data. Experimental conditions: 0.1 M KCl supporting electrolyte; $c^0_{Zn^{2+}} = 1.7 \times 10^{-5}$ M; $c^0_{Cd^{2+}} = 1.6 \times 10^{-5}$ (curves *2–4*); $c^0_{Cd^{2+}} = 1.6 \times 10^{-4}$ (curve *6*).

Fig. 9 presents curves calculated by Eqn. (51) for the following parameters: $r_0 = 0.043$ cm; $D_{R_1} = 2 \times 10^{-5}$ cm^2 s^{-1}; $D_2 = 7.9 \times 10^{-6}$ cm^2 s^{-1}; $z_1 = z_2$.

It follows from Eqn. (6) that, when $i \rightarrow 0$, then $\tau \rightarrow \infty$; however, owing to the chemical oxidation of the amalgam, in practise the transition time is always finite and equal to τ_C; it can be obtained from Eqn. (51) subject to the condition $\tau_0/\tau = 0$ (or can be found graphically). For example, when $c_2^0/c_{R_1}^0 = 0.33$, then $\tau_C = 70$ s, i.e. is equal to the maximum transition time in the chemical oxidation of the amalgam. When $c_2^0/c_{R_1}^0 \leq 0.01$, the error in the determination of the transition time due to the chemical oxidation of the amalgam may be neglected.

The experimental results obtained in the study of the electrochemical oxidation of a zinc amalgam in the presence of Cd^{2+} ions in solution are presented in Fig. 9 in the form of circles. Those on curves *2–4* and *6* correspond to different durations of preliminary electrolysis (240, 80, 40, and 90 s respectively). The satisfactory agreement between the experimental and theoretical curves is noteworthy.

Barański and Galus[85] described two methods of reducing the corrosion of amalgams in the presence of various impurities in solution: (1) by adding surface-active substances (which complicates the theoretical interpretation of the results) and (2) by additional preliminary electrolysis in an unstirred solution. A "diffusion barrier" is then created for Ox_2, as a result of which its concentration at the electrode surface falls. This procedure has been used[86] in a study of a multicomponent system under chronopotentiometric conditions.

Electrophilic Amination†

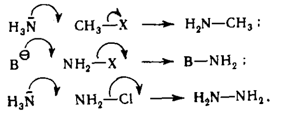
E.Schmitz

The review is devoted to reactions in which amino-, alkylamino- and acylamino-groups are transferred to nucleophilic agents. Electrophilic aminating agents are chloramine, hydroxylamine-*O*-sulphonic acid, oxaziridines unsubstituted at the nitrogen atom, and *N*-acyloxaziridines. The formation of three-membered rings with two heteroatoms, occurring as intramolecular electrophilic amination, is discussed.
The bibliography includes 99 references.

CONTENTS

I. INTRODUCTION

The majority of the reactions with the aid of which amino-nitrogen is introduced into molecules proceed as nucleophilic substitutions. The nucleophilic agent is ammonia or an amine, which substitutes another group, for example, in the interaction of ammonia with alkyl halides [reaction (1)]. These reactions have been known for a long time, have been thoroughly investigated, and are therefore not considered in this review.



(1)
(2)
(3)

Substitution reactions in which nitrogen-containing compounds behave as electrophilic agents are encountered more rarely. In these reactions [see Eqn. (2), which formulates the general case involving a base B^-] the nitrogen is linked to a group which is substituted in the course of the reaction by a nucleophilic agent. The Raschig synthesis of hydrazine [reaction (3)], in which chloramine aminates an ammonia molecule via an electrophilic mechanism[1], is a prototype of reactions of this kind. Together with chloramine, hydroxylamine-*O*-sulphonic acid later came to be used as an aminating agent[2]. The ability of certain oxaziridines to transfer NH and NCOR groups has been discovered in recent years[3]. Reactions of compounds of this type are very similar and are treated in this review as electrophilic amination. The reactions involving transfer of nitrogen-containing groups in which the intermediate formation of nitrenes has been firmly established or postulated are not discussed. A number of reviews have been devoted to such reactions[4-7]. Reactions in which the intermediate stage proceeds via the solvolysis of chloramines, nitrenium ions, and cations with an electron sextet are likewise disregarded[8].

II. REACTIONS OF CHLORAMINE AND SUBSTITUTED CHLORAMINES

An example of electrophilic amination with the aid of chloramine which has been known for a long time and has been most thoroughly investigated is the Raschig synthesis of hydrazine[1]. It has been firmly established that, in contrast to frequently expressed hypotheses, 1,1-elimination from chloramine followed by the interaction of NH with ammonia does not occur and there is instead a synchronous dissociation of the N−Cl bond and the formation of the N−N bond [see Eqn. (3)][9].

The role of the base in the initial method for the synthesis of hydrazine can be accounted for by partial deprotonation to give the chloramide anion. Thus the formation of hydrazine should be regarded as electrophilic amination in which chloramine and the chloramide anion behave as competing electrophilic agents:

$$\begin{array}{l} NH_2-Cl \xrightarrow{NH_3} H_2N-NH_2 \\ \quad\uparrow\downarrow \\ {}^{\ominus}NH-Cl \xrightarrow{NH_3} H_2N-NH_2\,. \end{array} \qquad (4)$$

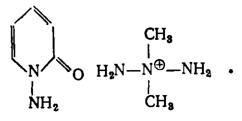
Later studies of the interaction of chloramine with primary[10], secondary[11], and tertiary[12] amines showed that the presence of a strong base is not a precondition for the formation of the N−N bond: the majority of studies on the synthesis of alkylhydrazines have been carried out with chloramine–ammonia mixtures, obtained by the gas-phase chlorination of ammonia, which were combined with amines without adding a strong base. It has been shown[13] that the amination of tertiary amines by chloramine follows second-order kinetics. The ratios of the rates of interaction of ammonia, n-propylamine, and di-n-propylamine with chloramine are 1 : 140 : 460.[14]

The interactions of chloramine with the most important classes of nucleophilic agents and their anions have been studied in the last 20 years. In base-catalysed amination 2-pyridone gives rise to 1-aminopyridone (I);[15] on interaction with chloramine, *NN*-dialkylhydrazines form triazanium salts (II).[16,17] Phosphites give rise to aminophosphonium chlorides (III),[18] triphenylarsine and stibines are converted into arsonium and stibonium salts (IV) and

---

† Translated into Russian from German by T.A. Burtseva and retranslated into English.

(V),[20] while aminosulphinium salts (VI) are formed from thioethers[21].



(I) (II)

On treatment with an excess of chloramine, the latter are capable of combining with a second NH group[22,23].

$H_2N{-}P^{\oplus}(n\text{-}Bu)_3Cl^{\ominus}$ (III) $H_2N{-}As^{\oplus}(C_6H_5)_3Cl^{\ominus}$ (IV)

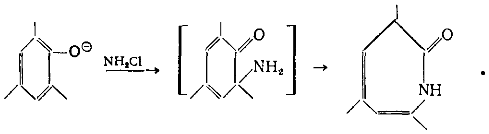
$H_2N{-}Sb^{\oplus}R_3Cl^{\ominus}$ (V) $H_2N{-}S^{\oplus}R_2X^{\ominus}$ (VI) .

Relatively little is known about amination at a carbon atom. The interaction of chloramine with a Grignard reagent[24], which makes it possible, for example, to obtain a good yield of benzylamine from benzylmagnesium chloride [Eqn. (5)], was achieved comparatively long ago. Subsequently chloramine was used to convert into amines, via reaction (6), the products of the hydroboration of olefins[25]:

$$C_6H_5{-}CH_2{-}MgCl \xrightarrow{NH_2Cl} C_6H_5{-}CH_2{-}NH_2\ , \tag{5}$$

$$(C_6H_5)(CH_3)C{=}CH_2 \rightarrow (C_6H_5)(CH_3)CH{-}CH_2{-}BH_2 \xrightarrow{NH_2Cl} (C_6H_5)(CH_3)CH{-}CH_2{-}NH_2\ . \tag{6}$$

When polyalkylphenols react with chloramine, amination at the oxygen atom does not occur, as believed previously; instead, the ring is expanded to give a lactam in which the first stage must be regarded as *C*-amination[26]:



(7)

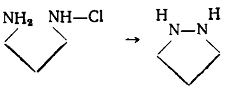
On the other hand, *O*-amination is possible for alkoxides and it has been suggested for the synthesis of *O*-alkylhydroxylamines[27]:

$$RO^{\ominus}\ NH_2{-}Cl \longrightarrow RO{-}NH_2\ . \tag{8}$$

We may also recall the interaction of chloramine with oximes to form diazo-compounds, which was known previously only for a diketomonoxime[28], was later extended to simpler ketoximes[20], and was used finally to synthesise diazomethane [Eqn. (9)]:[30]

$$R_2C{=}NOH \xrightarrow{NH_2Cl} R_2\overset{\ominus}{C}{-}\overset{\oplus}{N}{\equiv}N\ . \tag{9}$$

Analysis of the extensive literature on chloramine leads to the striking observation that only a few reactions of chloramine can be extended to *N*-chloroalkylamines. The formation of the N–N bond between the amine and *N*-chloroalkylamine can be achieved only with simultaneous ring closure[31]:



(10)

The interaction of *N*-chloroalkylamines, RNHCl, and *N*-chlorodialkylamines, R_2NCl, via the electrophilic amination mechanism has been described only for powerful nucleophilic agents, in particular for sulphur- and phosphorus-containing compounds. For example, chloramine reacts with mercaptides to form sulphenamides[32]:

$$R'{-}S^{\ominus} + R{-}NH{-}Cl \rightarrow R'{-}S{-}NH{-}R\ . \tag{11}$$

Thiocyanate is aminated by reaction with *N*-chlorodialkylamines to form *N*-thiocyanatoamines[33]:

$$^{\ominus}SCN + (CH_3)_2N{-}Cl \rightarrow (CH_3)_2N{-}SCN\ . \tag{12}$$

Tri(hydroxymethyl)phosphine reacts with *N*-chlorodimethylamine to form the N–P bond[34]:

$$(HOCH_2)_3P + (CH_3)_2N{-}Cl \rightarrow (CH_3)_2N{-}P^{\oplus}(CH_2OH)_3\ . \tag{13}$$

The amination of azide ions to give substituted aminoazides has been reported[33]. The amination of Grignard reagents by *N*-chloroalkylamines is possible[35].

Reactions of chloramine via the electrophilic amination mechanism take place also in the alkaline cleavage of chloramine to nitrogen and ammonia, which has been known for a long time. It has been shown that hydroxylamine is formed in the first stage [Eqn. (14)][36] and this is followed by the electrophilic amination of hydroxylamine to diimide [reaction (15)]. The formation of diimide is confirmed by the powerful hydrogenating effect in the decomposition of chloramine in alkaline solutions; for example, cinnamic acid is hydrogenated under these conditions of hydrocinnamic acid[37]:

$$HO^{\ominus} + NH_2Cl \rightarrow HO{-}NH_2\ , \tag{14}$$

$$HO{-}NH_2 + NH_2Cl \rightarrow [HO{-}NH{-}NH_2] \rightarrow HN{=}NH\ , \tag{15}$$

$$2\,HN{=}NH \rightarrow N_2 + N_2H_4\ , \tag{16}$$

$$N_2H_4 + NH_2Cl \rightarrow HN{=}NH + NH_3\ , \tag{17}$$

$$\overline{3\,NH_2Cl \rightarrow N_2 + NH_3\ .} \tag{18}$$

Bearing in mind that, on disproportionation, two diimide molecules form nitrogen and hydrazine and that the latter may be oxidised to diimide, which requires the consumption of yet another chloramine molecule, it is possible to obtain a sequence of reactions [reactions (14)–(17)], which reflects the overall formation of nitrogen and ammonia from three chloramine molecules [Eqn. (18)].

The alkaline decomposition of dichloramine, in which two molecules of the latter decompose with formation of nitrogen, chlorite, and hypochlorite, has been studied recently[38]:

$$2\,NHCl_2 + 4\ {}^{\ominus}OH \rightarrow N_2 + 3\,Cl^{\ominus} + ClO^{\ominus}\ . \tag{19}$$

The pronounced chlorinating effect on substrates, subjected to the action of radicals (for example ethyl ether or cyclohexene), observed in the decomposition of dichloramine in alkaline media, permitted the conclusion that the reaction begins with electrophilic amination and the formation of trichlorohydrazine. The elimination step then results in the formation of dichlorodiimide, which is regarded as a source of atomic chlorine:

$$2\,NHCl_2 \rightarrow Cl_2N{-}NH{-}Cl \rightarrow Cl{-}N{=}N{-}Cl \rightarrow N_2 + 2\,Cl^{\cdot}\ . \tag{20}$$

The reactions with *N*-halogenoamines have been recently discussed by Kovacic et al.[39]

III. REACTIONS OF HYDROXYLAMINE-*O*-SULPHONIC ACID AND *O*-ACYL DERIVATIVES OF HYDROXYLAMINE

Another widely used aminating agent is hydroxylamine-*O*-sulphonic acid (HSA). It was obtained for the first time by Sommer and coworkers[2,40], who also discovered the ability of HSA to convert primary and secondary aliphatic and aromatic amines into hydrazines.

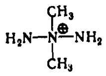
It follows from the data of these investigators, who later studied the preparative use of HSA, that the rate of reaction depends on the nature of the compound aminated. For example, secondary amines react with HSA at 0°C in the course of several hours and tertiary amines react in a few minutes[41]. Evidently, the nucleophilic agent is involved in the rate-limiting stage of the reaction.

The preliminary decomposition of HSA to NH and sulphate, which has been sometimes suggested, is therefore unlikely. Furthermore, it has been shown that the reversible decomposition to NH and sulphate does not occur either: partial decomposition of HSA in dilute NaOH solution in the presence of labelled sulphate does not result in the formation of radioactive HSA.[42] Therefore, an electrophilic mechanism in which a new linkage is formed and sulphate is displaced synchronously, must be adopted for all amination reactions with the aid of HSA, which are faster than the decomposition of HSA in the absence of a nucleophilic agent:

$$R_3N\; H_2N{-}OSO_3^\ominus \longrightarrow R_3\overset{\oplus}{N}{-}NH_2 + SO_4^{\ominus\ominus} \qquad (21)$$

Subsequently amination by HSA was developed into a preparative method for the synthesis of substituted hydrazines. Gever and Hayes[43] obtained ethyl-, propyl-, isopropyl-, n-butyl-, n-pentyl-, and 2-hydroxyethylhydrazines by the amination of primary amines. An excess of the amine is usually employed in order to suppress the self-decomposition of HSA in an alkaline medium and the subsequent reaction of the resulting hydrazine with HSA. Gösl and Meuwsen[41] and Sisler et al.[44] reported almost simultaneously the synthesis of hydrazine from HSA. The former investigators were able to aminate primary, secondary, and tertiary aliphatic amines to give the corresponding hydrazines. Sisler et al. aminated in accordance with Eqn.(21) tertiary aliphatic amines and dimethylaniline to form hydrazinium salts. Under suitable conditions, aniline is converted into phenylhydrazine in 80% yield[41]. Pyridine gives rise to the N-aminopyridinium cation (VII). The corresponding products are obtained from alkylpyridines and quinoline. NN'-Dimethylhydrazine is aminated to give the dimethyltriazanium cation (VIII):[45]

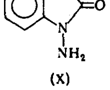
(VII)



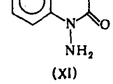
(VIII)

(IX)

The amination of aziridine to an N-amino-derivative (IX) has been described[46], but the yield is low. In certain cases an acylated nitrogen atom is sufficiently nucleophilic after deprotonation to be aminated by HSA. Thus, cyclic acid amides, for example compounds (X) and (XI), have been converted into hydrazides with the aid of HSA.[47] Evidently, simple acid amides have not, as yet, been made to undergo this type of reaction.



(X)

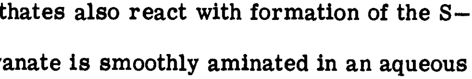


(XI)

Hydrazineisodisulphonate is obtained comparatively easily in accordance with Eqn.(22):[48]

$$HN(SO_3H)_2 \xrightarrow{KOH;\ HSA} H_2N{-}N(SO_3H)_2\,. \qquad (22)$$

In the presence of a large excess of HSA, the N-alkyl group is split off from sulphonamides in the form of a hydrocarbon. Under these conditions, N-amination probably takes place with subsequent elimination of the sulphinate residue[49]:



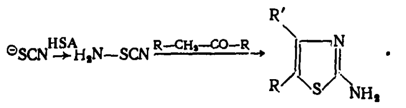
$$R{-}NH{-}SO_2{-}R' \xrightarrow{HSA} R{-}\underset{NH_2}{\underset{|}{N}}{-}SO_2{-}R' \rightarrow R{-}N{=}NH \rightarrow RH\,. \qquad (23)$$

Alkoxides react via the electrophilic amination mechanism with formation of O-alkylhydroxylamines. O-Alkylhydroxylamines have been obtained from simple C_2-C_4 alcohols and benzyl alcohol in yields of 27–49%.[50] In the presence of KOH, phenol is aminated by HSA to O-phenylhydroxylamine[51]:

$$C_6H_5{-}O^\ominus + H_2N{-}OSO_3^\ominus \rightarrow C_6H_5{-}ONH_2\,. \qquad (24)$$

Similarly to the reaction employing chloramine, triphenylphosphine and thioethers can be aminated with the aid of HSA.[52] In the latter case only one NH group adds on. Xanthates also react with formation of the S–N bond[53].

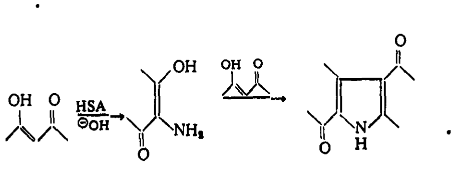
Thiocyanate is smoothly aminated in an aqueous alkaline solution. The thiocyanatoamine formed is of interest because it converts ketones into aminothiazoles in satisfactory yields[54]:



(25)

The olefin hydroboration products can be converted by the Brown reaction into amines by a treatment not only with chloramine but also with HSA.[24]

Relatively little is known about the electrophilic amination of carbanions, although in the instances described the reaction proceeds very smoothly. In dilute NaOH solution, acetylacetone reacts with HSA below room temperature in the course of several minutes. If two moles of the diketone per mole of HSA are used, the amination product condenses with the excess diketone into a pyrrole derivative[55,56]:



(26)

Acetoacetic ester derivatives also give rise to pyrrole compounds.

Hieber and Buetner[57] aminated the hydrogen tetracarbonylferrate anion:

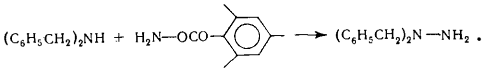
$$HFe(CO)_4^\ominus \xrightarrow{HSA} Fe(CO)_4NH_2\,. \qquad (27)$$

When the reaction with HSA, which usually takes place in aqueous alkaline solutions, is considered, account must be taken of the competing alkaline decomposition of HSA. In the case of chloramine this decomposition leads to the formation of a mole of NH_3 and N_2. This overall result [see Eqn.(32)] can also be represented by a series of amination stages [Eqns.(28)–(31)].[58] The reaction begins with the amination of the hydroxide ion; it has been shown with the aid of ^{18}O that the oxygen in the hydroxylamine produced originates from water[59]. The amination of hydroxylamine to diimide has been demonstrated by the fact that double bonds are hydrogenated both in the alkaline decomposition of HSA and in the reaction occurring in a mixture of HSA and hydroxylamine[58]:

$$\begin{array}{lr} HO^{\ominus} + HSA \rightarrow HO{-}NH_2\ , & (28) \\ HONH_2 + HSA \rightarrow HN{=}NH\ , & (29) \\ 2\,HN{=}NH \rightarrow N_2 + N_2H_4\ , & (30) \\ N_2H_4 + HSA \rightarrow H_2N{-}NH{-}NH_2{-}HN{=}NH + NH_3\ , & (31) \\ \hline 3\,HSA \rightarrow N_2 + NH_3\ . & (32) \end{array}$$

The hypothesis of the formation of triazane at an intermediate stage in reaction (31) has been proved by the fact that the reaction of [^{15}N]hydrazine with HSA results in the formation of some labelled NH_3.[58]

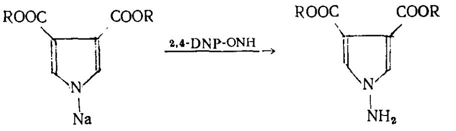
There has been no lack of attempts to discover other electrophilic aminating agents. These began with hydroxylamine containing an active group capable of being eliminated. The first studies were carried out by Carpino[60], who found that *O*-mesitoylhydroxylamine aminates dibenzylamine to dibenzylhydrazine:



(33)

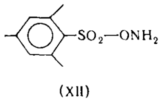
The same investigator reported later[51] the amination of carbazole to *N*-aminocarbazole (in 60% yield), of naphthalimide to *N*-aminonaphthalimide (in 81% yield), of benzylbenzamide to the corresponding hydrazine, of *N*-tosylated 1-aminomethylnaphthalene to the *N*-amino-derivative, and of t-butyliminodicarboxylate to the corresponding hydrazine derivative[62].

Sheradski[63] discovered the effective aminating activity of *O*-(2,4-dinitrophenyl)hydroxylamine. He was able to aminate in 88–95% yield sodium phthalimide, *N*-tosylbenzylamine, and pyrrole-3,4-dicarboxylate ester[63]:

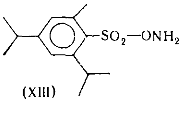


(34)

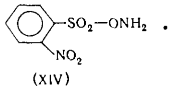
CH acids, such as methyl fluorene-9-carboxylate and diethyl phenylmalonate, are also aminated[64]. Tamura and coworkers[65–67] achieved electrophilic amination with the aid of *O*-mesitylenesulphonylhydroxylamine (XII), *O*-picrylhydroxylamine, and two other *O*-sulphonated hydroxylamines [compounds (XIII) and XIV)]:



(XII)



(XIII)

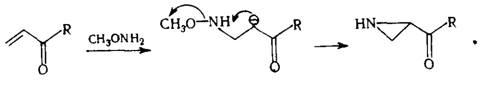


(XIV)

It proved possible to aminate tri-n-butylamine, diphenyl sulphide, diphenyl sulphoxide, triphenylphosphine, quinoline, pyridazine, pyridine, and substituted pyridines. The amination of tertiary amines takes place particularly smoothly and is used to synthesise *N*-amino-derivatives of alkaloids[68].

IV. THE SYNTHESIS OF THREE-MEMBERED RINGS WITH TWO HETEROATOMS

The formation of a new bond in electrophilic amination plays an insignificant role in the syntheses of three-membered rings with a single heteroatom. Of the large number of syntheses of aziridines, mention should be made only of the reaction of $\alpha\beta$-unsaturated ketones with *O*-alkylhydroxylamines, which may be regarded as electrophilic amination[70]:

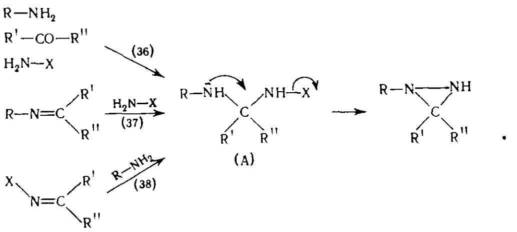


(35)

However, electrophilic amination is a dominant process in the synthesis of three-membered rings with two heteroatoms. If one disregards certain photochemical reactions, the three-membered ring is formed in this case always with the closure of the bond between the two heteroatoms. In the synthesis of diaziridines this bond is always formed as a result of electrophilic amination.

Syntheses of Diaziridines

Numerous versions of the synthesis of $\overline{C-N-N}$ rings are known. It proceeds as the reaction between a carbonyl compound, an amine, and an aminating agent, and it is frequently immaterial whether all three reactants are made to react simultaneously [Eqn.(36)], or whether the carbonyl compound and the amine form initially a Schiff base which then reacts with the aminating agent [Eqn.(37)], or whether the product of the condensation of the carbonyl compound and the aminating agent is made to react with the amine [Eqn.(38)]. Ring closure via the geminal stage (A) is an intramolecular analogue of the Raschig hydrazine synthesis.

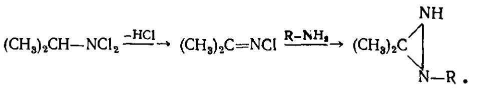


The synthesis of diaziridines with three substituents R, R′, and R″ is restricted to aliphatic compounds but is of general importance in this field. The nitrogen of the aminating agent can also carry an additional alkyl group.

The following versions of the synthesis of diaziridines, which usually takes place with satisfactory yields, have been described.

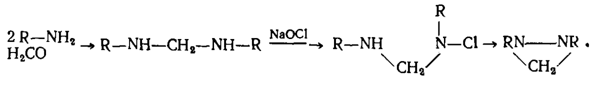
1. Ketone + NH_3 + $ClNH_2$. In this process ammonia is subjected to gas-phase chlorination and is made to react with acetone[71] or a stream of NH_3 + $ClNH_2$ is passed through the liquid ketone[72].
2. Schiff base + $ClNH_2$.[73] The reaction is carried out in an organic solvent. In this case *N*-chloroalkylamines react just as effectively as chloramine, which may be used to synthesise *NN′*-dialkylated diaziridines.
3. Ketone + NH_3 + HSA.[74]
4. Ketone + imine + HSA.[75]
5. *N*-Chloramino-derivative of ketone + NH_3 or amine[76].

This method may be simplified when the *N*-chlorimino-derivative of the ketone (XVI) can be obtained during the synthesis by eliminating HCl from *NN*-dichloramine (XV):[77]



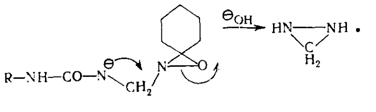
(39)

6. Oxime-*O*-sulphonic acid ($R_2C{=}N{-}OSO_3H$) + amine[78].
7. Schiff base + 3,3-dialkylaziridine[79].
8. Alkaline solutions of formaldehyde and a primary amine, in which the presence of methylenediamines may be postulated, react with hypochlorite to form diaziridines[80]:



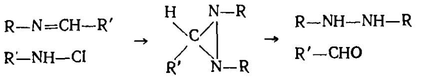
(40)

9. The diaziridine skeleton is formed in a reaction in which it is possible to isolate a geminal intermediate stage corresponding to the intermediate stage postulated in Eqns. (36)–(38) and (40):[81]



(41)

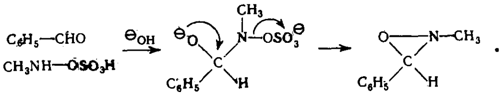
The particular importance of the synthesis of diaziridines consists in the fact that their formation is a stage in the economical syntheses of mono- and di-substituted hydrazines, which are readily formed on acid hydrolysis of diaziridines. For example, *NN*-dialkylhydrazines, which cannot be obtained by direct interaction of an amine and an *N*-chloroalkylamine, can be easily synthesised via a diaziridine by the reaction of primary amines (in the form of Schiff bases) and an *N*-chloroalkyl amine[82]:



(42)

Syntheses of Oxaziridines

In certain cases the two-component reaction of a carbonyl compound and an aminating agent leads to the formation of the oxaziridine ring[83]:

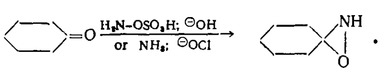


(43)

In this case it is also possible to postulate the formation at an intermediate stage of a product resulting from addition to the carbonyl group; this is indicated, for example, by the observation that in a series of cyclic ketones the maximum yield corresponds to the six-membered ketone. Ring closure is again represented as electrophilic amination. As was to be expected for electrophilic amination, ring closure has to be catalysed by a strong base, since oxygen becomes sufficiently nucleophilic only after deprotonation.

Such syntheses of oxaziridines have been achieved using simple aliphatic ketones, cyclohexanone, and certain aromatic aldehydes. *N*-Chloromethylamine or methylhydroxylamine-*O*-sulphonic acid are usually employed as aminating agents. For higher alkyl substituents, the yields are sharply reduced.

Treatment of suitable aldehydes or ketones in an alkaline medium by aminating agents without alkyl groups leads to oxaziridines unsubstituted at the oxygen atom. The reaction has been thoroughly investigated for cyclohexanone, which gives rise to 3,3-pentamethyleneoxaziridine in 50% yield on treatment with HSA in dilute NaOH solution[79]:



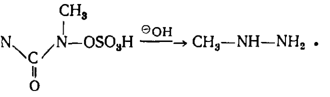
(44)

The synthesis of 3,3-pentamethyleneoxaziridine can be achieved even more simply by treating cyclohexanone with NH_3 and sodium hypochlorite[84]. The yield is about 70%. Both reactions are extremely fast. The interaction of cyclohexanone with NH_3 and hypochlorite takes place at 0° in 30 s and is at least 1000 times faster than the alkaline decomposition of chloramine in the absence of ketone. Thus the latter is involved in the rate-limiting stage of the process. One can also assume the addition of chloramine (or HSA) to the carbonyl group, which is followed by intramolecular electrophilic amination.

Diaziridinones, Iminodiaziridines, and Thiadiaziridine 1,1-Dioxides

The formation of hydrazine on treatment of urea with hypochlorite has been known for a long time[85]. To account for the course of the reaction, it is insufficient to employ the analogy with the Hofmann degradation of amides, since Ohme and Preuschhof were able to show that, although the reaction of asymmetric dimethylurea with hypochlorite yields *NN*-dimethylhydrazine [Eqn. (45)], *N*-hydroxy-*N*-methylurea-*O*-sulphonic acid (XVII) acted upon by alkali also reacts with formation of the N–N bond and gives rise to methylhydrazine [Eqn. (46)][86,87]:

$$(CH_3)_2N{-}CO{-}NH_2 \xrightarrow{\ominus OCl} (CH_3)_2N{-}NH_2\ , \qquad (45)$$



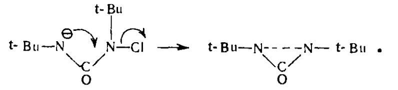
(46)

$$H_2N{-}\underset{\underset{O}{\|}}{C}{-}\overset{CH_3}{\overset{|}{N}}{-}OSO_3H \xrightarrow{\ominus OH} CH_3{-}NH{-}NH_2\ . \qquad (46)$$

(XVII)

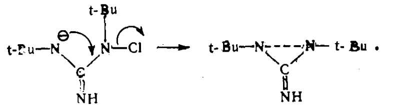
The first compound may be deprotonated by *N*-chlorination at the nitrogen atom, which is already linked to chlorine, creating thereby the structural precondition for the Hofmann amide degradation. In compound (XVII) only the unsubstituted nitrogen is deprotonated, which makes it more likely that the N–N bond is formed by intramolecular closure to give an intermediate three-membered ring.

Indeed, in the presence of t-alkyl substituents at both nitrogen atoms of urea, stable diaziridinones were obtained[88]:



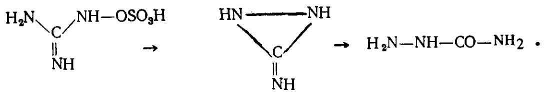
(47)

Later it was possible to obtain similarly iminodiaziridines. *N*-Chlorination of t-alkylguanidines and base-catalysed ring closure result in the formation of a three-membered ring[89]:



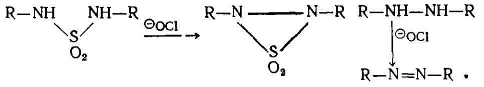
(48)

Before this, experiments with ^{15}N showed that semicarbazide is formed from hydroxyguanidine-*O*-sulphonic acid via an intermediate symmetrical stage, for which the structure of an iminodiaziridine was postulated[90]:



(49)

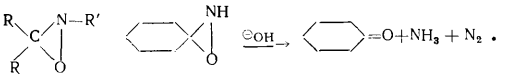
The formation of dialkylhydrazines and isoalkanes from dialkylsulphonamides by reaction with hypochlorite also proceeds via a three-membered cyclic stage, which has been recently demonstrated by the isolation of stable thiadiaziridine 1,1-dioxide[92]:



(50)

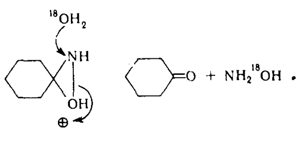
V. AMINATION BY OXAZIRIDINES UNSUBSTITUTED AT THE NITROGEN ATOM

While *N*-alkyloxaziridines (XVIII) are incapable of transferring their nitrogen to other molecules, such ability is shown to a marked extent by oxaziridines (XIX) unsubstituted at the nitrogen atom, which are comparable as regards effectiveness to aminating agents known for a long time, such as chloramine and HSA. All three types of compounds are decomposed by sodium hydroxide in the same way—with formation of NH_3 and N_2:



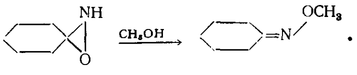
(XVIII) (XIX) (51)

Although cleavaged by aqueous acid solution, which in the case of *N*-alkyloxaziridines is of the same type as the cleavage of acetals and leads to the formation of a carbonyl compound and an alkylhydroxylamine, has the same preparative result for compound (XIX) (the formation of a ketone and hydroxylamine), the reaction proceeds via an amination mechanism: acid hydrolysis of compound (XIX) in the presence of $H_2^{18}O$ yields hydroxylamine containing the ^{18}O isotope (52.6%). Thus amination of water competes with cleavage via the acetal mechanism[93]:



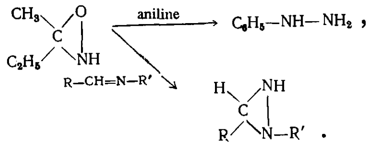
(52)

The occurrence of electrophilic amination when suitable nucleophilic agents are employed has been confirmed by the reaction products. Methanol is aminated by 3,3-pentamethyleneoxaziridine (XX) with formation of the O–N bond when the reaction is catalysed by both methoxide and strong acids[94]:



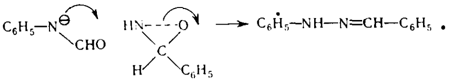
(XX) (53)

Aniline gives rise to phenylhydrazine [Eqn(54)], albeit in a yield of only 20%.[79] Aliphatic Schiff bases are aminated to diaziridines in satisfactory yields [Eqn.(55)]:[79]



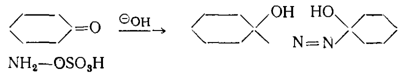
(54)
(55)

Acid amides are aminated only in the presence of strong bases as catalysts (this has been observed also for other aminating agents); after deprotonation, the amide nitrogen becomes sufficiently nucleophilic. Thus treatment of formanilide with 3-phenyloxaziridine results in the formation of benzaldehyde phenylhydrazone [reaction (56)][94]. It is remarkable that, when 3-phenyloxaziridine is decomposed by ethoxide in the absence of formanilide, a small amount of benzaldehyde phenylhydrazone is also formed. Evidently, 3-phenyloxaziridine rearranges to formanilide under the influence of the base (the two compounds are isomeric), this being following by amination in accordance with Eqn.(56):



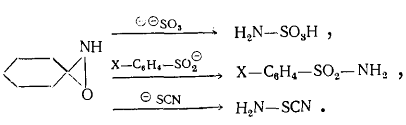
(56)

The intermediate formation of 3,3-pentamethylene-oxaziridine as the aminating agent can also be postulated in the synthesis of 1,1-dihydroxyazocyclohexane from cyclohexanone and HSA:[94]



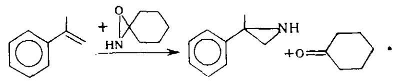
(57)

As was to be expected, strongly nucleophilic sulphur compounds are readily aminated by 3,3-pentamethylene-oxaziridine. For example, the reduction with sodium sulphite solution proceeds as amination of sulphur: sulphamic acid was isolated from the reaction mixture [Eqn.(58)][93]. The reaction with sulphinate anions also proceeds smoothly. Neutralised solutions of toluene-*p*-sulphinic acid or of *p*-chlorobenzenesulphinic acid react fully at room temperature in the course of several minutes. Sulphonamides have been isolated in 85% yield [Eqn.(59)][93]. Thiocyanate is also aminated at room temperature [Eqn.(60)][95].



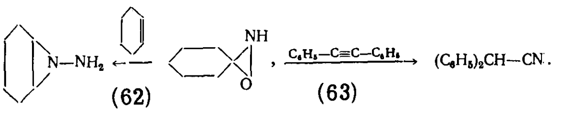
(58)
(59)
(60)

It has been recently observed that 3,3-pentamethylene-oxaziridine can transfer its NH groups to olefins. For example, *p*-chlorostyrene and 1-methyl-1-phenylethylene have been converted in the course of several hours at 110°C into the corresponding aziridines in accordance with Eqn.(61), the respective yields being 58% and 46%.[96] This reaction, which has been called "enamination", is the nitrogen analogue of epoxidation. The reaction mechanism has not as yet been elucidated, but the occurrence of active intermediate stages is unlikely:



(61)

On treatment with 3,3-pentamethyleneoxaziridine, cyclohexene becomes doubly aminated; *N*-aminoaziridine was isolated as the reaction product [Eqn. (62)]:



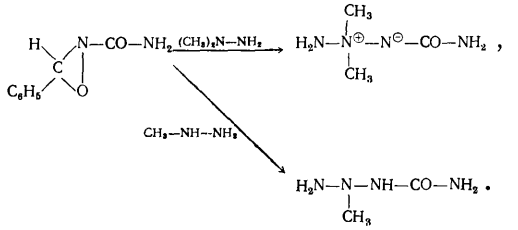
(62) (63)

Diphenylacetylene also reacts formally with addition of the NH group; after rearrangement of the phenyl groups, the reaction product is diphenylacetonitrile [reaction (63)].

VI. THE TRANSFER OF ACYLAMINO-GROUPS WITH THE AID OF *N*-ACYLOXAZIRIDINES

It has already been stated that oxaziridines alkylated at the nitrogen atom do not exhibit the aminating activity characteristic of the compounds in which the nitrogen atom is unsubstituted. On the other hand, *N*-acyloxaziridines are powerful aminating agents. Under suprisingly mild conditions, they frequently transfer the R–CON group to a nucleophilic agent.

For example, the strongly nucleophilic aliphatic hydrazines react fully even at room temperature in the course of several minutes. Triazaniumbetaine is formed in 80% yield from 2-carbamoyl-3-phenyloxaziridine and *NN*-dimethylhydrazine [Eqn. (64)][97]. Under the same conditions, methylhydrazine gives rise to triazanecarbonamide [Eqn. (65)]:



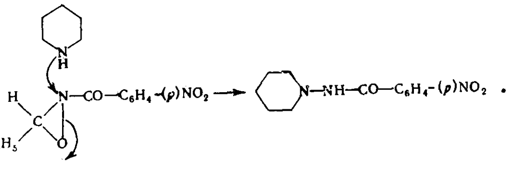
(64)

(65)

The corresponding compounds have been obtained from adducts of phenyl isocyanate or *p*-nitrophenyl isocyanate and 3-phenyloxaziridine by reaction with dialkyl- and monoalkyl-hydrazines.

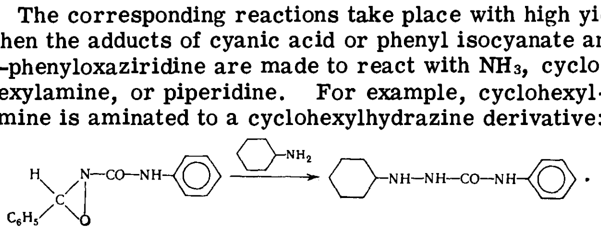
However, a precondition for the reaction is the presence of a phenyl group at the carbon atom of oxaziridine. The triazine derivatives obtained are very unstable: at room temperature they exist for several minutes. They can be obtained only by virtue of the extremely high reactivity of *N*-acyloxaziridines. The formation of the N–N bond must be again regarded as electrophilic amination. The oxaziridine is not cleaved to benzaldehyde and acylnitrene, since in the absence of a nucleophilic agent acyloxaziridines are completely stable under the reaction conditions.

Aliphatic amines react similarly to hydrazines[98]. As a result of the closure of the N–N bond, acid hydrazides or semicarbazides are formed. For example, an acid hydrazide is formed from 2-(*p*-nitrobenzoyl)-3-phenyloxaziridine and piperidine at 0°C in 92% yield in the course of several minutes:



(66)

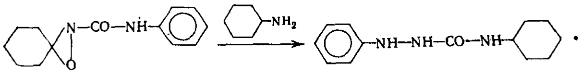
The corresponding reactions take place with high yields when the adducts of cyanic acid or phenyl isocyanate and 3-phenyloxaziridine are made to react with NH_3, cyclohexylamine, or piperidine. For example, cyclohexylamine is aminated to a cyclohexylhydrazine derivative:



(67)

A precondition for these amination reactions is the presence of a phenyl group at the carbon atom of the oxaziridine ring.

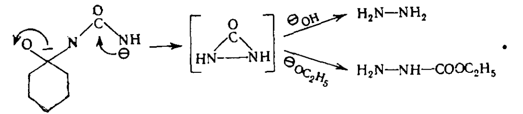
A fundamentally different result is obtained when the oxaziridine derived from cyclohexanone is made to react with cyclohexylamine[99]:



(68)

It is very remarkable that the interaction of analogous compounds with the same reagent in accordance with Eqns. (67) and (68) yields isomeric semicarbazides, where the two substituents change places. Evidently, yet another N–N bond, joining the two nitrogen atoms of the acyloxaziridine, is formed.

This second reaction is catalysed by bases. After deprotonation, the amide nitrogen probably attacks the nitrogen in the three-membered ring [Eqn. (69)]. A new three-membered ring (diaziridinone) is then formed from the oxaziridine ring. The formation of hydrazine [Eqn. (69)] in the presence of sodium hydroxide and the formation of hydrazinecarboxylate ester in the presence of sodium ethoxide are extremely likely and have indeed been observed when the above compounds were used.



(69)

The interaction of the intermediate diaziridinone [according to Eqn. (68)] following the addition of cyclohexylamine would have led to the formation of phenylcyclohexylsemicarbazide, whose substituents would have been in the positions observed for the final product.

---o0o---

Comparison of electrophilic amination, which can also be regarded as nucleophilic substitution at a nitrogen atom, with reactions involving nucleophilic substitution at a carbon atom, shows that the latter reactions have been investigated in very great detail, including their mechanisms, while the mechanisms of nucleophilic substitution at a nitrogen atom have been very little studied.

The kinetics of the reactions of chloramine and certain alkylchloramines in the Raschig synthesis of hydrazine have been investigated. The studies of the reactions involving hydroxylamine-*O*-sulphonic acid have been concerned with syntheses on a preparative scale. The available information about amination with the aid of oxaziridines is based largely on synthetic studies and a few superficial kinetic investigations. Despite this, in the present review an attempt has been made to survey the available information from a single standpoint concerning the mechanism of electrophilic amination. This is justified to some extent by the fact that the majority of the studies discussed have been carried out in recent years and have been stimulated by definite ideas about the mechanism of the process.

The Reactivity of Epithio-compounds†

A.V.Fokin and A.F.Kolomiets

The available information about the reactions of epithio-compounds with nucleophilic and electrophilic agents, about the homolytic reactions of alkene sulphides, and about reactions leading to the elimination of sulphur with formation of alkenes is examined, the mechanisms of the opening of thiiran rings are discussed, and the comparative characteristics of the reactivities of O- and S-heteroanalogues of cyclopropane compounds are given.
The bibliography includes 276 references.

CONTENTS

I. INTRODUCTION

The increasing interest in the chemistry of sulphur-containing organic compounds is not fortuitous and is due primarily to the urgent necessity for the utilisation of large amounts of sulphur and its simple compounds, the reserves of which are continuously increasing as a result of the increasing output of the metal extracting industry. In terms of this aspect, the chemistry of thiirans has unlimited possibilities. It is sufficient to mention that the methods of synthesising epithio-compounds developed in recent years are based on the use of sulphur chlorides, carbon disulphide, carbon oxide sulphide, metal sulphides, and other simple sulphur compounds [1].

In contrast to oxirans, the chemistry of which is closely related to the large-scale manufacture of a wide variety of substances and materials, thiirans have not as yet found extensive applications. The prospects for the practical utilisation of epithio-compounds became apparent only in the last decade. The polymerisation reactions of thiirans, which have become an independent field of study, are specially important from this point of view [2-4].

The most notable advances in the synthesis of high-molecular-weight compounds (HMC) based on thiirans have been achieved after the discovery of the high initiating capacity in these processes of organic and inorganic derivatives of zinc-subgroup metals. Using catalysts of this type, methods have been developed for the stereospecific polymerisation of racemic thiirans [5-8] and procedures for the formation of elastomeric homo- and co-polymers [9-19], thermoplastic fibre-forming high-molecular-weight compounds [20], and latexes resembling rubber latexes [21]. Polymers synthesised by this method are frequently vulcanised by sulphur [22] and can be readily worked by casting or pressing [23,24]; the articles obtained are resistant to corrosive media, solvents, and light, and possess useful mechanical properties. Elastomeric poly(alkylene sulphides) are satisfactorily covulcanised with rubbers [25,26]. The covulcanisates obtained exhibit low swellability in organic solvents and an enhanced resistance to the action of light.

Various methods for anionic and cationic polymerisation of thiirans [27-31] and for their copolymerisation with other monomers [32-35], whereby it is possible to obtain high-molecular-compounds with properties valuable in practice, have been extensively studied. The possibility of imparting water-repellent properties and of increasing the light resistance of materials made of synthetic and natural polymers by grafting poly(alkylene sulphides) on to them has also been demonstrated. The above, by no means complete, list of applications of the polymerisation capacity of thiirans shows that their practical utilisation in the immediate future is feasible.

The possibility of direct applications of thiirans has been studied much less. Among the compounds examined, there are substances with a high nematocidal activity [36] and with insecticidal [37], bactericidal [38-40], and herbicidal [41] properties. However, their use in practice is limited because of their extremely unpleasant smell. For the same reason, the use of epithio-compounds as components of pesticidal preparations is unlikely, despite their high stabilising activity [42]. The unpleasant smell makes it possible to use certain thiirans to impart an odour to gases and poisonous liquids [43].

The employment of epithio-compounds as intermediates in the synthesis of anticorrosion and antiwear additives to lubricating oils and greases, surfactants, flotation reagents, extractants, sorbents for hydrometallurgy, and pesticidal preparations is more promising. The advances achieved in research in the above fields are in many respects determined by the level of knowledge of the reactivities of the compounds.

The chemistry of epithio-compounds is at present being established. During the last ten years, studies have been made on the reactions of thiirans with a wide variety of electrophilic and nucleophilic compounds. The first qualitative and semiquantitative determinations have been made of the reactivities of thiirans. The extensive application of physicochemical methods to demonstrate the structures of the reaction products made it possible to reassess the characteristics of the reactions involving the opening of thiiran rings. For these reasons, the latest reviews on the chemistry of thiirans available to the Soviet reader [44,45] no longer reflect the present state of the problem. In the present paper an attempt is made to give a systematic account and a critical assessment of the available information about the reactivities of epithioalkanes.

---

† Sulphur-containing heteroanalogues of cyclopropane derivatives are also called epithioalkanes, alkylene sulphides, and thiirans [1].

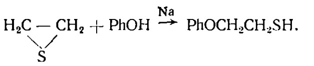
II. NUCLEOPHILIC CLEAVAGE REACTIONS

Alcohols, phenols, phosphites, thiols, organometallic compounds, primary and secondary amines, certain C–H acids, and metal hydrides have been involved in the nucleophilic opening of the three-membered ring of epithio-compounds. The characteristics of the above reactions have been by no means completely elucidated and in analysing the results one can only speak of the most general relations between the properties of the starting materials, the nature of the products, and the conditions governing their formation.

a. Reactions with Hydroxy-Compounds

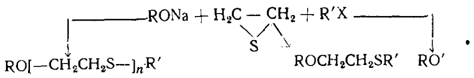
The attempts to introduce water and ethanol into reactions with 2-methylthiiran in the absence of catalysts led to the formation of a complex mixture of oligomeric products[46]. Ring opening occurred only under severe conditions (100°C). Thiiran and 2-methylthiiran react vigorously with water and alcohols in the presence of various alkaline agents[47–54], forming polymeric products. Thiiran itself polymerises particularly readily under these conditions (at room temperature). The polymerisation of 2-methylthiiran in alcoholic solutions of bases requires moderate heating. Monomeric products are not formed in reactions of thiirans with alcohols in the presence of bases and with alkali metal alkoxides.

Sodium phenoxide is said[55–57] to condense with thiiran to form 2-phenoxyethanethiol:

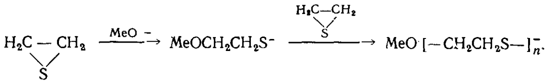


However, it has been shown recently[58] that polymerisation reactions are the main processes in this case too and monomeric products are formed in extremely small amounts.

Certain hypotheses concerning the nature of the nucleophilic reactions involving the opening of thiiran rings by hydroxy-compounds may be based on data obtained in studies of competing reactions in sodium alkoxide (phenoxide)–thiiran–electrophilic agent systems[59]. The opening of the thiiran ring by sodium methoxide and phenoxide in non-polar media proceeds at a satisfactory rate only at 40–50°C and is accompanied by polymerisation reactions. In the presence of electrophilic reagents, polymerisation reactions are suppressed. Depending on the properties of the electrophilic agent, low-molecular-weight oligomeric substances or products of the alkylation of 2-methoxy-(phenoxy)ethanethiol are formed under these conditions:

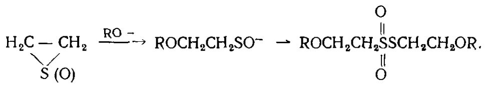


In the presence of strong electrophilic agents such as allylic alkyl halides, the reactions in the above system lead to monomeric products, and diethers of ethylene monothioglycol are formed in yields up to 50%. These results led to the hypothesis that, in media of low polarity, the electrophilic properties of thiiran and allylic alkyl halides are comparable. A study[59] has shown that the polymerisation reactions of thiirans with hydroxy-compounds in the presence of alkaline catalysts are due to the formation of thiolate anions, which are more reactive than alkoxide anions:

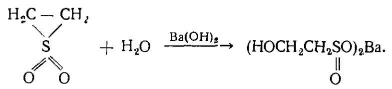


The ability of hydroxy-compounds to cleave thiiran rings comparatively readily has been used to graft poly(ethylene sulphide) and poly(propylene sulphide) to cotton, cellulose, paper, and similar materials in order to make them light resistant, water repellent, etc.[60–66].

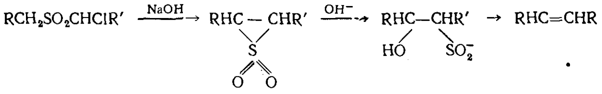
In contrast to thiirans, episulphoxides and episulphones are cleaved by hydroxy-compounds to monomeric products. On heating with water and alcohols, thiiran 1-oxide interacts according to the equation[67]



In the presence of barium hydroxide, the thiiran 1,1-dioxide ring undergoes hydrolytic cleavage under mild conditions[68]:

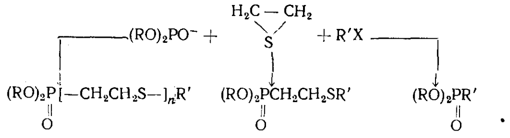


In the presence of sodium and potassium hydroxides a wide variety of alkylene episulphones, which are intermediates in the Ramberg–Baeckland rearrangement[1], react similarly:



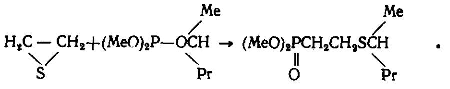
b. Reactions with Phosphites

The acidity of dialkyl phosphites is higher almost by two orders of magnitude than that of alcohols. Despite this, the reactions of sodium dialkyl phosphites with thiiran lead to polymeric products only[69]. Polymerisation takes place also when a mixture of dialkyl phosphite and thiiran is treated with sodium alkoxides. In the presence of alkyl halides, the polymerisation reactions are suppressed. In a system of competing reactions between dialkyl phosphites, thiiran, and alkyl halides, the direction of the process is determined by the relative reactivities of the electrophilic agents:



In the presence of allylic alkyl halides, the reactions proceed only with formation of monomeric products. Thus, as in the reactions with hydroxy-compounds, the polymerisation of thiiran on interaction with dialkyl phosphites in the presence of bases is a consequence of the more pronounced nucleophilic properties of the resulting thiolate anions compared with dialkyl phosphite anions:

Trialkyl phosphites eliminate sulphur from epithio-compounds under comparatively mild conditions (see below). However, according to patent data[70], phosphites with secondary alkyl groups are involved in thiiran ring opening reactions:

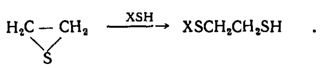


c. 2-Mercaptoalkylation of Thiols

The cleavage of the thiiran ring by thiols takes place even in the absence of catalysts. The reaction conditions are determined by the nature of the nucleophile and of the epithio-compound. According to a patent[71], aliphatic thiols interact with thiiran at 100–200°C, forming mixtures of 2-alkylthioethanethiols (up to 50%) with products of oligomerisation reactions:

2,3-Tetramethylenethiiran does not react with aliphatic thiols under these conditions[46]. According to a later report[72], thiiran condenses with thiols in the presence of a two-fold excess of the latter even at 50–70°C.

2-Mercaptoalkylation is facilitated with increase of the acidity of the thiol. Hydrogen sulphide in methanol condenses with thiiran at 45–60°C, forming ethylene dithioglycol and oligomeric products[73]. Thiophenol[72], dialkyl phosphorodithioic, phosphonothioic, and phosphonodithioic acids react under similar conditions with formation of monomeric reaction products[74–77]:

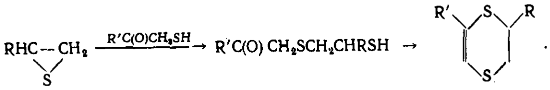


[X=Ph, (RO)$_2$P(S), R (R'C;P(S)].

Thus unambiguous non-catalysed reactions occur only between thiirans and highly nucleophilic thiols. The relatively mild conditions of the above reactions make it possible to graft thiiran to wool fibres and human and animal hair[78,79]. In the latter case the reactions involve cysteinyl residues of protein molecules.

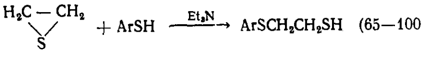
The condensation of thiirans with thiols is promoted by bases. 2-Methyl-, 2,3-tetramethylene-, and 2-hexylthiirans react with sodium and potassium hydrogen sulphides under mild conditions[46,80,81]. Like 2-chloromethyloxiran, 2-chloromethylthiiran forms polymeric products in this reaction[82]. The epithio-compound proved to be less reactive than its oxygen analogue. On moderate heating in the presence of sodium methoxide or ethoxide, aliphatic thiols condense with thiiran, 2,2-dimethylthiiran, and 2,3-tetramethylenethiiran[46,73,83–86]. The yield of monomercaptoalkylation products for stoichiometric proportions of the reactants does not exceed 40–50%, but may be raised to 75% by using a twofold excess of the thiol[83]. Similar results were obtained also in reactions of 2-methylthiiran[86,87], 2-mercaptomethylthiiran, and its acetyl analogue[87]. The amount of catalyst does not have a marked influence on the yield of reaction products.

In the presence of alkali metal alkoxides, primary, secondary, and tertiary aliphatic thiols were made to react with thiirans. The yield of condensation products was found to decrease with increasing steric effects at the mercapto-group[46]. 2-Alkoxyalkanethiols react with thiirans just as readily as other primary thiols[83,85]. On reaction with thiirans, α-mercaptoketones form 2-mercaptoalkylation products, which cyclise under the reaction conditions to 2,3-dehydro-1,4-dithiane derivatives[88]:



Reactions involving 2-mercaptoalkylation of thiols catalysed by organic bases have been investigated. *o*-Aminothiophenol reacts smoothly with thiiran at 20°C [89]:

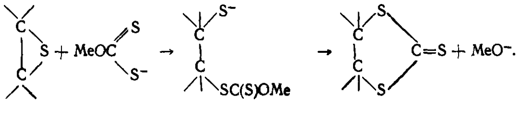
In the presence of triethylamine, thiophenol and its halogeno-, methyl-, and methoxy-substituted homologues condense with thiiran at 40–50°C [90]:



For equimolar proportions of the reactants, monomeric products are formed quantitatively when sterically unhindered thiophenols are used[91]. Quantitative 2-mercaptoethylation of aliphatic thiols and *o*-substituted thiophenols proceeds only in the presence of an excess (100–200%) of the initial thiol. The condensation of thiiran with thioacetic acid under these conditions is accompanied by polymerisation reactions.

The addition of thiophenols to thiiran in non-polar media catalysed by triethylamine proceeds with somewhat greater difficulty than the addition to oxiran[91]. Thiophenol and *p*-thiocresol are quantitatively titrated by oxiran at 20°C, while titration by thiiran requires heating above 40°C. The mode of opening of the thiiran ring by thiolate anions has been investigated[84,87,92] and it has been shown that 2,2-dimethylthiiran is cleaved mainly in accordance with Krasuskii's rule at the carbon atom with the largest number of hydrogen atoms[84]. However, products with the "anomalous" structure (primary thiols) are formed in small amounts (up to 4%). 2-Methylthiiran also reacts with thiols in accordance with Krasuskii's rule[87]. This conclusion was confirmed in a later study[92] where the structure of the condensation product was demonstrated by gas-liquid chromatography (GLC) and NMR:

Unusual reactions between thiiran and salts of thio- and dithio-carbonic acids have been discovered. Potassium methyl xanthate converts 2,3-tetramethylenethiiran into 1,2-cyclohexylene trithiocarbonate[80,93]. The reaction proceeds via a ring-opening stage according to the mechanism



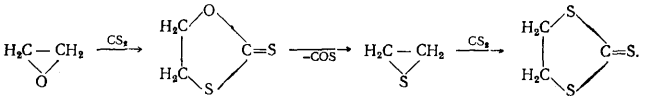
In polar media the cleavage of thiiran and oxiran rings by xanthates proceeds with equal ease. For this reason, the reactions of oxirans and thiirans with carbon disulphide and alkalis in methanol give rise to the same products—trithiocarbonates[80,93–97]. With increase of the size of the alkyl group in the xanthate, the yield of the condensation product falls because of side reactions. The reaction of ethyl xanthate with steroid epoxides already gives rise to small amounts of unsaturated compounds together with dithiocarbonates, while in the reaction with butyl xanthate the unsaturated compounds are the only products[97].

The formation of alkenes is probably associated with steric effects in the opening of the thiiran ring. In the reaction with methyl xanthate even thioglycidic acids, which readily eliminate sulphur, are smoothly converted into trithiocarbonates[98].

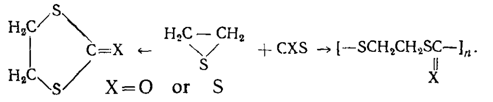
The formation of trithiocarbonates is not the only pathway in the reactions of thiirans with xanthates. High-molecular-weight compounds containing dithiocarbonic acid groups in the polymer chain react with thiiran like the usual thiols. Thus, on treatment of viscose fibres with thiirans, the xanthate groups in the polymer matrix are not split off[99]. The nucleophilic opening of the thiirans by thiols is widely used in the synthesis of polymers. By grafting poly(alkylene sulphides) to alkaline viscose, water repellent viscose fibres are obtained[99]. Elastomeric high-molecular-weight compounds have been obtained by the copolymerisation of 2-methylthiiran with 1,3-dimercaptopropane in the presence of tertiary amines[100]. Certain thiols (sodium sulphide and hydrogen sulphide, hydrogen sulphide, and 1,2-dimercaptoethane) are effective catalysts in the polymerisation of lower epithio-compounds in polar media[101]. Hydrogen sulphide and aliphatic thiols are used as effective cocatalysts of organic and inorganic zinc-subgroup metal derivatives in the polymerisation and copolymerisation of various thiirans[102-105]. Zinc xanthates[106] and iron, cobalt, and other metal mercaptides[107] have also been used as polymerisation catalysts.

d. Condensation of Thiirans with Thiono-Compounds

The possibility of the nucleophilic condensation of thiiran with thiono-compounds was suggested for the first time by Durden et al.[108] in order to explain the formation of ethylene trithiocarbonate in the reaction of oxiran with carbon disulphide catalysed by triethylamine:



Razuvaev and coworkers confirmed this hypothesis experimentally having shown that in the presence of triethylamine as the catalyst thiiran condenses with carbon disulphide[109,110] and carbonyl sulphide[111,112], forming monomeric cycloaddition products or regular low-molecular-weight polymers:

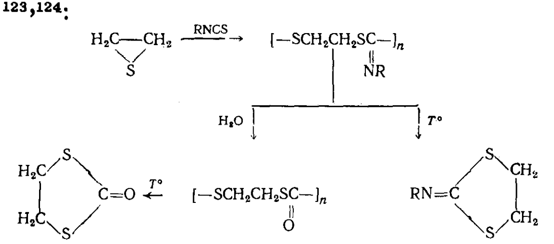


The reaction proceeds even at 20°C and at 95–100°C reaches completion in several hours. In the above reactions carbon disulphide is much more reactive than carbonyl oxide sulphide. Apart from oxiran, 3-methyloxiran and 2,3-tetramethyleneoxiran condense with carbon disulphide and carbonyl sulphide. 2-Chloromethylthiiran does not enter into these reactions probably because of the inactivation of the catalyst in the reaction mass.

The mechanism of the above reactions has not been investigated. Presumably the species initiating the process is the thiolate anion formed when the thiono-compound reacts with triethylamine. The product of its condensation with a thiiran molecule undergoes an intramolecular rearrangement or reacts with a second molecule of the thiono-compounds, propagating the polymer chain.

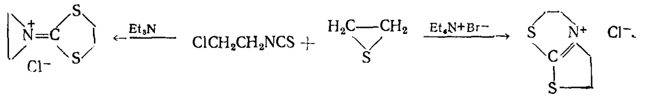
The nucleophilic addition of carbon disulphide and carbonyl sulphide to thiirans proceeds under somewhat more severe conditions than in the reactions with oxirans. As a result, the reactions of thiirans with carbonyl sulphide and carbon disulphide are used under suitable conditions to obtain epithio-compounds and alkylene monothiocarbonates and dithiocarbonates[113-122].

The thiono-compounds used in reactions with thiirans included alkyl and aryl isothiocyanates. The condensation of thiiran and 2-methylthiiran with methyl, ethyl, n-butyl, phenyl, *p*-tolyl, and α-naphthyl isothiocyanates proceeds under mild conditions in the presence of triethylamine as the catalyst. The reaction products are low-molecular-weight polymers, which are decomposed by bases and acids[123,124]:



Polymers with higher molecular weights are formed when the reactions are catalysed by butyl-lithium and sodionaphthalene[125-130]. The rate of copolymerisation of thiirans is reduced in this case with increase of the molecular weight of the isothiocyanate and when the electron-accepting properties of the substituent at the isothiocyanato-group are enhanced. The process proceeds via a stepwise mechanism with participation of "live" polymer molecules. The degree of reaction increases with increase of the basicity of the solvent, exceeding 90% in hexamethylphosphoramide. It is believed that the thiolate anion formed when the catalyst reacts with the isothiocyanate initiates the copolymerisation.

In contrast to unsubstituted alkyl isothiocyanates, 2-chloroethyl isothiocyanate reacts with thiiran to form monomeric products: 1-(1,3-dithian-2-yl)aziridinium chloride in the presence of triethylamine as the catalyst and 2,3,5,6-tetrahydrothiazolo[2,3-*b*]thiazolinium chloride in the presence of tetraethylammonium bromide[131]:

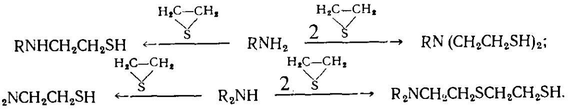


e. 2-Mercaptoalkylation of Amines

Nucleophilic reactions involving the opening of thiiran rings by nitrogen-containing compounds have been most thoroughly investigated among processes of this type. Despite this, the published studies are confined mainly to the description of the reactions of thiirans with primary and secondary amines. Ammonia, hydroxylamine, hydrazine, and acid amides and imides have not so far been 2-mercaptoalkylated.

The report of the synthesis of monomeric products of the condensation of thiirans with primary and secondary aliphatic, aromatic-aliphatic, and aromatic amines first appeared in the patent literature[132]. Thiiran and 2-methylthiiran react with amines in a closed vessel at

100–200°C. It was assumed that, depending on the reactant ratio, mono- or di-mercaptoalkylation products are formed:

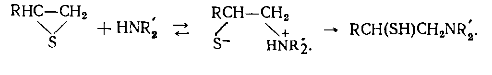


Under the conditions described in the above patent[132], thiiran was condensed with various secondary amines[133,134]. Gilmann and Woods[135] described the reaction of thiiran with lithium diethylamide and showed that the yield of product is in this case even lower than in Ref. 132. The structure of primary thiols was attributed to products of the condensation of 2-methylthiiran with amines[132], i.e. the "anomalous" opening of the thiiran ring by these substances was postulated. Hansen[136,137], who investigated the reaction of dimethylamine with thiiran and 2-methylthiiran in ether, later reached a similar conclusion.

The reactions of thiiran, 2-methylthiiran, 2,2-dimethylthiiran, and 2,3-tetramethylenethiiran with primary and secondary amines were described extensively for the first time by Snyder et al.[138], who showed that the rate of reaction of primary and secondary amines with thiirans at 100°C, using stoichiometric reactant ratios, depends significantly on steric effects. The reaction products were obtained in a high yield only from sterically unhindered amines. Amines with the iso-structure are mercaptoethylated with greater difficulty than n-alkylamines. Diphenyl- and dicyclohexyl-amines are not mercaptoethylated at 100°C. Among thiirans, the unsubstituted thiiran is the most reactive. With increase of the bulk of the substituents in the thiiran ring, the reactivity of the latter falls. Thiirans can be arranged in the following sequence in terms of decreasing capacity for cleavage by amines: thiiran > 2-methylthiiran > 2,2-dimethylthiiran > 2,3-tetramethylenethiiran.

According to Snyder et al.[138], the addition of secondary amines to 2,2-dimethylthiiran leads to the formation of tertiary mercaptans. This disproves the hypothesis of the "anomalous" opening of thiiran rings by amines and shows that the nucleophilic agent attacks the ring carbon atom with the greatest number of hydrogen atoms, in accordance with Krasuskii's rule. The "normal" cleavage of the thiiran ring by amines was subsequently demonstrated in reactions of secondary amines with 2-methylthiiran and 2,2-dimethylthiiran[139], alkoxy- and aryloxy-derivatives of 2-methylthiiran[140,141], 2-phenylthiiran[142], aminomethylthiirans[143], and 2-vinylthiiran[144].

The principal characteristics of the reactions of thiirans with amines, obtained by Snyder et al., in qualitative and semiquantitative studies, were confirmed by the kinetic data[145]. The study of the influence of the basicity of amines and steric factors on the rate of cleavage of thiiran rings in dioxan at 60°C suggested a typical S_N2 mechanism for these reactions. The first step is believed to be slow attack by the nucleophilic agent on the relatively unhindered ring carbon atom, after which there is rapid migration of a proton from the nitrogen atom to the sulphur atom:



However, Oddon and Wylde's ideas[145] concerning the formation of an intermediate dipolar adduct are doubtful. Analysis of data for the influence of the structure of the amine on the optimal conditions in the formation of monomeric condensation products suggests synchronous transfer of a proton to the sulphur atom and of the nucleophilic species to the carbon atom. Otherwise the reaction is accompanied by polymerisation processes.

The influence of solvents on 2-mercaptoalkylation reactions of amines was discussed wisely for the first time in a report by Braz[54]. It was shown that thiiran reacts with secondary amines even without heating. In order to exclude the polymerisation of thiiran, it is desirable to carry out the reactions in an excess of the amine employed or in non-polar solvents in the presence of an excess of the amine. At 50–60°C the lower amines react rapidly with thiiran. These results[54] were confirmed by other studies and have been widely used by many investigators[146–149]. It proved possible to condense thiiran with aziridine in non-polar solvents, the two compounds copolymerising readily in the absence of a solvent[149].

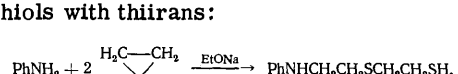
Other investigators made somewhat different recommendations concerning the choice of solvents. Thus it is recommended that thiirans be condensed with highly polar amines under homogeneous conditions using their solutions in a mixture of benzene and anhydrous alcohol[148,150]. The 2-mercaptoalkylation of *N*-methylaniline by 2,3-tetramethylenethiiran proceeds smoothly in aqueous alcohol, but does not occur in the absence of a solvent[46]. 2-Phenylthiiran undergoes sulphur-elimination reactions with piperidine and morpholine in the absence of solvents[151]. Normal addition products are formed in the mixture of benzene and alcohol and the degradation of the thiiran is not observed.

The above and other similar data[140,143,147] suggest that the optimal conditions for the 2-mercaptoalkylation reactions depend greatly on the electrophilic properties of the thiiran and on the basicity of the amine. The polarity of the medium facilitates the nucleophilic opening of the thiiran ring by amines, which may be used only in reactions with amines of low basicity. Highly basic amines can be made to react with relatively unreactive thiirans in polar solvents. The lower representatives of the class of thiirans polymerise extremely easily under these conditions. This conclusion is confirmed by the results of Reynolds and coworkers[152,153] obtained in a study of the mercaptoethylation of amines by ethylene monothiocarbonate and other similar compounds, which react via the stage involving the formation of thiiran. In the general case the formation of monomeric products of the condensation of amines with thiirans requires reaction conditions (temperature, solvent, and reactant ratio) which exclude the possibility of nucleophilic sulphur elimination and tend to reduce the stability of the sp^3-hybrid state of the nitrogen atom.

The reactions of thiirans with primary aliphatic and aromatic amines can proceed with formation of mono- and di-2-mercaptoalkylation products. Thus it has been shown[54–57,85,132,138,145–150,154–165] that, under homogeneous conditions in non-polar media and media of low polarity, substituted and unsubstituted alkylamines condense with thiirans on heating, forming mainly mono-(2-mercaptoalkyl)amines. 2-Chloromethylthiiran reacts with primary amines to form polymers[143].

Aromatic amines condense with thiirans under more severe conditions than aliphatic amines. In order to complete the reaction, heating to 100–110°C is usually necessary. The products of the condensation of an amine molecule and two thiiran molecules, which are formed to some extent in the reactions, are secondary amines according to some data[54,142]. The structure of tertiary amines was attributed to similar substances in other investigations[132,138]:

Bulavin's report[160] deals with the structure of these substances. The author showed that aniline in a non-polar solvent or in the absence of a solvent reacts with thiiran to form the tertiary amine—bis-(2-mercaptoethyl)phenylamine. The same product was obtained by condensing thiiran with *N*-(2-mercaptoethyl)aniline. Secondary amines are formed only when the reaction is catalysed by sodium ethoxide, i.e. under the conditions for the condensation of thiols with thiirans:



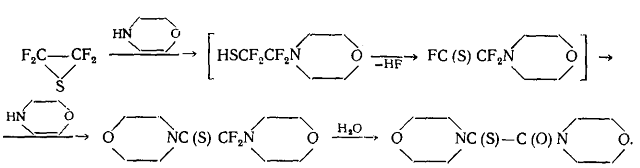
Aminoacid esters react with thiiran similarly to aniline. Thus in non-polar media thiiran can be used, like oxirans, for the exhaustive 2-mercaptoalkylation of primary amines. Under these conditions, best results are obtained in two-stage rather than single-stage synthesis[132,160].

The catalytic effects in 2-mercaptoalkylation reactions of amines have been little studied. The promoting influence of phenols in the condensation of thiiran with amines is noted in a patent[132]. However, it was later shown[138] that phenol and aluminium chloride do not catalyse these reactions.

According to patent data[166], the condensation of thiiran with primary amines is facilitated in the presence of aluminosilicates.

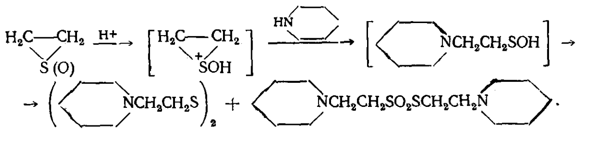
Apart from primary and secondary amines, cyanamide, guanylurea, biguanide[167–169], and monophosphorylated phenylenediamines[165] have been introduced into the reaction with thiiran. The structures of the products formed were not elucidated.

Unusual reactions occur between tetrafluorothiiran and morpholine[170]. The product of the primary cleavage of the C–S bond readily undergoes dehydrofluorination with formation of difluoro(morpholino)thioacetyl fluoride. The latter reacts with an excess of morpholine to form a morpholide, which is converted in the presence of water into the dimorpholide of thio-oxalic acid:



The reactions proceed under mild conditions, which shows that tetrafluorothiiran has marked electrophilic properties.

The nucleophilic opening of the thiiran 1-oxide ring by piperidine takes place readily in the presence of an acid catalyst[67]. The reaction results in the formation of di-(2-piperidinoethyl) disulphide and the 2-piperidinoethyl ester of *NN*-cyclopentamethylenethiolotaurine:



The comparatively high rates of cleavage of thiiran rings by amines are used in polymerisation processes. Ammonia, alkylenediamines, and alkylenepolyamines are effective cocatalysts of zinc-subgroup metal compounds for the preparation of polymers (copolymers) in bulk[12,21,171] and also of latexes of vulcanisable rubbers based on thiirans[21].

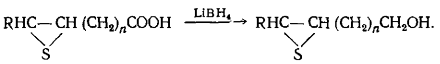
f. Reactions of Thiiran with Metal Hydrides and Tetrahydroborates

Mousseron and coworkers were the first to use lithium tetrahydroaluminate for the reduction of tetramethylthiiran and 2,3-tetramethylenethiiran[172,173]. The reaction resulted in the formation of the corresponding thiols in yields up to 85%. Later Bordwell et al.[174] used this reaction to demonstrate the mode of opening of the thiiran ring by the nucleophilic AlH_4^- species. The reduction of 2-methylthiiran, 2-butylthiiran, and 2,3-tetramethylenethiiran leads to secondary thiols, which indicates the rupture of the C–S bond involving the sterically unhindered carbon atom. The same mode of cleavage obtains in the reduction of 2-hexylthiiran[175] and 2-alkoxymethylthiirans[176] by lithium tetrahydroaluminate:

The unambiguous occurrence of the "normal" opening of the thiiran ring in reduction by lithium tetrahydroaluminate has been demonstrated by GLC[92]. The reduction process is accompanied by the inversion of the molecular configuration, as shown by data obtained in a study of the reactions of 2,3-dimethylthiiran isomers with lithium tetradeuteroaluminate[177]. Epithio-derivatives of carbohydrates are reduced similarly to the usual aliphatic epithio-derivatives[178].

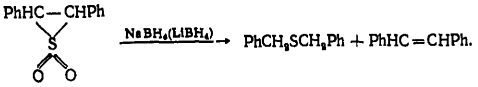
A side process in the reactions discussed above is polymerisation of thiirans. In many cases this is the only process. It has been shown that, in the presence of lithium tetrahydroaluminate, 2-alkoxymethylthiirans are reduced while 2-phenoxymethylthiiran polymerises[176]. The polymerisation of 2-hexylthiiran by lithium tetrahydroaluminate proceeds readily and quantitatively in tetrahydrofuran, although in ethyl ether mainly the reduction of the thiiran takes place[175]. Polymerisation reactions in such cases are due to the pronounced polarisation of the nucleophilic agent in the reaction complex or to the specific solvation of the cation, which stabilises the thiolate anions of the final products.

In contrast to lithium tetrahydroaluminate, tetrahydroborates do not reduce the thiiran ring under mild conditions. Thiiranylcarboxylic acids form the corresponding thiiranyl alcohols in these reactions[179]:



Sodium trithionodihydroborate behaves as a source of elemental sulphur in its reactions with thiirans[180]. The reaction results in the formation of polymers with disulphide linkages, the reduction of which yields 1,2-dimercaptoalkanes:

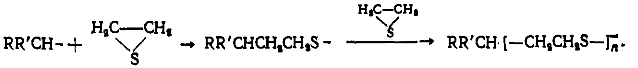
An interesting example of the reductive cleavage of the C–C bond in the thiiran ring has been described[181]. When 2,3-diphenylthiiran 1,1-dioxide reacts with sodium and lithium tetrahydroborates, dibenzyl disulphide is formed together with small amounts of a product of side reactions—stilbene:



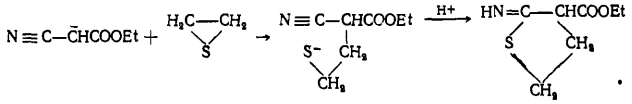
Lithium tetrahydroaluminate and sodium and lithium hydrides do not cleave the C–C bond.

g. The Opening of the Thiiran Ring by Carbanions

Despite the high basicity of carbanions, their interaction with thiirans leads to polymerisation[182]. The latter is probably due to the greater susceptibility of the thiiran ring to cleavage by thiolate anions than by carbanions:

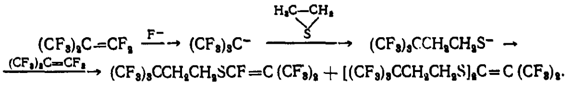


Monomeric products of the condensation of thiirans with substances generating carbanions are formed only when effective acceptors of thiolate anions are present in the reaction sphere. Examples of such reactions are the condensation of thiiran, 2-methylthiiran, and 2,2-dimethylthiiran[182] as well as 2-phenylthiiran[181] with cyanoacetic ester via the mechanism



The cyano-group of the initial compound serves as the acceptor of thiolate anion in these reactions, which leads to the formation of iminotetrahydrothiophen derivatives as cyclisation products. The above reactions are accompanied by the polymerisation of thiirans. The yield of monomeric products is higher the lower the reactivity of the thiiran competing with the cyano-group in processes involving the capture of thiolate anions.

An interesting example of the opening of thiiran rings by carbanions has been described[183]. The reaction of octafluoroisobutene with thiiran in the presence of potassium or caesium fluoride is accompanied by the nucleophilic opening of the thiiran ring and nucleophilic substitution of a fluorine atom in the perfluoro-olefin by the thiolate anion formed. The first reaction step involves the formation of the carbanion:



The yield of monomeric condensation products in the above reaction is higher than in the reaction of thiiran with cyanoacetic ester, which can be accounted for by the more effective capture of thiolate anions by perfluoroisobutene.

III. ELECTROPHILIC CLEAVAGE REACTIONS

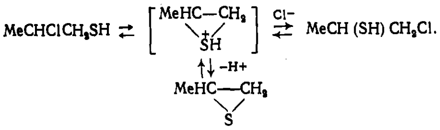
A wide variety of electrophilic agents have been introduced into electrophilic reactions involving the cleavage of thiirans: hydrogen halides and their aqueous solutions, other inorganic and organic acids, halogens, carboxylic acid halides and anhydrides, sulphur, phosphorus, and arsenic halides, isothiocyanatoarsines, alkyl halides, and compounds with multiple bonds (nitriles, ketens, carbonyl and thiocarbonyl compounds, and perfluoroalkenes). Together with these, thiirans condense with nucleophilic agents (alcohols, thiols, tertiary amines) in the presence of initiators of electrophilic processes.

a. Reactions with Acids

Delepin and coworkers[47,49] showed that the reactions of thiiran with dilute hydrogen halides lead to the formation of polymeric products. Only in the presence of concentrated hydrochloric acid with cooling is thiiran converted into 2-chloroethanethiol[47] and in the presence of hydrobromic acid into 2-bromoethanethiol[49]. Together with monomeric substances, oligomers are formed in these reactions:

2,3-Tetramethylenethiiran and 2-chloromethylthiiran react with concentrated hydrochloric acid on cooling similarly to thiiran itself, polymerising in boiling acid[46].

The reactions of substituted alkylthiirans with aqueous hydrochloric acid solutions may be regarded as reversible. It has been shown[92] that 2-chloropropanethiol isomerises in the presence of water with formation of a mixture of substances containing about 60% of 2-methylthiiran:



α-Chloro-β-mercaptoalkanecarboxylic acids undergo similar reactions with 10% HCl.[184] In this case equilibrium is strongly displaced towards the formation of the thiiran:

The opening of the ring in these compounds also occurs only in concentrated hydrochloric acid solutions.

Anhydrous hydrogen halides in ether or methylene chloride cleave thiirans under mild conditions with formation of monomeric products only[73,92,142,185-189].

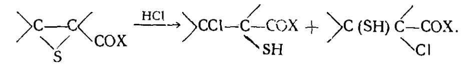
The mode of cleavage of the ring in asymmetric thiirans by hydrogen halides was investigated by chemical methods in early studies. According to some workers[185-188], the reactions of 2-methylthiiran and 2-chloromethylthiiran with hydrogen halides lead to primary thiols, i.e. the thiiran ring is cleaved "anomalously" at the ring carbon atom with the smallest number of hydrogen atoms.

Only Stewart and Cordts[190] demonstrated the occurrence of "normal" ring opening in 2-methylthiiran by hydrogen chloride. However in a later report[142] the primary thiol structure was also attributed to the product of the reaction of 2-phenylthiiran with hydrogen halides.

Schwarts[92] made a careful study of the mode of cleavage of the rings in 2-methyl-, 2,2-dimethyl, and 2-chloromethyl-thiirans by anhydrous hydrogen halide solutions in ether and methylene chloride by GLC and NMR. He showed that the reactions proceed in different ways, with formation of a mixture of products of the "normal" and "anomalous" ring opening. Reactions in accordance with Krasuskii's rule predominate. The content of products with the "normal" structure in the resulting mixture is 76% for 2-methylthiiran, 66% for 2,2-dimethylthiiran, and 96% for 2-chloromethylthiiran. In the presence of water or hydrochloric acid, the primary thiols formed isomerise. The content of products with the "anomalous" structure in the equilibrium mixture reaches 90–98%:

$$\underset{(76\%)}{\mathrm{MeCH(SH)CH_2Cl}} + \underset{(24\%)}{\mathrm{MeCHClCH_2SH}} \overset{H+}{\rightleftarrows} \underset{(10\%)}{\mathrm{MeCH(SH)CH_2Cl}} + \underset{(90\%)}{\mathrm{MeCHClCH_2SH}}.$$

This property of 2-halogenoalkanethiols explains to some extent the contradictory results of early investigations and of Schwarts's study of the mode of cleavage of the thiiran ring by hydrogen halides. Different types of cleavage of the thiiran ring in αβ-epithioglycidic acids and their derivatives by concentrated hydrochloric acid have been observed[184]:



The first ideas concerning the mechanism of the reactions of thiirans with hydrogen halides were described by Davies and Savige[185,186]. The authors suggest that the reaction proceeds via the formation of an episulphonium cation, which is cleaved to the corresponding carbonium ion:

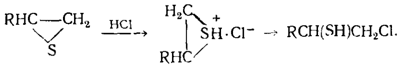
A similar reaction mechanism was proposed by Oddon and Wylde[188] on the basis of the authors' demonstration that the reactions of anhydrous hydrogen chloride and hydrogen bromide with thiiran are of second order.

The possibility that the reactions proceed by a carbonium mechanism was confirmed in an experimental test[191]. It was shown that tetrahydrofuran, which tends to undergo reactions of this type, forms a mixture of ω-halogenobutyl acetate and 1,4-bisdiacetoxybutane in the reaction with hydrogen halides in the presence of acetic anhydride. 1,4-Bisdiacetoxybutane may be the main product when hydrogen halide is slowly introduced into a solution of tetrahydrofuran in acetic anhydride. Even under these conditions, thiiran reacts with hydrogen halides to form only 2-halogenoethyl thioloacetates:

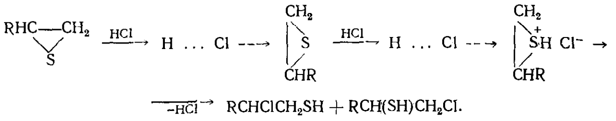
It was therefore concluded that the formation of monomeric products of the condensation of thiirans with hydrogen halides is hardly likely to be associated with the formation of carbonium ions.

Presumably only the reactions of thiirans with dilute solutions of hydrogen halides proceed via the carbonium mechanism, which is promoted by the effective solvation of the chloride ion by water molecules. In such reactions thiiran polymerises, because the carbonium ion involving the primary carbon atom is extremely electrophilic. Substituted thiirans form carbonium ions with the charge at the secondary or tertiary carbon atom. Their reduced reactivity is the reason for the stability of substituted thiirans in dilute acids noted above.

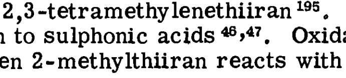
The formation of monomeric products in the reactions of thiirans with concentrated solutions or anhydrous hydrogen halides is a consequence of the formation and opening of the thiiranium halide ring in a close ion pair, which should lead to the formation of "normal" cleavage products:



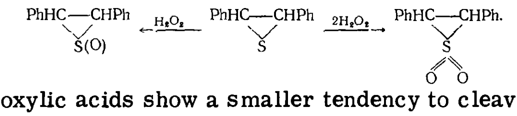
The low basicity of the sulphur atom in thiirans suggests the possibility that the reaction proceeds via a trimolecular mechanism involving the preliminary formation of π complexes:



The reactions of thiirans with other inorganic acids have been little investigated. Sulphuric acid is an active initiator of the polymerisation of thiiran[47–49], 2-methylthiiran[48], 2-chloromethylthiiran[192,193], tetramethylthiiran[194], and 2,3-tetramethylenethiiran[195]. Nitric acid oxidises thiiran to sulphonic acids[46,47]. Oxidative cleavage also occurs when 2-methylthiiran reacts with hydrogen peroxide[190]:



Thiiran is converted under these conditions into poly(ethylene sulphones)[68,196] and arylthiirans react without ring opening[197,198]:



Carboxylic acids show a smaller tendency to cleave thiiran compounds. Thiiran polymerises slowly in acetic acid and 2-methylthiiran and butylene sulphide remain unchanged in acetic acid solutions in the absence of heat[47,48]. 2,3-Tetramethylenethiiran condenses with acetic acid on heating, forming a mixture of monomeric and oligomeric products[146,199]. Under severe conditions, higher carboxylic acids condense with thiiran[200]. In the presence of oxygen, the 2-mercaptoethyl ethers formed initially are oxidised to disulphides:

In contrast to unsubstituted carboxylic acids, trifluoroacetic acid undergoes an exothermic reaction with thiiran, initiating its polymerisation under any conditions and for any order of mixing of the reactants[201]. Thiiran reacts smoothly with perbenzoic acid, forming polymers of thiiran 1,1-dioxide[68]. Substituted thiirans are oxidised by peracids to thiiran oxides and dioxides[197,198].

b. Reactions with Carboxylic Acid Anhydrides

The anhydrides of unsubstituted carboxylic acids condense with thiiran[192,200,202,203], 2-methylthiiran[92,185], 2,2-dimethylthiiran[186], and 2,3-tetramethylenethiiran[109] under severe conditions in the presence of pyridine as the catalyst. The reaction products are diesters of 2-mercaptoalkanols. Only epithio-derivatives of steroids fail to react with acetic anhydride even in the presence of pyridine[204,205].

According to some data[185,186], the cleavage of the thiiran ring by acetic anhydride takes place in accordance with Krasuskii's rule and is a second-order process. An S_N2 reaction mechanism was therefore postulated. However, subsequently it was shown that the opening of the ring of 2-methylthiiran by acetic anhydride takes place in different ways. The proportions of the products with the "normal" and "anomalous" structures (86 and 14%) in these reactions are almost the same as in the analogous reactions with hydrogen halides. It was also shown that the reactions of acid anhydrides with thiiran are promoted not only by bases but also by their hydrochlorides and the ease of reaction is determined primarily by the reactivity of the anhydride. Trifluoroacetic anhydride undergoes an exothermic reaction with thiiran even in non-polar media without catalysts[201]:

Thus the above reactions can be regarded as the usual processes involving electrophilic cleavage of thiirans.

c. Reactions with Acyl Halides

Acetyl, chloroacetyl, and aroyl chlorides as well as the bromides and iodides of aliphatic and aromatic carboxylic acids have been made to react with a wide variety of thiirans. According to Ivin's data[206], acid chlorides react only on heating. Acid bromides and particularly iodides undergo exothermic reactions with thiiran and 2-methylthiiran. With increase of the molecular weight of the acid halide, its capacity for condensation with thiirans diminishes. Aroyl chlorides react with greater difficulty than acetyl chloride[46]. 3,5-Dinitrobenzoyl chloride and benzoyl fluoride initiate the polymerisation of thiiran and their reactions with the latter compounds do not lead to monomeric products.

A wide variety of thiirans, including unsubstituted thiiran[136,203,206-208], 2-methylthiiran[46,92,185,206,209], 2-chloromethylthiiran[46,73,92,186], 2,2-dimethylthiiran[92], 2-phenylthiiran[142], and 2,3-tetramethylenethiiran[46,199] condense smoothly with acyl halides. 2-Mercaptomethylthiiran reacts smoothly with acetyl chloride in the presence of bases to form 2-acetylthiomethylthiiran[210,211]:

On heating, chlorocarbonic esters react with thiirans similarly to acyl chlorides[212]:

Phosgene undergoes exothermic condensation with thiiran and 2-methylthiiran via only one C–Cl bond. The attempts to achieve exhaustive substitution by 2-chloroethylthio-groups on heating were unsuccessful. Only in the presence of triethylamine as catalyst does the phosgene molecule condense with two thiiran molecules[213]:

Tertiary amines in the presence of traces of moisture or tertiary amine hydrohalides are effective catalysts of the reactions of thiiran with relatively unreactive acyl chlorides[208]. In the presence of pyridine hydrochloride or pyridine and moisture at 40–60°C thiiran condenses quantitatively with aryloxyacetyl chlorides. In the absence of catalysts, thiiran polymerises. The following mechanism may be postulated for the above reaction:

$$RC(O)Cl + Py \cdot HCl \rightarrow RC(O)Py^+Cl^- + HCl;$$

$$RC(O)Py^+Cl^- + ClCH_2CH_2SH \rightarrow RC(O)SCH_2CH_2Cl + Py \cdot HCl.$$

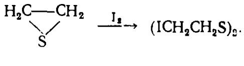
The opening of the 2-methylthiiran and 2-chloromethylthiiran rings by acetyl chloride and acetyl iodide and of the 2-methylthiiran ring by phosgene proceeds "anomalously" at the secondary ring carbon atom according to a number of investigations[185,206,212]. However, it has been shown by GLC and NMR [92] that mixtures of substances are formed in the reactions of 2-methyl-, 2-chloromethyl, and 2,2-dimethyl-thiirans with acetyl chloride and bromide and also with aroyl chlorides. The products of the "normal" cleavage of thiiran rings are mainly formed (54–85%). Only in the reaction of 2,2-dimethylthiiran with acetyl chloride do the "anomalous" pathways, accompanied by the formation of isobutenyl thioloacetate, predominate.

It is striking that in the 2-methylthiiran–*p*-aroyl chloride series a significant influence of the ring substituent on the proportions of the "normal" and "anomalous" products was not demonstrated[92]. The insignificant influence of the electrophilic properties of the acyl chloride on the mode of thiiran ring opening indicates a complex mechanism of the above reactions. Depending on the nature of the reactants employed and the reaction conditions, the electrophilic opening of the thiiran ring by acyl halides occurs to some extent via the carbonium mechanism or via the formation of an acyl sulphonium ion and the cleavage of the ring of the latter in the state of a contact ion pair. In many cases the process is decisively influenced by the presence of traces of moisture in the reaction sphere and by the involvement of the hydrogen halide in the ring opening step.

d. Reactions with Halogens

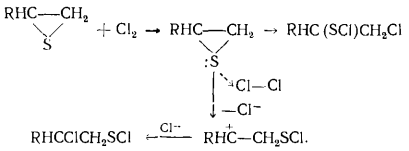
The earlier attempts to halogenate thiirans under severe conditions were unsuccessful. The exothermic reaction of thiiran with bromine yielded a viscous product of unidentified composition. 1,2-Dichlorocyclohexane and polymeric products were obtained by the chlorination of 2,3-tetramethylenethiiran under similar conditions[46,47]. The extensive study of the above reactions began only after the investigations by Stewart[192,214], who achieved the chlorination and bromination of 2-methylthiiran under mild conditions. It is now known that thiiran[215], 2-methylthiiran[92,192,214,215], 2-chloromethylthiiran[92,143], 2-phenylthiiran[142], and 2,2-dimethylthiiran[92,142] are smoothly chlorinated in solution in halogenoalkanes. In the absence of traces of moisture from the reaction, the halogenation reactions are not accompanied by the polymerisation of the thiirans and are usually completed after the introduction of the halogen into the reaction sphere. Depending on the reactant ratio, di-(2-halogenoalkyl) sulphide or 2-halogenoalkylsulphenyl halides are formed:

Like chlorine, sulphuryl chloride readily enters into the reaction[215]. The iodination of thiiran, 2-methylthiiran, and 2,3-dimethylthiiran is completed at the stage involving the formation of di-(2-iodoalkyl) sulphides:



In order to demonstrate the mode of ring opening, the products of the halogenation of 2-methylthiiran were converted into derivatives of 2-substituted alkanesulphonic acids the properties of which were compared with those of substances of known structure[192,214]. The "normal" opening of the thiiran ring was demonstrated in this way. The mode of 2-methylthiiran ring opening was also established by condensing with alkenes the 2-halogenoalkanesulphenyl halides formed in the reaction and by identifying the resulting sulphides in the form of their derivatives[215]; the "anomalous" opening of the 2-methylthiiran ring was thus demonstrated. Schwarts[92] showed by GLC and NMR that the above reaction takes place in several ways. The main products in the resulting mixture have the "normal" structure (55–85%), but in 2,2-dimethylthiiran the C–S bond is cleaved preferentially at the tertiary carbon atom:

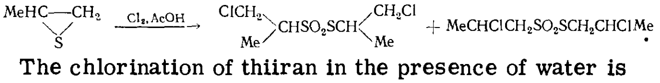
It is of interest that under the usual conditions tetrafluorothiiran does not interact with chlorine and bromine[170]. The reaction apparently requires comparatively marked nucleophilic properties of the ring heteroatom, which creates conditions favouring the heterolytic addition of a halogen molecule to the thiiran:



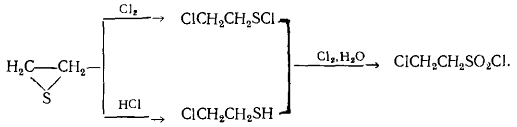
The chlorination and bromination of 2-methylthiiran in the presence of water and other hydroxy-compounds leads to the formation of products of the oxidative cleavage of the ring[92,192,214]. It has been shown[92] that the exhaustive oxidation of 2-methylthiiran by chlorine in water results in a mixture of substances where "normal" ring opening predominates:

The proportions of the "normal" and "anomalous" products are the same as in chlorination under anhydrous conditions. This suggests that the oxidative processes take place after the opening of the thiiran ring, which occurs in aqueous media via the same mechanism as under anhydrous conditions.

Exhaustive oxidative ring cleavage also occurs in the chlorination of 2-phenylthiiran[142] and 2-chloromethylthiiran[143] in aqueous acetic acid. In anhydrous acetic acid it is also possible to obtain a product of the partial oxidation of 2-methylthiiran by chlorine[192]. In this case a mixture of isomeric 2-chloroalkanethiyl esters of 2-chloroalkanesulphonic acids is probably formed:



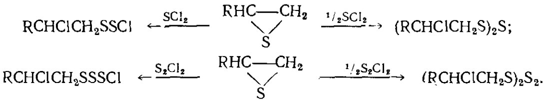
The chlorination of thiiran in the presence of water is always accompanied by the polymerisation of the former[217]. The reason for this is the unusually high capacity of thiiran for polymerisation via a cationotropic mechanism. The conditions for such reactions are created at the very beginning of the process on formation of a dilute HCl solution. The chlorination of thiiran in the presence of concentrated hydrochloric acid makes it possible to eliminate polymerisation reactions and to obtain 2-chloroethanesulphonyl chloride in a high yield. The unambiguous course of the reactions is in this case due to the involvement of hydrogen chloride in the ring opening processes:



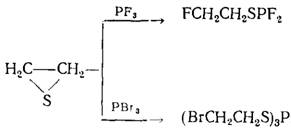
e. Reactions with Non-Metal Halides

Sulphur halides react smoothly with thiirans in non-polar media[218,219]. Thus sulphenyl chlorides condense, on cooling their solutions in carbon tetrachloride, with thiiran, 2-methylthiiran, and 2,2-dimethylthiiran, forming the corresponding disulphides. According to Epshtein et al.[218], "anomalous" ring opening takes place in these reactions:

Sulphur chlorides react with thiirans under similar conditions[219]. Depending on the reactant ratio, di- and tri-sulphenyl chlorides or tri- and tetra-sulphides are formed in the reactions of sulphur monochloride and dichloride with thiiran and 2-methylthiiran. The structures corresponding to the "anomalous" ring cleavage were also attributed to these products:

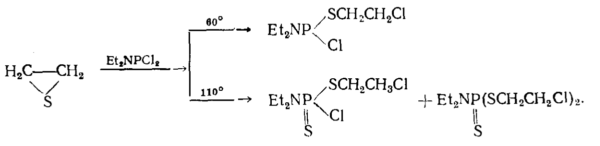


The reactions of phosphorus halides with thiiran proceed less smoothly. According to patent data[220–222], phosphorus trifluoride and tribromide condense with thiirans, forming 2-halogenoalkanethiol esters:



Phosphorus chloride dibromide and dichloride bromide as well as phosphoryl bromide react similarly.

Phosphorus trichloride condenses with thiiran and 2-methylthiiran only in the presence of zinc chloride. Depending on the reactant ratio, mono- and di-addition products are formed[223,224]. Exhaustive substitution by 2-chloroalkylthio-groups is accompanied by the polymerisation of thiirans. In the absence of catalysts, *NN*-diethylphosphoramidous dichloride reacts with thiirans on moderate heating (60–70°C), forming small amounts of monoaddition products. On heating above 100°C, a mixture of phosphorodithioate and phosphorotrithioate was obtained:



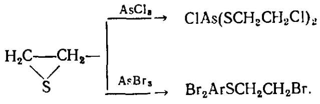
Alkyldichlorophosphines condense unambiguously with thiiran and 2-methylthiiran via one P–Cl bond[225,226]. It is assumed that the opening of the 2-methylthiiran ring takes place at the secondary carbon atom:

Condensation reactions between thiirans and phosphorous(III) chloride apparently takes place in steps. This may be a consequence of inductomeric and weaker mesomeric effects of the 2-chloroalkanethiol groups. The presence of substituents with a strong *+M* effect (amino-groups) at the phosphorus atom virtually rules out the possibility of condensation.

Among other phosphorus compounds, complexes of alkyltetrachlorophosphoranes and aluminium trichloride have been made to react with thiiran[227,228]. The reaction is accompanied by the elimination of sulphur from thiiran:

Phosphorus pentafluoride initiates the polymerisation of thiirans and does not form monomeric products on reacting with them[229,230].

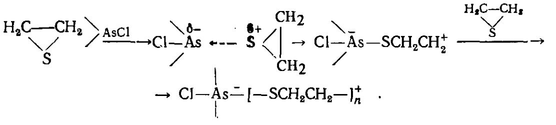
In dilute carbon tetrachloride solutions arsenic halides condense with thiiran, forming monomeric products in low yields[231]:



Under these conditions, arsenic trifluoride initiates the polymerisation of thiiran. Dialkylchloroarsines and alkyldichloroarsines condense with thiiran even in concentrated solutions and in the presence of pyridine or its hydrochloride as catalysts are converted quantitatively into 2-chloroethylthioarsinites[232]:

The reactions of thiiran with arsenic trichloride in concentrated solutions lead to oligomeric products even in the presence of catalysts:

The ability of arsenic chlorides to initiate the polymerisation of thiiran increases in the series of compounds characterised by decreasing electron density at the arsenic atom ($R_2AsCl < RArAsCl < Ar_2AsCl < RAsCl_2 < ArAsCl_2$). This suggests that polymerisation reactions are caused primarily by the strength of the $3p_\pi-4d_\pi$ bonding between the sulphur and arsenic atoms in the reaction complex and by the low reactivity of the chlorine atoms in it:



The catalytic effect of pyridine hydrochloride is due to the appearance in the reaction sphere of highly reactive hydrogen chloride and the activation of nucleophilic substitution at the arsenic atom:

$$R_2AsCl + Py \cdot HCl \rightarrow R_2AsPy^+Cl^- + HCl;$$

$$R_2AsPy^+Cl^- + HSCH_2CH_2Cl \rightarrow R_2AsSCH_2CH_2Cl + Py \cdot HCl.$$

Dialkylisothiocyanatoarsines react with thiiran similarly to chloroarsines[223,234]. The reactions proceed only in the presence of substances promoting the formation of thiocyanic acid in the reaction sphere, which is the reason for the anomalous conversion of isothiocyanatoarsines into 2-thiocyanatoethyl thioarsinites:

In contrast to sulphur, phosphorus, and arsenic halides, halogenosilanes, and isothiocyanatosilanes do not interact with thiiran even in the presence of catalysts[235].

f. Reactions with Alkyl Halides

According to Merill and Perkins[194], the reaction of tetramethylthiiran with methyl iodide is more difficult than the corresponding reaction of acyclic sulphides. Regardless of the nature of the thiiran employed, the reaction leads to the formation of trimethylsulphonium iodide[46,236–238] and not *S*-alkylthiiranium iodide. The available data suggest that the primary reaction products are unstable. The opening of their rings leads to polymerisation reactions and to partial formation of linear sulphides. The latter are readily iodomethylated, which leads to degradative transformations:

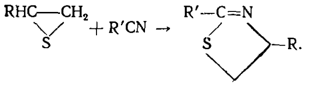
2-Phenylthiiran is alkylated by dimethyl sulphate at room temperature[239]. However, in this case the thiiranium salt or its monomeric cleavage product were not isolated either. Only 2,5-diphenyldithiane was isolated in a low yield.

The usual products of the electrophilic opening of the rings of thiiran and 2-methylthiiran were obtained only when the latter reacted with alkyl *α*-chloroalkyl ethers in the presence of mercury(II) chloride[240]:

The reactions proceed under mild conditions. The "anomalous" cleavage of the 2-methylthiiran ring by alkyl *α*-chloroalkyl ethers is postulated.

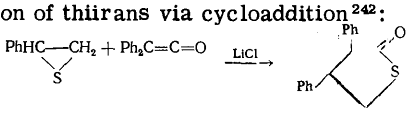
g. Cycloaddition Reactions of Thiirans

Several examples of such reactions are known. In the presence of strong inorganic acids the nitriles of aliphatic acids and thiirans react to form thiazolines[241]:



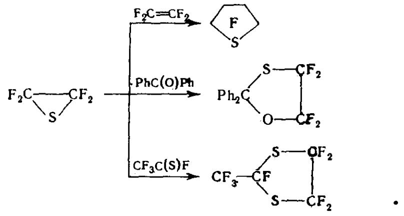
The condensation reactions are stereospecific, which shows that the cycloaddition proceeds via a stage involving the formation of a *π* complex of the thiiran molecule and the iminocarbonium ion. The thiirans polymerise simultaneously with condensation, in consequence of their cationotropic reactions.

The reaction of diphenylketen with 2-phenylthiiran in the presence of lithium chloride is the next example of the condensation of thiirans via cycloaddition[242]:



Thiiran and its aliphatic derivatives polymerise under these conditions.

A high capacity for cycloaddition reactions is characteristic of tetrafluorothiiran[170]. This compound condenses with tetrafluoroethylene to form octafluorotetrahydrothiophen, with benzophenone to form 2,2-diphenyloxathiolan, and with thioacetyl fluoride to form 1,3-dithiolan:



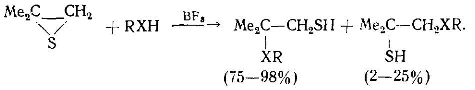
Only diphenyl sulphoxide enters into exchange reactions with tetrafluorothiiran:

$$F_2C{-}CF_2 + PhS(O)Ph \rightarrow FC(O)CF_2S{-}SCF_2C(O)F.$$

h. Electrophilic Condensation Reactions with Nucleophilic Agents

The condensation reactions of thiirans with alcohols and thiols in the presence of boron trifluoride or boron trifluoride-ether have been investigated[142,183-185] and it has been shown that 2,2-dimethyl- and 2-phenyl-thiirans give rise to monomeric products in 20–40% yield on reaction with primary alcohols and thiols. Steric effects at the nucleophilic centre lead to a sharp decrease of the yield of monomeric products. 2-Methyl- and 2,3-tetramethylene-thiirans polymerise in these reactions.

According to conductimetric titration data, the products of the condensation of 2,2-dimethylthiiran and alcohols and thiols consist of a mixture of substances in which the "anomalous" isomers predominate:



$$\underset{S}{Me_2C{-}CH_2} + RXH \xrightarrow{BF_3} \underset{\substack{XR\\(75-98\%)}}{Me_2C}{-}CH_2SH + \underset{\substack{SH\\(2-25\%)}}{Me_2C}{-}CH_2XR.$$

Similar results were obtained also in the reaction of ethanol with 2-phenylthiiran catalysed by sulphuric acid[243].

The condensations of thiiran with lauryl alcohol and nonylphenols were investigated recently in the presence of catalysts for electrophilic reactions[58]. It was established that HCl, $SnCl_4$, and BF_3 promote the formation of 2-mercaptoethylation products. However, the yield of monomeric substances is low and polymeric products are mainly formed.

An example of the condensation of tertiary amines with 2-methylthiiran in the presence of boron trifluoride-ether and sulphur dioxide has been described[244]:

$$\underset{S}{MeHC{-}CH_2} + Me_2NR + SO_2 \xrightarrow{Et_2O\cdot BF_3} {}^{-}O_2SSCH_2CHMe{-}\overset{+}{N}Me_2R.$$

IV. ELIMINATION OF SULPHUR

The capacity to split off sulphur is one of the characteristic properties of thiiran. Sulphur is usually eliminated on pyrolysis and on moderate heating in the presence of metals, metal oxides, and bases.

a. Pyrolytic Elimination of Sulphur

The thermal stability of thiirans depends significantly on their structure. The presence of electronegative substituents at the ring carbon atoms sharply increases the tendency of the thiiran to split off the sulphur atom. On heating, sulphur is readily eliminated from tetraarylthiirans[243-245], 2,2-diaryl-3,3-diethylthiirans[246], tetrachlorothiirans, and symmetrical diaryldichlorothiirans[247]:

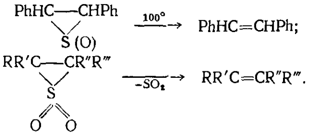
$$\underset{S}{RR'C{-}CR''R'''} \xrightarrow[-S]{T^\circ} RR'C{=}CR''R'''.$$

Monosubstituted thiirans, including 2-phenylthiiran[151], 2,3-tetramethylenethiiran[195], and 2-hexylthiiran[175] split off sulphur with somewhat more difficulty.

The elimination of sulphur takes place particularly readily (and quantitatively) in the presence of copper bronze[248-250]. The mild conditions in this sulphur elimination reaction make it possible to obtain even relatively unstable keten mercaptals and their derivatives[248,249]:

Zinc oxide is a less effective sulphur-eliminating agent[251].

Thiiran 1-oxides are converted into olefins on heating in toluene[252]. The 1,1-dioxides are cleaved even more readily on heating[253-256]:



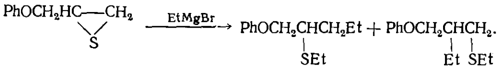
Thiirene 1,1-dioxides, which are more stable than thiiran dioxides, also tend to split off sulphur dioxide[257].

Investigations have shown that the pyrolytic elimination of sulphur from thiirans takes place via a homolytic mechanism. The deformation of the heterobonds as a result of the involvement of the ring electrons in π-conjugated systems greatly facilitates the process. The ease of the homolysis of heterobonds in the thiiran ring is attributed to the weak bonding and antibonding nature of the C–S σ bonds.

b. Elimination of Sulphur in Nucleophilic Thiiran Ring Opening Reactions

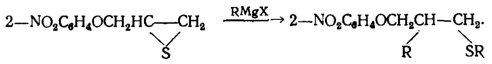
The elimination of sulphur from thiirans is promoted by bases. αβ-Epithioglycidic acids and their derivatives[93,184] and 2,3-diphenylthiiran[93] split off sulphur in the presence of bases even at room temperature. Secondary amines eliminate sulphur from 2-phenylthiiran in non-polar media[151].

When 2,3-tetramethylenethiiran and substituted 2-methylthiirans are treated with Grignard reagents and other organometallic compounds in non-polar media, sulphur is eliminated from the thiirans[174,238]. It has been shown for the reactions of *cis*- and *trans*-butene sulphides with butyllithium that this process is stereospecific[258]. In many instances Grignard reagents behave also as alkylating agents in relation to thiirans. According to Takeda[141], phenoxymethylthiiran reacts with ethylmagnesium bromide to form a mixture of "normal" and "anomalous" products:



$$\underset{S}{PhOCH_2HC{-}CH_2} \xrightarrow{EtMgBr} PhOCH_2\underset{SEt}{CH}CH_2Et + PhOCH_2\underset{Et}{CH}\underset{SEt}{CH_2}.$$

Higher alkyl magnesium bromides react with phenoxymethylthiiran to form only "normal" products of thiiran ring cleavage and with *o*-nitrophenoxymethylthiiran to form only the "anomalous" products:



$$2\text{—}NO_2C_6H_4OCH_2HC\text{—}CH_2 \xrightarrow{RMgX} 2\text{—}NO_2C_6H_4OCH_2CH\text{—}CH_2 .$$

When thiiranylalkanecarboxylic acids are reduced by lithium tetrahydroborate[179] and 2-hexylthiiran is reduced by lithium tetrahydroaluminate[175], alkenes are also formed:

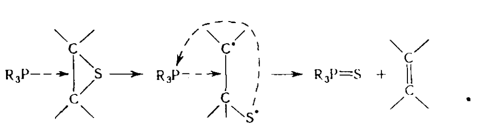
$$RHC\text{—}CH(CH_2)_nCOOH \xrightarrow{LiBH_4} RHC{=}CH(CH_2)_nCH_2OH;$$

$$n\text{-}C_6H_{13}HC\text{—}CH_2 \xrightarrow{LiAlH_4} n\text{-}C_6H_{13}CH{=}CH_2 .$$

The latter reaction occurs only in non-polar media. In tetrahydrofuran 2-hexylthiiran polymerises. Sulphur is also eliminated in the reactions of epithio-derivatives of steroids with higher alkyl xanthates[97]. Conditions favouring nucleophilic sulphur elimination reactions and the similarity of the effects of structural factors on the pyrolytic and nucleophilic sulphur elimination processes indicate their homolytic mechanisms. Ring opening in nucleophilic sulphur elimination reaction proceeds most probably at the stage involving the formation of transition complexes comprising the thiiran and the nucleophilic agent under conditions preventing charge transfer.

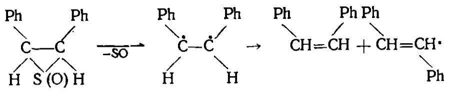
c. Elimination of Sulphur by Phosphites and Phosphines

Trialkyl phosphites and phosphines behave as nucleophilic agents in such reactions. Their inability to dissociate, low polarity and polarisability, and their high capacity for the homolytic formation of the thiophosphoryl linkage determine an unambiguous course of the process. The results obtained in a number of studies[46,176,238,258-266] show that the ease of sulphur elimination depends primarily on the basicity of the nucleophilic agent. Thus sulphur is eliminated by triethyl phosphite only on heating (100–110°C), while tributyl- or triphenyl-phosphine eliminates sulphur even at 20°C. The rate of reaction depends little on the polarity of the solvent and is of first order with respect to each reactant. The process is sterospecific to the extent of 99–100%. All these factors are consistent with a homolytic mechanism of the sulphur elimination process:

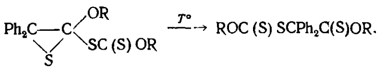


V. FREE-RADICAL REACTIONS

Free-radical reactions are to a large extent characteristic of thiirans with electronegative substituents at the ring carbon atoms. The commonest reactions of this type are the pyrolytic syntheses of alkenes from thiirans. The free-radical mechanism of the pyrolytic reactions of the thiiran ring have been demonstrated[252]. Thermal degradation of *trans*-2-phenylthiiran 1-oxide takes place stereospecifically with quantitative formation of *trans*-stilbene. Pyrolysis of the *cis*-isomer is accompanied by racemisation. This indicates the intermediate formation of a biradical, tending to isomerise with formation of the energetically more favourable conformer:

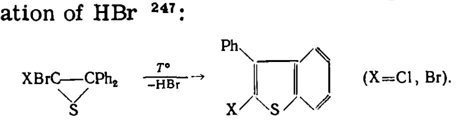


The free-radical mechanism of the pyrolytic transformations of thiirans is the cause of their unusual reactions. For example, the pyrolysis of *S*-(2-alkoxy-3,3-diaryl-2-thiiranyl) xanthates leads to mercaptoacetic acid derivatives instead of olefins[266]:



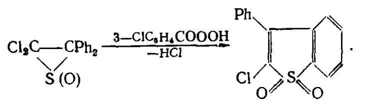
$$\xrightarrow{T^\circ} ROC(S)SCPh_2C(S)OR.$$

The pyrolysis of 2,2-diaryl-3,3-dichlorothiirans is accompanied by the formation of olefins. However, their bromo-derivatives rearrange to derivatives of benzo[*b*]thiophen with elimination of HBr[247]:

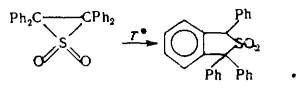


(X=Cl, Br).

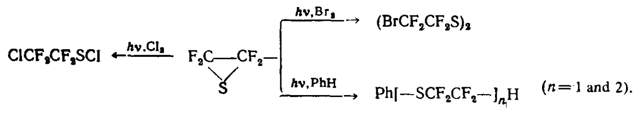
The thiiran–thiophen rearrangement takes place also in oxidative reactions of certain thiirans[202]:



In the above examples the C–S bond undergoes homolytic cleavage. An example of pyrolytic ring opening at the C–C bond is also known. Thus tetraphenylthiiran 1,1-dioxide isomerises to a dihydroisothianaphthene derivative on heating[267]:



Polyfluorothiirans undergo free-radical reactions particularly readily[170,268,269]. On irradiation with ultraviolet light, they are readily chlorinated and brominated and condense with benzene:



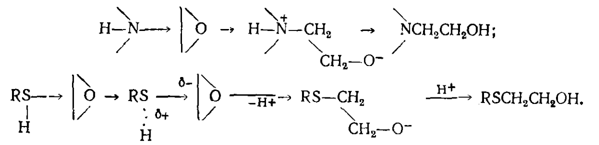
Tetrafluoro- and chlorotrifluoro-thiirans polymerise on irradiation or in the presence of di(trifluoromethyl) disulphide and form copolymers with ethylene and propene.

Thiiran and its simplest homologues show a smaller tendency to undergo free-radical reactions. On being irradiated, these substances polymerise[270,271], but the quantum yield of the reactions is comparatively low. Radical reactions are facilitated in the presence of substances capable of forming charge-transfer complexes[272]. This suggests that the increased stability of thiiran and its alkyl-substituted homologues under the conditions of homolytic reactions is a consequence of the oscillatory properties of the heterobond in their rings, associated with the low probability that the $n \rightarrow \sigma^*$ transitions of the lone electron pairs of the sulphur atoms to the antibonding orbitals of the C–S σ bond will become allowed. A similar phenomenon has been noted in a study of poly(alkylene sulphides), the free-radical reactions of which involve the dissociation of C–C bonds and not C–S bonds[273].

VI. CONCLUSION

The present state of the chemistry of thiirans is to a large extent determined by the development of the comparative chemistry of three-membered heterocycles. Comparison of the properties of thiirans and their oxygen analogues, the heteroatoms of which have the same number of valence electrons in different energy states, is of greatest interest.

There are no unambiguous hypotheses concerning the relation between the reactivities of oxirans and thiirans. However, it is frequently stated that the rates of cleavage of thiiran rings are somewhat lower than those of oxiran rings. Our comparison of the data presented in this review with surveys of the chemistry of liquid-phase reactions of oxirans[44,274] failed to confirm such ideas and showed that an unambiguous answer to this question, unrelated to the reaction conditions, is impossible. This may be illustrated by the following example. The reactions of oxirans with amines are known to occur in polar aprotic solvents, and take place particularly readily in water and alcohols, i.e. under conditions favouring the transition of the nitrogen atom to the sp^3-hybrid state. There is a similar phenomenon also in uncatalysed reactions of oxirans with thiols, the occurrence of which is associated with the presence of hydroxy-compounds in the reaction sphere. In non-polar media, thiols condense with oxirans only in the presence of basic catalysts[275]. Thus one of the characteristics of the nucleophilic oxiran ring cleavage reactions is the necessity to activate the formation of ionic transition complexes, without which the process does not occur under the usual conditions:



In contrast to oxirans, thiirans react smoothly with amines and thiols in non-polar media without catalysts, which suggests that the thiiran ring has more pronounced electrophilic properties than the oxiran ring. The optimal conditions for the formation of monomeric condensation products in these reactions are associated with the creation of conditions for a virtually synchronous formation of a covalent bond between the nucleophilic atom and the ring carbon atom and proton transfer to the sulphur atom. The hydride transfer is mediated by the molecules of the nucleophilic agent, as a result of which the excess of the latter increases the yield of monomeric reaction products:

Consequently, in non-activated nucleophilic ring opening reactions thiirans are distinguished by lower energy barriers to the processes and higher reactivities than oxirans. This is quite natural, bearing in mind the weak bonding and antibonding nature of the C–S σ bond.

The ratio of the rates of the nucleophilic opening of oxiran and thiiran rings changes in polar media. Oxirans react somewhat more readily with amines in dioxan and with thiols in non-polar media in the presence of basic catalysts. In alcohols the opening of the oxiran ring by thiolate anions also takes place quantitatively even below 0°C. In this case thiirans interact on moderate heating. The reversal of the relative reactivities in the above reactions is due to the much smaller sensitivity of thiirans to solvolysis[276] and the impossibility of activating the thiiran ring by the formation of hydrogen bonds. The above facts are intrinsically extremely interesting, since they indicate a definite role of polarisation effects in oxiran and thiiran ring opening reactions.

The energetics of the transition states probably determine the ratio of the reactivities of oxirans and thiirans in electrophilic ring opening processes. This is manifested most clearly in the reactions of the above compounds with phosphorus and arsenic halides. The high rates of reaction of oxirans with phosphorus halides and of thiirans with arsenic halides are attributed to the possibility of the $(n-1)p_\pi - nd_\pi$ interaction between the reacting molecules in the transition complex. A deviation from the above rule is accompanied by a sharp decrease of reactivity. This example demonstrates the impossibility of an unambiguous estimation of the relative reactivities of thiirans and oxirans also in their electrophilic cleavage reactions.

It is noteworthy that, from the standpoint of the chemistry of three-membered saturated heterocycles, the reactivity of thiirans is of special interest. Their low sensitivity to solvolysis, the high lability of the heterobond, and the high polarisability of the heteroatom in thiirans make it possible to discover even fine details of the effects of substituents and of the influence of the structure of the reactants on the reactivity and its nature. Only in the chemistry of thiirans are there so many instances of reactions with the same reactant where all types of transformations of the heterocycle are possible depending on the conditions: elimination of the heteroatom, condensation with formation of monomeric substances, and polymerisation. A detailed elucidation of the nature of this phenomenon is of undoubted interest from the standpoint of the chemistry of three-membered heterocyclic compounds.

The data presented in this review indicate the scope of the synthesis of sulphur-containing substances on the basis of thiirans which has been by no means completely elucidated. However, the known reactions of thiirans already make it possible to obtain by simple technological procedures a wide variety of products of interest for the synthesis of physiologically active and technically valuable compounds. The introduction of these chemically reactive compounds into agricultural practice, into hydrometallurgical processes, and other branches of the National Economy would make it possible to limit the use of stable substances which accumulate in the biosphere and contaminate it.

Xylitol and Its Derivatives

A.N.Anikeeva, G.M.Zarubinskii, and S.N.Danilov

The literature data on the pentahydric alcohol xylitol are reviewed. The methods for the preparation of xylitol, its ethers, esters, nitrogen-, halogen-, and sulphur-containing derivatives, acetals, ketals, anhydroxylitols, and their various derivatives are examined and the spectroscopic methods for demonstrating the structures of certain xylitol derivatives are discussed. The therapeutic and diagnostic, dietary, and industrial applications of xylitol and its derivatives are briefly considered. The bibliography includes 553 references.

CONTENTS

I. INTRODUCTION

Until recently xylitol was manufactured on an industrial scale only in the Soviet Union, which has adequate reserves of pentosan-containing raw material. The introduction of xylitol as a commercial product, its physiological activity, and its high reactivity (due to the presence of five free hydroxy-groups) led to its being investigated by chemists, biochemists, and pharmacologists. It rapidly became popular in the food industry, where it began to be used directly, and as a sugar substitute in food products for diabetics. An extensive literature on the chemistry of xylitol, the synthesis of its derivatives, the methods for its analysis, and therapeutic properties exists in various journals, compilations, conference proceedings, and patents. However, so far there has not been even a brief survey of this research.

In the present review the authors attempt to survey the literature data published up to 1974, which makes it possible to assess the advances achieved in the study of the chemistry of xylitol and to outline new promising applications of this polyol.

II. METHODS FOR THE PREPARATION OF XYLITOL

The laboratory and industrial methods for the synthesis of xylitol are based on several of the usual methods in the chemistry of polyols.

The Reduction of Xylose

Syrupy xylitol was obtained for the first time by Bertrand[1] and Fisher[2,3] by the reduction of D- and L-xyloses with sodium amalgam. Aqueous solutions of D-xylose were also hydrogenated in the presence of platinum oxide[4], Raney nickel[5-8], nickel[9] and nickel–cobalt–chromium catalysts on calcium triphosphate[10], nickel on kieselguhr[11,12], nickel–iron carbonate[13] and nickel–copper catalysts on bentonite[14], and titanium–niobium or vanadium–nickel catalysts[15]. Ashida reduced monoses on an aluminium–nickel alloy[16] in non-aqueous solvents: cyclohexanol[15,17,18] and tetrahydrofuryl alcohol[16]. The hydrogenation of aqueous methanol solutions of xylose[19-30] in the presence of Raney nickel and its reduction with aqueous solutions of sodium tetrahydroborate[31,32] and lithium tetrahydroaluminate[33] has been described. Under these conditions, the pentitol was obtained quantitatively from D-xylo-γ-lactone and D-xylityl pentanitrate[34,35].

Karabinos and Ballun[36] developed a convenient method for the preparative synthesis of polyols by the reduction of aldoses and ketoses with Raney nickel. Greighton[10] described an electrochemical reduction of xylose to xylitol. D-Xylitol has also been obtained from 4-*O*-methylglucuronoxylan[37].

Other Methods

Multistage syntheses of xylitol from divinylmethanol[38] and acrolein[39-42] have been described. The oxidation of the terminal glycol group of a hexose or a hexitol followed by reduction yields monoses[43,44] with a smaller number of carbon atoms. 2,4:3,5-Di-*O*-ethylidene-L-xylitol was synthesised in this way from industrial D-sorbitol[45]. Hydrogenolysis of sorbitol[46] yielded a mixture of polyols containing xylitol. Xylitol has been obtained by a microbiological procedure[47-53] and has been isolated from plant material[54-59] and from peat[60,61].

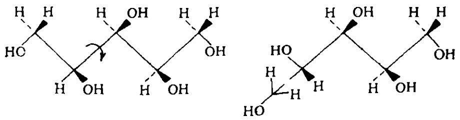
In solutions of anhydrous hydrogen fluoride other pentitols isomerise to xylitol[62,63]. Xylitol derivatives can be obtained by benzoate exchange from sulphonyl derivatives of other pentitols[64].

III. THE STRUCTURE AND PHYSICOCHEMICAL PROPERTIES OF XYLITOL, THE STEREOCHEMISTRY OF XYLITOL AND ITS DERIVATIVES, AND COMPLEX FORMATION

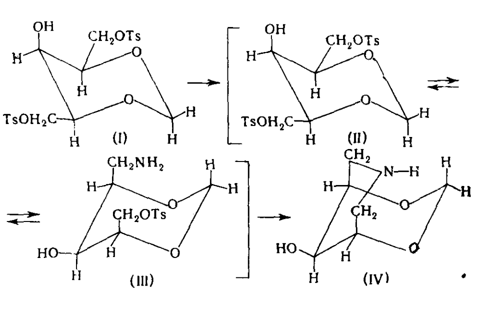
The structure of xylitol was demonstrated by Bertrand[65], Fischer[2,3], and Neuberg[66]. Bertrand obtained 2-iodopentane from xylitol and thus demonstrated the linearity of the hydrocarbon chain and the fact that it consists of five atoms. Fischer and Neuberg oxidised xylitol to DL-xylose and established that this does not entail isomerisation, so that the configurations of the hydroxy-groups of xylitol and xylose are identical. Two crystalline forms of xylitol have been described: a metastable monoclinic form melting at 61–61.5°C,[11,12] which is spontaneously converted into the stable orthorhombic form melting at 94–94.5°C.[12,19,67,68] Apart from two studies[11,12], other instances of the synthesis of the xylitol melting at 61–61.5°C have not been described.

Like other polyols, xylitol is soluble in a limited number of polar solvents: in concentrated sulphuric and hydrochloric acids, water, pyridine, dimethylformamide (DMF), dimethyl sulphoxide (DMSO), and hexamethylphosphoramide and to a limited extent in methanol and ethanol. The temperature variation of its solubility in 96% ethanol and water has been studied[69,70], which is important for the technological processes involved in the synthesis of xylitol[7,71–82]. The thermal[83,84], radiation-induced[85], and photochemical[86] degradation of xylitol has been studied. Mai[87] calculated the dissociation constants of the OH groups; the Taft constants and the transport numbers of xylitol in a membrane and in solutions have also been evaluated[88]. The conductometric titration[89] and the cathodic overvoltage in the electrolysis[90] of aqueous xylitol solutions have been investigated.

The reactivities of individual OH groups of unsubstituted xylitol have been scarcely characterised. The synthesis of 1,5-di-*O*-tritylxylitol confirmed the higher reactivity of the primary OH groups[13,91], which is characteristic of all monoses and polyols. Esterification of xylitol by aliphatic C_6–C_{30} acids in the presence of acid and basic catalysts leads to mixtures of monoesters (60–75%) and diesters (20–35%).[92–96] An increase of the temperature of duration of esterification is accompanied by the formation of anhydro-derivatives[93,97,98]. The kinetics and mechanism of the sulphonation reaction have been studied by Yamazaki[99]. It has been found by X-ray diffraction[100] that the xylitol molecule is an asymmetric conformer with a non-planar zig-zag chain owing to the interaction between C_n–O and C_{n+2}–O bonds. Indeed, the study of models showed that interactions via 1,3-bonds lead to rotation about the $C_{(3)}$–$C_{(4)}$ bond with displacement of $C_{(5)}$ from the zig-zag plane[57,101,102]. The distortions of the planar conformer are manifested particularly clearly in the presence of bulky charged substituents, as confirmed by NMR.[103]



It has been suggested that there are no intermolecular hydrogen bonds in the crystals[104].



Some information about the structure of xylitol is provided by the study of complex formation. Xylitol forms complexes with acids, bases and salts. The stable crystalline complex $C_5H_{12}O_5.Ca(OH)_2.4H_2O$ has been described[105]. Copper(II) complexes[106] are used for the analysis and separation of mixtures of polyols. Xylitol forms complexes with boric acid[107,108], with alkali and alkaline earth metal borates[109–111], with cerium(IV) salts[112–114], with pyridine, and with nicotinic and other organic acids[115]. The complexes with iron(III) salts and with citrate[116] are physiologically active. It is believed that the complexes are formed via adjoining OH groups.

The conformations of cyclic acetals of xylitol have been more thoroughly investigated[117]. Danilov and Zarubinskii[118–121] showed that 2,4-*O*-methylenexylitol and its derivatives exist in the *C*-conformations stabilised by the equatorial CH_2OH groups. Presumably the conformation is additionally stabilised by the intramolecular hydrogen bond between the axial $C_{(3)}OH$ group and the oxygen atoms of the acetal ring[122]. The reactivity of the $C_{(3)}OH$ group has been studied and it has been found that in esterification by acid anhydrides the equatorial OH group (*ribo*-configuration) reacts faster, while the axial OH group (*xylo*-configuration) reacts faster with acid chlorides[123]

The formation of an imine when 2,4-*O*-methylene-1,5-di-*O*-tosylxylitol is treated with ammonia[124] should involve an inversion of the conformation. The $C_{(3)}OH$ group in the imine forms part of two rings simultaneously: in one of these it is axial and in the other equatorial, which makes it difficult to interpret the NMR spectra of these compounds.

IV. DERIVATIVES OF XYLITOL

1. Esters (Table 1)

Esters[125–145] are obtained by the usual methods: (1) By esterifying the polyol with an excess of acid, acid anhydride, or an acid chloride in the presence of a catalyst or a base. The first xylitol derivative, the pentaacetate, was synthesised in this way[1,11,32,125–129]. Esterification may be accompanied by the formation of anhydro-derivatives[13,130–133]. For a 1 : 1 ratio of the polyol and the acid, the reaction proceeds with formation of a mixture of a monoester and diesters in proportions of 2 : 1–3 : 1.[92–96,134] (2) By the reduction of the corresponding xylitol derivatives; 2,3,5-tri-*O*-benzoyl-D-[135] and 5-deoxy-5-fluoro-L-xylitols[136] were obtained in this way. (3) With intermediate protection of some of the OH groups. For example, 1-*O*-esters have been obtained by the esterification of di-*O*-isopropylidenexylitol with subsequent hydrolysis of the ketal protecting group[137,138]. Trifluoroacetic acid has been suggested as the hydrolysing agent[144].

Direct interaction with inorganic acids yielded xylityl pentanitrate[32,139–141] (stable below 5°C) and sulphate esters[119,120]. When xylitol is heated with concentrated hydrochloric acid, the product is a mixture of 5-chloro-5-deoxyxylitan as the main component[74]. The interaction of xylitol with phosphorous, hypophosphorous, and phosphonous acid[97,143,145,146] results in the formation of a mixture of xylitol and xylitan derivatives. The structure of cyclic xylitol phosphotriesters[147] has been determined with the aid of the Arbuzov reaction.

2. Ethers

Xylityl ethers are also obtained by standard methods. Interaction with alkyl and aryl halides in the presence of bases yielded 1,5-di-*O*-tritylxylitol[13,91,148], penta-*O*-allylxylitol[149], and trimethylsilyl[150,151] and β-cyanoethyl ethers[152].

2,3,4-Tri-*O*-benzyl-1,5-bis-*O*-*p*-nitrobenzoylxylitol	98	153

2,3,4-Tri-*O*-benzylxylitol[153], 2- and 3-*O*-methyl-D-xylitol[154,155], and 2,3-di-*O*-ethyl-D-xylitol[156] were synthesised by reducing xylose derivatives. 1-*O*-Methylxylitol was synthesised from the di-*O*-isopropylidene ketal[119,120,157]. Kochetkov et al.[158] synthesised 2,3,4-tri-*O*-methylxylitol by shortening the chain of D-glucopyranosidouronamide with subsequent reduction of the product. 2-*O*-(4-*O*-Methyl-α-D-glucopyranosyl)-D-xylitol has been isolated from natural products[46] and other similar derivatives have been identified[47,48].

3. Amino-derivatives (Table 2)

1-Amino-1-deoxy-D-xylitol has been synthesised by the reductive amination of D-xylose[159,160] and by the hydrogenation of D-xylose phenylhydrazone[161] or oxime[162]. The bis(phenylhydrazone) of D-threopentulose was reduced similarly to 1,2-diamino-1,2-dideoxy-D-xylitol[163]. Ammonolysis of 2,3-anhydroribose yielded 3-amino-3-deoxyxylitol[164]. Hydrogenation of *N*-amino-D-xylopiperidinose or its dimer, obtained by the acid hydrolysis of 5-deoxy-5-hydrazino-1,2-*O*-isopropylidene-D-xylofuranose, leads to 1,5-imino-1,5-dideoxy-D-xylitol[165,166]. Haskell and Hanessian[167,168] synthesised 5-acetamido-5-deoxy-D- and -L-xylitols from derivatives of iditol mercaptals.

Deamination of 1-deoxy-1-methylaminoxylitol with nitrous acid[169–171] led to 1-deoxy-1-methylnitrosamino-D-xylitol instead of the expected xylitan[172]. Veksler and coworkers[173–176] obtained the quaternary ammonium salts $R\overset{+}{N}(CH_3)_2Alk\overset{-}{Br}$ (R is a xylitol or xylitan residue and Alk is a long-chain $C_{10}-C_{18}$ alkyl group) from 1-deoxy-1-dimethylaminoxylitol by alkylation with alkyl bromides.

4. Deoxy-derivatives (Table 3)

Deoxy-derivatives have also been synthesised by the usual methods of carbohydrate chemistry. Hydrogenation of xylose derivatives yielded 3-acetamido-3,5-dideoxy-D-xylitol[164]. A series of consecutive reactions $RCH_2OH \rightarrow RCH_2OTs \rightarrow RCH_2I \rightarrow RCH_3$[177] or the elimination of sulphur from diethyl mercaptal[178] (R is a xylitol residue) have been used to synthesise 1-deoxyxylitol.

Table 3. Deoxy-derivatives of xylitol.

Name	M.p., °C	References
1-Deoxyxylitol	Syrup	177,178
Tetra-*O*-acetyl-1-deoxy-D-xylitol	62–63	177,178
2-Deoxy-D-xylitol	Syrup	180,181
2-Deoxy-D-tetraphenylcarbamoylxylitol	200–201	180,181
3-Deoxy-D-xylitol	70–71	182,184
3-Deoxy-D-tetraphenylcarbamoylxylitol	205–206	181
Tetra-*O*-benzoyl-3-deoxy-D-xylitol	104	184
3-Acetamido-1,2,4-tri-*O*-acetyl-3,5-dideoxy-D-xylitol	Syrup	164

By shortening the chain of 3-deoxy-D-galactose, a 2-deoxyxylitol derivative was synthesised[179–181]. 3-Deoxyxylitol has been obtained from the epoxides of L-arabinose and D-ribose[182–184].

Hurd and Bonner[185-187] and then Gertsev and Makarov-Zemlyanskii[188] obtained 1,1-deoxy-1,1-di-*C*-phenyl-D-xylitol and its analogues by the *C*-glycosylation of acetyl-β-D-xylose using benzene in the presence of aluminium chloride. Zhdanov and coworkers[189-196] used the organomagnesium synthesis for the same purpose.

5. Thio-derivatives (Table 4)

Stanek and coworkers[199] obtained tetra-*O*-acetyl-1-benzylthio-1-deoxy-L-xylitol from 1,2-*O*-isopropylidene-5-*O*-tosyl-D-xylofuranose, debenzylated it to 1-deoxy-1-thio-L-xylitol, and characterised it in the form of the octaacetyldisulphide and *S*-auro-1-deoxy-1-thio-L-xylitol. Derivatives of the D-series were obtained similarly.

6. Acetals and Ketals (Tables 5–11)

The methods for the synthesis of cyclic acetals and ketals of xylitol and for the demonstration of their structure are well known. Simple empirical rules have been formulated for the formation of acetals[43,200–207], based on the fact that the rings must cause the minimum distortion of the zig-zag polyol chain. It is necessary to consider the stereochemical stability of the molecule as a whole, when the differences between the eclipsed groups C–C/C–H and C–H/C–H and the electrostatic repulsion between the *gauche* C–O/C–O bonds begin to play the main role[208]. The structures of pentitol ketals agree fairly well with these conclusions[209].

The bulk of the groups adjoining the carbonyl groups play a decisive role in the formation of ketals. One of the authors of the review failed to obtain the hexachloroisopropylidene ketal of xylitol under the conditions for the synthesis of trifluoroisopropylidene ketals. The influence of temperature on the reaction has been little studied, although it is known that an increase of reaction temperature accelerates the formation of dioxolans[210,211]. There have been no studies of the role of the solvent, which might form hydrogen bonds[212,213] and thus influence the structure of the product.

The resistance of the acetal linkage to acid hydrolysis increases with increase of the negative inductive effect in the acetal group. This has been confirmed by the stability series of the acetal linkages as a function of the acetal group: $(CF_3)_2C > CF_3-C-CH_3 > CH_2 > CH_3CH > (CH_3)_2C \geqslant C_6H_5CH$.

The structures of the acetals have been demonstrated by various methods: by selective hydrolysis, chemical modification, and the study of physicochemical constants; for example, the study of the solvolysis constants[214] helped in confirming the *cis*-decalin structure for di-*O*-benzylidenexylitol. It is interesting to note that in the synthesis of this diacetal the monoacetal could not be isolated from the reaction mixture, although it has been stated in the literature that this is possible[157]. Consequently the rate of formation of the second ring greatly exceeds the rate of formation of the first in dibenzylideneacetals of xylitol.

Methyleneacetals. 2,4 : 3,5-Di-*O*-methylenexylitol was obtained for the first time by Ness et al.[43,215] from tri-*O*-methylene-D-sorbitol by selective hydrolysis with subsequent shortening of the chain. The acetal was then synthesised by treating xylitol with formaldehyde[216] or paraformaldehyde[217] in the presence of concentrated hydrochloric acid. Acetolysis of the diacetal leads to 2,4-*O*-methylenexylitol, which does not contain *α*-glycol groups. Schmidt and Nieswandt[218] synthesised 3,5-*O*-methylenexylitol by the selective oxidation of the 1,2-*O*-methylene group in 1,2 : 3,5-di-*O*-methylene-D-xylofuranose to the carbonate group with its subsequent hydrolysis and reduction of the reaction product. This reaction may be of general applicability[219].

Numerous derivatives of di-*O*-methylenexylitol[173,176,220] and mono-*O*-methylenexylitol[119,124,217,221-225] have been obtained. 1,5-Di-*O*-benzoyl-2,4-*O*-methylenexylitol has been oxidised to the corresponding 3-xylulose derivative; it has been shown[226] that this greatly reduces the resistance of the acetal ring to hydrolysis and the free ketose isomerises to a mixture of erythro- and threo-2-ketoses.

Ethylideneacetals. Ness and Fletcher[45] obtained 2,4 : 3,5-di-*O*-ethylidene-L-xylitol by shortening the chain of 1,3 : 2,4-di-*O*-ethylidene-D-sorbitol. Foster et al.[227] synthesised the D-analogue by a similar procedure. The monoacetal derivative has also been obtained[228].

Benzylideneacetals. 2,4 : 3,5-Di-*O*-benzylidenexylitol was obtained for the first time by condensing xylitol with benzaldehyde in the presence of concentrated hydrochloric acid in order to purify the xylitol[1,2]. Its solubility in organic solvents has been determined[229]; it has been shown that the diacetal contains one free OH group[215,230]. 2,4-*O*-Benzylidenexylitol has been synthesised by shortening the chains of 3,5-*O*-benzylidene-D-gluco-D-*gulo*-heptitol[231], 2,4-*O*-benzylidene-D-sorbitol[232], and 2,4-*O*-benzylidene-D-glucuronomercaptal[233] and by the reduction of the diethyl mercaptal of 2,4 : 3,5-di-*O*-benzylidene-D-xylose[234,235].

Various derivatives of the diacetal[119,120,175,176,215,225,236-238] and the monoacetal[228,239] have been described and the kinetics of the esterification of the diacetal have been studied[240]. It has been found that the acetylation of 1,5-di-*O*-benzoyl-2,4-*O*-benzylidenexylitol in DMSO[239] proceeds with formation of methylthiomethyl derivatives. Angyal and James[241] obtained (1*R*)- and (1*S*)-1,5-di-*O*-acetyl-2,4-*O*-benzylidene-1,3-*O*-methylene-(1-hydroxy-L-)xylitol from 2,4-*O*-benzylidene-D-sorbitol. On treatment with aluminium isopropoxide, 2,4 : 3,5-di-*O*-benzylidene-D-aldoxylose gives rise to 2,4 : 3,5-di-*O*-benzylidene-1-deoxy-D-xylit-1-yl-2′,4′ : 3′,5′-di-*O*-benzylidene-D-xylonate via the Claisen–Tishchenko reaction[242].

Acetylsalicylidene- and Salicylideneacetals. Rusanova et al.[243,244] obtained acetylsalicylidene- and salicylidene-acetals by condensing xylitol with the corresponding aldehydes and achieved their interconversion.

Isopropylideneketals. Among the methods for the synthesis of ketals, the condensation of xylitol with acetone in the presence of concentrated sulphuric acid is most frequently used[5,157,245,246]. Derivatives formed via the free OH group have been identified[177,220,225,237,247-249]. It was shown later that the crystalline 2,3 : 4,5-isomer is mainly formed[64,250,251]. An admixture of 10–30% of the 1,2 : 4,5-diketal has been detected by NMR. The isomers have been separated by preparative gas–liquid chromatography (GLC).

A diketal of the L-series has been obtained by shortening the chain of 1,2 : 3,4-di-*O*-isopropylidene-L-iditol[252]. Foster and coworkers[64] converted 1,2 : 4,5-di-*O*-isopropylidene-3-*O*-tosylribitol into 1,2 : 4,5-di-*O*-isopropylidenexylitol by benzoate substitution. Kochetkov and Usov[253] obtained 5-*O*-benzoyl-1,4-dideoxy-2,3-*O*-isopropylidene-D-xylitol from the diethyl mercaptal of 5-*O*-benzoyl-2,3-*O*-isopropylidene-L-arabinose by treatment with methyltriphenylphosphonium iodide.

Trifluoroisopropylideneketals. Zarubinskii and Danilov[119,222] synthesised 2,3 : 4,5-bis-*O*-(trifluoroisopropylidene)xylitol by condensing xylitol and trifluoroacetone in concentrated sulphuric acid solution. The presence of 1,3-dioxolan rings was established in the model derivatives which the above workers obtained: 1,2-*O*-(trifluoroisopropylidene)glycerol and 3-*O*-methyl-1,2 : 4,5-bis-*O*-(trifluoroisopropylidene)xylitol[254]. 1,3-Dioxan rings are characteristic of trifluoroacetone-xylitan derivatives[121]. Thus the condensation of xylitol and trifluoroacetone results in the formation of the 2,3 : 4,5-diketal, consisting of a mixture of several diastereoisomers owing to the non-equivalence of the substituents at the carbonyl carbon atom[254].

Cyclohexylideneketals. Anikeeva and Zarubinskii[220] obtained a diketal containing a primary OH group by condensing xylitol with cyclohexanone[243]. The reaction of 2,4-*O*-methylenexylitol with cyclohexanone led to the synthesis of 3,5-*O*-cyclohexylidene-2,4-*O*-methylenexylitol, which is formed more slowly than di-*O*-cyclohexylidenexylitol. If it is possible to assign a definite structure of the derivative to the rate of its formation[255], then the last diketal is probably a mixture of the 2,3 : 4,5- and 1,2 : 4,5-isomers, by analogy with di-*O*-isopropylidenexylitol.

7. Anhydroxylitols (Table 12)

Mono- and di-anhydro-derivatives of xylitol have been synthesised by two main methods.

Synthesis by intramolecular nucleophilic substitution. The reaction is carried out under acid or alkaline conditions. Various acids are used as the acid catalysts[256−263]. The acid-catalysed conversion of pentitols into anhydro-derivatives leads to the formation of 1,4-anhydro-derivatives, which has been explained by the favourable steric disposition of the OH groups[264]. The anhydro-derivative usually retains the configuration of the initial polyol. However, Hudson and Barker[264] showed that in the presence of acids D-arabitol is converted into the 1,4-anhydro-derivatives of D-arabitol (62.6%), L-ribitol (7.6%), D-ribitol (3.3%), L-xylitol (11.7%), D-xylitol (4.3%), D-lyxitol (6.2%), and L-lyxitol (0.7%). Assuming that the reaction proceeds via an S_N2 mechanism, it is possible to explain the formation of anhydro-derivatives with the D-arabo- and D-lyxo-configurations by the attack of the O^- anionic group at $C_{(2)}$ or $C_{(4)}$ on carbon atoms with primary OH groups and the formation of derivatives with L-xylo- and L-ribo-configurations can be accounted for by the attack of the O^- group at $C_{(1)}$ or $C_{(5)}$ on carbon atoms with secondary OH groups. In the latter case the configuration is inverted. The relative rates of cyclisation increase in the following sequence: lyxitol < arabitol < xylitol < ribitol < 1-deoxy-D-arabitol < 2-deoxy-D-arabitol. Barker[265] determined the rates of conversion of hexitols into 1,4-anhydro-derivatives and arranged them in the following sequence: mannitol < gulitol < galactitol < altritol < sorbitol < iditol < talitol < allitol. In the two series the qualitative dependence of the rate of cyclisation on the configuration of the OH groups at the first four carbon atoms is the same[143,256].

1-Phosphate esters of xylitol readily form xylitans. By treating 1-amino-1-deoxy-ribitol with a mixture of hydrochloric and nitric acids, Kuhn and Wendt obtained ribitan[262]. Similarly 1-deoxy-1-nitrosaminoxylitol can serve as the starting material for the synthesis of xylitan[162]. Similar mechanisms have been proposed for these reactions[258]. Fletcher and coworkers[62] found that ribitan triacetates and tribenzoates form a mixture of ribitan, lyxitan, ribitol, xylitol, and arabitol in liquid HF solution, while the corresponding D-xylitan derivatives give rise to ribitan alone.

A second method for the synthesis of a wide variety of anhydro-derivatives involves intramolecular substitution of sulphonate esters. The reaction proceeds via an S_N2 mechanism and, when the sulphonyl group is attached to a secondary carbon atom, the closure of the oxygen-containing ring proceeds with Walden inversion at this carbon atom. The intramolecular substitution of sulphonates proceeds under the influence of the usual basic agents, although the formation of anhydro-derivatives in an acid medium has also been described[266].

Hartman and Barker[267] determined the characteristics of the formation of anhydro-derivatives for different positions of the tosyl and OH groups. Gray et al.[268] showed that the presence of the benzyloxy-group at the $C_{(4)}$ atom in 1-*O*-tosyl derivatives promotes the substitution of the tosyl group. It is suggested that the reaction involves the formation of an oxonium ion stabilised by the aryl substituent. The rate of cyclisation depends on the configuration of the OH groups responsible for the steric interactions in the transition and ground states.

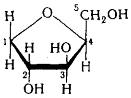
1,3-Anhydro-2,4-*O*-methylenexylitol was obtained by treating 2,4-*O*-methylene-1-*O*-tosylxylitol with an aqueous or aqueous acetone solution of alkali[178,221]. Under the same conditions, the 3-*O*-tosyl derivative remained unchanged[121]. Danilov and Kazimirova[269] and then Wiggins[270] synthesised the 1,4 : 3,5-dianhydroxylitol, the structure of which was established by Ustyuzhanin, Sidorova, and Danilov[197,271,272]. 1,4 : 2,3-Dianhydroxylitol was obtained from 1,4-anhydro-5-chloro-5-deoxy-2-*O*-tosylxylitol[273,274] and 1,4 : 2,5-dianhydroxylitol was synthesised from 2,5-anhydro-3,4-di-*O*-tosyl-D-xylitol[275].

Synthesis by reduction methods. Fletcher and Hudson[276] hydrogenated 2,3,4-tri-*O*-acetyl-D-pyranoxylal or eliminated sulphur from 1-phenylthio-β-D-xylopyranoside triacetate and obtained 1,5-anhydro-2,3,4-tri-*O*-acetylxylitol. The same product was obtained by eliminating sulphur from 1-thio-β-D-xylopyranose[277] or β-D-glucopyranosyl-*NN*-dimethyldithiocarbamate[278] on Raney nickel.

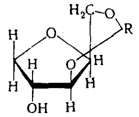
1,4-Anhydroxylitol (xylitan) and its derivatives. Xylitan has been manufactured in the Soviet Union since 1950 and has been studied more thoroughly than other anhydro-derivatives. It was described for the first time by Grandel[260] and Carson and Maclay[259], who isolated crystalline hygroscopic xylitan, melting at 38°C, and showed that it contains one primary and two vicinal secondary OH groups, which confirmed the 1,4-anhydro-structure.

A wide variety of ethers, esters, and thio-derivatives of xylitan are known[62,143,150,163,220,259,268,279-283]. Among the sulphonates of the anhydro-derivative, unsaturated compounds have been synthesised in the presence of DMS solution of KI and zinc dust[281,284,285]. Methylene[92,220,224,225,237,271,286-288], ethylidene[289], and benzylidene[220,225,237,271,286] acetals and isopropylidene[220,224,237,271,286,288], cyclohexylidene[220,271,286], and trifluoroisopropylidene ketals[120] and their derivatives, including polymeric derivatives[289,290], have been described. Halogeno-[117,176,197,222,269,271,291] and amino-derivatives[274,283,292,293] have been obtained.

The structures of cyclic acetals and ketals of 1,4-anhydroxylitol (V) have been studied mainly by the authors of the present review. It has been established[279] that the acetal and ketal groups occupy the same 3,5-positions [compounds (VI)]. Examination of the xylitan model showed that the tetrahydrofuran ring fixes rigidly the *trans*-disposition of the $C_{(2)}-C_{(3)}$ hydroxyls and therefore the formation of acetal and ketal linkages involving these groups is apparently hindered. 1,4-Anhydroribitol, in which there is a *cis*-disposition of the hydroxyls at $C_{(2)}$ and $C_{(3)}$ is known to form 2,3-ketals readily[294].



(V)



(VI)

Danilov and coworkers showed that the second anhydro-ring in 1,4-anhydroxylitol is also formed via the 3- and 5-hydroxyls and the product is therefore 1,4 : 3,5-dianhydroxylitol and not the 1,4 : 2,5-derivative as had been believed previously[269,271,272]. The nucleophilic substitution of the tosyl group at $C_{(2)}$ in dianhydroxylitol proceeds via an S_N2 mechanism with inversion of the configuration at this atom and the formation of lyxitol derivatives[275].

Xylitol derivatives in which the substituent is linked to the polyol molecule via a carbon–carbon bond have been synthesised. These compounds (Table 13), which have been obtained from xylose, do not have an aldehyde group and we have therefore classified them as xylitol derivatives, although in the original studies the authors called them xylose derivatives. For this reason, two names are quoted for these compounds in the Table.

V. PHYSICAL METHODS FOR THE DETERMINATION OF THE STRUCTURES OF CYCLIC ACETALS

The experimental determination of the structures of acetals is usually difficult: in the course of chemical reactions occurring during partial acid hydrolysis, there is a possibility of the isomerisation and migration of the acetal and acyl groups. Hydrolysis is inapplicable to stable rings and the structures of the diastereoisomers of acetals with various groups attached to the carbonyl moiety cannot be determined by purely chemical methods. Numerous studies using model acetals showed that spectroscopic methods are the most promising for the determination of the structures of cyclic acetals. They require small amounts of the test substance, the analysis is carried out under neutral conditions, and both the structure and conformation of the derivative are determined.

Table 13. *C*-Substituted xylitol derivatives.

Name	M.p., °C	References
1-Deoxy-1,1-di-*C*-phenyl-D-xylitol	167–168	185,186
1-Deoxy-*α*-*C*-phenyl-*β*-*C*-*p*-tolylxylitol	163.5–164.5	185,186
2,3,4-Tri-*O*-acetyl-1-*C*-anisoyl-1-deoxy-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-*C*-anisoyl-1-deoxy-D-xylitol)	129.5–130.5	189
2,3,4-Tri-*O*-acetyl-1-*C*-chlorophenyl-1-deoxy-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-*C*-chlorophenyl-1-deoxy-D-xylitol)	149.5–150.5	189
2,3,4-Tri-*O*-acetyl-1-*C*-chloroanisoyl-1-deoxy-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-*C*-chloroanisoyl)-1-deoxy-D-xylitol)	151–153	189
2,3,4-Tri-*O*-acetyl-1-*C*-bromoanisoyl-1-deoxy-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-*C*-bromoanisoyl-D-xylitol)	159–160	189
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-nitroanisoyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-nitroanisoylxylitol)	155.5–156.5	189
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-phenethyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-phenethyl-D-xylitol)	130.5–131	189
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-nitrophenethyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-nitrophenethyl-D-xylitol)	165.5–167	189
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-diphenyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-diphenyl-D-xylitol)	191–192	190
2,3,4-Tri-*O*-acetyl-1-*C*-allyl-1-deoxy-D-xylose (2,3,4-tri-*O*-acetyl-1-*C*-allyl-1,5-anhydro-1-deoxy-D-xylitol)	Syrup	190
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-thienyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-thienyl-D-xylitol)	151–152	190
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-*o*-tolyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-*o*-tolyl-D-xylitol)	110–111	195
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-dibromophenethyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-dibromophenethyl-D-xylitol)	80–81.5	195
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-dichlorophenethyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-dichlorophenethyl-D-xylitol)	Syrup	195
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-dibromoallyl-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-dibromoallyl-D-xylitol)	123–124	195
2,3,4-Tri-*O*-acetyl-1-deoxy-1-*C*-*dithiocyanatoallyl*-D-xylose (2,3,4-tri-*O*-acetyl-1,5-anhydro-1-deoxy-1-*C*-dithiocyanato-allyl-D-xylitol)	95.5–98	195
1-Deoxy-1-*C*-*β*-indol-D-xylitol	140–145	194
1-Deoxy-1-*C*-hexachlorocyclohexyl-D-xylitol	Syrup	194
1-Deoxy-1-*C*-phenyl-D-xylitol	168–169	188,196
1,5-Anhydro-1-deoxy-1-*C*-phenyl-D-xylitol	148–148.5	187,196
2,3,4-Tri-*O*-benzoyl-1-deoxy-1-*C*-phenyl-D-xylose (1,5-anhydro-2,3,4-tri-*O*-benzoyl-1-deoxy-1-*C*-phenyl-D-xylitol)	168	196

Infrared spectroscopy [295] of acetals and ketals of aldo- and keto-pentofuranoses, aldo- and keto-hexofuranoses, saccharic and uronic acid salts, lactones, and polyols did not reveal the presence of the characteristic bands of 1,3-dioxolans. Bands at 2820–2830 cm^{-1} [296] and at 2770 and 1030 cm^{-1}, [297] which characterise O–C–O stretching vibrations, have been found for 1,3-dioxans. It has been shown that xylitol derivatives with methylene acetal rings [142,255,298] are also characterised by a band in the region of 2800 cm^{-1}. Infrared spectra are used to demonstrate the presence of various functional groups in xylitol derivatives [109,121,217,299] and for the detection of the formation of hydrogen bonds [300].

NMR is used to determine the structures and stereochemistry of the cyclic acetals of monoses and polyols. Evidently 1,2- and 1,3-acetals should be formed in each case in the form of a mixture of two isomers with respect to the positions of the groups at the carbon atom of the acetal bridge. The possibility of the diastereoisomerism of cyclic benzylidene acetals was suggested for the first time by Fischer [301] and later such isomerism was actually observed [162,302,303]. Model substituted and unsubstituted *trans*- and *cis*-5-hydroxy-2-phenyl-1,3-dioxans (benzylidene glycerols) have been paricularly thoroughly investigated [304–314].

The structures of the mono- and di-*O*-acetals of monoses and polyols have been established by ^{1}H NMR. [312,315,316] In particular, the signals of the acetal protons of di-*O*-benzylidenexylitol [317] have been found at τ = 4.79 and 4.85, which confirms the presence of 1,3-dioxan rings with a *cis*-disposition of the groups and the 2,4 : 3,5-structure. The ^{1}H NMR spectra of monomethylenexylityl acetates made it possible to demonstrate the existence of one axial and two equatorial acetyl groups [318].

The proton signals in the NMR spectra of the methyl groups in ketals depend on the relative positions of these groups [266]. This made it possible to show that di-*O*-isopropylidenexylitol is a mixture of two isomers—one giving rise to signals of methyl protons at τ = 8.78 and 8.73 with an intensity ratio of 1 : 3, which corresponds to the 2,3 : 4,5-structure, and another with signals of equal intensity at τ = 8.81 and 8.73 corresponding to the 1,2 : 4,5-structure.

The relation between the structure of the ketal rings and the chemical shift of the fluorine nuclei in trifluoroisopropylidene derivatives has been described [120,121,254,319]. It has been found that the influence of the steric environment on the chemical shift of the fluorine nuclei in the CF_3 group exceeds by a factor greater than 50 the corresponding value for CH_3 groups. These spectra established the quantitative proportions of the diastereoisomers. The NMR and infrared spectra are usually investigated at the same time [118,217,299]. NMR with Fourier transformation yields more information than the proton spectra [320].

VI. METHODS FOR THE ISOLATION AND IDENTIFICATION OF XYLITOL AND ITS DERIVATIVES

Laboratory methods for the column chromatography of xylitol on neutral sorbents [321,323] and the chromatography in aqueous ethanol on ion-exchange resins in salt-forms [323,324] have been described. Ion-exxhange methods are used much more frequently to remove salts from xylitol solutions both in laboratory practice [58,61,325,326] and in industrial manufacturing processes [75,327]. Complexes of xylitol and its derivatives are chromatographed on ion-exchange resins [20,59,328].

Thin-layer chromatography of xylitol and its derivatives [176,329] and GLC of methyl ethers [330], trimethylsilyl derivatives [331–333], trifluoroacetates [333,334], methylated acetates[335], acetates[336], methyl ethers[337], acetals, and ketals[338] are widely used. Methods have been developed for GLC of biological media containing xylitol[329] and for quantitative GLC of polyols with automatic integration of peak areas[340]. Paper chromatography of xylitol[60,341–347] and its derivatives[168,348,349] and molybdate[350] and borate[351] complexes has been used and quantitative paper chromatography of xylitol has been developed[352,353].

Xylitol can be identified on the basis of the mobility of germanate[154], phenylboronate[111,154], and copper complexes in paper electrophoresis[106]. Mass-spectrometric techniques have been developed for the acetates[129,354], methylated acetates[355], methyl ethers[356], benzylidene[357,358] and trimethylsilyl derivatives[359,360], cyclic xylityl phenylboronates[110], and trisaccharides containing xylitol[361]. Xylitol can also be identified by colour reactions[362] and Kofler microscopy[363]. Methods have been proposed for the determination of the OH groups[364]. Quantitative and qualitative analytical methods for xylitol[365] include colorimetric and polarimetric techniques whereby the polyol can be determined in preserved food[366,367] and in atmospheric dust[368].

VII. THE USES OF XYLITOL

1. In Medicine

Studies on the metabolism and clinical applications[369–380], biochemistry, and the mechanism of the action of xylitol[381–383] have been published. It has been shown by the tracer atom method that in the organism xylitol may be formed[383] by the decarboxylation of D-glucuronic acid. The pentosephosphate, glucuronoxylulose[384], and glycerophosphate metabolic cycles[385,386] are thus related.

The lethal dose[387–389] and rational norms for the consumption of xylitol have been determined, since the introduction of excessive amounts of xylitol into the organism entails an increase in weight[388,390,391], although the number of calories produced by xylitol is lower than that produced by glucose[392]. The maximum permissible harmless xylitol contents in water have been established[393]. The intravenous injection of an excess amount of a 10% xylitol solution (in excess of 4.4 g kg^{-1}) produces poisoning symptons[394], which vanish when the administration is terminated. It has been established that the elimination of xylitol from blood is a first-order process[395].

Since it has been found that xylitol increases the level of insulin in animals[371,375,396–415], a detailed study has been made of the physiological action of the polyol on the human organism[416]. A scheme has been proposed for the biosynthesis of proinsulin and insulin in the presence of xylitol[417,418]. Its influence on the carbohydrate and lipid metabolisms of healthy[412,419–424] and sick human beings[420,425–430] of different ages has been investigated. It has been found that xylitol is readily assimilated even by premature and newly born infants[431,432]. Peroral and intravenous administration of xylitol lowers the concentration of lactates[433,434], glucose, and acetoacetic acid in blood and increases the insulin content[394,406,413,422,435–441]. At the same time there is an increase in the amount of glycogen in the liver[377,395], a fall of the level of acetone, and a change in the amount of aminoacids in urine[442].

Xylitol stimulates gastrosecretion[441,443], the biosynthesis of uronic acids[388,444], ATP,[445] corticosteroids hormones[372,373,446,447], proteins[446], and growth hormones[448] and chalcogenetic, choleretic, and pancreatic activities[449–452]. Xylitol has a favourable effect on the functioning of healthy[374,376,444,453,454] and cirrhotic liver[408,409,454,455], reduces haemolysis under the influence of primaquine[365], stabilises the level of bilirubin[388,451], lowers the content of aliphatic acids in the blood[433,439,456,457], stimulates the activity of dehydrogenases[415,458,459], and inhibits isomerases[460]. It is used to inhibit the suppression of adrenocortical activity in hormonal treatment[373,447,461–463]. On the other hand, the introduction of adrenalin suppresses the secretion of insulin caused by xylitol[434]. Thus the effect of xylitol presumably depends on its concentration[451].

It has been found that xylitol is assimilated more slowly than glucose[388], since the organism must become adapted to its assimilation[371,464,465]. Xylitol may serve as a source of energy for cardiac muscle[445,466]. Intravenous administration of xylitol during anaesthesia[467] causes smaller shifts in blood composition than the introduction of glucose. It has been noted the xylitol causes caries to a lesser extent[468], since cariogenic streptococci[389] require a considerable time to become adapted to the assimilation of xylitol[469]. It has been shown that it increases the level of aminopeptidase *B*[469,470] and has a favourable effect during stress[471,472] and in parenteral feeding[394,473–475].

Even prolonged administration of xylitol does not alter the frequency and depth of respiration, arterial pressure, and cerebrocortical activity (up to 1 g kg^{-1})[387] and does not affect the level of uric acid, triglycerides, glycerol, α- and β-lipoproteins, and total cholesterol[424]. D-Xylose or its possible metabolic products, including xylitol, are capable of causing cataract in rats[476].

Xylitol has been recommended for use in gastroenterology[477], in duodenal tubage[450], and in diabetic diets[392,424,478–480]. Cerebral scleroses, hypertonia, and pellagra are treated with xylityl pentanicotinate, which exhibits a vasodilating activity[133,481]. Xylitol derivatives of hydroxycinnamic[482] and 2-hydroxy(acetoxy)-5-iodobenzoic acids[483] exhibit anti-inflammatory activity. Aminoderivatives[228] are analgesics[484].

Xylitol solutions containing hydroxymethylaminomethane are administered intravenously[484] and the xylitol–Fe^{3+}–citrate complex[116], which increases the level of haemoglobin, is administered intramuscularly. Calcium deficiency is compensated by medicinal compositions based on xylitol and calcium carboxylates[485]. The compatibility of xylitol solutions with various combinations of 36 medicinal substances used in infusion has been studied[486]. Quaternary ammonium salts based on xylitol exhibit bacteriostatic activity[173,176]. Xylitol is introduced into ointment bases[487] and into compositions for the pressing of tablets[488].

Methods have been developed for the quantitative determination of xylitol in blood[489,490] and in urine[455], which make it possible to diagnose hepatitis[491] and cirrhosis of the liver[455]. Xylitol is an effective blood preservative, which protects it from haemolysis and the formation of methaemoglobin, reduces methaemoglobin[492–495], and promotes the coagulation of blood[496]. The metabolism of xylitol in erythrocytes has been studied[497]. Xylitol solutions stabilise bacterial cultures in lyophilisation[498] and plant cells in freezing with liquid nitrogen[489,490,499,500]. The latter behaviour is attributed to conformational changes in the plasma–membrane system[501]. Xylitol inhibits[495,502] or promotes[494,503] the germination of various plant seeds.

2. In the Food Industry

Xylitol is being used increasingly to sweeten food products[480,504] together with other synthetic sweetening agents, which are usually employed in low-calorie diets[505]. It is interesting that the maximum sweetness of xylitol is achieved following the addition of 0.06% NaCl; mixtures of xylitol with sodium glutamate, saccharin, and organic acids have been studied[506,507]. Xylitol[504,508] and surfactants based on xylitol and $C_{10}-C_{30}$ aliphatic acids[509], which can be readily blended with dough, are used in the bread baking industry and in preserving fruit[366,510]. Milk with added xylitol has been recommended for the feeding of infants[511]. The taste, colour, bouquet, and stability of alcoholic drinks are improved by the addition of 0.5–3% of xylitol[512].

Xylityl esters of saturated and unsaturated acids[92–96] are relatively non-toxic and can be added in large concentrations (up to 10 wt.%)[509] to food products, in which they serve as dispersing, emulsifying, and surface-active agents. Such esters are soluble in oils, are dispersed in warm water[513], do not cause allergy, and are used as stable non-ionogenic emulsifying agents in cosmetic preparations[131,514–516] and for the stabilisation of food fats[517]. In aqueous solutions xylitol stabilises cysteine[518].

3. In Engineering

Xylitol replaces glycerol as a regulator of foaming[519] and as a plasticiser[520]. In aqueous solutions it protects metals from corrosion[521,522]. Xylitol-containing fluorescent pigments have been prepared[523]. Varnishes, drying oils[524], dyes, adhesives, resins[81,135,182,524–529], wetting and surface-active agents[92–96,134,173–177,228,380,530], non-ionogenic[531] and ionogenic emulsifying agents[173–176], de-emulsifying agents[532–534], polyurethane foam plastics[535,536], film-forming polyurethanes[537,538], polyphthalates[539], and hardening agents for water-soluble polymers[540] are manufactured from xylitol derivatives.

Synthetic tanning agents have been obtained by the condensation of xylityl esters with benzaldehyde and formaldehyde[541] and the condensation of the esters with epoxyethane yielded surfactants with bacteriostatic activity[96]. The product of the electrochemical alcoholysis with xylitol of natural fatty acid triglycerides (linseed oil) is used in the paint and varnish industry[542]. The monoesters of fatty acids and xylitol are employed in dying polyamide fibres[543], in the treatment of viscose staple fibre[544,545], and as deflocculating and flotation agents[137,546,547]. Mixtures of methyl and ethyl ethers of xylitan[548] and mixtures of xylityl esters of resin and tall oil acids[549] have found technical applications. Hardening acrylate oligoesters[550–552], polymethacrylate esters[290], and polycondensation resins[553] have been synthesised on the basis of xylitol.

Synthesis and Properties of Interpenetrating Networks

Yu.S.Lipatov and L.M.Sergeeva

The preparation and the properties of interpenetrating networks are described. Data are reported on the effective density of branch points, and the dependence of viscoelastic characteristics on temperature, proportions of initial components, and mode of preparation. Results are reported for the morphology and mechanical strength indices. The physicochemical properties of interpenetrating networks can be influenced by inorganic fillers previously introduced into one of the components. A list of 35 references is included.

CONTENTS

I. INTRODUCTION

A promising method for modifying the properties of polymers is to prepare mixtures, which may yield materials combining the properties of diverse component polymers. A special place among investigations of such mixtures is occupied by recent studies[1-15] on the production and properties of interpenetrating networks. These are complicated systems comprising two or more three-dimensional network polymers, not chemically combined but inseparable because of mechanical interlocking of chains resulting from the conditions of preparation.

Interpenetrating networks have now been obtained from analogous[1] or chemically related[3] polymers, as well as from systems differing completely in chemical structure and in mode of preparation[6-8]. Thus their preparation can be regarded as a new method for "mixing" not only definitely incompatible but also network polymers, which enables the properties of the latter to be modified. The production of interpenetrating networks from polymers of the most diverse chemical structure is especially promising, since their combination should give materials with a wide range of properties.

II. PREPARATION OF INTERPENETRATING NETWORK POLYMERS

Two methods are available for obtaining interpenetrating networks. The first method consists in swelling a network polymer (first network) in a liquid polymer or oligomer capable of subsequently setting to form a network of a different chemical type (second network) (Fig. 1). Chemical reaction cannot occur between chains of the two network polymers; it is responsible solely for mechanical interlocking of the unlike chains. This method was applied to poly(ethyl acrylate) and polystyrene[2]: the cross-linked polyacrylate (network *1*) was obtained by photopolymerisation in the presence of benzoyl peroxide and diethylene glycol dimethacrylate as cross-linking agent; the resulting sheets were then swollen in styrene with addition of the above initiator and cross-linking agent, and subsequent photopolymerisation gave cross-linked polystyrene (network *2*) embedded in network *1*. Interpenetrating networks were obtained similarly on the basis of poly(ethyl acrylate) and poly(methyl methacrylate) (with tetraethylene glycol dimethacrylate as cross-linking agent)[3,4,12], polystyrene and polybutadiene[15], and also a styrene–divinylbenzene copolymer[1]. In the last case the copolymer was first prepared in the presence of benzoyl peroxide (first network), and specimens were swollen in a mixture of styrene and divinylbenzene with subsequent polymerisation to give a second network embedded in a matrix of the first network of the same nature.

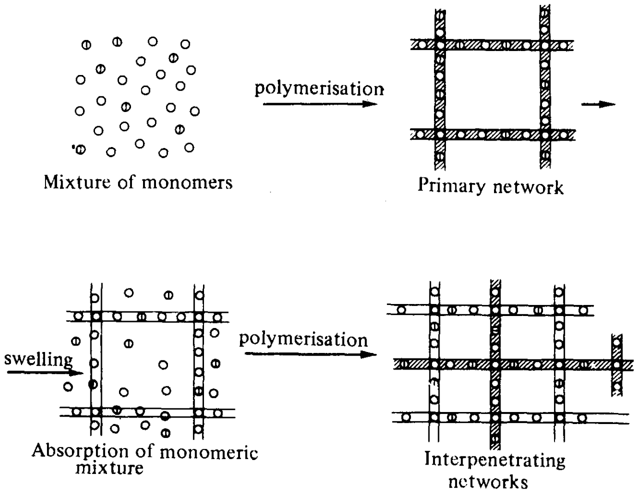

Figure 1. Diagram of first method of generation of interpenetrating networks.

The second method consists in the simultaneous cross-linking of two different polymers already mixed in the same solvent or in suspension. The polymers are selected to ensure mutually independent formation of network structures and to exclude chemical interaction between unlike chains. Frisch et al.[6-10] have used this method to obtain interpenetrating networks consisting of polyurethane based on tolylene di-isocyanate, polyoxypropylene glycol and a polyacrylate, polyurethane and polybutadiene–styrene, and polyurethane and polychloroprene: 50% aqueous emulsions of the polymers containing a cross-linking agent and a stabiliser were stirred vigorously for 1 h, after which films were poured from the resulting composition and kept at a fixed temperature.

The first method of preparation is the more promising, firstly because it permits a more uniform distribution of unlike chains. Secondly, interpenetrating networks can be obtained from the same pair of polymers but with properties varying between wide limits depending on which component is obtained first. This has been shown for cross-linked poly(ethyl acrylate) (network *1*) and a copolymer of styrene with methyl methacrylate (network *2*).[12] If network *1* is synthesised first, and then swollen in a monomer serving as intermediate for the second network, the properties of the resulting interpenetrating networks differ considerably from the "inverse" product obtained when network *2* is synthesised first. We shall discuss the properties of such networks in a later Section.

III. EFFECTIVE DENSITY OF BRANCH POINTS

A fundamental characteristic of the structure of a network polymer is the effective density of branch points, which must therefore first be determined and compared with those in the individual network polymers in order to describe the properties of interpenetrating networks.

Shibayama and Suzuki made such an investigation on interpenetrating networks comprising styrene–divinylbenzene copolymers[1] obtained by the first method to give W_2/W_1 ratios of 1–2 (where W_1 and W_2 are the weights of the first and second networks). The effective density of the network ν_e, determined by means of the equation

$$\nu_e = E/3dRT,$$

where E is the modulus of rubberlike elasticity and d the density of the specimen, was compared with the density of the network ν_T calculated from the ratio of the monomers in first and second networks. Fig. 2 illustrates the dependence of ν_e on ν_T for the first network (line *1*) and for the interpenetrating networks (line *2*). Values of ν_e are evidently higher for the latter, which was attributed[1] mainly to an increase in the number of mechanical contacts on interpenetration of the two networks. The swelling of these specimens in toluene and in acetone was less than those of the individual polymer networks, which confirms the increase in ν_e for the interpenetrating networks. Similar results were obtained by Millar[11] for the same system.

Frisch et al.[6,8,10] have studied the density of cross-linking of interpenetrating networks obtained from chemically different polymers. They determined ν_e by means of the Cluff–Gladding relation[16]

$$\nu_e = \frac{2}{3}\,\frac{h_0 S}{3A_0 RT},$$

where h is the height of the undeformed swollen cylindrical polymer specimen, A_0 its cross-sectional area, S the slope of the linear dependence of the compression of the specimen on the applied stress, R the universal gas constant, and T the absolute temperature. Frisch suggests that, if ν_e for the interpenetrating networks is greater than the arithmetic mean calculated from the ratio of the initial polymers, the networks should exhibit interpenetrability: i.e. he regards ν_e for the mixed system as a measure of the degree of interpenetrability of the networks.

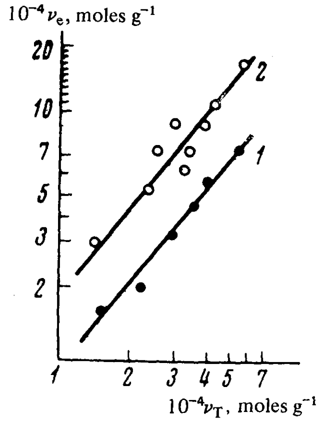

Figure 2. Dependence of ν_e on ν_T for: 1) first network; 2) interpenetrating networks based on styrene–divinylbenzene copolymer.

Table 1. Densities of cross-linking ν_e of interpenetrating networks and of individual components.

System	$10^4\cdot\nu_e$, mole cm^{-3}	Φ_3, %	System	$10^4\cdot\nu_e$, mole cm^{-3}	Φ_3, %
Poly(butadiene-styrene)	0.094	—	Polyurethane + polyacrylate	0.392	9.5
Polyacrylate	0.385	—	Polyurethane + poly-(butadiene-styrene)	0.055	—
Polyurethane	0.350	—	Polyurethane + polychloroprene	0.390	21.9
Polychloroprene	0.306	—	Polyacrylate + poly(butadiene-styrene)	0.342	42.5

The mixed system is considered to comprise three phases—networks *1* and *2* with an intermediate region *3*—the total network density of which is defined as

$$\nu_e = \Phi_1(\nu_e)_1 + \Phi_2(\nu_e)_2 + \Phi_3[(\nu_e)_1 + (\nu_e)_2],$$

where $(\nu_e)_1$ and $(\nu_e)_2$ are the network densities of the individual polymers, and the Φ are the fractions by volume of the different regions, with $\Phi_1 + \Phi_2 + \Phi_3 = 1$. If $\Phi_1 = \Phi_2$, we have $\nu_e = \frac{1}{2}[(\nu_e)_1 + (\nu_e)_2]\,(1 + \Phi_3)$, and therefore $\Phi_3 = [\nu_e - (\nu_e)_0]/(\nu_e)_0$, where $(\nu_e)_0$, the density of cross-linking of the system in the absence of interpenetrability, is given by the arithmetic mean of the ν_e for the individual components. Thus Φ_3 represents the degree of interpenetrability. Table 1 lists values of ν_e obtained by Frisch et al.[6] for the system and for the individual components. In several cases $\Phi_3 > 0$, which suggests interpenetrability, but for the polyurethane–poly(butadiene–styrene) system

$\Phi_3 < 0$, since $\nu_e < (\nu_e)_0$. This is explained by the plasticising action of poly(butadiene–styrene) on the polyurethane network. It was also found that this interpenetrated system swells considerably more than did the individual polymers, which confirms the observed diminution in ν_e relative to the components.

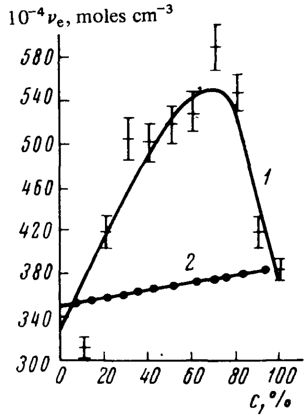

Figure 3. Dependence of effective density of cross-linking of interpenetrating networks on polyacrylate concentration c: 1) experimental; 2) theoretical.

Interesting results on the composition dependence of the density of cross-linking were obtained by Frisch[6] for a polyurethane–polyacrylate system. Fig. 3 shows an extremal dependence of density of cross-linking of the interpenetrating networks on the polyacrylate content. Maximum ν_e is observed at 70% of the latter. The absolute densities of cross-linking are considerably greater than those calculated from the stoichiometric composition. This system will be considered in greater detail in connection with mechanical properties.

IV. EFFECT OF TEMPERATURE ON VISCOELASTIC PROPERTIES

A considerable proportion of research on interpenetrating networks has been concerned with mechanical properties and their temperature dependence. Such an approach provides information on temperature transitions, as well as some indication of the compatibility of the components.

Investigation of the temperature dependence of Young's modulus for the poly(ethyl acrylate)–poly(methyl methacrylate) system[5] has revealed a broad transition region, and dilatometric examination shows also a glass point. Curves representing the variation of the modulus during stretching under creep conditions obtained[4] for the same system show a broad transition region. The range of dispersion of Young's modulus is greater for interpenetrating networks. From the results obtained for this system Sperling suggests that poly(ethyl and methyl methacrylates) are partly compatible components in the formation of interpenetrating networks.

Examination of the relaxation properties of polymer mixtures, e.g. for 50 : 50 mixture of poly(vinyl chloride) and SKN-40 [butadiene–acrylonitrile] synthetic rubber[17], also revealed a single broad transition region.

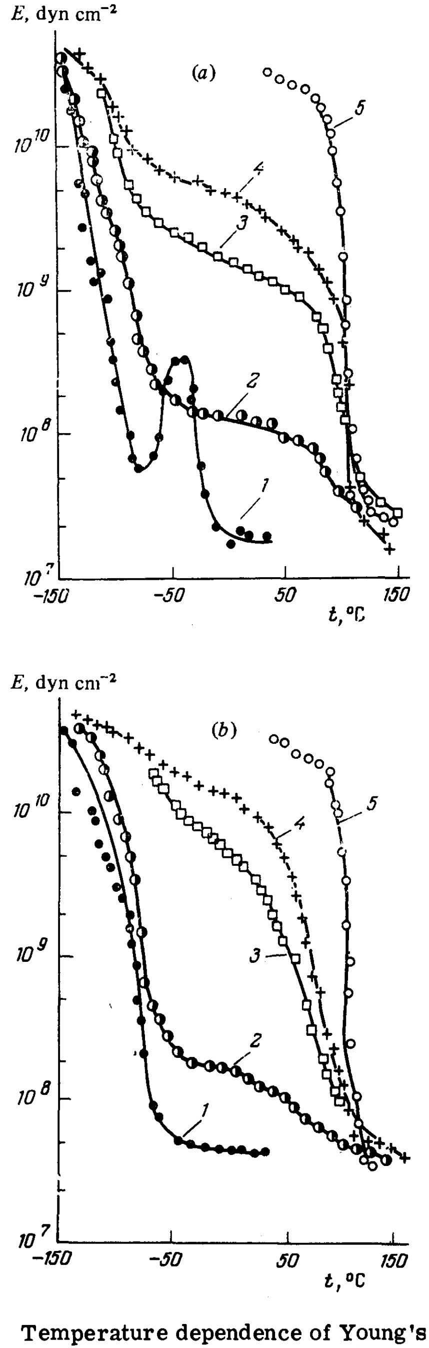

Figure 4. Temperature dependence of Young's modulus for interpenetrating networks containing different quantities (%) of polystyrene: (a) first: 1) 0; 2) 24.4; 3) 61.6; 4) 75.7; 5) 100; (b) second: 1) 0; 2) 25.6; 3) 56.9; 4) 72.4; 5) 100.

Interpenetrating networks based on poly(ethyl acrylate) and polystyrene[2] exhibit different properties from the above system: the temperature dependence of Young's modulus reveals two transitions, corresponding to the respective polymers (at −16 and 75°C). The occurrence of two glass points clearly indicates the formation of two polymer phases in systems of this type. The transition temperatures do not correspond to the glass points of the homopolymers: that of poly(ethyl acrylate) is −22°C, and that of polystyrene 100°C. This was attributed to incomplete phase separation and the existence of an intermediate region in the interpenetrating networks.

Interesting results on the temperature dependence of Young's modulus E were obtained by Sperling for interpenetrating networks based on a crystallising and a non-crystallising homopolymer—respectively polybutadiene and polystyrene—first series[15,18]. A second series of specimens was obtained from non-crystallising polybutadiene with polystyrene. The temperature dependence of the modulus (Fig. 4) reveals for the first series two transition regions, with the glass point corresponding to polybutadiene in the interpenetrating networks higher than in the homopolymer, and that corresponding to polystyrene in the mixed system lower than in the pure polymer. Similar results were obtained for interpenetrating networks based on polystyrene and a polyacrylate.

Incidentally, closer approach of maxima in binary systems was observed when the method of dielectric losses was used to investigate polymers containing polymeric fillers[19], which was attributed to the mutual influence of the components on the molecular mobility of the polymer chains.

Table 2. Incompatibility numbers for first and second series of interpenetrating networks.

Series	Styrene, %	I.N.	Series	Styrene, %	I.N.
First	61.6 75.7	0.81 0.90	Second	56.9 72.4	0.62 0.65

Interpenetrating networks based on crystallising polybutadiene do not crystallise over the temperature range investigated (Fig. 4*a*), exhibiting merely a steeper fall in modulus with temperature than for the second series. The transition ranges are broader in the latter than in the first series. Sperling suggests that the degree of incompatibility should be assessed from the results. He introduces the concept of "incompatibility number (I.N.)", which can be calculated from the temperature dependence of the modulus by means of the equation

$$\text{I.N.} = 1 - \frac{X_1^{-1} + X_3^{-1}}{2X_2^{-1}},$$

where $X = \mathrm{d}(\lg E)/\mathrm{d}T$, the subscripts *1* and *3* correspond to the two transition ranges, and *2* denotes the plateau between the transitions. The incompatibility number varies from zero for a compatible system to unity for an incompatible system. The values listed in Table 2 show that the components of the first series are more incompatible than those of the second series. The reason is that the polybutadiene in the former series crystallises; the possibility of crystallisation or increase in the degree of order in this series tends to increase the incompatibility number.

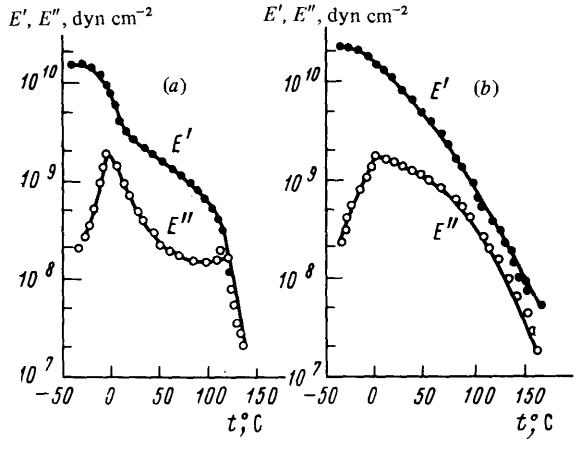

Figure 5. Temperature dependence of E' and E'' for interpenetrating networks of: *a*) 48.8% of poly(ethyl acrylate) plus 51.2% of polystyrene; *b*) 47.1% of poly(ethyl acrylate) plus 52.9% of poly(methyl methacrylate).

Interpenetrating networks of poly(ethyl acrylate) and a copolymer of styrene and methyl methacrylate, with tetraethylene glycol dimethacrylate as cross-linking agent, were chosen[13] for the investigation of viscoelastic properties because the components of the copolymer were chemically different and incompatible polymers, while the polyacrylate and the polymethacrylate were partly compatible, as noted above. It was supposed that the degree of compatibility of the interpenetrating constituents would vary considerably with composition. An additional reason for the choice was that polystyrene and poly(methyl methacrylate) have closely similar glass points (100 and 105°C), so that their copolymer would have a similar glass point, which would simplify analysis of the experimental results. Interpenetrated specimens were obtained with different contents of methyl methacrylate in the copolymer and also with different proportions of the constituent polymers, yielding diverse properties. The temperature dependence of the complex modulus of elasticity for the systems based on poly(ethyl acrylate) and polystyrene reveals two transition ranges for both real and imaginary parts E' and E'' (Fig. 5*a*). The transition corresponding to the former polymer is 10 deg above that for the polystyrene homopolymer. In Sperling's view this indicates some molecular compatibility. With interpenetrating systems based on the polyacrylate and the copolymer the peak in the temperature dependence of E'' becomes broader in the copolymer, and the second transition gradually disappears. Interpenetrating systems comprising the polyacrylate and the polymethacrylate exhibit only one transition in the temperature dependence of E' and E'' (Fig. 5*b*), covering a temperature range around 100°C; these results support the earlier conclusion concerning the compatibility of this system.

With a high content of the elastomeric component—poly(ethyl acrylate)—the real part E' drops rapidly after a low-temperature transition (Fig. 6*a*), but with a low content it varies little with temperature (Fig. 6*b*). From this Sperling deduces that the elastomer forms the continuous phase in the first case, whereas the plastic phase is continuous in the second case.

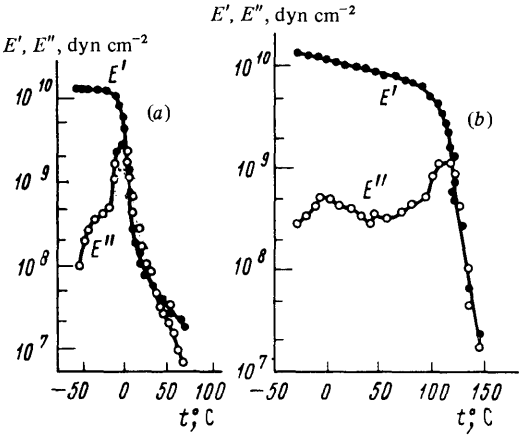

Figure 6. Temperature dependence of E' and E'' for interpenetrating networks of poly(ethyl acrylate) and polystyrene: *a*) 74.4% + 25.6%; *b*) 23.9% + 76.1%.

This worker showed also[13] that the components of the complex modulus and their temperature variation depend on the mode of preparation of the system. The experimental results plotted in Figs. 5 and 6 relate to interpenetrating networks in which the elastomeric part had been synthesised first, and the second network had been polymerised in it (after the monomeric mixture had swollen). But if the second network is prepared first, and then the first network—poly(ethyl acrylate)—is polymerised in it, the resulting "inverse" network exhibits a different temperature dependence of the modulus. The "inverse" system was more rigid than a system obtained by the first method, which indicates the continuity of the polystyrene phase in this network.

Thus investigation of the viscoelastic properties of these systems has shown that those based on poly(ethyl acrylate) and polystyrene are almost incompatible, whereas those comprising the polyacrylate and poly(methyl methacrylate) exhibit considerable miscibility. Materials having different degrees of compatibility are obtained by varying the ratio of the components and the content of the polymethacrylate.

In the investigation of the viscoelastic properties of interpenetrating networks of polyurethane and the polyacrylate, Frisch tried to apply to the results a model developed by Takayanagi[20] for mixtures of polymers. The polyacrylate was regarded as a matrix in which the polyurethane was dispersed. He used the equation

$$E^* = \lambda\left(\frac{\psi}{E^*_{\mathrm{pu}}} \cdot \frac{1-\psi}{E^*_{\mathrm{pa}}}\right)^{-1} + (1-\lambda)E^*_{\mathrm{pa}}$$

in which E^*, E^*_{pu}, and E^*_{pa} are the complex moduli of the system, polyurethane, and the polyacrylate respectively. The parameters ψ and λ are related by the formula $\psi\lambda = \Phi_{\mathrm{pu}}$, the fraction by volume of polyurethane in the system. The closest agreement with the experimental results is obtained by assigning to λ the values 9.45, 0.620, and 0.88, and to ψ the values 0.667, 0.806, and 0.795 for percentage ratios of the polyacrylate to the polyurethane of respectively 70/30, 50/50, and 30/70. The experimental results were satisfactorily described by one of the models developed for mixtures of polymers.

Sperling et al.[13] also showed that the experimental viscoelastic results for the interpenetrating networks were described satisfactorily in terms of Bauer's model[21], in essence a modified Takayanagi model[20]. The applicability of mechanical models developed for mixtures comprising one polymer dispersed in a matrix of another provides additional indirect evidence that interpenetrating networks constitute a two-phase system.

V. MECHANICAL STRENGTH CHARACTERISTICS

In the preparation of interpenetrating networks it is important to compare their mechanical strength indices with those for the individual polymers, and it is also necessary to monitor the variation of these indices with the ratio of the initial network polymers.

Investigation of the strength properties of the systems based on crystallising and non-crystallising polybutadienes with polystyrene (the first and second series above) has shown[18] that a system having a low polystyrene content behaves as a reinforced elastomer, exhibiting high strength and elongation. Increase to 50% of polystyrene is accompanied by an increase in strength to tenfold that of cross-linked polybutadiene. The maximum elongation at rupture is also greater for the interpenetrating networks than for cross-linked polybutadiene. The former are comparable in strength with a block copolymer of styrene and butadiene, but considerably stronger than the random copolymers. The first series are rather stronger than the second series, as a consequence of the ability of polybutadiene in the former to crystallise when stretched. The impact strength of interpenetrating networks having a high polystyrene content exceeds those of a graft copolymer of the same nature and of a styrene homopolymer by factors of 4 and 15 respectively.

The strength properties of interpenetrating networks of poly(ethyl acrylate) and a copolymer of styrene and methyl methacrylate[13] depend on which network was the first to be obtained. The "inverse" system (with the copolymer obtained first) is considerably stronger than the "straight" system, but maximum elongation at rupture is greater with the latter. Systems of this type, containing a large proportion of the copolymer, have properties almost unaffected by variation in the composition of the copolymer, i.e. by change in the ratio of styrene to methyl methacrylate in it. Such behaviour has been interpreted in terms of the morphology of the networks, as will be described below.

Frisch et al.[6,8] obtained several interpenetrating systems that were usually intermediate in strength between the component networks. In most cases the experimental strength and maximum elongation were smaller than the theoretical values calculated from the composition. The system formed by polyurethane and a polyacrylate was an exception: its experimental strength exceeded the calculated value, and was almost equal to that of pure polyurethane. However, interpenetrating networks of polydimethylsiloxane and a polyacrylate are stronger than either of the component polymers.

Interpenetrating networks of polyurethane and a polyacrylate showed an unexpected variation in strength properties with the content of the latter polymer (Fig. 7): the strength passed at 10% of the polyacrylate through a minimum, and at 75% through a maximum considerably above the strength of pure polyurethane. Frisch attributed the minimum to a decrease in the concentration of hydrogen bonds resulting from introduction of the less polar polyacrylate, which is then functioning as a plasticiser. Subsequent increase in strength is due to a greater number of tangles (contacts) in the system, which tend to "overcome" the diminished concentration of hydrogen bonds. The tangles are assumed to reach a maximum at 75% of the polyacrylate. This is supported by the maximum density of cross-linking at 70% of the polyacrylate (Fig. 3). The density of cross-linking then diminishes, and hence the strength falls. The presence of polyurethane confers great stretchability on this system; in most cases the maximum elongation at rupture determined experimentally exceeds the calculated value.

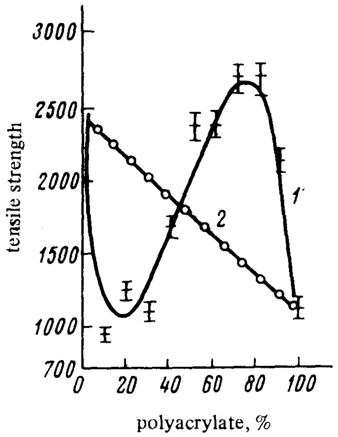

Figure 7. Dependence of tensile strength of interpenetrating networks of polyurethane and a polyacrylate on the content of the latter: 1) experimental; 2) calculated.

The above non-monotonic variation in strength properties and density of cross-linking has been observed in the properties of polyurethanes as functions of the content of inorganic fillers (Aerosil and carbon blacks).[22] In the case investigated by Frisch, the polyacrylate might be regarded as a polymeric filler for the polyurethane. Regarding the properties of interpenetrating networks as those of polymer–polymeric filler systems has been an extremely fertile approach[14], which we shall discuss in detail in connection with the properties of filled interpenetrating networks.

VI. STRUCTURE

Electron-microscopic investigation of the morphology of various types of interpenetrating networks undertaken by Frisch et al. and also by Sperling et al.[12,16] confirms the presence of two polymeric phases deduced from the viscoelastic properties.

Electron micrographs obtained by Frisch et al.[6,8] for a polyacrylate and for polyurethane separately revealed no clearly defined structures, whereas those for the interpenetrating networks exhibited regions differing in optical density, which were regarded as indicating the presence of two phases corresponding to the individual components. Furthermore, the distance between regions of polyurethane embedded in the polyacrylate matrix diminished as the polyurethane content increased from 30% to 50%, and at 70% polyurethane had become the matrix, in which polyacrylate regions were embedded: i.e. inversion had occurred. In this last case the strength was at a minimum (Fig. 7). Increasing the content of the "rigid" phase (the polyacrylate) produces an initial increase in strength, as noted earlier, to reach a maximum at a 70% content. Unfortunately, micrographs were not obtained at higher polyacrylate contents, so that further comparison of the mechanical characteristics with the morphology of the interpenetrating networks is impossible.

Sperling has made an electron-microscopic examination of ultrathin sections of interpenetrating networks of poly(ethyl acrylate) and a copolymer of styrene with methyl methacrylate[13]. The micrographs reveal a complicated cellular structure with cells of ~ 1000 Å, containing a fine structure with regions of ~ 100 Å. With equal quantities of the polyacrylate and polystyrene, the cell boundaries consist of the polyacrylate, while the intracellular region is filled with polystyrene. With equal quantities of the polyacrylate and of the copolymer, the cell boundaries become less well defined with increase in the content of methyl methacrylate in the copolymer, and the regions of fine structure become larger. When the polystyrene units have been completely replaced by poly(methyl methacrylate), no cellular structure is evident on the micrographs, but the system consists of two phases, exhibiting regions of the polymethacrylate and of the polyacrylate. When the ratio of polyacrylate to copolymer is 75/25, i.e. with elastomeric interpenetrating networks, two polymer phases are observed. Initially, when pure polystyrene enters the system, the dimensions of its regions vary between 800 and 1500 Å, while the polyacrylate particles are 100 Å in diameter. On the introduction of poly(methyl methacrylate) units the copolymer particles contract to 200–750 Å, and a fine dispersion of polyacrylate particles in the polymethacrylate is observed when their ratio is 75/25; no cellular structure is detected. When the ratio of polyacrylate to polystyrene (or the copolymer) is 25/75, the morphology varies little with the content of polystyrene or copolymer having a variable quantity of poly(methyl methacrylate). The cellular structure is considerably less well defined than in the previous cases. The strength characteristics remain practically unchanged in the last case, as noted above.

In all the systems poly(ethyl acrylate)—the polymer formed first—constitutes a matrix in which particles of the second polymer phase are disseminated. However, with inverse systems—in which polystyrene, poly(methyl methacrylate), or a copolymer thereof has been formed first—the matrix is a plastic polymer phase in which are distributed particles of the polyacrylate of mean size 150 Å. Thus the morphology of the system is determined by the network produced first, which forms the matrix. Furthermore, the nature of the matrix governs the mechanical strength parameters: if the matrix is the elastomeric polyacrylate, the system is deformed to a greater extent; conversely, if the rigid component—polystyrene, the polymethacrylate, or the copolymer—was the first to be produced, the resulting system undergoes less deformation.

Investigations of the morphology of polymer mixtures in general have revealed only in certain cases[23] such small particles of polymeric phases (≤ 100 Å) as observed by Sperling for the above systems. This is a specific effect of the first method for obtaining interpenetrating networks, which permits the heterogeneity of the complex system to be diminished. In the second method, used by Frisch et al.,[6,8] considerably larger polymeric phase regions are obtained. These results confirm the above considerations on the advantages of the first method.

Thus the morphological investigations combined with the mechanical properties of the systems indicate that the strength characteristics are determined by the polymer network that forms the matrix. This has been clearly shown by Sperling[12,13] in an examination of the morphological, viscoelastic, and other mechanical properties of interpenetrating networks of poly(ethyl acrylate) and a copolymer of styrene with methyl methacrylate.

Nevertheless, the morphological investigations support the two-phase character of the systems deduced from the viscoelastic properties. The heterogeneity depends on the composition and the mode of preparation; in some cases it is very slight, as noted above. However, these methods of investigation cannot give a criterion of the true, thermodynamic compatibility of the components. Yet hardly any study has been made of the changes in thermodynamic functions accompanying the mixing of network polymers; a few data only are available on the temperature dependence of heat capacity for interpenetrating networks.

VII. CALORIMETRIC AND SPECTROSCOPIC STUDY

The application by Frisch of differential scanning calorimetry to interpenetrating networks of polyurethane and a polyacrylate indicated some interaction between the component polymers[6]. This method gave glass points for the individual polymers identical with those obtained from mechanical relaxation data. In contrast to dynamic mechanical results, however, a single continuous transition was observed for the interpenetrated system, not two glass points. Frisch explained this by specific features of the two methods: whereas mechanical relaxation involves the movement of chain segments, large units—whole molecules or groups of molecules—must be considered in calorimetric measurements. In other words, the presence of a single glass point indicated by viscoelastic results was attributed by Frisch to compatibility or interpenetration of segments, whereas the presence of a transition established from heat-capacity measurements represented mixing of small groups of molecules. In the opinion of the Reviewers the explanation given by Frisch can hardly be accepted as satisfactory. It is more probable that such divergence in the results obtained by the two methods is due to a difference in their resolving power.

No new absorption bands were detected on the application of infrared spectroscopy to interpenetrating networks of polyurethane and the polyacrylate[6]: only bands characteristic of the individual polymers were observed. Hence chemical interaction does not occur between the mixed three-dimensional systems.

VIII. FILLED INTERPENETRATING NETWORKS

It has been noted above that interpenetrating networks can usefully be regarded as containing a polymeric filler. Investigation of the effective density of branch points in network polymers into which inorganic fillers have been introduced at the stage of formation of the three-dimensional network showed[22] that the network is more imperfect in the presence of the large surface area than when polymerisation occurs in the absence of a filler. The reason is that the strongly developed filler surface at the beginning of the reaction may increase the rate of termination of reaction chains at the surface, with a consequent diminution in the frequency of network formation, which becomes more imperfect. Adsorption of growing polymer chains on the filler surface at later stages in the reaction produces a considerable decrease in their mobility, which affects the rates both of growth and of termination. All this tends to result in a more imperfect structure of the three-dimensional network.

In view of the above considerations the Reviewers have compared[14] the properties of individual network polymers containing inorganic fillers with those of filled interpenetrating networks and of such systems filled with Aerosil introduced into one of the polymers. Polyurethane was the first network, and was then swollen in a mixture of styrene and divinylbenzene with addition of benzoyl peroxide and further polymerisation of the second, copolymer network. Determinations were first made of the densities of the specimens and the effective frequencies of branch points both in the initial components and in the interpenetrated system. The experimental densities were intermediate between those of the individual networks, in agreement with results obtained by some workers[4,6] but contradicting those obtained by Millar[11], who found that the density of the interpenetrating networks had increased relative to those of the initial components. The experimental densities were in several cases, in particular with small W_2/W_1 ratios, less than the additive values. With increase in this ratio and in the filler content the experimental density approaches the theoretical value and then exceeds it, which is especially noticeable at high W_2/W_1 ratios and the maximum filler content.

Flory's method[24] was used for the quantitative assessment of the variation in frequency of interpenetrating networks. Dioxan was used for swelling, since the temperature dependence of the volume fraction v_2 of the polymer in the swollen gel showed that the parameters for interaction of the individual network polymers with this solvent were very closely similar at $\psi \simeq 0.30$. Hence this value can be used to calculate the network frequency in the interpenetrated system. The results listed in Table 3[14] show that the experimental effective network densities ν_e/v are always smaller than the additive values calculated from those of the individual networks.

The effective density of branch points for the system investigated is "intermediate" between those of the individual networks: it exceeds the density of polyurethane and is less than ν_e/v for the copolymer. These results were explained on the basis of the above views and earlier ideas on the structure of filled polymers[25,26]. Interpenetrating networks can be regarded as filled systems in which one of the networks is a continuous network polymeric filler for the other. An attempt can then be made to describe the properties by the effect of a filler on the structure of a network formed in its presence. It had already been established that the structure of a polymer network produced in the presence of a solid surface always

differs from that of an unfilled polymer: for example, the effective network density of a polymer formed in the presence of a dispersed filler is usually less than the network frequency of the unfilled polymer. In the production of interpenetrating networks the second network, i.e. the styrene–divinylbenzene copolymer, is formed in the presence of an existing first network (polyurethane), i.e. in the presence of a solid surface. As in a filled polymer, therefore, defects may appear here in the network owing to a diminished quantity of chemical branch points and the generation of "free ends" in the network. The effective density of branch points in the second network, formed in the presence of the first network, will therefore be smaller than the frequency of the individual second network.

Nevertheless, chain entanglements are formed during polymerisation, which act as additional network branch points, and hence increase the total density of branch points in the interpenetrating networks. The experimental ν_e/v will be greater or less than the additive value depending on which of the effects predominates, and in some cases equality may be expected. In view of the above considerations the suggestion by Frisch that ν_e/v be regarded as an index of the compatibility of the components in the interpenetrating networks cannot be accepted unreservedly: the components may be partly compatible even when $(\nu_e/v)_{\text{exp}} < (\nu_e/v)_{\text{theor}}$.

Inspection of Table 3 shows also that the difference between experimental and theoretical values of ν_e/v increases with the content of cross-linking agent in the second network, and especially with the content of the latter in the system, i.e. with increase in W_2/W_1. A similar type of variation in ν_e/v is found for interpenetrating networks containing an inorganic filler previously introduced into the first network: the difference between experimental and theoretical values increases with the content of the second network and with its "hardening" resulting from increase in its content of cross-linking agent—divinylbenzene.

Both these factors—increase in the content of divinylbenzene in the second network and increase in the ratio W_2/W_1—tend to increase the number of rigid phenyl groups in unit volume, which prevents formation of chemical branch points in the interpenetrating network and also "hardens" the chain segments between the branch points, preventing formation of physical branch points by the interaction of polar groups. The latter effect is very significant, since it had been established earlier[27] that the proportion of physical links in polyurethane networks is very large. However, the introduction of rigid blocks, as occurs in the system described here, decreases this proportion. All these increase the divergence between experimental and calculated ν_e/v. Thus the effective density of cross-linking of interpenetrating networks is determined by the chemical structure of the initial components and also by their proportions.

Temperature transitions in these systems have been studied by measuring dielectric losses at 300 Hz over a wide temperature range (from −130 to +120°C)[14]. The styrene–divinylbenzene copolymer does not exhibit a maximum value of $\tan\delta$ within this range. Results are therefore reported for the temperature dependence of $\tan\delta$ for the polyurethane network and for the interpenetrating networks with a constant W_2W_1 ratio and different quantities of filler (Fig. 8). A maximum in $\tan\delta$ corresponding to dipole–segmental losses of cross-linked polyurethane (Table 4) is observed at −10°C, and shifts to −4°C on introduction of the maximum quantity of filler, owing to the restriction of segmental mobility of the chains between the branch points of the polyurethane network. This is consistent with effects observed earlier[28].

Increase in the filler content in the interpenetrating networks displaces $\tan\delta_{\max}$ to higher temperatures. A similar effect is produced by increasing the degree of cross-linking in the second network. Thus an analogy can be drawn between the effects of the filler and of rigid blocks of the second network on the molecular mobility of the chains between branch points of the first network. The combined effect of these factors shifts the maximum losses from −10 to 0°C: i.e. a considerable decrease in segmental mobility of the chains occurs between branch points in the first network. The absolute value of $\tan\delta$ is greatly diminished, which also indicates increased chain rigidity in the first network.

A structural investigation of this system was made also under a UEMV-100V electron microscope by the

replica method with preliminary treatment in the oxygen plasma of a high-frequency discharge[29]; the individual networks were also examined. A polyurethane rubber is characterised (Fig. 9*a*) by clearly defined globules of size 0.2 μm and by the presence of interglobular regions. The styrene–divinylbenzene copolymer exhibits smaller globules (0.05 μm), which are considerably less well defined (Fig. 9*b*). Specimens of the interpenetrating networks contain coarser globules (0.4 μm) than in the first network, separated by interstructural regions (Fig. 9*c*). The globules are considerably farther apart than in the first network.

From these results it was concluded that formation of the second network in the presence of the first is accompanied by an increase in the distance between the globules in the latter as the interglobular regions become filled with the copolymer. At the same time the globules themselves become larger (Fig. 9*c*). Thus during swelling of the first network in the mixture of monomers, the latter penetrates not only into the interglobular regions but also into the globules themselves, in which copolymerisation also takes place. Thus introduction of the second network has a significant influence on the structure of the first, leading to increased heterogeneity of the system.

In contrast to the structural investigations made by Sperling and by Frisch, the Reviewers examined[14] the effect of a filler (Aerosil) on the structure of the first network and on the interpenetrating networks obtained from it. Introduction of 1% of Aerosil into polyurethane suppresses the formation of large globules in the first network (Fig. 10*a*), so that the resulting system containing the filler previously introduced into the first of the constituent networks differs from the unfilled system (Fig.

10*b*) in having less clearly defined structural inhomogeneity. Thus the introduction of a filler into interpenetrating networks may change significantly the structure and probably the physicomechanical properties.

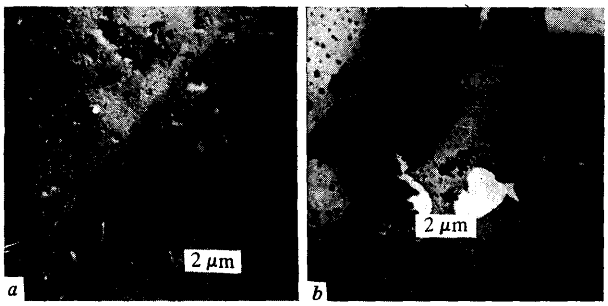

Figure 10. Micrographs of platinum–carbon replicas of surfaces of: *a*) polyurethane rubber filled with 1% of Aerosil; *b*) interpenetrating networks of polyurethane and of a copolymer, filled with 1% of Aerosil, of styrene and divinylbenzene.

The physicochemical and mechanical properties of a polymer are largely determined by the density of packing of the macromolecules. When applied to network polymers, this becomes the density of packing of chain segments between chemical branch points. Any change in intermolecular interactions in the system leads to a change in the density of packing of the macromolecules.

Table 5. Specific surfaces and cohesive energy densities of individual and interpenetrating networks containing various quantities of Aerosil.

Network (W_2/W_1) plus Aerosil	Surface, $m^2\ g^{-1}$	Energy, cal cm^{-3}
First (polyurethane)	24.20	84 ± 1.5
Second (styrene–divinylbenzene)	4.96	95 ± 1.5
Unfilled 0.3	21.10	100 ± 1.5
0.3 + 0.5%	16.12	100 ± 1.5
0.3 + 1%	11.16	–
0.3 + 0.5%	8.37	–
0.66 + 1%	4.03	–
2.98 + 1%	2.03	–
Unfilled 0.443	–	100 ± 1.5

The variation in the porosity of the interpenetrating networks of polyurethane and the styrene–divinylbenzene copolymer, both filled and unfilled, was investigated by the Reviewers[14]. Since the second network is formed in the presence of the already formed first network (filled and unfilled), the process obviously being accompanied by adsorption of growing chains at the surface of the filler and of the first network, changes must be expected in the porosity and other parameters of the polymer.

The variation in the porosity was assessed from the sorption of hexane, which is inert towards the interpenetrating networks, and can thus be used to determine the specific surfaces of these polymers[30,31]. Fig. 11 shows that all the isotherms are sigmoid. The BET equation can be applied to such isotherms to calculate the specific surface, which serves here as a measure of porosity[31]. The calculated results (Table 5) show that the first network has a considerably larger specific surface than has the second. Values for the interpenetrating networks are intermediate between those for the individual networks, but closer to the specific surface of the second network.

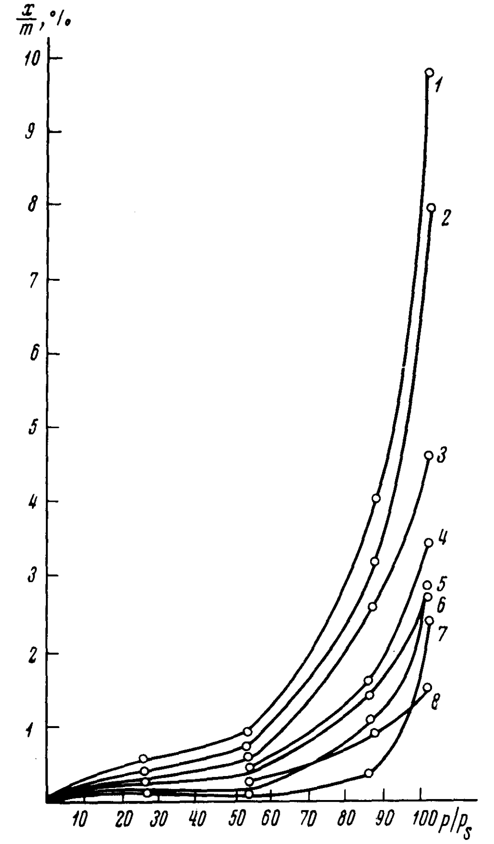

Figure 11. Isotherms for the sorption of hexane vapour by individual and interpenetrating networks with different W_2W_1 ratios and contents (%) of Aerosil: 1) unfilled polyurethane; 2) 0.3 + 0; 3) 0.3 + 0.5; 4) 0.3 + 1; 5) 0.3 + 5; 6) 0.66 + 1; 7) 2.98 + 1; 8) unfilled copolymer of styrene with 3% of divinylbenzene.

The specific surface decreases, i.e. the porosity diminishes, with increase in the ratio W_2/W_1 and in the Aerosil content of the first network. The specific surfaces of the system and of the second network are so small that these polymers can be regarded as non-porous sorbents in Kiselev's classification[32], whereas polyurethane appears as a finely porous sorbent.

Thus entanglements of chain segments of these two networks with a high content of the second network polymer have a considerable effect on the porosity of the system.

This may cause an increase in the density of specimens at high W_2/W_1 ratios, so that the experimental density becomes greater than the theoretical value, as noted above. On the other hand, the density of cohesive energy for the interpenetrating networks is rather greater than those of the individual networks (Table 5). Hence intermolecular interaction is greater in such systems than in the separate networks.

Comparison of the properties of filled and unfilled interpenetrating networks indicates that, if interpenetrating networks are regarded as a filled system in which one component network is a filler for the other, the ideas developed by the Reviewers[22,25,26] on the effect of a filler on the structure of a polymer network can be applied to such systems. We must remember that we are then dealing with a polymeric filler, and must bear in mind that, in contrast to systems with mineral fillers, not only are the properties of the polymer matrix influenced by the filler surface but the properties of the polymeric filler itself also change[19].

The above account shows that the problem of preparing interpenetrating networks and studying their properties is only in an initial stage of development, although the possibilities of the practical application of such materials can already be foreseen. Solution of the fundamental problems of production still lies in the future. In conclusion, therefore, we would like to discuss briefly certain aspects suitable for immediate investigation.

---o0o---

The primary problem in the synthesis of interpenetrating networks is the mechanism of formation of the second network in the matrix of the first, in view of the chemical and structural heterogeneity of any network polymer[33]. If our model based on the analogy with filled polymer systems is accepted, the matrix will clearly change significantly the conditions of formation of the second network at the interface with the first, and hitherto this has been almost entirely ignored. It is quite obvious that the second network, produced in the first, will never be identical in structure with the network of the same polymer obtained under comparable conditions (of temperature, proportions of components, etc.). Formation of the second network takes place from the very start in the highly viscous medium of the swollen first lattice, i.e. actually under gel conditions. Thus the second network will begin to be formed immediately at the gel point, as it were, but how the gel of the second network will actually be formed, what will be the parameters of this gelation (the extent of reaction at the gel point, the molecular-weight distribution, etc.), is still obscure. By analogy with filled systems the supermolecular structure of the first network will also influence formation of the second network. Therefore additivity of the properties of the two networks cannot in principle be expected: where it is observed, the reasons must be sought.

If the second network is formed by a polymerisation mechanism, chain transfers to molecules of the first network are entirely probable, so that chemical bonding of the two networks is possible even when such bonding should not occur in view of the nature of the two systems. The role of such reactions and the degree of bonding of the networks are still to be elucidated.

The process is complicated also by thermodynamic incompatibility and separation into two phases during formation of the second network. The morphological data reported indicate that the second network is actually formed in interstructural regions of the first, so that structure formation is taking place under complicated conditions. The diagrammatic representation of the structure (Fig. 1), therefore, does not correspond to the actual situation, and perhaps we should speak not of interpenetrating networks but of "parallel" or "coexisting" networks. The structural approach to network formation developed previously[33,34] will therefore be especially fertile.

An important task of research on structure and properties is to establish the effect of the extent of swelling of the first network, the temperature, and the thermodynamics of the "solvent", monomers of the second network, etc. It is necessary also to assess the thermodynamic interaction between the two networks and the possibility of formation of a transition layer and combined supermolecular structures (structural incompatibility), since many properties are determined by the inhomogeneity of the resulting system; as with mixtures of polymers, optimum properties will develop at a certain degree of structural heterogeneity.

Thus we have been the first to detect by reverse gas chromatography the formation of a transition region in interpenetrating networks of polyurethane and a styrene-divinylbenzene copolymer, and have estimated the enthalpy of mixing as a function of the ratio of the networks[35]. However, formation of this region does not indicate compatibility of the component networks, since the experimental enthalpy of mixing was positive. We must therefore speak rather of forced compatibility in such systems. The appearance of a transition region is probably connected with the mechanism of the formation of interpenetrating networks.

Further research is thus required to elucidate specific aspects of the formation and the structure of interpenetrating networks which govern their properties and potential applications.

Properties of Low Polymers and Their Solutions

V.P.Shaboldin, V.G.Chervin, A.I.Krasheninnikov, and V.N.Demishev

Published information is surveyed on the behaviour of low polymers of diverse chemical structure and on their dilute and concentrated solutions. Consideration is given to the important role of terminal groups, to the influence of the hydrodynamic permeability of a coil on polymer - solvent interaction, to the enhanced mobility of short chains, their flexibility, etc. A list of 108 references is included.

CONTENTS

I. INTRODUCTION

Interest in the properties of polymers with low degrees of polymerisation has recently grown considerably, owing to the importance of their practical applications. These compounds are widely used in the manufacture of polymeric paints, coatings, varnishes, special adhesives, plastic foams, reinforced plastics, thickening additives for lubricating oils, plasticisers, cements and various compositions containing a solid filler, and diverse intermediates[1-4]. Such polymers are also employed in the synthesis of several high polymers. The ability of low polymers to undergo deformation at low shear stresses is exploited to simplify the technology of the production of several polymeric materials.

Thus it is not fortuitous that research papers on them have appeared during recent years. However, the structure and the properties of low polymers and their solutions, in contrast to macromolecular compounds, have been insufficiently studied to date, and published information is fragmentary as to the component composition of the specimens investigated and contradictory as to results. For this reason polymers with low degrees of polymerisation have not yet been fully utilised. Nor has the technology of the production of macromolecular compounds from them been adequately developed.

II. BEHAVIOURAL FEATURES OF LOW POLYMERS AND THEIR SOLUTIONS

The term "oligomers" is applied to compounds of molecular weight below 10 000, whether homogeneous or inhomogeneous in composition. Low polymers occupy a special position, in a transition region between compounds of low and of high molecular weight. The study of short-chain polymers may therefore indicate the molecular weight at which a molecule acquires the properties of a polymer and when a substance can be said to be macromolecular. Low polymer systems and their solutions, while having relatively low molecular masses, possess characteristic rubberlike elasticity[5,6]. Nevertheless, they do not obey many of the rules that have been discovered for high polymers. The past study of the structure of solutions of polymers[7,8] of low molecular weight has been relatively slight, whether theoretical or experimental. Molecular-weight determinations on such polymers and investigation of the properties of their dilute solutions have been accomplished by the modified methods used for high polymers (low-angle X-ray scattering[9], viscosimetry[10], osmometry[11-13]), as well as by methods developed solely for short-chain polymers (cryoscopy and ebullioscopy[14-16], end-group analysis[17], isothermal distillation[18]).

Light scattering provides a most sensitive and accurate method for obtaining reliable information on the structure of macromolecules in dilute solutions[19]. It is interesting in the relative simplicity of the measurements combined with the fairly rapid provision of very accurate data on the conformational properties of macromolecules, size, molecular weight, degree of chain branching, structure-forming processes, etc. However, light scattering can be used to examine polymers only of sufficiently high molecular weight, when the particle size exceeds significantly the wavelength. This method has therefore been regarded as inapplicable to oligomers.

During recent years, in connection with progress in computer techniques, it has become common to investigate model systems of oligomers with computer experiments[20-22], by particular Monte Carlo methods[20-28]. The results obtained for model systems not only provide an idea of the structure of the macromolecule and its behaviour in solution but also permit analysis of earlier theoretical views.

Published information on the properties of low polymers and their solutions shows that, unlike compounds with high degrees of polymerisation, these systems possess several characteristics that cannot be interpreted by the usual theory of polymer solutions: (i) terminal groups of short-chain macromolecules have a significant role, and such macromolecules are able to interact not only among themselves but also with solvent molecules, which may reasonably be expected to influence the shape, size, and permeability of the coil; (ii) these compounds have a transition region of conformations between coil and rod, from compounds of low molecular weight to polymers; (iii) the hydrodynamic permeability of the coil affects polymer-solvent interaction, and the permeability varies with decrease in the length of the macromolecular chain in the transition region; (iv) the effect of long-range interaction diminishes; (v) short chains show enhanced mobility and are capable of orientation and interaction in the field of longitudinal and transverse velocity gradients at low shear stresses; and (vi) oligomers show almost the same capacity for elastic deformation, which is due to the presence of short, flexible chains, relatively unstable intermolecular bonds, and a mobile, fluctuating network. Many investigations have shown that these factors have a significant influence on the hydrodynamic, conformational, thermodynamic, and rheological properties of oligomers.

III. PROPERTIES OF DILUTE SOLUTIONS

The interaction between macromolecules in dilute solutions is divided into short-range and long-range interactions[29], between repeating units respectively comparatively near together and far apart in the polymer chain. Such interactions of units in the same chain are one of the factors responsible for the excluded-volume effect.

One of the main characteristics of a macromolecule in solution is its thermodynamic (equilibrium) flexibility $(\bar{h}_0^2/\bar{h}_{\mathrm{fr}}^2)^{1/2}$, where the $(\bar{h}_0^2)^{1/2}$ are the unperturbed dimensions of the coils, when the effect of long-range interactions is balanced by interaction with the solvent (second virial coefficient $A_2 = 0$), and $(\bar{h}_{\mathrm{fr}}^2)^{1/2}$ are the corresponding dimensions with free rotation of the units in the chain. The dimensions of a macromolecular coil depend on the character of the intra- and inter-molecular interactions, and can be estimated as

$$\alpha_0 = (\bar{h}^2/\bar{h}_0^2)^{1/2},$$

in which α_0 is Flory's coil-swelling coefficient[30] and the $(\bar{h}^2)^{1/2}$ are the dimensions of the coil in an actual solvent.

For oligomers little experimental study has been made of the effects of the nature of the solvent and of the degree of polymerisation on the dimensions of the coil and its properties. Coil size and shape have been determined by optical and viscosity measurements in studies of the properties of dilute solutions of low polymers[9,10,31-35]. Tsvetkov, Frisman, et al.[33-35] examined the dependence of the intrinsic dynamic birefringence on the molecular weight of polyoxypropylene glycols and polystyrene of low molecular weights. From the results the persistent lengths of macromolecules of the oligomers and the molecular-weight dependence of the intrinsic viscosity could be determined. In an investigation of the properties of dilute solutions of polyurethanes and of butadiene–acrylonitrile rubbers of low molecular weight in various types of solvents use of the Stockmayer–Fixman theory enabled the dimensions and the swelling coefficients of real coils to be determined and the flexibility of the macromolecular chain to be estimated by light scattering[10,31,36]. The depolarisation factor, characterising the form of a macromolecular coil of polypropylene glycol, was investigated[32] as a function of the molecular weight and the concentration of the polymer by the use of light scattering. The low-angle scattering of light and of X-rays was used[9] not only to determine the molecular weight and the shape of macromolecules of cellulose nitrate with low molecular weight but also to establish the presence in dilute solution of association complexes, which break down with time.

In contrast to these fragmentary results, a considerably larger number of theoretical studies have been made on the conformational properties of oligomer macromolecules, e.g. on the effect of terminal groups[37,38] (to which a significant role was assigned, in contrast to high polymers). However, conclusions reached from different theories are often mutually contradictory. Experimental results cannot be used for an objective assessment of theoretical predictions, since an exact analytical relation between the measured parameters and the conformations of the macromolecules is lacking. In this situation the application of modern computer experiments and numerical methods has permitted a close approach to solving important problems in connection with the properties of the macromolecules of oligomers.

The majority of results obtained by the Monte Carol method in computer experiments have led to a dependence of the mean distance between end-groups h_{N} and the mean radius of inertia R_{N} on the number of segments N of the form

$$\langle h_N^2\rangle = AN^{Y_n}; \tag{1}$$

$$\langle R_N^2\rangle = BN^{Y_R}, \tag{2}$$

where A, B, Y_{n}, and Y_{R} are empirical constants. The results in most papers lead to the condition $Y_{\mathrm{n}} = Y_{\mathrm{R}} = Y = 1.2$ for all lattices. Simulation by a continuum[28] gives $Y_{\mathrm{n}} \neq Y_{\mathrm{R}}$, which shows that representation of $\langle h_{\mathrm{N}}^2\rangle^{1/2}$ as a multiple of $\langle R_{\mathrm{N}}^2\rangle^{1/2}$ is not always correct: these parameters increase at different rates with increase in the degree of polymerisation. Equations (1) and (2) were deduced from the condition that the interaction potential of the segments is represented by a rigid sphere:

$$\Phi(r) = \begin{cases} 0, & r > d; \\ \infty, & r < d, \end{cases} \tag{3}$$

where r is the distance between the centres of the segments and d is the sum of their van der Waals radii. The functional dependence (1) and (2) is preserved for interaction between segments of a different type, but Y_{n} and Y_{R} vary with $\Phi(r)$. With increase in the energy of attraction the index Y_{n} decreases, to reach unity at some $\Phi(r)$ (the θ point). Equations (1) and (2) are inapplicable in worse solvents than the θ solvent. The interesting result was also obtained that the θ conditions do not correspond to a single point but occupy a region in which most of the conformational parameters, e.g. $\langle h_{\mathrm{N}}^2\rangle$ and $\langle R_{\mathrm{N}}^2\rangle$, assume their own θ values. Computer methods yielded

$$\alpha_N^2 = \langle h_N^2\rangle/N; \tag{4}$$

$$\alpha_{j,N}^2 = \langle h_{j,N}^2\rangle/j, \tag{5}$$

where α_{N}^2 and $\alpha_{\mathrm{j,N}}^2$ are the increases in the distances respectively between the terminal segments and between segments separated by j other segments in a macromolecule comprising N segments. The method of dimerisation was used[39] to construct chains containing up to 4096 segments. Values of $\alpha_{\mathrm{j,N}}^2$ were calculated for $j = 16, 32, \ldots, \frac{1}{2}N$. The results showed that

$$\alpha_N^2 \propto N^{1/5}, \tag{6}$$

as suggested by Flory[30], and that the relation

$$\alpha_N^3 - 1 \propto N^{1/2}, \tag{7}$$

which follows from Fixman's theory[40], is incorrect.

Knowledge of the coordinates of each segment for the whole time of a computer experiment permits not only calculation of the quantities of Eqns. (4) and (5) but also determination of the number of various types of contacts

$$E = E_{ll} + E_{lm} + E_{mm} \tag{8}$$

between segments of the same and different macromolecules in solution, where E_{mm}, E_{lm}, and E_{ll} are the numbers of intramolecular contacts between respectively internal, terminal and internal, and terminal segments. An analogous expression can be written for the number of intermolecular contacts k between macromolecules. Fig. 1 illustrates the dependence of the number of the various types of contacts on the degree of polymerisation P found in a computer experiment. For a model of a macromolecule based on a simple cubic lattice the variation in the total number of intramolecular contacts was given[41] as

$$E = 0.292 \cdot P - 1.15. \tag{9}$$

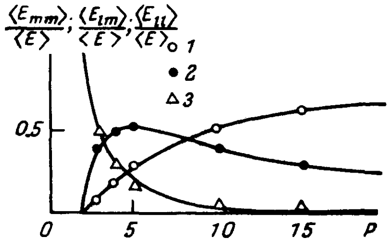

Figure 1. Dependence of number of polymer–polymer contacts on the degree of polymerisation P for a model based on a simple cubic lattice: 1) $\langle E_{mm}\rangle / \langle E\rangle$; 2) $\langle E_{lm}\rangle / \langle E\rangle$; 3) $\langle E_{ll}\rangle / \langle E\rangle$.

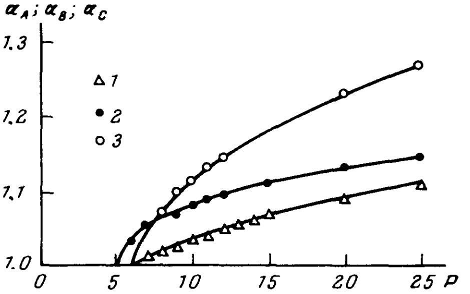

Figure 2. Dependence of coefficients of expansion on degree of polymerisation for a model based on the graphite lattice: 1) α_A (poor solvent); 2) α_B (good solvent for terminal groups); 3) α_C (good solvent for internal groups).

(*a*) Effects of Terminal Groups and of Coil Permeability on Hydrodynamic Properties

Fig. 2 illustrates the dependence of the coefficient of expansion of the macromolecule on the degree of polymerisation and the quality of the solvent, obtained by the Monte Carlo method. This experiment clearly reveals the effect of terminal groups and their relationship to the solvent. The coefficient of expansion always increases with the degree of polymerisation, but most rapidly in a good solvent for terminal and internal segments.

The Mark–Kuhn–Houwink equation[42,43]

$$[\eta] = KM^a$$

expresses the relation between the intrinsic viscosity $[\eta]$, from which the hydrodynamic volume of the coiled macromolecule in dilute solution is estimated, and its molecular weight M, where K and a are constants for a given homologous series. The parameter a, representing the form and the density of the coil, depends on the nature of the solvent and on the hydrodynamic interaction within the space of the coil, and varies mainly from 0.5 to 1. Experimental study of this dependence for several oligomers has established that, for a series of polymer–solvent systems, a decreases as the molecular weight diminishes: i.e. the dependence of $\lg[\eta]$ on $\lg M$ is non-linear (Fig. 3).

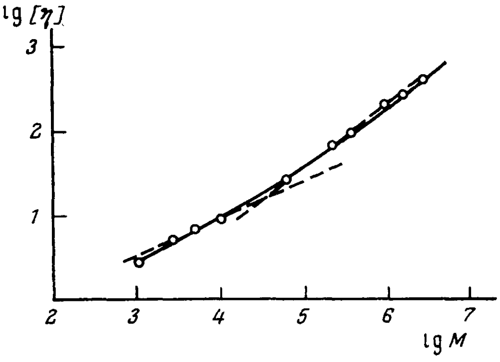

Figure 3. Dependence of $\lg[\eta]$ on $\lg M$ for poly(methyl methacrylate) in benzene at 30°C.

Thus it was shown, for the binary systems formed by benzene with poly(methyl methacrylate)[44] and by water with polyethylene glycol[45], that a is independent of the nature of the solvent for small molecular weights, and is close to 0.5 (which is characteristic of a θ solvent). A possible explanation is that the swelling coefficient α_0 approaches unity in the absence of θ conditions: i.e. long-range interactions are absent. This contradicts all existing theories of solutions, which predict that $\alpha_0 = 1$ only at the θ point with either the second virial coefficient A_2 or the molecular weight approaching zero. The results indicate also that, with decrease in chain length in macromolecules of these oligomers, a small hydrodynamic permeability appears, which is typical of macromolecules under θ conditions. This effect can be attributed to the possibility of interaction between end-groups of small macromolecules, which will change the form of the coil, by decreasing its dimensions (making it more compact), which explains the diminished viscosity.

Several other studies[16,46–49], on oligourethanes, rubbers of low molecular weight, polyethers, polyethylene glycols, etc., showed that a varies from 0.5 to 1 depending on the nature of the solvent, as with high polymers. But several other investigations[50–52] revealed a tendency for a to increase—not to decrease—as the molecular weight fell. Hydrodynamic theories of polymer solutions suggest that, for permeable Gaussian chains[53], such behaviour is probably due to an increase in the permeability of the coils with decreased molecular weight of the polymer. As a consequence, the slope of the plot of $\lg[\eta]$ against $\lg M$ should increase with fall in molecular weight. The Debye–Bueche[54], Kirkwood–Riseman[55,56], and Zimm–Kuhn[57-60] theories predict, with increase in permeability (weakening of hydrodynamic interaction) and short chains, direct proportionality between viscosity and molecular weight ($[\eta] = KM^a$, where $a = 1$), and decrease in the shielding coefficient σ.

Long-range effects (non-ideality of solutions), like short-range effects (chain rigidity), influence the conformations of flexible chains[61,62]. High values of the exponent a obtained in a θ solvent (in the absence of the excluded-volume effect) indicate a loose structure and permeability of the coil, and hence enhanced rigidity of the chain. Nevertheless, volume effects in non-ideal solvents lead to swelling of the coil and to a corresponding increase in a. In order to determine the true flexibility of a macromolecular chain, therefore, the influence of volume effects should be excluded.

Calculation then becomes useful, since the excluded-volume effect can either be disregarded or estimated. Thus at high degrees of polymerisation 32% of terminal groups occur within a sphere described by the radius of inertia of the macromolecule[27]. Nevertheless, taking into account excluded-volume effects lowers the number of end-groups in this sphere to 18%.[23] Thus the excluded-volume effect leads to the removal of terminal groups from the sphere of tne macromolecule.

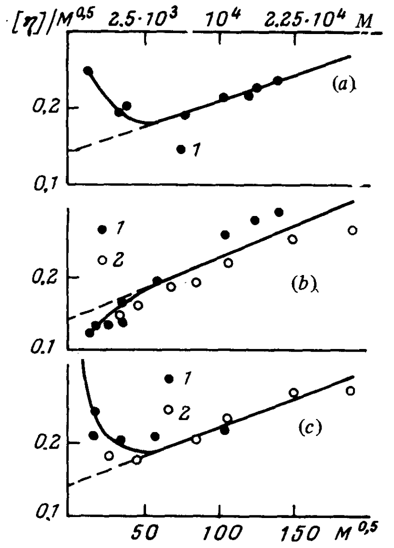

Figure 4. Dependence of $[\eta]/M^{0.5}$ on $M^{0.5}$ for polyethylene glycol in: *a*) methanol; *b*) benzene; *c*) water at: 1) 20°C; 2) 30°C.

The theories of Kuhn[58,59], Hearst[63], etc. are applied to rigid chains. With relatively flexible macromolecular chains, which are coiled quite compactly even in good solvents, the flow effect is almost absent, and the Stockmayer–Fixman equation is used[40]. With such molecules volume effects can be eliminated by extrapolating the hydrodynamic parameters to low molecular weights by means of the theory of the excluded volume[48,62]. Stockmayer and Fixman suggested the formula

$$[\eta]=KM^{0.5}+FM,$$

for the molecular-weight dependence of intrinsic viscosity, in which F and K, both independent of molecular weight, represent respectively short-range and long-range interactions. The constants are found by plotting the dependence of $[\eta]/M^{0.5}$ on $M^{0.5}$ by means of the Stockmayer–Fixman graph, and thus these interactions are determined for wider molecular-weight limits than is possible from the Mark–Kuhn–Houwink equation.

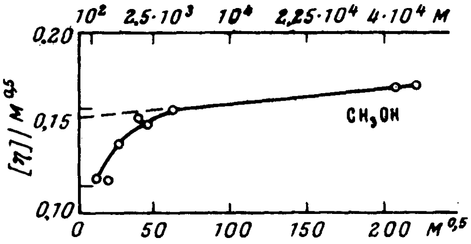

Figure 5. Dependence of $[\eta]/M^{0.5}$ on $M^{0.5}$ for the monophenyl ether of polyethylene glycol in methanol at 25°C.

Experimental viscosity results obtained for solutions of polyethylene glycol in methanol, benzene, and water and for its monophenyl ether in methanol[46,64], together with other results[47,48], have revealed more clearly the applicability of the Stockmayer–Fixman equation. Positive and negative departures from the equation are usually observed at a molecular weight of 3000, independent of the nature of the solvent and the end-groups (Figs. 4 and 5). This is apparently due to the effects both of the polymer chain and of the terminal groups. The value of K is independent of the solvent, which indicates that short-range interaction is independent of solvent and end-groups. Positive departures from the equation in methanolic and aqueous solutions of polyethylene glycol are caused by increase in size of the oligomer macromolecules resulting from interaction between terminal hydroxyls and the solvent. Negative deviations, which are observed both in benzene solutions of polyethylene glycol and in methanolic solutions of its monophenyl ether, are apparently caused by coiling of the macromolecule under the influence of repulsive forces between end-groups and solvent molecules. This range of molecular weights is regarded as the region of oligomers, possessing the properties of compounds of low molecular weight.

The general Stockmayer–Fixman equation shows that the intrinsic viscosity of oligomers is proportional to the square root of their molecular weight, which is confirmed by several investigations. Nevertheless, this principle does not hold for certain oligomers: here there is an approximately linear variation with the molecular weight[65]. The Huggins constant K' in the equation

$$\eta_{sp}/c = [\eta] + K'[\eta]^2c$$

is a measure of the affinity between polymer and solvent. On the basis of data for high polymers K' is now regarded as independent of molecular weight[66]. In θ solvents it is usually approximately 0.5 (or greater), and in good solvents $K' = 0.2-0.3$.

However, experiments on oligomers indicate that in most cases the Huggins constant assumes anomalous values. Several studies showed that the constant increases with decrease in the molecular weight of the oligomers[67-69], and may even exceed those for high polymers[70,71]. In certain cases a considerable increase occurs (to several units) with decrease in the chain length[72]. This is governed by the structure of the macromolecules and the nature of the solvent. The variation of K' with molecular weight is usually less marked in poor than in good solvents. Another study showed[73] that the experimental values correspond to the Huggins equation only within a narrow range of molecular weights. The formula

$$K' = eM^{d_0} + b_0,$$

was proposed, in which d_0 and b_0 were independent of molecular weight.

A complicated dependence of K' on molecular weight has been found in several studies[72]. Values of K' are largest at very low molecular weights. Increase in M to 2000–3000 is accompanied by a rapid fall in K', and further increase by a smooth decrease, which then slows down (Fig. 6). The increase in K' with decrease in molecular weight is attributed by some authors to an increase in the density of the coiled macromolecule. Molecules of greater chain length are regarded as more prolate and less spherical than those with short chains. This is apparently because short molecules are densely packed, weakly solvated coils, relatively impermeable to the solvent. This is consistent with diffusion results.

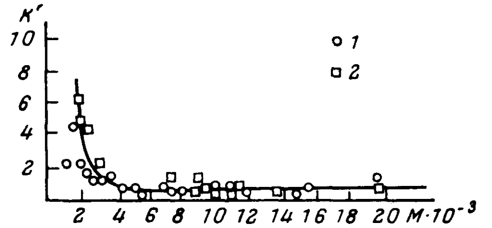

Figure 6. Dependence of the Huggins constant K' on the molecular weight of poly(methyl acrylate) in: 1) acetone; 2) θ solvent.

Dimensions of macromolecular coils approaching the unperturbed values were determined[72-76] from the measured diffusion coefficients of polystyrene in solutions, which enables the Flory coefficient[30] to be calculated. The chain rigidity thus found for the oligomer macromolecule approached that of high polymers, which was attributed to an increased effect of thickness on the chain dimensions[77]. Other workers[78,79] also obtained for certain oligomers (polyoxypropylene and polyoxyethylene glycols) values of q in the equation $D = K_\alpha M^{-q}$ closely similar to the corresponding values for long chains. This indicates that the hydrodynamic characteristics of oligomer molecules in solution can be described quite accurately by hydrodynamic theories based on the model of an impermeable Gaussian coil exhibiting slight thermodynamic interaction with the solvent.

(*b*) Conformational Transitions in Macromolecules of Oligomers

The second virial coefficient A_2 represents the interaction between polymer and solvent:

$$\pi/c = RT\,(1/M + A_2c + \ldots),$$

where R is the universal gas constant, T the absolute temperature, c the concentration, M the molecular weight, and π the osmotic pressure. According to Flory's theory[80,81] A_2 is independent of the molecular weight of the polymer. In practice, however, agreement with theory is found only at the θ point or with slight departures from ideality. The greater the deviation from θ conditions, the more marked is the dependence of the second virial coefficient on the molecular weight.

An equation for this dependence based on many experimental results was[82]

$$A_2 = a_1/M^{0,5} + b_1,$$

where a_1 and b_1 were theoretical constants independent of the molecular weight. Research showed that the equation was valid for exothermic and endothermic systems, as well as for θ conditions over a wide range of molecular weights. In the study of solutions of polystyrene in benzene, toluene, and naphthalene (exothermic systems), for example, a linear dependence was observed for molecular weights from 500 to 5×10^6 (Fig. 7).[14] The corresponding range for an endothermic system (poly(methyl methacrylate) in acetone) was from 200 to 7.8×10^6.[83]

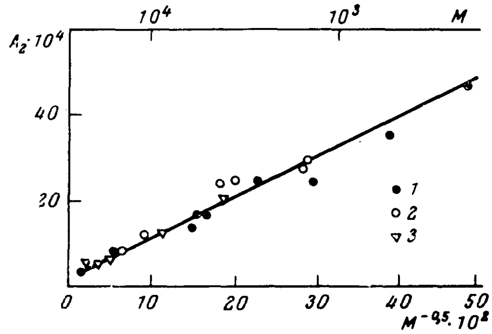

Figure 7. Dependence of second virial coefficient A_2 on molecular weight M for the exothermic systems comprising polystyrene in: 1) naphthalene; 2) benzene; 3) toluene.

Nevertheless, polystyrene[84] and poly(methyl methacrylate)[85] in good solvents showed departures from the suggested equation at low degrees of polymerisation (Fig. 8). In particular, the second virial coefficient was found[84] to be negative for dimers, to reach a positive maximum when $P = 4$, and then gradually to decrease with increase in molecular weight (Fig. 9). These results indicate that the equation holds up to the maximum, where the substance possesses polymeric properties. The presence of a maximum indicates a transition in the form of the macromolecule from coiled to rod-shaped, which can apparently be interpreted as a transition to compounds possessing the properties of polymers.

The above considerations are consistent with the dependence of the entropy contribution B_S on the degree of polymerisation P in the polystyrene–benzene system (Fig. 10).[14] The entropy is approximately zero for the dimer, reaches a maximum when $P = 4$, and then gradually diminishes with increase in molecular weight. It is known to have its maximum value when the molecule is elongated into a rod, and its minimum value when the molecule is coiled into a sphere. Maximum entropy was therefore interpreted as the transition point between extended and coiled states of the molecules.

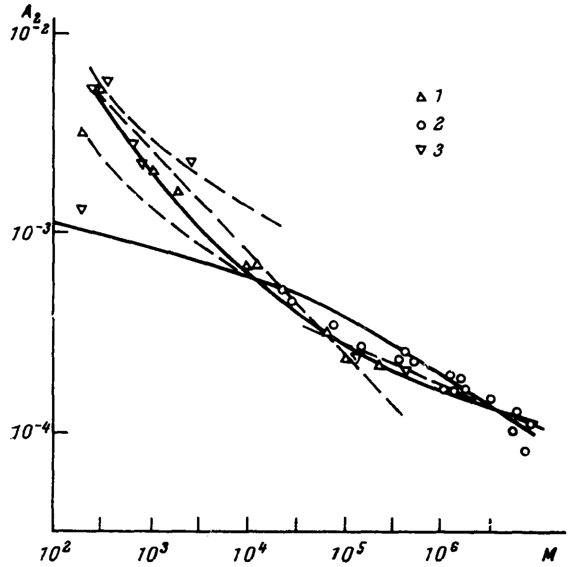

Figure 8. Dependence of second virial coefficient A_2 on molecular weight M for the endothermic system comprising poly(methyl methacrylate) in acetone, obtained by: 1) osmometry; 2) light scattering; 3) X-ray examination.

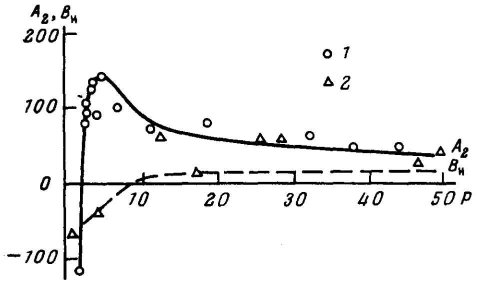

Figure 9. Dependence of second virial coefficient A_2 and of enthalpy coefficient B_H on degree of polymerisation of oligostyrene in: 1) naphthalene; 2) benzene.

Application of a calorimetric method[86] to polystyrene in benzene and cyclohexane, poly(methyl methacrylate) in acetone, and polyvinylcarbazole in benzene showed[84] that, at the initial degrees of polymerisation, the enthalpies of mixing almost always pass through maxima (as do the second virial coefficient and the entropy). Further increase in molecular weight produces hardly any change in the enthalpy (Fig. 11). This effect was explained in terms of the interaction energy of end-groups in the oligomer macromolecules.

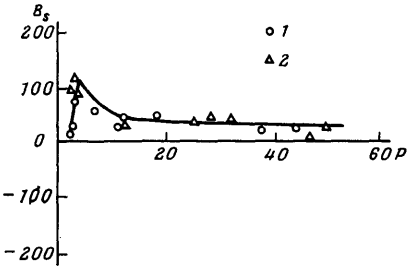

Figure 10. Dependence of entropy coefficient B_S on degree of polymerisation P for oligostyrene in: 1) naphthalene; 2) benzene.

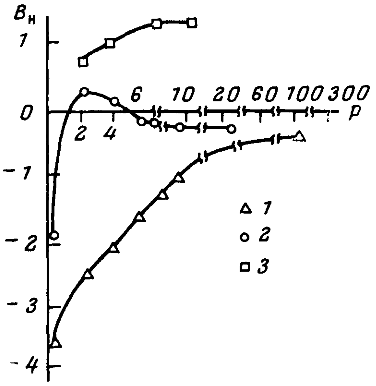

Figure 11. Dependence of enthalpy coefficient B_H on degree of polymerisation for: 1) poly(methyl methacrylate) in acetone; 2) polyvinylcarbazole in benzene; 3) a polycarbonate in dioxan.

(c) Structure Formation in Solution with Increase in Concentration of Low Polymers

With increase in the concentration of dilute solutions of polymers the macromolecules interact and form association complexes or aggregates. Staudinger[87] first formulated the concept of the lowest concentration—the critical concentration c_{cr}—at which the polymer molecules begin to come into mutual contact. Many studies have shown that this concentration depends on the molecular weight of the polymer and its chemical structure, the nature of the solvent, and the temperature. The critical concentration usually increases with decrease in molecular weight, deterioration in the quality of the solvent, and rise in temperature, which is a consequence of the weakening of interaction between the macromolecules under these conditions. It can be determined from the break in the linear concentration dependence of viscosity, intensity of light scattering, optical density, and other properties of the polymer. However, some studies[77,88] of the concentration c dependence of the reduced viscosity η_{sp}/c revealed a breakdown of the linear dependence at subcritical concentrations. These anomalies were attributed to supercoiling of the macromolecules at high dilutions[77,88], and by other workers to decrease in the effective radius of the capillary resulting from adsorption of the polymer on its walls[89,90].

Association begins sooner in oligomers than in high polymers. Incipient structure formation was observed, in solutions of butadiene–acrylonitrile rubbers having molecular weights of $(1.4-2.7) \times 10^4$, at concentrations of 0.1–0.5 g/100 ml.[31] Critical concentrations in benzene solutions of polystyrene of molecular weight $(1.5-33) \times 10^3$ varied from 0.5 to 1.5 g/100 ml.[90]

In several studies[15,91] anomalies were absent up to fairly high concentrations of low polymers in solution. This applied to poly(methyl methacrylate) and poly(ethyl acrylate) of molecular weight $(1-20) \times 10^3$ up to 0.2 g/100 ml.[15] Investigation of dilute solutions ($c < 0.1$ g/100 ml) of SKN-18 [butadiene–acrylonitrile synthetic rubber] at 20–60°C showed that the intensity of light scattering by the solutions remained unchanged with rise in temperature, which indicated that association had not occurred[31]. In solutions containing macromolecules of high polymers at corresponding concentrations, however, the apparent molecular weight decreased at 60°C; this was attributed to the breakdown of association complexes[92].

IV. RHEOLOGICAL PROPERTIES

Considerably less study has been made of the structure of low polymers and their concentrated solutions than of dilute solutions. Only comparatively recently have publications appeared on the rheological properties of certain polyethers and polyisobutylenes of low molecular weight and on those of their solutions. The structural features of polymers and their solutions (great size of macromolecules, formation of network structures, etc.) are responsible for several flow anomalies, e.g. departure from Newton's viscosity law[29]. This is apparent in the rubberlike elasticity possessed by solutions of several polymers.

Unlike high polymers, oligomers possess almost the same capacity for rubberlike elastic deformations, which are in the nature of relaxation processes involving change in the conformations of the macromolecules under the influence of shear stresses. This feature is attributed to great flexibility of the macromolecules and the presence of a mobile, fluctuating network with temporary contacts produced by intermolecular interaction. The systems are mainly thixotropic in character, with relatively unstable bonds and long relaxation times. They can be regarded as a new type of cross-linked systems, occupying a position intermediate between concentrated solutions, polymer jellies, and solutions of substances of low molecular weight capable of cross-linking[6,93,94].

Many methods have now established that several concentration ranges exist in solutions of polymers, differing in degree of order of the chains, conformational properties of the macromolecules, and their interaction. This is responsible for differences in rheological properties[95,96]. The concentration ranges can be arbitrarily divided as indicated below.

1. Very dilute solutions, in which macromolecules are present as isolated coiled coils. With increase in concentration the chain molecules straighten out, interact, and form structures.
2. More concentrated solutions, in which, as a consequence of intermolecular contacts, the macromolecules in the form of prolate coils form the ideal three-dimensional network described by Büche[97] or are arranged in isolated association complexes or aggregates. A structural network appears at higher concentrations of oligomers than of high polymers.
3. Concentrated solutions, in which the ideal network may be consolidated by the formation of new bonds with other macromolecules ($c > c_{cr}$). The macromolecules then have small free volumes and are characterised by considerable mutual penetration of segments.
4. Highly concentrated solutions, in which ordered structures are formed, different for polymers in different physical states and of different chain lengths[98]. The mutual interlacing of segments of the macromolecules produces a continuous network of bonds, with a consequent considerable increase in viscosity[97].

All the above ranges for transformation in polymer solutions are reversible with change in concentration. Examination of the viscoelastic properties of such solutions over all concentration ranges will give an idea of the nature and the rates of redistribution of conformations of chain molecules, as well as of their mutual arrangement, i.e. of the structure of the solutions[99,100].

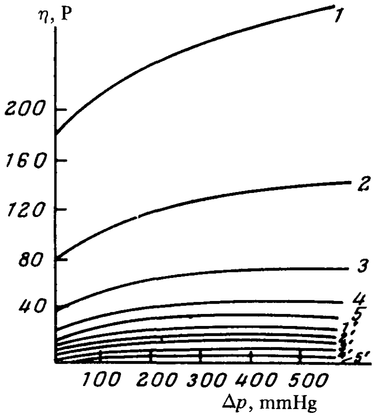

Figure 12. Flow curves for polyesters—poly(ethylene glycol adipates)—of molecular weight 2050 and 790 (unprimed and primed curves respectively) at (°C): 1) 20; 2) 30; 3) 40; 4) 50; 5) 60.

Study of the flow of certain oligomers and their concentrated solutions has shown a difference in rheological behaviour between these compounds and high polymers. For example, investigation of polyethers—polyoxolanyloxypropylene glycols—and polyesters—poly(diethylene glycol adipates)—and their concentrated solutions has shown[101] that the viscosity of the system in a longitudinal velocity gradient (in a capillary viscometer) increases with the shear stress, in some cases reaching a maximum. These antithixotropic effects degenerate with rise in temperature and with dilution. They were attributed to intensified interaction of the macromolecular chains of the oligomers on orientation in the flow. The viscosity is then affected by the molecular weight. With several oligomers such antithixotropic effects develop only at low stresses. When the shear stress arises above a critical value, thixotropic breakdown of the previously formed structure occurs, and the usual process of flow is observed, as with high polymers[102]. Other studies[103-105], using both capillary and rotary viscometers, revealed in the oligomers investigated and their concentrated solutions, together with thixotropic breakdown, a region of antithixotropy at low shear stresses. This phenomenon is also connected with intensified interaction of oriented macromolecules under the influence of transverse and longitudinal velocity gradients. Anomalous viscosity effects are more marked with oligomers of lower molecular weight, which can be explained by the enhanced rigidity of shorter chains and their greater mobility (Fig.12).

Büche[106] used the concept of free volume to develop theoretically the resistance to the flow of polymers, which arises from interaction between segments, mutual friction of segments during movement of the polymer chain, and the formation of a network structure by the meshing of segments and macromolecular chains. Relative movement of macromolecules is facilitated with decrease in the molecular weight of the polymer or dilution of its solution, and flow becomes more intense. This is apparent in a decrease in viscosity and in the heat of activation of viscous flow[107,108], which, after certain fairly high degrees of polymerisation have been reached, remains constant and independent of molecular weight[103]. The smaller the macromolecules the higher the concentrations at which intermolecular interaction and departure from Newtonian flow become apparent.

Enzyme Electrodes

I.V.Berezin and A.A.Klësov

The literature data on the use of immobilised enzymes in analytical chemistry are reviewed and the fundamental conditions for the creation of kinetic methods in enzymatic analysis are described. The types of enzyme electrodes and the factors influencing the response of such electrodes, their stability, and sensitivity are discussed in detail. The possible pathways towards further development of enzyme electrodes for use in laboratory and technological practice and for monitoring the environment are considered.

The bibliography includes 69 references.

CONTENTS

I. INTRODUCTION

The last decade has been marked by a vigorous development of research in the field of the immobilisation of enzymes and their use for technological, analytical, and scientific purposes. The conversion of enzymes into a water-insoluble state with retention of catalytic activity made it possible to extend greatly our ideas concerning the possibility of using bio-organic catalysts in a wide variety of different fields of chemistry, fine chemical engineering, pharmacology, and medicine. Because of their high specificity, enzymes have already been used for many years in analytical chemistry; hundreds of studies devoted to kinetic methods in enzymatic analysis are published annually. The use of immobilised enzymes for these purposes stimulated the creation of methods of "reagent-free" analysis whereby continuous analysis of aqueous solutions of organic (and in many instances inorganic) compounds is possible in principle.

In their turn, the achievements in this field have promoted the development of effective methods for monitoring the state of the environment, clinical diagnosis, etc. Finally, the so called "enzyme electrodes", developed in recent years, permit rapid automatic analysis of multicomponent systems on the basis of combined "electrode-enzyme" electrochemical systems which exhibit a high selectivity in the determination of individual compounds or classes of compounds.

The attention devoted at the present time to the development of enzyme electrodes and to the study of the prospects for their application in analytical chemistry is partly due to the vigorous development of methods for the isolation, purification, and identification of enzymes. According to data presented at the Symposium on Biotechnology and Bioengineering in Henicker[1], the number of enzymes which have been discovered and characterised has increased from 80 in 1928 to 1500 in 1969, and continues to grow exponentially with a ten-year doubling period.

The present review is an attempt to summarise and give a systematic account of studies on the use of immobilised enzymes in analytical chemistry published up to April 1974, and to assess the immediate prospects in this field.

II. THE SPECIFICITY OF ENZYME ACTION

The most characteristic feature of enzymatic catalysis is the specificity of enzyme action. At least three general qualitative types of specificity have now come to be differentiated from this extremely comprehensive term: specificity with respect to the medium, specificity with respect to the reaction, and substrate specificity (specificity with respect to the structure of the substrate). The first two types of specificity are usually expressed in the fact that the enzyme catalyses a reaction of a particular type under specified conditions and constitutes the basis for the subdivision of enzymes into the corresponding classes (oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases or synthetases)[2]. The substrate specificity of the enzyme is its most characteristic feature, which has not yet found adequate analogies in non-enzymatic catalysis, and makes it possible to characterise unambiguously and to identify the given enzyme among hundreds and thousands of others. The usual phenomenon in enzymatic reactions is that the enzyme catalyses the reaction of only one stereochemical form of the substrate, being completely inactive in relation to other stereoisomers (the so called stereochemical specificity of the enzyme).

In many instances the enzyme exhibits absolute specificity, catalysing the reaction of only one substance and not reacting with its derivatives or homologues. Thus, butanediol dehydrogenase catalyses the conversion of butane-2,3-diol into acetoin, but altogether fails to oxidise ethylene glycol, glycerol, ethanol, isopropyl alcohol, isobutyl alcohol, isopentyl alcohol, or glucose[3]. Lactaldehyde reductase, which catalyses the reversible conversion of D-lactaldehyde into propane-1,2-diol, is completely inactive in relation to L-lactaldehyde, acetaldehyde, propionaldehyde, glycolaldehyde, acetol, glyoxylic acid, pyruvic acid, D-galactose, D-mannose, D-fructose, D-or L-arabinose, and L-rhamnose[4]. Mannitol dehydrogenase, which catalyses the conversion of D-fructose into mannitol, does not act on D-glucose, D-mannose, or D-ribose[5]. The activity of glucose oxidase, which oxidises β-D-glucose with formation of gluconic acid, is four times lower with respect to 2-deoxy-D-glucose, 50 times lower with respect to 6-methyl-D-glucose, 100 times lower with respect to D-mannose and D-xylose, and 200 lower with respect to α-D-glucose; the enzyme altogether failed to have any action on the remaining 80 sugars which had been tested as substrates[6]. Formaldehyde dehydrogenase, which oxidises formaldehyde to formic acid, does not react with acetaldehyde, glycolaldehyde, and benzaldehyde[7]. Benzaldehyde dehydrogenase, which converts benzaldehyde into benzoic acid, altogether fails to oxidise acetaldehyde, propionaldehyde, crotonaldehyde, formaldehyde, and DL-glyceraldehyde[8]. Among all the aliphatic aldehydes, aminobutyraldehyde dehydrogenase acts only on 4-aminobutyraldehyde, oxidising it to 4-aminobutyric acid[9].

On the other hand, many enzymes exhibit broad specificity without the imposition of stringent requirements on the structure of the substrate. Thus a large number of compounds having the general formula $R_1CH(R_2)COR_3$, where the substituents R_1, R_2, and R_3 can have virtually infinitely variable structures, can serve as substrates for α-chymotrypsin[10]. The extremely broad specificity of α-chymotrypsin may be illustrated by the fact that this enzyme is capable of catalysing the hydrolysis of proteins, peptides, esters, amides, hydrazides, alkylamides, acid anhydrides, acid chlorides, hydroxamides, anilides, thioesters, oxazolones, cyclic peptides, cyclic phosphates, lactones, and sultones; in some cases it is also capable of cleaving the C–C bond. Aldehyde oxidase exhibits group specificity with respect to aliphatic aldehydes, catalysing the oxidation of formaldehyde (1.0), acetaldehyde (4.6), propionaldehyde (5.1), butyraldehyde (12.2), valeraldehyde (2.4), and crotonaldehyde (7.6); the relative reactivities of the aldehydes in this enzymatic reaction are indicated in brackets[11].

The high enzyme specificity (absolute or group specificity) in combination with favourable factors such as the high rate of enzymatic processes, the mild reaction conditions (room temperature, atmospheric pressure, neutral pH of the medium, etc.), and a fairly wide selection of available enzymes have ensured the development of a new trend in analytical chemistry—kinetic methods in enzymatic analysis. Enzyme-catalysed reactions are used to determine substrates, inhibitors, activators, and in many instances the enzymes themselves (this applies primarily to the analysis of biological liquids in clinical laboratories). The use of enzymes in analytical chemistry has been considered in a number of reviews and monographs[12-19]. However, despite a number of the evident advantages of kinetic methods in enzymatic analysis, their use in laboratory practice has so far been fairly limited. One of the main reasons for this is still the high cost of the majority of enzymes, which virtually precludes the large-scale application of enzymatic analytical methods (because enzymes can be used only once owing to the extremely laborious procedures needed for their regeneration from the mixture). This disadvantage is compounded also by the low stability of the majority of enzymes, which frequently leads to their complete inactivation in several days, and sometimes in several hours under the optimal conditions for analytical purposes.

Thus, in order to increase the "technological applicability" of enzymes, it is necessary to increase their stability, on the one hand, and to ensure the possibility of their repeated use on the other. In principle this is achieved by converting enzymes into heterogeneous catalysts by immobilising them.

III. THE IMMOBILISATION OF ENZYMES

The immobilisation of enzymes is a procedure whereby they are converted into a water-insoluble state with retention (partial or complete) of catalytic activity. Immobilised enzymes are usually obtained by the following methods (see the relevant reviews[20-24]):

1. The covalent attachment of enzyme molecules to a water-insoluble carrier (cellulose, agar, dextran, glass, paper, fabrics, polystyrene, nylon, metals, ion-exchange resins, etc).
2. The entrainment of the enzyme in a gel or polymer network.
3. The covalent cross-linking of enzyme molecules with one another using a di- or poly-functional reagent.
4. The adsorption of the enzyme on water-insoluble carriers (as a rule ion-exchange resins).
5. Microencapsulation (the enclosure of an enzyme solution in semipermeable capsules 5–300 μm in size).

The first two immobilisation methods are most often used. The covalent binding of the enzyme to a carrier leads to a stable system in which the protein cannot be desorbed when the temperature, pH, or the ionic strength of the reaction medium are changed, and also when the substrate is added to the reaction medium. The method based on the entrainment of the enzyme in a gel is distinguished by simplicity and the absence of appreciable influences on the active centre of the enzyme. In any case the immobilisation of enzymes makes possible their repeated use in practice when catalytic processes are carried out in periodic or continuous operation "enzyme reactors". Furthermore, the immobilisation of enzymes frequently increases their stability. According to the data quoted in Melrose's review[21], in thirty out of fifty different variants of immobilisation the stability of the immobilised enzyme was higher than that of the corresponding soluble enzymes, in eight cases the stability decreased on immobilisation, and in twelve cases the stability hardly changed following immobilisation.

Bearing in mind that the stability of immobilised enzymes is influenced to a high extent by the nature of the carrier, the nature of the grafting agent, and the method and conditions of the immobilisation (in all instances there is a possibility of a large number of different variants), it is clear that the possibilities of stabilising enzymes on immobilisation have been by no means exhausted. As an example, one may quote the data of Kaplan and coworkers[25] according to which lactate dehydrogenase, which loses 100% of its activity after incubation for approximately 1 h, retains its activity fully under the same conditions for at least 35 days following immobilisation on porous glass with the aid of glutaraldehyde.

IV. THE APPLICATIONS OF IMMOBILISED ENZYMES IN ANALYTICAL CHEMISTRY

The use of immobilised enzymes, whereby routine chemical analyses can be carried out on individual samples or in a stream (with repeated employment of the same enzyme preparation), has to a large extent solved the problem of the high cost of enzymatic analytical methods and has frequently increased the accuracy of the analytical procedure. There exist two general approaches to the analytical determination of the concentrations of reagents (substrates) in the test system. In one of them the enzymatic reaction is continued until the complete exhaustion of the substance to be determined (or until the attainment of an equilibrium in the system between the initial reactants and products), while recording at the same time the change in a suitable physical or chemical property of the system, the amount of substrate in the initial specimen being calculated from the amount of product formed. In the second approach use is made of kinetic analytical methods, the rate of appearance of the product or of the disappearance of the substrate in the enzymatic reaction being determined and the initial substrate concentration being calculated from the corresponding calibration curve. This method is also applicable to the determination of the concentrations of effectors (inhibitors or activators), which are present in the reaction system. Both approaches have been applied in practice using immobilised enzymes.

The first study in which the use of immobilised enzymes for analytical purposes was described was carried out in 1965 by Guilbault and coworkers [26], who found that cholinesterase entrained in a starch gel and deposited on a foam plastic plate (to increase the mechanical strength of the immobilised enzyme) retained its activity for 12 h. The activity of the enzyme in the hydrolysis of butyrylthiocholine iodide was determined electrochemically using platinum electrodes between which a direct current was passed. Depending on the rate of the enzymatic reaction, the potential of the system changed from 150 mV (the oxidation potential of the reaction product–thiocholine) to 350–400 mV (the potential of the oxidation of the iodide of the substrate to iodine), which made it possible to investigate the influence of the added effectors on cholinesterase under continuous conditions. In the same year Guilbault and Kramer [27] used similarly immobilised cholinesterase to detect small amounts of organophosphorus insecticides in air. Foam plastic plates impregnated with starch gel containing immobilised cholinesterase have been used recently to devise a continuous analyser for water designed to detect rapidly subtoxic concentrations of anticholinesterase compounds [28].

A common disadvantage of all these devices is their instability due to the appreciable elution of the enzyme from the starch gel. Coprecipitation of cholinesterase with aluminium hydroxide and suspension of the resulting preparation in a starch gel with subsequent impregnation of a foam plastic plate enabled Goodson et al. [29] to obtain a stable enzyme system capable of functioning for 56 h without appreciable loss of enzyme. During this period, 2700 litres of water were passed through the carrier with the immobilised cholinesterase. According to the results of Goodson et al. [29], the immobilised enzyme gives a response after 3 min when water contains 0.2 part per million of 2,2-dichlorovinyl dimethyl phosphate. Gutknecht and Guilbault [30] also reported the development of an enzyme system for the continuous monitoring of cyanide ions in drainage waters, which is based on the specific reaction of immobilised injectase (β-cyanoalanine synthase).

Hicks and Updike [31] determined glucose and lactic acid by means of a column with glucose oxidase and lactase dehydrogenase immobilised on a polyacrylamide gel. The substrate specimens were passed through columns filled with gel-enzyme particles of standard size and subjected to lyophilic drying, mixed with indicators changing colour on interaction with the corresponding products of enzymatic reactions, and passed through the spectrophotometer cuvette. The authors [31] noted an appreciable increase of the stability of lactase dehydrogenase following immobilisation in the gel. Thus at 37°C the activity of soluble lactase dehydrogenase decreases to 10% of the initial value after 2 h, while that of the gel-enzyme remains completely unchanged for 10 h under the same conditions. Guilbault and Das [32] made a comparative study of starch and polyacrylamide gels as carriers for the immobilisation of cholinesterase and urease. Noting that immobilisation in the starch gel can be carried out under milder conditions, the authors [32] point out the higher stability of enzymes in the polyacrylamide gel.

Hornby et al. [33] developed a method for the automated analysis of solutions for glucose having immobilised glucose oxidase on the inner surface of a polystyrene tube (375 cm long, with an internal diameter of 2 mm). The activity of the enzyme was recorded at 35°C and pH 5.6 by the calorimetric determination of hydrogen peroxide (the product of the enzymatic reaction) using potassium iodide. The apparatus permitted 40 analyses per hour, glucose being determined quantitatively over the concentration range 5×10^{-4} M–10^{-2} M. According to the authors' data [33], the tube with immobilised glucose oxidase did not exhibit an appreciable loss of catalytic activity in the course of 1.5 months.

Subsequently Hornby and coworkers abandoned the polystyrene carrier because of its pronounced hydrophobic properties, and their later studies on the immobilisation of enzymes [34–36] were carried out using nylon. Thus urease, bound via glutaraldehyde to the inner surface of a partly hydrolysed nylon tube [34,35] (2 m long, with an internal diameter of 1 mm), was used to determine urea in the course of four months, more than 400 analyses being carried out during this period. Urate oxidase, immobilised on a nylon powder, was used to analyse aqueous solutions of uric acid [35] in the concentration range 10^{-5}–10^{-4} M. However, carboxy-groups, ionised under experimental conditions, remain on the carrier surface after partial hydrolysis of the nylon, which makes the carrier unsuitable for the immobilisation of many enzymes.

In order to extend the scope of the proposed method, Hornby et al. [36] converted the carboxy-group of the carrier into an amide form by treatment with *NN*-dimethyl-1,3-propylenediamine and used the modified carrier to immobilise lactate dehydrogenase, malate dehydrogenase, and alcohol dehydrogenase, which permitted the analysis of aqueous solutions for pyruvic acid, oxaloacetic acid, and ethanol respectively. According to their data [36], the method is suitable for the quantitative determination of 4×10^{-5}–2×10^{-4} M pyruvate, 2×10^{-5}–1.6×10^{-4} M oxaloacetate, and 0.01–0.1 M ethanol. All the immobilised enzymes fully retained their activity in the course of 20 days. During this period, each was used to perform at least 1000 analyses. Under these conditions, the soluble enzymes lost more than 90% of their activity.

In a recent study by Weibel et al. [37], a general method was developed, in relation to the analysis of solutions for their glucose content, for quantitative determination of compounds in the course of the enzymatic conversion of which oxygen dissolved in water is absorbed. In the determination of glucose, the solution analysed is passed with the aid of a micropump through a 5 × 35 mm column containing glucose oxidase bound covalently to porous glass and is passed through a cell containing a Clark oxygen electrode. The analysis can be carried out either under kinetic conditions or on the basis of the degree of reaction established following the completion of the enzymatic process. A single analysis takes 2 min and the error in the determination of glucose does not exceed 1–2%. According to the results[37], the column functions for more than 2 weeks when used daily in the course of 8 h.

Mosbach and coworkers[38] described the use of flow microcalorimetry in kinetic methods for enzymatic analysis using immobilised enzymes. The advantages of the method are the possibility of analysing opaque solutions and high sensitivity (down to 10^{-6} M of the substance to be determined).

An interesting and very promising approach to the selective determination of small amounts of metals was demonstrated recently by Stone and Townshend[39,40]. Fungal polyphenol oxidase was immobilised by being bound covalently to Enzacryl AA (obtained by reducing a copolymer of acrylamide, *p*-nitroacrylanilide, and *NN'*-methylenebisacrylamide) and was then dialysed until the complete removal of copper(II) ions forming part of the enzyme active centre. The resulting inactive apoenzyme is reactivated reproducibly and very selectively on being incubated with trace amounts of Cu^{2+} (10–200 ng), the observed rate of the enzymatic reaction being unambiguously related to the Cu^{2+} concentration in the solution being analysed (a linear relation between the rate of reaction and the concentration of copper ions in solution was observed in the concentration range 10^{-7}–2×10^{-6} M Cu^{2+}). The authors[39] noted that, in relatively large volumes of solutions being analysed, it is possible to determine 10^{-15} mg/ml of Cu^{2+} ions with the aid of this method. The stability of the immobilised polyphenol oxidase makes it possible to store it for 3 months in aqueous solution at pH 7.0 and 6°C.

In all the analytical applications of immobilised enzymes described above, the enzyme activity was determined by the reaction of the biocatalyst with the corresponding substrates or by the reaction of products of the enzymatic reaction with the corresponding indicators specially introduced into the test system. However, "reagent-free" enzymatic analytical methods, based on the use for this purpose of the so called "enzyme electrode" consisting of electrochemical devices on the sensor element of which an immobilised enzyme is deposited, have been developed to the greatest extent at the present time. Such an electrode possesses the fundamental properties required for the analytical system—specificity to the given reaction and the reagent being determined (provided that the latter is a specific substrate of the given enzyme)—and permits rapid analysis of the reaction mixture (generally speaking, the rate of analysis depends both on the characteristics of the electrochemical system itself and on the values of the kinetic parameters of the enzymatic reaction).

When the enzyme electrode comes into contact with the test solution, containing, in particular, the specific substrate of the given enzyme, the enzymatic reaction takes place in the layer near the electrode. If the product (or the substrate) of the reaction is electrochemically active, then the rate of the absolute change in electrode potential is a measure of the amount of the reagent being determined in the mixture subjected to analysis. The advantage of this analytical method is that it can be automated and continuous quantitative determination of the given reagents, including those in complex chemical or physiological systems, is possible.

The first enzyme electrode, constructed for a continuous determination of the concentration of glucose with the aid of immobilised glucose oxidase, was described by Updike and Hicks[41] in 1967. The same authors introduced the term "enzyme electrode"[41,42] for a system consisting of the polarographic oxygen electrode on the surface of which a layer of polyacrylamide gel 25–50 μm thick with entrained glucose oxidase has been deposited. When the electrode prepared in this way is immersed in a solution containing glucose, the substrate and oxygen diffuse from the solution into the layer of the gel-enzyme. The enzymatic oxidation of glucose

$$\beta\text{-D-glucose} + O_2 \rightarrow \text{D-glucono-}\delta\text{-lactone} + H_2O_2, \qquad (1)$$

which takes place in the immediate vicinity of the electrode surface, reduces the diffusional flux of oxygen through the plastic membrane of the Clark oxygen electrode, which in turn leads to an increase of the electrode current. Thus the change of the current in the electrode system depends on the rate of the enzymatic reaction and hence on the concentration of glucose in the mixture being analysed. By plotting the appropriate calibration curve, the authors[41–43] were able to determine glucose quantitatively also in biological solutions and tissues.

A similar principle served as a basis of the design of other enzyme electrodes (see the next Section), the characteristics of which are compiled in Table. Each electrode is specific either to one particular compound (urea, L-asparagine, L-glutamine, D-glucose, etc.) or exhibits group specificity (L- or D-aminoacids, primary alcohols, various penicillins). Naturally, the nature of the selectivity of the enzymatic reaction determines the region where the given enzyme electrode can be applied.

The use of coupled enzymatic reactions for analytical purposes leads to fundamentally new possibilities in the preparation of selective enzyme electrodes. This approach has so far been demonstrated only on a single example—the determination of L-phenylalanine with the aid of L-aminoacid oxidase and peroxidase, immobilised in a polyacrylamide gel on the surface of an electrode sensitive to iodide ions[44]. The operation of the electrode in the coupled enzyme system is based on the following reactions:

$$\text{L-aminoacid} + O_2 \xrightarrow{\text{L-aminoacid oxidase}} \text{2-oxo-acid} + NH_3 + H_2O_2; \qquad (2)$$

$$H_2O_2 + 2H^+ + 2I^- \xrightarrow{\text{peroxidase}} I_2 + 2H_2O. \qquad (3)$$

During the enzymatic reaction, the steady-state concentration of iodide ions at the electrode surface decreases, the rate of decrease of the I^- concentration depending on the amount of L-phenylalanine in the solution being analysed[44].

V. THE DESIGN OF ENZYME ELECTRODES

All enzyme electrodes consist of an electrochemical sensor of one type or another, on which a layer of immobilised enzyme is deposited. Apart from the polarographic oxygen electrode, which has been used for the analytical determination of glucose with the aid of immobilised glucose oxidase[41–43], this reaction has also been followed by an enzyme electrode based on a platinum disc coated with a thin layer of glucose oxidase bound chemically to a polyacrylamide gel[45,46]. The electrode is immersed in the solution to be analysed and a potential of 0.6 V is established in the system (with respect to the saturated calomel electrode). Glucose diffuses to the layer of the gel-enzyme on the electrode, where it reacts in accordance with Eqn. (1). The hydrogen peroxide formed is oxidised on the platinum electrode, so that the observed current is proportional to its concentration and hence to the initial concentration of glucose. Wingard et al.[47], who used a different design of the platinum electrode, determined by a similar method the concentration of glucose with the aid of immobilised glucose oxidase. Polarographic enzyme electrodes have also been used by Clark for the analytical determination of glucose[48] and L-aminoacids[49] with the aid of immobilised glucose oxidase and L-aminoacid oxidase. Recently Clark[1] developed a method for the determination of methanol and ethanol in aqueous solutions and vapours with the aid of a polarographic enzyme electrode containing immobilised alcohol dehydrogenase. The sensitivity of the enzyme electrode is such that it gives an appreciable response to human breath 16 h after the consumption of alcoholic drinks.

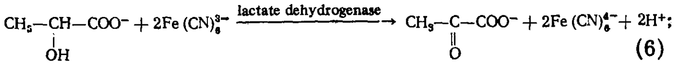
Williams et al.[50] described an enzyme electrode in which glucose oxidase immobilised in a gel was deposited on a platinum electrode and covered by a dialysis film to prevent the diffusion of the enzyme into the solution. The glucose in the solution being analysed diffuses into the layer of gel-enzyme in an amount proportional to its bulk-phase concentration. A distinctive feature of the enzyme electrode employed in this investigation[50] is that benzoquinone was used as the oxidant instead of oxygen. It was shown[50] that benzoquinone can also oxidise glucose under the influence of glucose oxidase, so that the reaction mechanism in the layer near the electrode and on the electrode can be formulated as follows:

$$\text{glucose} + \text{benzoquinone} + H_2O \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + \text{hydroquinone}; \qquad (4)$$

$$\text{hydroquinone} \xrightarrow{Pt} \text{benzoquinone} + 2H^+ + 2e. \qquad (5)$$

The advantage of this method is that the concentration of benzoquinone in the reaction mixture can be readily followed. In addition, there is a possibility of measurements over a longer linear range of glucose concentrations compared with the method in which the oxygen content in the aqueous solution is recorded during the reaction. By carrying out the reaction in a buffer solution (to keep the pH constant during the reaction) and by recording the current in the electrode system, it is possible to determine quantitatively the glucose content in the mixture being analysed.

A similar approach was used by Williams et al.[50] for the analytic determination of lactic acid with the aid of immobilised lactate dehydrogenase:



$$CH_3{-}\underset{\displaystyle OH}{\underset{|}{CH}}{-}COO^- + 2Fe(CN)_6^{3-} \xrightarrow{\text{lactate dehydrogenase}} CH_3{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}COO^- + 2Fe(CN)_6^{4-} + 2H^+; \qquad (6)$$

$$2Fe(CN)_6^{4-} \xrightarrow{Pt} 2Fe(CN)_6^{3-} + 2e. \qquad (7)$$

The oxidation of lactate by hexacyanoferrate(III) is catalysed by a preparation of yeast lactate dehydrogenase containing cytochrome B_2 as the cofactor.

Ion-selective electrodes, on the basis of which a major proportion of enzyme electrodes have been constructed, are fundamentally distinctive electrochemical sensors. The first enzyme electrode of this type was proposed in 1969 by Guilbault and Montalvo[51,52] for the quantitative determination of urea in aqueous solutions. It was prepared by depositing a layer of polyacrylamide gel containing urease on the surface of a glass cation electrode sensitive to ammonium ions. When the enzyme electrode is immersed in a solution containing urea, the substrate diffuses into the layer of immobilised enzyme, which catalyses the hydrolysis of urea via the following mechanism:

$$H_2N{-}CO{-}NH_2 + 2H_2O + H^+ \xrightarrow{\text{urease}} 2NH_4^+ + HCO_3^- \ . \qquad (8)$$

Ammonium ions, which are products of the hydrolytic reaction, are recorded by the cation electrode, so that the observed potential is proportional, within certain limits, to the concentration of urea in the sample being analysed.

This approach was subsequently developed by Guilbault and coworkers for the determination of L- and D-aminoacids[53-58], asparagine[55], and glutamine[59]. However, the authors noted[56,57,60] that the selectivity of commercial cation electrodes so far precludes their use for the analysis of biological liquids without a preliminary removal of the interfering K^+ and Na^+ ions by ion exchangers. The modification of enzyme electrodes is therefore directed at the present time mainly towards an improvement of the selectivity of their electrochemical response (see the next Section).

Characteristics of enzyme electrodes.

Enzyme	Method of immobilisation	Substance to be determined	Sensitivity	Response time	Stability	Conditions of determination	Refs.
Urease	entrainment in gel	urea	10^{-3}-1 mg ml^{-1}	25-60 s	–	$[E]_0$ = 175 mg ml^{-1}	51
	entrainment in gel	urea	5 x 10^{-5}-10^{-2} M	40-60 s	2 weeks	$[E]_0$ = 175 mg ml^{-1}, 25°, pH 7.0 (tris-buffer)	52,56,67
	entrainment in gel and enclosure in cellophane film	urea	5 x 10^{-5}-10^{-2} M	–	3 weeks at 25° without appreciable decrease of activity	ditto	52,56,57
	entrainment in gel and enclosure in cellophane film	urea	11-81 mg %	–	–	in blood serum	56
	entrainment in gel and enclosure in cellophane film	urea	0.55-3.50 g/100 ml	–	–	in urine	56
	entrainment in gel	urea	10^{-5}-10^{-2} M	60-180 s	1 week without appreciable loss of activity	$[E]_0$ = 175 mg ml^{-1}, 25°, pH 7.0 (tris buffer)	57
	enclosure between electrode and dialysis film	urea	5 x 10^{-5}-10^{-2} M	–	–	$[E]_0$ = 100 mg ml^{-1}, 25°, 0.1 M NaCl, pH 7.0 (tris buffer)	61
	entrainment in gel	urea	10^{-5}-10^{-3} M	15 min	more than 2 weeks	37°, pH 7.4 (physiological saline soln.)	61

		L-leucine	3×10^{-4}–10^{-3} M	–	–	–	
		L-methionine	3×10^{-3}–10^{-3} M (2% reproducibility)	–	–	–	
D-Aminoacid oxidase	entrainment in gel	D-phenylalanine	–	–	–	–	
		D-alanine	–	–	–	–	
		D-valine, D-methionine, D-leucine, D-norleucine, D-isoleucine	5×10^{-5}–10^{-2} M	–	3 weeks without appreciable loss of activity	25°, pH 8.2 (tris buffer)	55
	enclosure between electrode and dialysis film	–	–	–	appreciably less stable than previous electrode	–	55
Penicillinase	entrainment in gel	benzylpenicillin, ampicillin, nafcillin, phenoxymethylpenicillin, cyclicillin, dicloxacillin	10^{-4}–5×10^{-2} M (reproducibility varied from 9 to 17% in 3 days for different electrodes)	15–30 s	2 weeks (after this the time required for readings increases by a factor of 3–5)	$[E]_0 = 125$ mg ml^{-1}, pH 6.4. room temp., (not measured)	62
	enclosure between electrode and dialysis film	benzylpenicillin	5×10^{-4}–10^{-2} M	2 min	3 weeks	$[E]_0 = 50$ mg ml^{-1}, pH 6.8 (phosphate buffer), 0.1 M NaCl	61
Asparaginase	entrainment in gel	L-asparagine	5×10^{-6}–10^{-2} M	–	28 days without appreciable loss of activity	$[E]_0 = 25$ units ml^{-1}, 25°, pH 8.0 (tris buffer)	55
	enclosure between electrode and dialysis film	L-asparagine	–	–	50% loss of activity after 4 days	ditto	55
Glutaminase	entrainment in gel*	–	–	–	–	–	59
	enclosure between electrode and dialysis film	L-glutamine	10^{-4}–10^{-1} M	1–2 min	12 h	$[E]_0 = 150$ mg ml^{-1}, 25°, pH 5.5 (tris buffer)	59
β-Glucosidase	entrainment in gel	amygdalin	10^{-5}–10^{-2} M	15–40 s	3 days	$[E]_0 = 100$ mg ml^{-1}, 25°, pH 10.4	64
	entrainment in gel and enclosure in cellophane film	amygdalin	5×10^{-6}–10^{-3} M	1 min	crystalline membrane dissolves after 200 hours of continuous operation	$[E]_0 = 50$ mg ml^{-1}, 25°, pH 12.7	63
Glucose oxidase	entrainment in gel	glucose	–	–	–	37°, pH 3.2–10.3	47
	entrainment in gel	glucose	0.15–2.0 mg ml^{-1}	30–180 s	± 10% change in activity after the first 24 h at room temp.	$[E]_0 = 1$ mg ml^{-1} or 10 mg ml^{-1}, pH 7.4 (phosphate buffer)	41
	enclosure between electrode and dialysis film	glucose	10^{-3}–10^{-1} M	–	–	$[E]_0 = 200$ mg ml^{-1}, pH 6.9 (phosphate buffer), 0.1 M Na_2SO_4	61
	enclosure between electrode and dialysis film	glucose	2×10^{-3}–2×10^{-2} M	3–10 min	–	pH 4 (phosphate buffer) or blood; $[E]_0 = 1$ mg ml^{-1}	50
	chemical binding to gel	glucose	5×10^{-4}–2×10^{-2} M	12 s (from init. velocities or 1 min steady-state current)	increase of activity at a rate of 1.4% in 20 days followed by a decrease at a rate of 0.3–0.7% per day for 300 days	pH 6.0 or 6.6 (phosphate buffer), 30°	45,46
	entrainment in gel	glucose	5×10^{-4}–2×10^{-2} M	ditto	increase of activity from 0 to maximum in 40 days followed by a decrease at a rate of 0.3–0.4% per day for 160 days	pH 6.6 (phosphate buffer), 30°	46

Table (contd.).

Enzyme	Method of immobilisation	Substance to be determined	Sensitivity	Response time	Stability	Conditions of determination	Refs.
	entrainment in copolymer of ethylene glycol methacrylate and ethylene glycol dimethacrylate (in proportions of 100:1)	glucose	–	1 min	1.5% decrease of activity per day at 25°C	$[E]_0$ = 1-10 mg ml^{-1}, pH 7.2 (phosphate buffer), 25°	69
	enclosure between electrode and cellophane film	glucose	5×10^{-4}–2×10^{-2} M	1 min	decrease of response at a rate of 2-3% per day	pH 6.6 (phosphate buffer), 30°	46
Lactate dehydrogenase	enclosure between electrode and dialysis film	lactic acid	10^{-4}–2×10^{-3} M	3-10 min	–	blood	50
Alcohol dehydrogenase	enclosure between electrode and cellophane film	methanol, ethanol	10^{-9}–2.5×10^{-8} M	2 min	decrease of activity by a factor exceeding 2 in 12 h	physiological buffer soln., pH 8.5	1

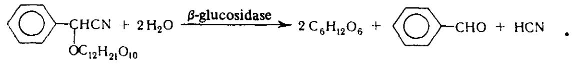
*The electrode was completely inactive.

In studies by Mosbach and coworkers[61] and Papariello et al.[62], enzyme electrodes were prepared by depositing a layer of the immobilised enzyme on a glass pH electrode, with the aid of which the concentration of hydrogen ions, formed as a result of the enzymatic reaction, was recorded. Enzyme electrodes for glucose[61] [reaction (9)], urea[61] [reaction (8)], and various penicillins[61,62] [reaction (10)] have been developed on the basis of this method:

$$\text{glucose} + O_2 + H_2O \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + H_2O_2; \quad (9)$$

$$\text{penicillin} + H_2O \xrightarrow{\text{penicillinase}} \text{penicilloic acid}. \quad (10)$$

Finally in 1971 Rechnitz and Llenado[63,64] described a new type of enzyme electrode in which a non-glass membrane was used as the electrochemical sensor. They developed[63,64] an analytical method for the determination of amygdalin using for this purpose a solid electrode consisting of a crystalline cyanide sensor coated by a layer of β-glucosidase immobilised in polyacrylamide gel. In the enzymatic hydrolysis of amygdalin [reaction (11)] the cyanide ions formed near the electrode as the reaction product diffuse through the layer of gel to the surface of the crystalline membrane and are recorded potentiometrically by the electrode system:



.(11)

The Table shows that the principal method used to immobilise the enzyme on the electrode involves its entrainment in a gel (in many cases the layer of the gel-enzyme was also covered by a cellophane film to reduce the diffusion of the enzyme from the gel into the solution). Approximately one-third of enzyme electrodes have been prepared by the simple entrainment of the enzyme between the electrode surface and the dialysis film. Finally, covalent binding of the enzyme to a carrier was used as the immobilisation method in only three investigations[45,46,58], but the authors noted a somewhat higher stability of enzyme electrodes with chemically combined enzymes compared with electrodes based on gel-enzymes.

The simplest method for the preparation of an enzyme electrode involves the mechanical entrainment of the enzyme between the sensor element of the electrode and the film membrane which retains the enzyme near the electrode but is permeable to substrate and product molecules (a dialysis film with definite pore dimensions is usually employed for this purpose). As a rule this enzyme immobilisation procedure does not impair the characteristics of the enzyme electrode relative to an enzyme immobilised in a gel on the surface of the sensor (see Table). Furthermore, it has been noted[54,56] that, in the determination of L-aminoacids with the aid of L-aminoacid oxidase, the gel-enzyme electrode was less stable and had a longer response time compared with the electrode coated by a thin layer of enzyme solution enclosed in a dialysis film. In addition, the authors[54] point out that riboflavin, added to the acrylamide solution as the polymerisation catalyst, inhibits L-aminoacid oxidase, which also impairs the electrode characteristics. On the other hand, the immobilisation of the enzyme in a polyacrylamide gel for electrodes based on D-aminoacid oxidase and asparaginase greatly increases their stability[55] (see Table). The attempts to immobilise the enzyme in a polyacrylamide gel for the glutaminase electrode resulted in a complete loss of activity by L-glutaminase[59], while the electrode covered by a dialysis film with an entrained thin layer of enzyme solution exhibited the normal response to the presence of L-glutamine in the mixture being analysed. Thus the available literature data so far do not allow one to give preference *a priori* to any one immobilisation procedure in the preparation of enzyme electrodes.

Almost all gel-enzyme electrodes about which there is at present information in the literature were prepared by immobilising enzymes in a polyacrylamide gel†. The

---

† In the study by J. Kulis and B. Panavo, which is being carried out at the present time at the Institute of Biochemistry of Lithuanian SSR, an enzyme electrode has been developed for glucose in which glucose oxidase is immobilised on the surface of a polarographic platinum electrode in a copolymer of ethylene glycol methacrylate and ethylene glycol dimethacrylate acids (see Table)[69].

differences consist only in the method of polymerisation (chemical or photoinitiated) used to prepare the gel-enzyme. The advantages of polyacrylamide gels are that the polymer formed can be readily granulated, the polymerisation is rapid, and, dpending on the reaction conditions, it is possible to obtain gels with different porosities[24]. The methods for the immobilisation of enzymes in a polyacrylamide gel on the electrode surface have been described in detail by Montalvo and Guilbault[65].

VI. KINETIC ASPECTS OF THE OPERATION OF ENZYME ELECTRODES. FACTORS INFLUENCING THEIR RESPONSE

The quantitative determination of reagents in mixtures being analysed with the aid of enzyme electrodes can be achieved in principle in three different ways: (a) by continuing the enzymatic conversion of the substrate until completion and by recording the total change in electrode response as a result of the reaction; (b) by measuring the rate of change of the electrode response in the initial period of the enzymatic reaction (in other words by determining a quantity proportional to the initial reaction velocity); (c) by recording the change in electrode response from the beginning of the reaction to the attainment of a constant response (in consequence of the establishment of a steady-state concentration of the reaction product in the layer near the electrode).

The first procedure is probably the most accurate; it is not subject to the influence of effectors (enzyme inhibitors or activators), which may be present in the reaction mixture; the inactivation of the enzyme immobilised on the electrode occurring during the reaction does not affect the analytical results, merely increasing the time required for the analytical determination; finally, the calibration plot for this method should be linear regardless of the initial concentration of the reagent being determined. However, for a comparatively rapid analysis, it is necessary in this case to have electrodes with a low diffusional resistance of the reaction layer with respect to the substrate and the product and a very high concentration of the enzyme in the layer adjoining the electrode, which is usually difficult and frequently impossible under real conditions. This factor probably explains why this method has never been used for analytical determinations with the aid of enzyme electrodes.

The main disadvantage of the second analytical method is that the initial velocity of the enzymatic reaction depends hyperbolically on the substrate concentration:

$$v = \frac{k_{cat}[E]_0[S]_0}{K_m + [S]_0} \quad , \tag{12}$$

where k_{cat} is the catalytic constant and K_m the Michaelis constant for the enzymatic reaction proceeding in accordance with the general mechanism

$$E + S \overset{K_m}{\rightleftharpoons} ES \xrightarrow{k_{cat}} E + P \ . \tag{13}$$

Eqn. (12), called the Michaelis–Menten equation, shows that the initial velocity of the enzymatic reaction is a linear function of substrate concentration only in the region where $[S]_0 \ll K_m$.

Guilbault and Lubrano[46], who used the "initial velocity" method to determine the concentration of glucose with the aid of immobilised glucose oxidase, noted the speed of this method (the measurement of the initial velocities took 4–12 s under the experimental conditions[46]) and its reproducibility (the error was less than 2%). The advantage of the "initial velocity" method has also been noted by Guilbault and Nagy[58].

In the vast majority of different versions of analyses carried out using enzyme electrodes (see Table), the method based on recording the steady-state electrode response in the system has been used. The essential feature of the method is that the steady-state concentration of the enzymatic reaction products in the layer of immobilised enzyme on the electrode, which is recorded by the electrochemical sensor, is attained after a definite period from the instant of immersion of the electrode in the solution being analysed.

Consider the following model. We have a plane membrane with a thickness l covering the sensor element of the electrochemical device and containing the immobilised enzyme at a concentration $[E]_0$. The electrochemical device with the membrane is immersed in a substrate solution at a concentration $[S]_0$. The partition coefficients of the substrate and enzymatic reaction product between the membrane and solution are δ_S and δ_P respectively. It is necessary to find the relation between the steady-state electrode potential in the system and the initial concentrations of the substrate and the immobilised enzyme (taking into account diffusion factors). According to Fick's second law, the rates of diffusion of the substrate and product within the membrane in a direction x at right angles to its surface are $D_S \frac{d_2[S]}{dx^2}$ and $-D_P \frac{d^2[P]}{dx^2}$, where D_S and D_P are the diffusion coefficients of the substrate and product respectively. The rate of the enzymatic reaction in the membrane is determined by the Michaelis–Menten equation [Eqn. (12)]. In the steady state (with respect to diffusion) of the system, the rates of these two processes should be the same:

$$D_S \frac{d^2[S]}{dx^2} = \frac{k_{cat}[E]_0[S]}{K_m + [S]} \quad , \tag{14}$$

$$-D_p \frac{d^2[P]}{dx^2} = \frac{k_{cat}[E]_0[S]}{K_m + [S]} \quad , \tag{15}$$

where [S] and [P] are the concentrations of the substrate and product in the membrane.

Blaedel et al.[66] carried out a detailed analysis of this model. They showed that, at low substrate concentrations $[S] \ll K_m$, the steady-state concentration of the product in the layer of the membrane near the electrode is defined by Eqn. (16), provided that the reaction does not alter the concentration ratio in the overall bulk of the solution before the attainment of the steady state:

$$[P] = \frac{\frac{\alpha D_s \delta_p}{t_p}\sinh \alpha l + \frac{D_s}{D_p}\cosh \alpha l - \frac{D_s}{D_p}}{\frac{\cosh \alpha l}{\delta_s} + \frac{\alpha D_s}{t_s}\sinh \alpha l}[S]_0, \tag{16}$$

where t_S and t_P are the corresponding mass-transfer coefficients, and

$$\alpha = \sqrt{\frac{k_{cat}[E]_0}{K_m D_s}} \quad . \tag{17}$$

At high substrate concentrations $[S] \gg K_m$ the steady-state concentration of the product is

$$[P] = \frac{k_{cat}[E]_0 l^2}{2D_p} + \frac{\delta_p k_{cat}[E]_0 l}{t_p} . \tag{18}$$

Thus in the region where $[S] \ll K_m$ the steady-state concentration of the product in the layer near the electrode and hence the steady-state response of the enzyme electrode vary linearly with substrate concentration in solution [Eqn.(16)], while in the region where $[S] \gg K_m$ the steady-state concentration of the product is independent of the initial substrate concentration [Eqn.(18)]. Furthermore, it is seen from Eqn.(16) that the enzyme concentration in the membrane influences the steady-state concentration of the product only up to a certain limit. For high values of $[E]_0$, the steady-state electrode response ceases to depend on the concentration of the immobilised enzyme; in this case we have the limiting value $[P] = (\delta_p t_s / t_p)[S_0]$. Finally, the steady-state electrode response depends also on the Michaelis constant and the catalytic constant for the enzymatic reaction (which are in their turn influenced by pH, temperature, ionic strength, etc.), on the diffusion coefficients of the substrate and product, and on the thickness of the reaction layer.

According to the Nernst equation, in the presence of charged products of the enzymatic reaction the potential of the electrode system should vary logarithmically with the activity of the product. Assuming that the steady-state concentration of the product defined by Eqn.(16) is approximately equal to its activity under the experimental conditions, the Nernst equation can be written as follows:

$$E = E^0 + \frac{RT}{nF} \ln \left\{ \frac{\frac{\alpha D_s \delta_p}{t_p} \sinh \alpha l + \frac{D_s}{D_p} \cosh \alpha l - \frac{D_s}{D_p}}{\frac{\cosh \alpha l}{\delta_s} + \frac{\alpha D_s}{t_s} \sinh \alpha l} [S]_0 \right\}, \tag{19}$$

or, in the case of a singly-charged ionic product ($n = 1$):

$$E = E^0 + 0.0591 \log [S]_0. \tag{20}$$

It follows from Eqn.(20) that at low substrate concentrations one may expect a potential change of 59.1 mV for a tenfold change in the initial substrate concentration (at 25°C). However, for the majority of real systems the electrode response is not fully of the "Nernst" type. As examples, one may quote the experimental slopes of plots of E against lg $[S]_0$, which are 0.055 (determination of urea[66]), 0.050 (determination of urea[67]), and 0.048 (determination of amygdalin[64]). In the determination of various penicillins (see Table), the slope varies from 0.052 for ampicillin to 0.038 for dicloxacillin[62]; the authors were unable to explain this finding, but suggested that the differences between the responses of enzyme electrodes with respect to various penicillins may be due to the different thicknesses of the gel layer on the electrode surface.

In the determination of glutamine with the aid of an enzyme electrode[59], this slope was found to depend on the pH, varying from 0.048 (pH 6.0) to 0.040 (pH 5.0), which indicates, according to the authors, the influence of hydronium ions on the ion-selective electrode. Guilbault and Montalvo[67] found that the response of the electrode, on the surface of which immobilised urease had been deposited, in relation to a standard ammonium chloride solution actually exceeded the response of the usual glass electrode reversible with respect to ammonium ions. The authors[67] explained the higher sensitivity of the enzyme electrode by the fact that, under the experimental conditions (pH 7.0), urease is negatively charged, so that the enzyme immobilised on the electrode behaves similarly to a cation exchanger.

When the solution being analysed contains "interfering" ions, which also influence the electrode potential[57], the dependence of the potential on substrate concentration can be formulated as follows:

$$E = E^0 + \frac{RT}{F} \ln \left\{ \frac{\frac{\alpha D_s \delta_p}{t_p} \sinh \alpha l + \frac{D_s}{D_p} \cosh \alpha l - \frac{D_s}{D_p}}{\frac{\cosh \alpha l}{\delta_s} + \frac{\alpha D_s}{t_s} \sinh \alpha l} [S]_0^{1/n} + \sum_i \eta a_i^{1/z} \right\}, \tag{21}$$

where η is the ratio of the selectivities with respect to the ions, a_i the activity of the interfering ion, and z its charge. The potential of the enzyme pH electrode should in fact vary in accordance with this law if the hydrogen ions formed as a result of the enzymatic reaction are determined in buffer solutions.

Mossbach and coworkers[61], who investigated the operation of enzyme pH electrodes in buffer solutions at different concentrations, showed that urea may be determined with the aid of the urease electrode at phosphate buffer concentrations not exceeding 0.01 M. It is seen from Eqn.(21) that, when the substrate concentration is reduced, the electrode potential tends to the constant value

$$E = E^0 + \frac{RT}{F} \ln \left(\sum_i \eta a_i^{1/z} \right). \tag{22}$$

The electrode potential tends to the same value when the concentration of the enzyme immobilised on the electrode is reduced. Thus, the S-shaped relation between the potential of the enzyme electrode and the logarithm of the concentration of the substance being determined in solution, which is usually observed experimentally, can be readily accounted for with the aid of Eqns.(16)-(22).

A considerable proportion of enzyme electrodes described in the literature (see Table) are sensitive to ammonium ions[60]. A significant disadvantage of these electrodes is their response to virtually all univalent cations[54], which can be described by the following sequence[59]: $Ag^+ > H^+ > K^+ > NH_4^+ > Na^+ > Li^+$. The low selectivity of cation electrodes with respect to ammonium ions has so far precluded the quantitative analysis of biological liquids for aminoacids and urea (with the aid of immobilised aminoacid oxidases, asparaginase, glutaminase, and urease) without their preliminary treatment using exchangers[56-59]. However, Guilbault and Nagy recently reported an improvement of the selectivity of electrodes based on urease[57] and L-aminoacid oxidase[58] by the addition of the antibiotic nonactin to the layer of gel-enzyme. Under these conditions, the selectivity of the electrodes was expressed by the ratios $[NH_4^+]/[K^+] = 6.5$ and $[NH_4^+]/[Na^+] = 750$. Montalvo[68] also reported an appreciable increase of the selectivity of the cationic glass cation electrode following the deposition on its surface of a thin hydrophobic membrane (a siliconopolycarbonate film) which is permeable to ammonium ions.

Guilbault and Montalvo[67] studied in detail the factors influencing the response of the urease electrode. Almost all the observed effects are consistent with Eqns.(16)-(22). The authors[67] also showed that, when urease is immobilised in a polyacrylamide gel on the surface of a cation-responsive electrode, the thickness of the gel and its composition have almost no influence on the steady-state response of the enzyme electrode. Thus, when the thickness of the gel is reduced from 350 to 60 μm, the steady-state response diminishes only by 2%; variation of the gel concentration from 5 to 17.6% for a constant ratio of the concentrations of the monomer and the cross-linking agent leads to a change in the response smaller than 2%; finally, variation of the concentration of the cross-linking agent in the system from 5 to 19% at a constant gel concentration also leads only to a very small change in the response of the enzyme electrode[67].

VII. THE STABILITY OF ENZYME ELECTRODES

The stability of enzyme electrodes or their ability to retain the catalytic activity of the immobilised enzyme over a period of time varies over fairly wide limits depending on the type of enzyme and the nature of its immobilisation. The main disadvantage of the immobilisation of the enzyme in a gel is its gradual "elution" into the solution surrounding the enzyme electrode[52,57,64], which leads to a gradual decrease of the activity of the electrode. As a rule, the stability of such electrodes can be increased by placing around the layer of the gel-enzyme a thin cellophane (dialysis) film, which is readily permeable to substrate and product molecules, but not to enzyme molecules[52,56,67]. Electrodes with a higher enzyme concentration in the layer deposited on them are usually more stable[54,55]. The stability of enzyme electrodes containing immobilised D-aminoacid oxidase greatly increased when they were stored in a solution of flavin-adenine dinucleotide, which is a cofactor of the enzyme[55,60]. When asparaginase was immobilised in a polyacrylamide gel, the stability of the corresponding electrode greatly increased compared with that of the homogeneous enzyme (see Table); on the other hand, the stability of L-aminoacid oxidase immobilised in a gel was significantly lower than that of the soluble enzyme[54]. Finally, the immobilisation of glutaminase in a polyacrylamide gel, carried out in a study by Guilbault and Shu[59], led to the complete inactivation of the enzyme. Thus both these and other available literature data (see Table) do not allow an *a priori* choice of the immobilisation procedure for the preparation of a stable enzyme electrode.

The most detailed and systematic study of the stability of gel-enzyme electrodes prepared under different conditions has been carried out by Guilbault and Montalvo[67]. The following factors influencing the stability of the urease electrode were noted: (a) the concentration of urea in the test solution; (b) the concentration of the enzyme in the gel; (c) the initial activity of the immobilised enzyme; (d) the thickness of the layer of the gel-enzyme on the electrode; (e) the light intensity during photopolymerisation; (f) the duration of photopolymerisation in the preparation of the gel-enzyme; (g) the temperature of the gel-enzyme during photopolymerisation; (h) the type of enzyme electrode.

Guilbault and Montalvo[67] found the optimal conditions for the preparation of the gel-enzyme under which the stability of the immobilised urease is highest (the enzyme works periodically for 3 weeks without appreciable loss of activity). It was shown that the stability of the electrode depends on the urea concentration in the solution being analysed, becoming impaired with increasing substrate concentration. According to a number of data[56,60,67], an increase of the stability of the enzyme electrode is observed with increase of the thickness of the gel-layer (from 60 to 350 μm), with increase of the enzyme concentration in the reaction layer, and, finally, when the layer of gel-enzyme on the electrode is covered by a thin cellophane film.

Guilbault and Lubrano[46] made a comparative study of the stabilities of three types of electrodes with immobilised glucose oxidase—bound chemically to derivatives of polyacrylic acid, entrained in a polyacrylamide gel, and immobilised in a thin layer of solution between the surface of the electrode and a cellophane film. It has been noted[46] that the third type of electrode not only loses its activity appreciably on storage in a buffer solution but also its response diminishes in each successive determination of the glucose concentration in solution. For this reason, this type of electrode has not been used for the analytic determination of glucose (see Table). The response of enzyme electrodes of the first two types reaches a maximum after they have been working for 20–40 days and then diminishes during 200–300 days (see Table), the electrode with chemically immobilised glucose oxidase being more stable than the gel-enzyme electrode. The authors[46] suggest that the bell-shaped curve for the dependence of the electrode response on time may be accounted for by the superposition of two effects—the gradual formation of diffusion channels in the matrix of the immobilised enzyme and the simultaneous denaturation of the latter.

VIII. PROBLEMS AND PROSPECTS

The wide scale and effective application of immobilised enzymes in analytical chemistry requires the solution of a number of general biochemical problems (the development of methods for the isolation and purification of enzymes, the development of methods for the determination of the catalytic activities of specific enzymes, the study of the mechanisms of the action of specific enzymes, the elucidation of factors influencing enzyme activity, etc.). Apart from these problems, which have no direct bearing on the subject of the present review, the following problems must be solved for the development of highly specific and economical enzyme electrodes suitable for the selective determination of a wide range of chemical compounds:

(1) An increase of the stability of immobilised enzymes to such an extent that they can function for several months and years.

(2) The determination of universal immobilisation methods permitting immobilisation by standard procedures suitable for all enzymes (or for specific groups of enzymes).

(3) An increase of the specificity of ion-selective electrodes with respect to particular ions (for example ammonium ions), which will permit the quantitative determination of given reagents with the aid of the corresponding enzyme electrodes in the presence of extraneous ions.

(4) An increase of the sensitivity of electrochemical systems with respect to electrochemically active products of the corresponding enzymatic reactions. This will make it possible to extend the limits of the sensitivity of enzymatic analytical methods towards lower concentrations of the given reagents.

In order to assess the possibilities of enzymatic analytical methods and the prospects of their development, it is sufficient to quote a by no means complete list of reagents the quantitative determination of which is of interest for analytical chemistry and which can be determined with the aid of enzyme electrodes. These reagents include aliphatic and aromatic alcohols, aldehydes, acids, hydroxyacids, ketoacids, dicarboxylic acids, aminoacids, esters, amides, carboxylic acid nitriles, primary, secondary, and tertiary amines, diamines, glycols (including ethylene glycol, propane-1,2-diol, and butane-2,3-diol), glycerol, acetoin, acetoacetate, hydrazine, hydroxylamine, ethanolamine, tyramine, nitroethane and other aliphatic nitro-compounds, phenols, *o*- and *p*-dihydroxybenzenes, xanthine, hypoxanthine, cholesterol, androsterone and other 3-α-hydroxysteroids, testosterone and other 3-β- and 17-β-hydroxysteroids, 20-dihydrocortisone, penicillins, sugars, thiols, diisopropyl phosphorofluoridate and other organophosphorus compounds, DDT, hydrogen peroxide, nitrates, nitrites, sulphites, hydrogen sulphide, ammonia, nitric oxide, pyrophosphate, halides, cyanides, and metal ions (calcium, barium, zinc, cadmium, copper, manganese, cobalt, and nickel ions).

It is noteworthy that, in order to determine any of these reagents, one can select, in principle, a suitable chain of coupled enzymatic reactions, with the substance to be determined at the beginning and the electrochemically active enzymatic reaction product at the end. In other words, in principle, a suitable enzyme electrode can be prepared for the quantitative determination of virtually any of the reagents enumerated above.

The Quenching of Singlet Oxygen

V.Ya.Shlyapintokh and V.B.Ivanov

The kinetics and mechanisms of processes involving the quenching of oxygen in the singlet state ($^1\Delta_g$) are examined. The rate constants for the deactivation of singlet oxygen in various solvents, for the reactions of singlet oxygen with unsaturated and aromatic compounds, and for processes involving the quenching of singlet oxygen by amines, metal complexes, and certain other compounds have been compiled. The influence of the polymer matrix on the reactivity of electron acceptors and the efficiency of quenching agents is considered and the role of singlet oxygen in photochemical oxidation reactions of low- and high-molecular-weight organic compounds is discussed.
The bibliography includes 77 references.

CONTENTS

I. INTRODUCTION

It was shown in 1964[1,2] that many photosensitised oxidation reactions proceed with participation of oxygen in an electronically excited singlet state and that "singlet" oxygen can give rise to oxidation products in nearly theoretical yields. These studies aroused much interest and stimulated theoretical and practical investigations of the properties and reactions of singlet oxygen. Among practical problems, the possibility of using singlet oxygen in preparative organic chemistry, the problem of smog and the pollution of the atmosphere, and the problem of protection of biological systems as well as low-molecular-weight and high-molecular-weight compounds from photosensitised oxidation have attracted particular attention.

In connection with the problem of improving the resistance of organic compounds to photochemical oxidation, questions concerning the efficiency of the quenching of singlet oxygen and the mechanism of the action of quenching agents are considered here. A number of recent reviews[3-9] of the properties and reactions of singlet oxygen may be recommended.

II. KINETICS OF PHOTOCHEMICAL OXIDATION BY SINGLET OXYGEN

In photosensitised oxidation reactions the main source of singlet oxygen ($^1O_2$) is believed to be the reaction involving the quenching of the triplet state of the sensitiser ^3S by oxygen in the ground state $^3O_2$:

$$^3S + {}^3O_2 \rightarrow {}^1S_0 + {}^1O_2, \qquad (1)$$

where $^1S_0$ is the ground singlet state of the photosensitiser. Other reactions are also known:

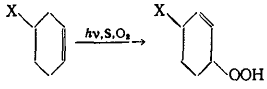
$$^1S_1 + {}^3O_2 \rightarrow {}^1S_0 + {}^1O_2, \qquad (2)$$

$$^1S_1 + {}^3O_2 \rightarrow {}^3S + {}^1O_2, \qquad (3)$$

where $^1S_1$ is the excited singlet state of the photosensitiser. However, the probability of these reactions is as a rule lower than that of reaction (1).

1. Characteristic Reactions of Singlet Oxygen

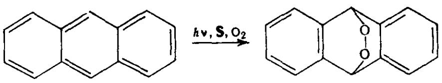
(a) Oxidation of olefins containing an allylic hydrogen atom to hydroperoxides. A characteristic shift of the double bond to the allylic position takes place in the reaction, for example:



(4)

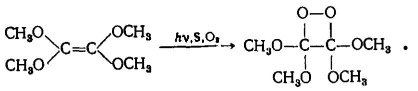
where X is a substituent.

(b) The addition of $^1O_2$ to diene hydrocarbons with formation of cyclic peroxides, for example:



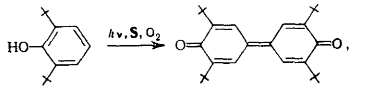
(5)

(c) Addition to olefins having an excess electron density at the double bond with formation of 1,2-dioxetans, for example:



$$(CH_3O)_2C{=}C(OCH_3)_2 \xrightarrow{h\nu,S,O_2} CH_3O{-}\overset{O-O}{\underset{CH_3O}{C-C}}{-}OCH_3\,. \qquad (6)$$

(d) The interaction of $^1O_2$ with reducing agents, for example phenols[10], sulphur-containing compounds[4,11,12], and amines[4,13-15], for example:

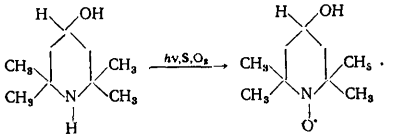


(7)

$$2\,(C_2H_5)_2\,S \xrightarrow{h\nu,S,O_2} 2\,(C_2H_5)_2\,SO, \qquad (8)$$

$$2\,(CH_3)_2\,SO \xrightarrow{h\nu,S,O_2} 2\,(CH_3)_2\,SO_2, \qquad (9)$$

$$H_2NCH_2CH_3 \xrightarrow{h\nu,S,O_2} H_2NCH\,(OOH)\,CH_3, \qquad (10)$$

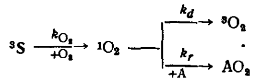


(11)

2. Kinetics of Oxidation in the Absence of Quenching Agents

The oxidation of compounds containing double bonds by singlet oxygen is hardly influenced by effective inhibitors of radical-chain oxidation processes, for example 2,6-di-t-butyl-4-methylphenol. On the other hand, tertiary aliphatic amines, which are typical $^1O_2$ quenching agents, do not inhibit the radical-chain oxidation of tetralin by molecular oxygen[16]. Thus, the oxidation by singlet oxygen of compounds with double bonds does not proceed via a radical-chain mechanism.

The kinetic scheme for the oxidation of an acceptor A can be formulated as follows:



$$ {}^3S \xrightarrow[+O_2]{k_{O_2}} {}^1O_2 - \left| \begin{array}{l} \xrightarrow{k_d} {}^3O_2 \\ \xrightarrow[+A]{k_r} AO_2 \end{array} \right. \tag{12} $$

Hence

$$ \frac{1}{\Phi_{AO_2}} = \frac{1}{\Phi_{^1O_2}} \left(1 + \frac{k_d}{k_r} \cdot \frac{1}{[A]} \right), \tag{13} $$

where Φ_{AO_2} and Φ^1O_2 are the quantum yields of the oxidation product AO_2 and of the formation of singlet oxygen respectively. Mechanism (12) can be used not only to describe reactions involving the addition of singlet oxygen to unsaturated compounds [reactions (4)–(6)] but also other reactions of singlet oxygen. Thus, it has been shown recently that the reactions of singlet oxygen with secondary and tertiary amines[15], in which a free valence is produced, are also fully described by scheme (12).

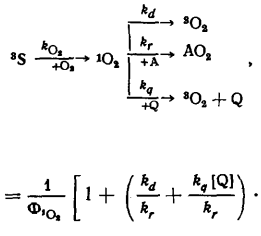
It is clear from Eqn. (13) that the yield of product is determined by the ratio of the rates of deactivation of $^1O_2$ and of the interaction of $^1O_2$ with the acceptor A. The maximum yield $\Phi_{AO_2} = \Phi^1O_2$ is reached under the following condition:

$$ k_r[A] \gg k_d. $$

The use of Eqn. (13) makes it possible to determine k_r/k_d—the relative reactivity of the acceptor towards $^1O_2$—from the dependence of the quantum yield on the concentration of the acceptor.

3. Kinetics of Oxidation in the Presence of Quenching Agents

In the presence of a quenching agent Q for singlet oxygen, the kinetic scheme for the oxidation of the acceptor becomes



$$ {}^3S \xrightarrow[+O_2]{k_{O_2}} {}^1O_2 \left| \begin{array}{l} \xrightarrow{k_d} {}^3O_2 \\ \xrightarrow[+A]{k_r} AO_2 \\ \xrightarrow[+Q]{k_q} {}^3O_2 + Q \end{array} \right. , \tag{14} $$

whence

$$ \frac{1}{\Phi_{AO_2}} = \frac{1}{\Phi_{^1O_2}} \left[1 + \left(\frac{k_d}{k_r} + \frac{k_q[Q]}{k_r} \right) \cdot \frac{1}{[A]} \right]. \tag{15} $$

It follows from Eqn. (15) that the variation of Φ_{AO_2} with [A] should be represented by a straight line when $1/\Phi_{AO_2}$ is plotted against 1/[A], and the parameters k_r/k_d and k_r/k_q, characterising the relative reactivities of the acceptor and the quenching agent in relation to $^1O_2$ respectively, may be determined from the dependence of the slope on [Q].

In the kinetic schemes (12) and (14) it was assumed that $\Phi^1O_2 = \Phi^3S$. However, these quantities are not equal when A or Q interacts with ^3S. If, for example, Q quenches only ^3S (with a rate constant k_Q) and not $^1O_2$, then

$$ \frac{1}{\Phi_{AO_2}} = \frac{1}{\Phi_{^3S}} \left(1 + \frac{k_q[Q]}{k_{O_2}[O_2]} \right) \left(1 + \frac{k_d}{k_r[A]} \right). \tag{16} $$

Like Eqn. (15), Eqn. (16) represents a linear plot of $1/\Phi_{AO_2}$ against 1/[A]. However, in contrast to Eqn. (15), the intercept on the ordinate axis depends on [Q]. Furthermore, the slope of the plot defined by Eqn. (16) depends on $[O_2]$. Quenching of the triplet state of the photosensitiser can be distinguished from the quenching of singlet oxygen by means of these features.

The use of Eqns. (13) and (15) makes it possible to obtain the kinetic parameters k_r/k_d and k_q/k_d from the concentration variation of the quantum yield and k_r/k_q from the concentration variation of the rate of oxidation.

4. The Efficiency of Quenching Agents in Liquid-Phase Systems

In order to obtain absolute values of the kinetic constants characterising the efficiency of quenching agents and the reactivities of singlet oxygen acceptors, the kinetics of the oxidation reactions were investigated and measurements were made of the lifetimes of singlet oxygen in various solutions using flash photolysis[17-25].

Table 1. The constants k_d for various solvents.

Solvent	$10^{-3}k_d$, s^{-1}	Refs.	Solvent	$10^{-3}k_d$, s^{-1}	Refs.

4:1 Bromobenzene-methanol	43	23			

Note: a) and b) Methylene Blue and Rose Bengal were used respectively as photosensitisers; c) estimated from data in this Table and those of Higgins et al.[26]

It follows from mechanism (12) that there is competition between reactions involving the spontaneous destruction of $^1O_2$ and its interaction with acceptors. Table 1 shows that the values of k_d change very markedly on passing from one solvent to another. These constants are large and correspond to the lifetimes of $^1O_2$ in various solvents ranging from a microsecond to a millisecond. For effective oxidation, the oxygen must be able to react with acceptors during this period; consequently, the rate constant k_r must also be large. It is seen from Eqn. (13) that the fraction η of singlet oxygen interacting with the acceptor is 0.5 when $k_d = k_r[A]$ or

$$ [A]_{\eta=0.5} = \frac{k_d}{k_r}. \tag{17} $$

Eqn. (17) shows clearly at which acceptor concentration or for which values of the kinetic constants the spontaneous destruction of oxygen and the oxidation process proceed at comparable rates.

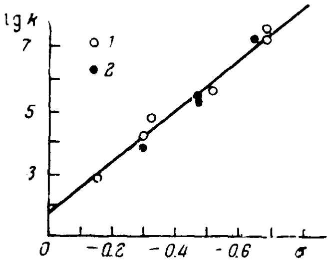

Figure 1. Dependence of the logarithms of the rate constants for the reactions of olefins with singlet oxygen on the σ_n constants of the substituents; 1) acyclic olefins; 2) cyclohexene derivatives.

The values of k_r for certain olefins and aromatic compounds are listed in Tables (2) and (3). It is seen that they depend very markedly on the structure of oxygen acceptors. On the other hand, the dependence of k_r on the nature of the solvent is comparatively slight. Fig. 1 shows that the influence of substituents on k_r can be described by the Hammett equation†.

The rate constants for the quenching of singlet oxygen by amines and their derivatives as well as by organometallic compounds are compiled in Tables 4 and 5. The rate constants for quenching by β-carotene are listed in the last rows of Table 2; the tables show that the rate constants for quenching by β-carotene and certain organometallic compounds are equal or close to diffusional constants. The constants k_q are very large for many amines. They can be described by the Hammett equation (see, for example, Young and coworkers[39,40]).

Note: a) Recalculated on the basis of $k_d = 2.8 \times 10^4$; b) recalculated on the basis of $k_r = 4 \times 10^7$ for dimethylanthracene; c) recalculated on the basis of $k_r = 4 \times 10^7$ for 2,3-dimethylbut-2-ene; d) recalculated on the basis of $k_d = 1 \times 10^5$; e) recalculated on the basis of $k_d = 6 \times 10^4$.

In contrast to the constants k_r for olefins and aromatic compounds, the constants k_q for amines can depend markedly on the solvent. However, the nature of the dependence is determined by the structure of the amine. For example, *NN*-dimethylaniline and methylamine quench $^1O_2$ in methanol more effectively than in Freon 113 ($C_2Cl_3F_3$) by three orders of magnitude. On the other hand, the rate constants for quenching by diethylamine and triethylamine differ only by a factor of several units in the same solvents.

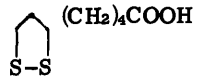
Above it was already noted that phenols, azides, and sulphur-containing compounds can behave as quenching agents for singlet oxygen. The kinetic constants for a very small number of compounds of these classes are known. Thus $k_q = 2.2 \times 10^8$ for NaN_3 in methanol[45], $k_q \leqslant 7 \times 10^7$‡ for hydroquinone in a 4 : 1 benzene–methanol

---

† In the example quoted, the σ_n constants of the substituents were used to construct the correlation plot.

‡ Quenches also ^3S.

mixture[11], $k_q = 6 \times 10^6$ for diethyl sulphide in the same solvent[11], and $k_r = 1 \times 10^8$ § for lipoic acid



in benzene[37].

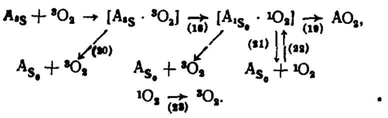
5. The Influence of the Polymer Matrix on the Kinetics of the Quenching Processes and Their Rate Constants

In the kinetic schemes for oxidation by singlet oxygen considered above, it was assumed that $^1O_2$ is formed as a result of interaction with the photosensitiser. However, photochemical reactions in which singlet oxygen is formed in a reaction involving the substance being oxidised (excited by light) and then itself interacts with the latter are well known and have been investigated in detail[46]:



(18)-(23)

Note: * Several new studies, in which the values of k_q were determined for a large number of transitional metal complexes, have been published recently[75-77]; the most effective of these quench singlet oxygen with nearly diffusional rate constants[77].
** Estimated from Felder and Schumacher's data[42] on the basis of $(k_q)_{DABCO} = 1 \times 10^7$.

Here singlet oxygen is formed in a reaction with the acceptor $A_{^3S}$ in the excited triplet state. A characteristic feature of this scheme is that the complex $A_{S_0} \cdot {}^1O_2$, the precursor of the product AO_2, is formed in two different reactions: in reaction (18) within a cage, designated by brackets (at the point of encounter of $A_{^3S}$ and $^3O_2$), and in reaction (22) between an unexcited acceptor molecule and singlet oxygen which has emerged from the cage into the bulk phase.

It is readily seen that, for the specified values of the kinetic constants, the kinetic law governing the reaction is determined by the concentration of A. In the region of very low values of [A] the complex $A_{S_0} \cdot {}^1O_2$ is formed exclusively via reaction (18) and the reaction involving the formation of AO_2 is of first order with respect to the substance oxidised.

---

§ It has not yet been established whether lipoic acid reacts with $^1O_2$ or whether it behaves as a quenching agent[37].

The $^1O_2$ species which have emerged from the cage [reaction (21)] are destroyed in reaction (23) without having sufficient time to react with A [reaction (19)], since the distances between the species A are very small. In the region of very high concentrations [A], the complex $A_{S_0}.^1O_2$ is formed via reactions (18) and (22). Having emerged from the cage each species $^1O_2$ reacts with A, and therefore the quantum yield is independent of [A]. In the region of moderate concentrations the complex $A_{S_0}.^1O_2$ is also formed via reactions (18) and (22), but the quantum yield increases with increase of [A]; the order of the reaction with respect to the substance oxidised is intermediate between first and second.

It has recently been shown[47-49] that, when the photochemical reaction is carried out in a polymer matrix, the kinetics are different: the order of the reaction with respect to the substance oxidised is much higher than the second and the reaction is rapidly retarded. As an example, Fig. 2 presents kinetic curves for the variation of the concentration of anthracene dissolved in a polystyrene film, in photochemical oxidation under the influence of light at a wavelength of 365 nm in air at room temperature. If irradiation is stopped at some instant, the specimen is heated at 95–100°C for 15–20 min in the dark, cooled to room temperature, and then irradiation is continued, the reaction starts again (curve *2*) and is again retarded under the conditions of continuous irradiation. With periodic and fairly frequent heating after irradiation (thermal activation), the reaction is faster (curve *3*) and follows liquid-phase kinetics.

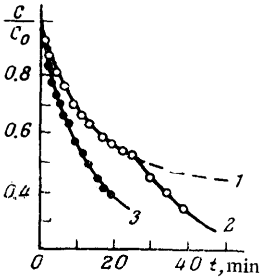

Figure 2. Variation of the concentration of anthracene C (initial concentration $C_0 = 2.8 \times 10^{-3}$ M) in a polystyrene film during irradiation in air with light at a wavelength of 365 nm: 1) continuous irradiation; 2) repeated irradiation after 10-min heat treatment at 100°C; 3) periodic conditions: after the determination of each experimental point indicated on the curve, the system was heated at 100°C for 10 min.

In general terms, the effect involving the rapid inhibition and arrest of the reaction can be accounted for by the fact that the polymer is an inhomogeneous system and therefore the probabilities of photochemical oxidation are not the same at various points within it. Species located at the points where the quantum yield is highest react initially, the quantum yield decreasing gradually in the course of the reactions. In order to describe the inhomogeneity of the polymer and the influence of the polymer matrix on the oxidation kinetics, a model has been proposed[48,49] according to which the substrate molecules in the polymer are located together with oxygen molecules in cages which differ in their permeability to oxygen. Within the framework of this model, the probability of the photochemical reaction is higher at low substrate concentrations for low permeability of the cage, since an increase of the lifetime of the A–$^1O_2$ pair corresponds to a decrease of permeability. On the other hand, at high concentrations of the acceptor A in the region corresponding to the preferential occurrence of the bimolecular reaction, species in cages with a high permeability react first. In this model the inhibition of the reaction is attributed to the gradual consumption of the species located in the regions of the polymer matrix more favourable for the reaction and thermal activation is accounted for by the restoration of the initial distribution of the substrate among the cages with different permeabilities as a result of the increase of the intensity of molecular motion at elevated temperatures. On the basis of the concepts described above, a quantitative theory of such self-inhibiting processes, involving oxidation by singlet oxygen, has been devised[49] for various selected laws governing the distribution of the cages with respect to permeability.

Table 6. Comparison of the kinetic constants for a solution (in methylene chloride) and a polymer (polystyrene) at room temperature[36].

Compound	Methylene chloride		Polystyrene		$\frac{(k_q/k_d)_L}{(k_q/k_d)_S}$	$\frac{(k_r/k_d)_L}{(k_r/k_d)_S}$
	$k_q \cdot k_d$, litre mole^{-1}	k_r/k_d, litre mole^{-1}	k_q/k_d, litre mole^{-1}	k_r/k_d, litre mole^{-1}

Anthracene	—	1.8	—	0.25	—	7

Note: The subscripts L and S denote the liquid and solid phases respectively (Ed. of Translation).

The first values of the rate constants for the quenching and oxidation processes[36] showed that the polymer matrix has a significant influence on these processes (Table 6). The correlation between the constants in the liquid and solid phases and the levelling of the kinetic constants for the solid phase are the most striking features. For example, the highest value of k_q/k_d for polystyrene is 50 times higher than the lowest value, whereas the corresponding values for methylene chloride differ by a factor of 5000. In other words, the efficiencies of various quenching agents differ much less in the solid phase than in the liquid phase. A similar levelling phenomenon was observed previously for the reactivities of various antioxidants in relation to peroxy-radicals in solid polystyrene[50]. In this case the levelling was accounted for by the dependence of the rate of the chemical reaction both on the reactivity of the antioxidants and on the mobility of the reactants in the polymer matrix. It is at present difficult to say whether this mechanism can be extended also to the $^1O_2$ quenching reactions, since there are few experimental data.

The data in Table 6 create the impression that the efficiency of the most powerful quenching agent is disproportionately reduced in the polymer matrix. Experiments with rubrene, tetracene, and anthracene also revealed that, on passing from the liquid to the solid phase, the values of k_q decrease less than those of k_r.

In polystyrene the quenching of $^1O_2$ by nickel(II) dibutyldithiocarbamate, bismuth(III) dimethyldithiocarbamate, and the nickel(II) salt of 3,5-di-t-butyl-4-hydroxybenzylphosphonic acid in polystyrene is not accompanied by a change in the absorption spectra of these substances. Their concentrations hardly change, which means that in both the solid polymer and in solutions the compounds quench $^1O_2$ via a physical mechanism.

III. THE QUENCHING MECHANISM

1. Quenching via Charge Transfer

Ideas about the quenching mechanism have been developed[51] on the basis of the observed correlation between the values of k_q for the gas phase and the ionisation potentials I_p of the quenching agents (amines). Later similar correlations were found for quenching by sulphur-containing compounds in the gas phase (Table 7) and by amines in the liquid phase (Table 8).

Table 7. The ionisation potentials of sulphur-containing compounds and the rate constants for the gas-phase quenching of $^1O_2$ by these compounds[12].

Quenching agent	I_p, eV	k_q, litre mole^{-1} s^{-1}
Methanethiol	9.44	$2.3 \cdot 10^3$
Dimethyl disulphide	9.05	$1.0 \cdot 10^4$
Thiophen	8.86	$3.6 \cdot 10^4$
Dimethyl sulphide	8.69	$1.6 \cdot 10^5$
Diethyl sulphide	8.42	$4.1 \cdot 10^5$

These correlations led to the conclusion that quenching takes place via the formation of a charge-transfer complex in which $^1O_2$ behaves as the electron acceptor[51]. This complex is formed only at the instant of collision and is not in equilibrium with the reactants. This is evident from the fact that the rate constant for the quenching of $^1O_2$ by amines (A) in the gas phase increases with temperature[51]. For an "equilibrium" complex, one might have expected the opposite relation, since an increase of temperature leads to a decrease of its equilibrium concentration.

The overall equation for the quenching process

$$^1O_2 + {}^1A_0 \rightarrow {}^3O_2 + {}^1A_0 \tag{24}$$

shows that it takes place with a change in the overall spin and therefore its probability should be reduced, according to Wigner's rule, particularly since the system considered here does not contain either heavy atoms or paramagnetic quenching agents or catalysts, which reduce the degree of prohibition as a result of spin–orbit interaction. However, it is believed[51] that, in a $^1O_2$–quenching agent system in the singlet state, even weak spin–orbit interactions are sufficient to reverse the spin.

The initial state of the $^1O_2$–$^1A_0$ system can be regarded as a superposition of the unperturbed singlet state of the complex $^1O_2.^1A_0$ and the singlet state of the charge-transfer complex $\lambda(^1CT)$, where λ indicates to what extent the compound $^1O_2.^1A_0$ has the properties of a charge-transfer complex. Accordingly, the final state may be represented as a superposition of the triplet state of the complex $^3O_2.^1A_0$ and the charge-transfer triplet state $\mu(^3CT)$. Since the singlet and triplet states of the charge-transfer complex differ little in energy, even a weak spin–orbit interaction between the singlet and triplet charge-transfer states (involving, for example, nitrogen or sulphur atoms) can convert the initial and final states into states with "mixed" multiplicity and thus allow at least partially the transition

$$^1[^1O_2 \cdot {}^1A + \lambda\,(^1CT)] \rightarrow {}^3[^3O_2 \cdot {}^1A + \mu\,(^3CT)]. \tag{25}$$

From this point of view, the observed correlation between the quenching rate constants and the ionisation potentials can be accounted for by the increase of the contribution of the charge-transfer states in the initial and final systems and by the corresponding increase of the mixing of states with different multiplicities[51].

Table 8. The rate constants for the quenching of $^1O_2$ by amines in methanol solution[39].

Quenching agent	I_p, eV	$k_q \cdot 10^{-6}$, litre mole^{-1} s^{-1}	Quenching agent	I_p, eV	$k_q \cdot 10^{-6}$, litre mole^{-1} s^{-1}
Cyclohexylamine	8.86	0.08	1,4-Piperazine	8.21	1.2
t-Butylamine	8.83	0.66	Diethylamine	8.01	1.9
Isopropylamine	8.72	0.05	Piperidine	7.85	0.92
Benzylamine	8.64	0.26	DABCO	7.52	7.3
Pyrrolidine	8.30	2.1	Triethylamine	7.50	9.3
Hexamethylenetetramine	8.26	0.20	*N*-Methylaniline	7.30	27
			NN-Dimethylaniline	7.10	120

The hypothesis that the $^1O_2$ quenching processes proceed via charge-transfer states was confirmed further in a study[40] of the quenching of $^1O_2$ and of the fluorescence of aromatic hydrocarbons by different amines, which takes place in an electronically excited charge-transfer complex formed by the aromatic compound and the amine. A linear correlation between the logarithm of the quenching rate constant and a quantity characterising the affinity of the excited singlet molecule for oxygen was demonstrated[40] for each amine investigated. It is of interest that the point characterising the rate constant for the quenching of singlet oxygen also fits on the straight line plotted for data on the quenching of the fluorescence of the singlet states of aromatic compounds.

2. Quenching via Energy Transfer

The quenching of $^1O_2$ via energy transfer proceeds in accordance with the equation

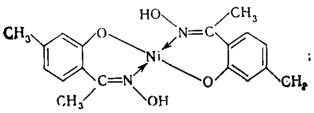
$$^1O_2 + {}^1Q_0 \rightarrow {}^3O_2 + {}^3Q_0, \tag{26}$$

where $^1Q_0$ and $^3Q_0$ are the ground singlet and triplet states of the quenching agent. This process does not require a change in the overall spin and is therefore allowed. The change in the multiplicity of the energy levels of oxygen alone is forbidden by Wigner's rule and its probability is therefore low. In order that reaction (26) should have a high rate constant, it is necessary that the condition $E^1O_2 \geqslant E^3Q_0$ holds for the energies of the corresponding states of oxygen and the quenching agent. Since E^1O_2 is only 22.6 kcal mole^{-1}, the energy of the triplet level of the effective quenching agent for $^1O_2$ must be very low.

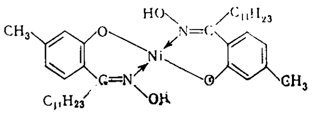
The first investigation of a quenching agent operating via an energy transfer mechanism was carried out by Foote et al.,[11] who observed a very marked (20-fold) decrease of the rate of photosensitised oxidation of 2-methylpent-2-ene (0.1 M) in the presence of a β-carotene concentration smaller by a factor of 1000. The efficiency of this quenching agent surpasses all others which have been investigated. The quenching process results in the *cis–trans* isomerisation of β-carotene. It was known that β-carotene quenches the low-energy (29 kcal mole^{-1}) triplet state of chlorophyll with a diffusional rate constant, i.e. $E^3Q_0 \leqslant 29$ kcal mole^{-1}.[52] The efficiency of the quenching of $^1O_2$ decreases when β-carotene, which contains a system of 11 conjugated bonds, is replaced by other quenching agents of this class but with shorter conjugated chains. The compound with five conjugated bonds altogether failed to inhibit the oxidation reaction.

Although the energy of the triplet level of β-carotene was unknown, Foote et al.[11] concluded on the basis of these findings that the quenching of $^1O_2$ by β-carotene proceeds via an energy transfer mechanism with a diffusional rate constant. The value of k_q which they adopted is listed in Table 2. The constant k_d calculated from it for methanol proved to be 1×10^5 s^{-1}, which agrees very well with subsequent direct measurements (Table 1).

The quenching of $^1O_2$ by the transfer of the electronic excitation energy to β-carotene was demonstrated by a direct method in a study[25] where singlet oxygen, obtained by laser flash photolysis induced the formation of the triplet state of β-carotene, and the kinetics of its accumulation and destruction were investigated. The constant k_q was found to be close to the value obtained[11] on the hypothesis that the quenching proceeds in each encounter between $^1O_2$ and β-carotene. Other quenching agents with low triplet levels were discovered by Farmilo and Wilkinson[25], for example:



;



.

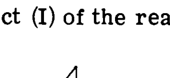
These quench $^1O_2$ with near diffusional rate constants—3.0×10^9 and 2.7×10^9 respectively. The quenching by these compounds apparently proceeds via the energy transfer mechanism. This can also be confirmed by the fact that, for example, the palladium complex having the same structure but with a higher triplet level quenches with a significantly lower rate constant (6×10^7).[25] Carlsson et al.[44] obtained $k_q > 10^9$ litre mole^{-1} s^{-1} (Table 5) for a number of organometallic compounds and at least some of them presumably function as energy acceptors. For less effective organometallic compounds, it has not so far been possible to establish any correlation between their geometry, properties, and ability to quench $^1O_2$.[22] However, in later investigations it was stated that diamagnetic nickel chelates quench $^1O_2$ and also the triplet state of ketones more effectively than the paramagnetic chelates[54]. It has been suggested[22] that the quenching mechanism may involve the formation of complexes of different kinds between the organometallic compounds and $^1O_2$.

IV. CHEMICAL REACTIONS OF QUENCHING AGENTS

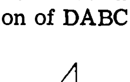
The data presented above show that substances with low ionisation potentials, which are typically reducing agents, and substances with a low triplet level are able to quench singlet oxygen. Presumably the reducing agents react with singlet oxygen, since it is an oxidising agent and the excited states formed after energy transfer to the triplet levels of the quenching agents react with both $^1O_2$ and $^3O_2$. The literature data[12,16] showing that certain quenching agents, for example diazabicyclo[2,2,2]octane (DABCO), ethyldiisopropylamine, *NNNN′*-tetramethylethylenediamine, and allylamine in bromobenzene and thiophen and methanethiol in the gas phase do not react at all with $^1O_2$ should probably be understood as merely an indication that the rate constants for the chemical interactions of these compounds with $^1O_2$ are low in absolute magnitude and are much smaller than the quenching rate constants.

Apart from the reaction with $^1O_2$, in photosensitised oxidation processes the quenching agent may interact with the triplet state of the photosensitiser. The reaction of the quenching agent (with $^1O_2$ or ^3S) which becomes dominant under the given conditions depends on the nature of the photosensitiser, the quenching agent, the medium, and the concentrations of the quenching agent and oxygen.

The possible involvement of the triplet states of sensitisers in the photochemical oxidation reactions of quenching agents belonging to the class of amines has been examined most fully and proved by Batholomew and Davidson[55,56]. In the first of these investigations, a study was made of the composition of the product and the quantum yields of the absorption of oxygen and the formation of products in the oxidation of primary, secondary, and tertiary amines as well as *N*-alkylanilines photosensitised by benzophenone were measured. Aliphatic amines reacted with formation of carbonyl compounds (after the rupture of the C–N bond) and imines. *N*-Alkylanilines formed products resulting from the rupture of the C–N bond. The involvement of amines in the direct reaction with ^3S was demonstrated by measurements of the quantum yields Φ_{O_2} of the absorption of oxygen. The values of Φ_{O_2} for tertiary amines, for example triethylamine (0.1 M in benzene) and tribenzylamine (0.1 M in benzene), exceed unity, although these compounds are known to be powerful quenching agents for $^1O_2$. Additional confirmation was obtained by investigating the composition of the products. *In vacuo* and in the presence of oxygen, the dealkylation reaction characteristic of *N*-alkylanilines takes place and the same product (I) of the reaction of DABCO (II) is formed:



(I)
,



(II)
.

In the second study[56], where the same reactions were investigated but dyes were employed as photosensitisers, the formation of the same products was observed, i.e. the dyes behave like benzophenone, which acts typically as a dehydrogenating agent. It was shown that the most readily oxidisable tertiary amines effectively decolorise the dye in the absence of oxygen and that the rate of photochemical oxidation increases with decrease of the concentration of oxygen. Both these findings support the involvement of amines in the direct reaction with ^3S.

Another mechanism, involving the direct interaction of amines with $^1O_2$, was examined and its validity was proved in other investigations[14,15]. The authors observed a new reaction of $^1O_2$—the formation of stable nitroxy-radicals in the sensitised oxidation of secondary and tertiary amines: homotropine, 1,1′- and 1,2′-diadamantylamines, 2,2,6,6-tetramethyl- and 1,2,2,6,6-pentamethyl-4-hydroxypiperidines, 4,4′-dimethoxy-, 4,4′-dicumenyl, and 4,4′-di-t-octyl-diphenylamine, and 2,7-di-t-octylphenothiazine. The oxidation was observed in liquid (8 : 1 benzene–ethanol mixture, concentration 10^{-3}–10^{-2} M) and solid [polystyrene, poly(methyl methacrylate), and polycarbonate] solutions irradiated with light corresponding to the absorption bands of the photosensitisers—Bengal Rose or Methylene Blue. The degree of conversion of amines in this process depends on the structure of the amine and the stability of the nitroxy-radicals and can reach several tenths. The involvement of $^1O_2$ in this reaction is confirmed by the lack of dependence of the measured rate constant for the formation of nitroxy-radicals on the oxygen concentration and the nature of the photosensitiser and also by the inhibition of the oxidation reaction by $^1O_2$ quenching agents, the efficiency of which may be calculated beforehand from the literature values of k_q.

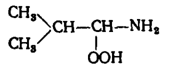
In most studies on the photosensitised oxidation of amines, the composition of the products and the rates and stoichiometries of the reactions are considered, but not the mechanisms of the primary photochemical processes. Below we shall therefore speak of the reactions of quenching agents in photosensitised oxidation processes without discussing specific mechanisms.

Table 9. The stoichiometry of the photosensitised oxidation of amines.

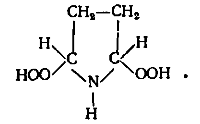
Amine	Absorption of O_2, moles per mole of substrate	References
Nicotine	1*	57
Methyl-, n-propyl-, isopropyl-, isobutyl-, and isopentyl-amines	1	13
Diethylamine, piperidine, pyrrolidine	2	13
Triethylamine	2.6	13
	3.06	28
t-Butylamine	No reaction	13

* Reaction in aqueous solution. The pyrrolidine component of the molecule is oxidised. In methanol three moles of O_2 are absorbed[32] instead of one.

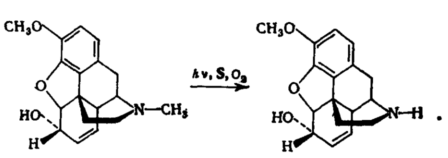
The data on the stoichiometry of the photosensitised amine oxidation reactions are presented in Table 9. According to Schenck[13], the formation of α-aminohydroperoxides corresponds to this stoichiometry, for example:



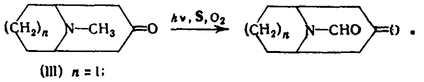
$$(CH_3)_2CH{-}CH(OOH){-}NH_2 ,$$



Accordingly, t-butylamine, which does not contain hydrogen atoms in the α-position, does not undergo photosensitised oxidation. However, as stated above, the photosensitised reactions can lead to other products—imines, carbonyl compounds, and products of the dealkylation of *N*-alkylamines[55,56]. Products of this type have been detected together with the formation of hydroperoxides in photosensitised oxidation reactions of primary, secondary, and tertiary n-butylamines.[57] Demethylation reactions have been observed in the photosensitised oxidation of steroid derivatives of the type $R{-}N(CH_3)_2$ (R = steroid residue)[58] and codeine[59]:



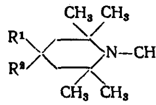
In the reactions of the alkaloids[60] pseudopelletierine (III) and tropinone (IV) and the steroid derivatives $R{-}N(CH_3)_2$,[58] the *N*-methyl groups were found to be oxidised to *N*-formyl groups, for example:



(III) *n* = 1;
(IV) *n* = 0

There are as yet no literature data concerning the ability of these compounds to quench $^1O_2$; they should probably behave as strong quenching agents, like other tertiary amines.

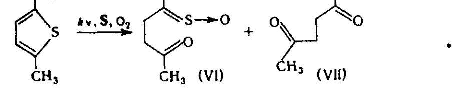
The absorption of oxygen by piperidine derivatives,



(V)

where $R^1 = R^2 = H$ or $R^1 = H$ and $R^2 = OH$, has been observed[41]. These compounds are probably oxidised fairly rapidly, since the rate of absorption of oxygen in the photochemical oxidation of 2-methylpent-2-ene (8×10^{-3} M), or 9,10-dimethoxyanthracene (8×10^{-3} M), or 9,10-dimethoxyanthracene (8×10^{-3} M) after the addition of compound (V) at a concentration of 5×10^{-2} M actually increases somewhat, although compounds (V) are known as quenching agents for $^1O_2$ (Table 4).

The absorption of oxygen and the formation of oxidation products were also observed in the presence of quenching agents of another class—sulphur-containing compounds. For example, analysis of the products of the oxidation of dimethyl and diethyl sulphides by singlet oxygen in the gas phase revealed the formation of sulphoxides[12]. The absorption of oxygen was observed in the photosensitised oxidation in methanol of disulphides related to cystine[61]. In the oxidation of 2,5-dimethylthiophen (0.01 M) photosensitised by Methylene Blue two main products were detected—the *cis*-sulphene (VI) and the *trans*-diketone (VII):



The ratio of the concentrations of (VI) and (VII) depends significantly on the solvent. In chloroform the yield of (VI) is 56% and that of (VII) 28%, while in Methanol the yields are 70% and 2% respectively.[62] The medium can have a significant influence not only on the composition of the product but also on the rate of oxidation. In this respect the influence of the medium is clearly manifested in the photochemical oxidation of β-carotene, which is

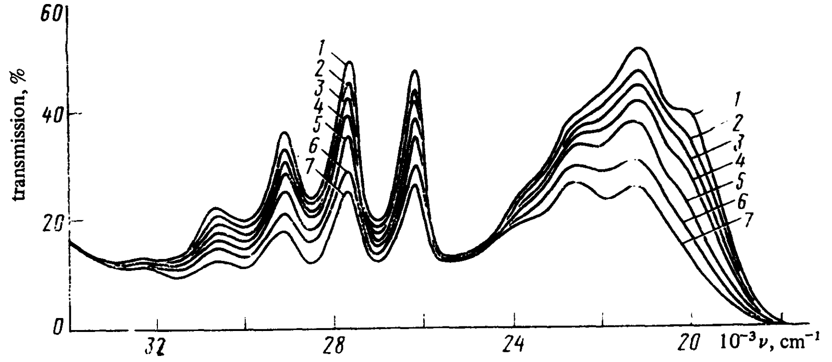


Figure 3. Changes in the absorption spectrum during the joint oxidation of anthracene (concentration 2.8×10^{-2} M) and β-carotene (concentration 0.67×10^{-2} M) in polystyrene; duration of irradiation (min): 1) 0; 2) 15; 3) 30; 4) 45; 5) 75; 6) 135; 7) 180.

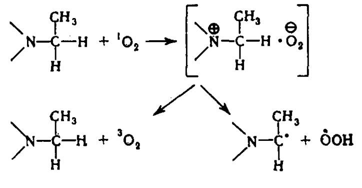
stable towards $^1O_2$ in solution but interacts readily with $^1O_2$ in a polymer matrix (polystyrene) with formation of an oxidation product, whose spectrum is illustrated in Fig. 3.[63]

Table 10. The ratios of the rates of physical and chemical quenching of singlet oxygen.

Quenching agent	Solvent	No. of $^1O_2$ quenching steps per reaction step	Refs.
β-Carotene	4:1 Benzene-methanol	>1000	11
β-Carotene	4:1 Benzene-methanol	<250	64
Diethyl sulphide	4:1 Benzene-methanol	20	11
NNN'N'-Tetramethyl-*p*-phenylenediamine	Methanol	>100	39
Diethyl sulphide	Gas phase	>40	12
Dimethyl sulphide	Gas phase	>16	12
Dimethyl disulphide	Gas phase	>1	12
Triethylene	Pyridine	9	28
Triethylamine	Gas phase	>100	28
Nicotine	Methanol	6	32
Mono-, di-, and tri-methylamines and mono-, di-, and tri-ethylamines	Gas phase	>100	51

The ratios of the rates for "physical" and "chemical" quenching presented in Table 10 show that the number of quenching steps per reaction step depends both on the properties of the quenching agent and on the medium in which the interaction takes place.

The mechanism of the effect of the solvent has not in essence yet been investigated. The hypothesis put forward by Smith[28] explains the tenfold increase of the rate constant for the chemical interaction of $^1O_2$ with triethylamine on passing from the gas phase to a pyridine solution by the increase of the lifetime of the triethylamine radical-cation in the polar solvent:



Very few rate constants for the chemical interaction of $^1O_2$ with quenching agents are as yet available. They are listed in Table 11.

Table 11. The rate constants for the chemical interaction of quenching agents with singlet oxygen.

Quenching agent	Solvent	k_r, litre mole^{-1} s^{-1}	Refs.
Dimethyl sulphide	Gas phase	1×10^4	12
Diethyl sulphide	Gas phase	1×10^4	12
Dimethyl disulphide	Gas phase	1×10^4	12
Diethyl sulphide	4:1 Benzene-methanol	3×10^5	11
Nicotine	Methanol	2×10^5	32
Triethylamine	Pyridine	1×10^6	28
4-Hydroxy-2,2,6,6-tetramethylpiperidine	8:1 Benzene-methanol	2.9×10^3*	15

V. TRENDS IN FUTURE RESEARCH

1. Quenching Agents Acting via a Charge-Transfer Mechanism

The most effective of the quenching agents investigated, acting via a charge-transfer mechanism, have reaction rate constants of about 5×10^8 litre mole^{-1} s^{-1}. There is no doubt that compounds with maximum possible efficiency, quenching $^1O_2$ in each encounter, can be obtained within the framework of this mechanism by introducing more powerful electron-donating substituents. However, it is so far difficult to answer the question whether such quenching agents would be suitable for practical use. Unduly strong reducing agents may prove to be unstable towards oxidation by oxygen in the ground state. Furthermore, the interaction of $^1O_2$ with an unduly strong reducing agent may lead to the formation of free radicals and hence to a radical-chain reaction of the substrate. Effects of this kind have been observed, for example, in a study[65] where, in an oxidation reaction photosensitised by thionine, a transition was observed to a radical mechanism after a change of substrate—from 9,10-dimethylanthracene and tetramethylethylene, which are weak reducing agents, to thiourea, which is a much stronger reducing agent. Finally, in order to be able to predict the suitability of quenching agents with maximum efficiency for practical employment, it is necessary to know the resulting ratio k_r/k_q, i.e. whether or not such quenching agents would react too rapidly with $^1O_2$. In order to be able to answer this question, one must investigate the dependence of k_r/k_q on the ionisation potentials or σ constants of the substituents in the quenching agents.

2. Quenching Agents Acting via the Energy Transfer Mechanism

It is evident from the foregoing that several very effective quenching agents, acting via the energy transfer mechanisms and deactivating $^1O_2$ in each encounter, are now known. The energy transfer from $^1O_2$ to an electronic level of the quenching agent probably takes place only on direct contact between the electron shells of $^1O_2$ and the energy acceptor. Transfer over large distances, for example via an inductive-resonance mechanism, is hardly possible, since the probability of a radiative transition of $^1O_2$ to the ground state is very low. One must therefore assume that the practical limit of the efficiency of the quenching agent has already been reached. Of the two types of quenching agents—compounds with a system of conjugated bonds and complexes—the latter are preferable, since the class of complexes is much larger and within its limits there is a much greater scope for obtaining stable quenching agents with the required properties. β-Carotene and compounds having similar structures are very reactive in relation to free radicals and are readily oxidised by molecular oxygen ($^3O_2$). There is therefore little prospect for their employment as quenching agents, although in plant organisms one of the functions of carotenoids is the quenching of $^1O_2$.[64]

One cannot rule out the possibility that carbon black, which contains structures with fairly long chains of conjugated bonds, can act similarly to β-carotene.

3. Quenching in Polymer Matrices and the Role of Singlet Oxygen in the Photochemical Oxidation Reactions of Polymers

It follows from the only investigation[36] which has so far been carried out that the efficiencies of quenching agents in a solid matrix (polystyrene) are to a large extent equalised. On the basis of general considerations, this effect is presumably related to the limitation of the diffusional mobility of oxygen and of molecular motion in the matrix, which hinders the formation of the activated complex. This is confirmed by data[36] showing that sharp changes in the kinetic constants occur in the region of the glass temperature (T_g). In order to elucidate the mechanism of this phenomenon, systematic studies on various polymers above and below T_g, combined with measurements of the diffusion coefficients of oxygen and of the characteristics of molecular mobility, are now required.

As far as one can judge from the available data[36], the efficiencies of quenching agents in polymers at $T < T_g$ differ comparatively little and therefore in selecting quenching agents one should be guided more by their stability during processing and under the conditions obtaining in the employment of polymers, their solubility in and compatibility with the polymer, their low volatility, etc. rather than by their efficiency in the liquid phase.

In the measurements of the efficiencies of quenching agents both in solution and in the solid phase, it is desirable to employ the formation of nitroxy-radicals during the oxidation of secondary or tertiary amines by singlet oxygen as the indicator reaction[15]. The ESR method is highly sensitive. It is therefore possible to measure the influence of quenching agents on the rate of accumulation of radicals under the conditions of an almost constant concentration of the indicator substance. Furthermore, measurement of the rate by ESR obviates the need to determine the rate from absorption spectra, which is sometimes difficult.

The possible involvement of $^1O_2$ in the photochemical oxidations of polymers began to be discussed in the literature in recent years[43,44,66-74]. Depending on the type of polymer, two mechanisms are considered. The first mechanism, which obtains in polymers containing double bonds, involves the direct interaction of $^1O_2$ with the macromolecule. The second mechanism, which applies to polymers without double bonds, presupposes the interaction of $^1O_2$ with the unsaturated compounds formed as a result of the photochemical process. In both mechanisms, the effect of $^1O_2$ reduces to the acceleration of the accumulation of hydroperoxides giving rise to photochemical branching. Processes involving the quenching by oxygen of the triplet states of carbonyl or aromatic compounds, which may be present as impurities or can form part of the composition of the macromolecules, are considered as sources of $^1O_2$.

Neither the first nor the second mechanisms has yet been proved. Very convincing experiments on certain polymers (for example polymers containing double bonds) established the possibility of their oxidation by the singlet oxygen generated chemically, or photochemically, or in an electric discharge. However the possibility, in principle, of the involvement of $^1O_2$ in the oxidation process does not by itself imply that the $^1O_2$ reactions really make any considerable contribution to the photochemical oxidation of polymers with double bonds in the absence of artificially created sources of $^1O_2$.

The difficulty of proving this mechanism consists in the fact that $^1O_2$ does not oxidise directly polymers without electron-accepting groups (unsaturated, condensed aromatic, etc.). The effect of $^1O_2$ must therefore be investigated not by itself but against the background of the photochemical reaction of the polymer, which generates groups capable of accepting $^1O_2$.

We believe that the problem of the involvement of $^1O_2$ in photochemical oxidation reactions of polymers can be usefully solved in two stages. The first stage involves the study of the possibility, in principle, of the acceleration of the photochemical oxidation of the given polymer with the aid of an artificial source of $^1O_2$. When a photosensitiser dye is used as the source of $^1O_2$, one can suggest for the elucidation of the possible involvement of $^1O_2$ experiments with two light sources—a short-wavelength source whose light is absorbed by the polymer or the photosensitising mixture and a long-wavelength source whose light is absorbed only by the dye. After appropriate control experiments with both sources, the acceleration of the photochemical reaction of the polymer with periodic or permanent inclusion of the additional long-wavelength source could probably be regarded as proof of the involvement of singlet oxygen.

In the second stage of the investigation it is necessary to measure the power of the internal source of singlet oxygen. A conclusion concerning the role of oxidation by singlet oxygen can probably be arrived at by comparing the power of the internal source with that of an external source sufficient for an appreciable acceleration of the photochemical process.

Polarographic Study of Aminoalkyl Esters of $\alpha\beta$-Unsaturated Acids and Their Reactions

Ya.I.Tur'yan, F.K.Ignat'eva, M.A.Korshunov, and V.S.Mikhlin

The review is devoted to the polarographic study of the reactions of aminoalkyl esters of $\alpha\beta$-unsaturated acids: electrochemical reduction, hydrolysis (including hydrolysis in a two-phase system), partition, and isomerisation. Detailed polarographic characteristics and equations for the polarographic wave and the kinetics and equilibria of the reactions using the limiting polarographic current are presented. The corresponding analytical applications of the method are considered. The kinetics and mechanisms of the processes are discussed from the standpoint of the structure of the electrical double layer, the acid-base properties of the aminoalkyl esters, and intramolecular hydrogen bonds in conjunction with correlation analysis. A comparison is made with data obtained by pH-stat and spectrophotometric methods. The bibliography includes 166 references.

CONTENTS

I. INTRODUCTION

Interest in aminoalkyl esters of $\alpha\beta$-unsaturated acids has been aroused comparatively recently and for this reason we shall consider briefly the problems concerning the applications of these esters and also the methods for their synthesis.

Aminoalkyl methacrylates and acrylates, monomers with functional groups, are used in the manufacture of a wide variety of polymeric materials: synthetic rubbers[1], rubber suitable for the manufacture of tyres[2], latexes[3], vulcanising agents for rubbers[4-9], fibreglass[10-18], anionic polyelectrolytes and polyampholytes[19-25], coatings[26-33], modified cellulose materials[34-37], and physiologically active polymers[38-42]. Certain other applications of the esters have also been described[43-53].

The following methods are used to synthesise esters of methacrylic and acylic acids containing in the alkoxy-radical a tertiary amino-group or a secondary amino-group with a t-alkyl or aryl substituent at the nitrogen atom[51-53]. (1) Esterification of aminoalcohols by unsaturated acids. The use of this method is limited owing to the necessity to remove from the required monomers an admixture of the salt of the initial acid and the aminoalcohol and also owing to the inadequate yields of the monomers. (2) Acylation of aminoalcohols by acid chlorides. The latter method is more universal and makes it possible to obtain high yields of the methacrylate and acrylate derived from a wide variety of aminoalcohols. However, owing to the low availability and high cost of acid chlorides, the applications of this method are as a rule limited to preparative laboratory syntheses. (3) Transesterification of lower unsaturated acid esters with aminoalcohols. Because of the low cost of the initial methacrylate and acrylate esters, their high purity and stability, and also the comparatively simple technology and high yields of the required monomers, this method is most widely used in practice. Alkaline metal, alkaline earth metal, and titanium alkoxides are used as effective process catalysts.

Methacrylates and acrylates containing in the alkoxy-group a primary amino-group or a secondary amino-group with unbranched or only slightly branched alkyl residues at the nitrogen atom are as a rule obtained in the form of hydrochlorides by the interaction of acid chlorides with aminoalcohol hydrochlorides.

The aminoalkyl methacrylate and acrylate esters discussed in this review were obtained mainly by transesterification (method 3) and from acid chlorides.

In connection with the expanding use of aminoalkyl esters of $\alpha\beta$-unsaturated acids, studies of the physicochemical properties of these compounds and the development of highly sensitive physicochemical methods for their determination are assuming increasing importance. This review is devoted to this problem and is concerned mainly with results obtained by the polarographic method: polarographic studies of the hydrolysis, isomerisation, and partition reactions and polarographic methods for the determination of the aminoalkyl esters. A number of important advantages of the polarographic method for the investigation of the kinetics and equilibria of the above reactions are noteworthy: (1) the possibility of recording kinetic curves without sampling; (2) the comparatively simple solution of the problem of the maintenance of a constant pH and ionic strength owing to the high sensitivity of the method, etc.

Since the polarographic method yields at the same time valuable information about the mechanism of the electrochemical reduction of the test compounds, these data have also been included in the review. Compared with methacrylate and acrylate esters without an amino-group in the alkoxy-moiety, the corresponding aminoalkyl esters are of considerable interest as regards their electrochemical behaviour, since, depending on the pH of the solution, they can exist in both protonated and non-protonated states. This factor makes it possible to investigate the intramolecular catalysis in the hydrolysis of the aminoalkyl esters as a function of the pH.

II. POLAROGRAPHIC CHARACTERISTICS AND THE MECHANISM OF ELECTROCHEMICAL REDUCTION

For comparison, we shall consider in this section also certain data referring to unsaturated acid esters without an amino-group in the alkoxy-moiety.

The possibility of the polarographic reduction of esters with $\alpha\beta$-conjugated double bonds (the carbonyl and ethylene bonds) was demonstrated for the first time in relation to methyl methacrylate[54]. The reduction wave of methyl methacrylate ($E_{1/2} = -1.92$ V; here and henceforth the potentials are quoted relative to the normal calomel electrode) was obtained in the presence of lithium chloride or tetramethylammonium iodide in 25% ethanol as the supporting electrolyte.

Data have been published[55-62] on the reduction of methacrylates without an amino-group in the alkoxy-moiety using non-aqueous and mixed solvents. The polarographic behaviour of methacrylates with substituents other than amino-groups in the alkoxy-moieties has been discussed[63,64]. The reduction involves the ethylene bond with formation of isobutyrate esters[55-57]:

$$CH_2{=}C(CH_3){-}C\begin{smallmatrix}\nearrow O\\ \searrow OR\end{smallmatrix} + 2e + 2H^+ \rightarrow CH_3{-}CH(CH_3){-}C\begin{smallmatrix}\nearrow O\\ \searrow OR\end{smallmatrix} \quad (1)$$

The reduction of methacrylates and acrylates containing an alkylamino-group has been studied[65-72] in both aqueous buffer solutions[65-67,71] and using non-aqueous solvents (alcohol, dimethylformamide[68-70]). The polarographic characteristics of acrylate and methacrylate esters in various supporting electrolytes are presented in Tables 1 and 2. To facilitate the comparison, the limiting current constant I_{lim} is defined as the limiting current divided by the characteristic of the capillary; the dimensions of I_{lim} are μA litre mole^{-1} mg$^{-2/3}$ s$^{1/2}$. The limiting current constant undivided by the capillary characteristic is denoted henceforth by K_{lim}.

The reduction of aminoalkyl methacrylates is irreversible like that of methacrylates containing alkoxy-moieties without an amino-group[63]; the slopes of the $E - \lg[\bar{i}/(\bar{i}_d - \bar{i})]$ straight lines is 75–85 mV for neutral buffer solutions and 60–67 mV for alkaline solutions[66,71].

In studies on the reduction of a number of aminoalkyl acrylates and methacrylates in dimethylformamide it was noted[70] that the limiting current constant is smaller approximately by a factor of two than in a protic solvent. However, the addition of proton donors (water, phenol, propargyl alcohol) to dimethylformamide leads to an increase of the limiting current to values approximately equal to those in a protic solvent (Table 1). In consequence of the differences between the properties of the free radicals formed in the first stage of the reduction of monomers, under these conditions the limiting current for the methacrylates reaches constant values at much lower concentrations of proton donors than for acrylates (see below)[57]. The increase of the limiting current in the presence of proton donors has been explained[70] by the fact that in non-aqueous dimethylformamide the process stops at the stage involving the formation of radical-anions,

$$CH_2{=}C(CH_3)COOR + e \rightarrow \dot{C}H_2{-}\bar{C}(CH_3)COOR, \quad (2)$$

which probably dimerise subsequently. The one-electron mechanism of the reduction of methacrylates in an aprotic medium (dimethylformamide) has been confirmed[62] for methyl methacrylate.

In the presence of proton donors, the radical-anion is protonated[70]:

$$\dot{C}H_2{-}\bar{C}(CH_3)COOR + HA \rightarrow \dot{C}H_2{-}CH(CH_3)COOR \quad (3)$$

which facilitates subsequent reduction. Calculation of the number of electrons involved in the reaction by the Il'kovich equation using the diffusion coefficients for compounds of a similar type showed that the reduction process involves the addition of two electrons[58,65,69]. However, in the case of the dimethacrylate derived from triethylene glycol the limiting currents in both anhydrous dimethylformamide and in the presence of proton donors are almost the same[74], which indicates the absence of the radical-anion protonation stage. This finding has been explained[74] by the possible amination of the radical-anion (or the dimeric biradical) by the tetraalkylammonium cations from the supporting electrolyte.

* K_a are the acid dissociation constants of the aminoesters taken from the literature[72,73].

** The currents I_{lim} in the alkaline pH range were found by extrapolation to zero time[71].

The protonation of the radical-anion observed in the presence of proton donors is evidently very rapid, since the values of $E_{1/2}$ and K_{lim} for methacrylates and acrylates without an amino-group in the molecules are independent of the pH (pH 7.5–12.5).[57]

The limiting current for the reduction of aminoalkyl methacrylates in an aqueous buffer solution at a pH close to that of the neutral medium is diffusional[65,71] (the slope of the $\lg i_{lim} - \lg H_{Hg}$ straight lines is 0.5; temperature coefficient 0.95–1.37% per degree), as for methacrylates without an amino-group in the alkoxy-moiety[63]. The values of $E_{1/2}$ and K_{lim} in the range pH < 8.5–9.5 are almost independent of the pH; $E_{1/2}$ is also independent of the concentration of the aminoalkyl ester and $\bar{i}_{lim}$ is directly proportional to its concentration.

In the alkaline pH range (pH > 8.5–9.5), the reduction process has a kinetic mechanism[66] (the slope of the $\lg \bar{i}_{lim} - \lg H_{Hg}$ straight lines is 0.26–0.39; temperature coefficient 2.5–3.9% per degree), which may in fact explain the decrease of the limiting current constant (Table 2). The kinetic mechanism of the reduction process in alkaline solution has been accounted for[66] by the influence on this reaction of the protonation of the neutral aminoalkyl ester molecule (at the nitrogen atom) preceding the electrochemical stage proper. The limiting current for the analogous esters without an amino-group remains diffusional also in the alkaline pH range[63]. The protonation of aminoalkyl esters proceeds in a very thin reaction layer at the surface of the electrode[66]. Under these conditions, the main proton donors are hydronium ions; on the other hand, with increase of pH and the acid dissociation constant of the aminoalkyl ester (K_a), water molecules may also be involved in the protonation stage[66]. In the region of kinetic waves, K_{lim} decreases with increasing pH and $E_{1/2}$ shifts towards negative values.

The following mechanism of the above electrode process has been proposed[66]:

$$\begin{tikzcd}
{} & RN \arrow[l, "e", "(III)"'] \arrow[r, shift left, "\overset{(I)}{H^+}"] & RNH^+ \arrow[l, shift left] \arrow[r, "e", "(II)"'] & {} \\
 & RN \arrow[u, "\text{diff.}"'] \arrow[r, shift left] & RNH^+ \arrow[l, shift left] \arrow[u, "\text{diff.}"']
\end{tikzcd}, \qquad (4)$$

including the occurrence in the general case of simultaneous reactions involving the reduction of the non-protonated (RN) and protonated (at the nitrogen atom; RNH$^+$) forms of aminoalkyl esters. In the region of the rise in the wave, there is then also electrochemical inhibition (the process is irreversible) in both simultaneous electron transfer stages.

Like methacrylates without an amino-group[63,75] and aminoalkyl esters of other acids[76], aminoalkyl methacrylates[66,71] are adsorbed on the mercury electrode[66,71]; however, at potentials more positive by 0.4–0.5 V than the half-wave potential, they are desorbed[66]. Bearing in mind the high negative reduction potential of aminoalkyl methacrylates, the influence of their adsorption on the chemical electrode reactions can probably be neglected.

In alkaline solutions (pH ⩾ pK_a) the simultaneous reduction reactions (II) and (III) take place [mechanism (4)]. If only reactions (I) and (II) occur (slow protonation), they are described by the kinetic equation[77]

$$E_{1/2} = \frac{RT}{\alpha n_a F} \ln \frac{10^{-3} n \bar{S} F k^0_{el}}{K_{lim}} + \Psi_1 \left(\frac{\alpha n_a - 1}{\alpha n_a} \right) + \frac{RT}{\alpha n_a F} \ln \frac{[H^+]}{K_a} + \frac{RT}{\alpha n_a F} \ln \frac{\bar{i}_d}{\bar{i}_{lim}}, \qquad (5)$$

where α is the transfer coefficient, n_a the number of electrons involved in the potential-determining reaction, $\bar{S}$ the surface area of the mercury drop (in cm^2), k^0_{el} the rate constant for the electrochemical stage (in cm s^{-1}) and Ψ_1 the potential in the outer Helmholtz plane.

When only reaction (III) takes place [mechanism (4)], $E_{1/2}$ is given by the equation[78]

$$E_{1/2} = \frac{RT}{\alpha n_a F} \ln \frac{10^{-8} n\bar{S}Fk^0_{\mathrm{el}}}{K_{\mathrm{lim}}} + \Psi_1. \tag{6}$$

It follows from Eqns. (5) and (6) that in alkaline solutions (αn_a = 0.8–0.9) in the presence of Li^+(LiOH) the relative influence of reactions (I) and (II) will be greater than in a solution at the same pH but in the presence of the $(Alk)_4N^+$ cation (the Ψ_1 potential is more negative in the case of Li^+).[79] The observed shift of $E_{1/2}$ towards negative values (Fig. 1) with increase of K_a in 0.02 M LiOH solution has therefore been explained[66] by the dominant influence on $E_{1/2}$ of the term of Eqn. (5) containing K_a.

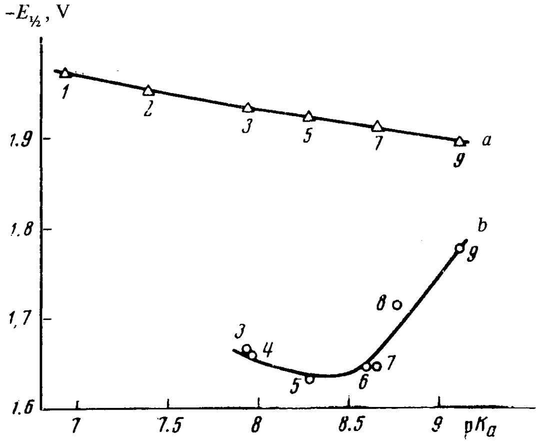

Figure 1. Variation of $E_{1/2}$ with the acid dissociation constants of aminoalkyl esters[66]: *a*) 0.02 M LiOH; *b*) universal buffer solution with LiOH + 0.03 M LiCl (pH 7.4; ionic strength 0.05). The numbers against the symbols correspond to the numbers of the esters in Table 2.

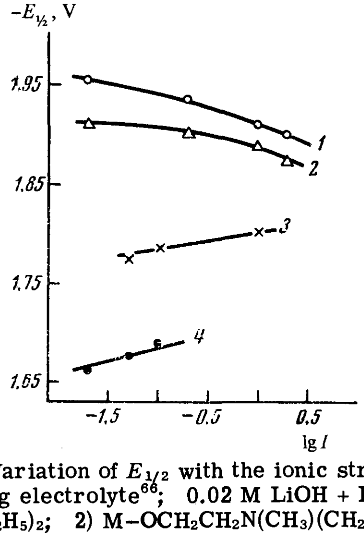

Figure 2. Variation of $E_{1/2}$ with the ionic strength *I* of the supporting electrolyte[66]; 0.02 M LiOH + LiCl; 1) $M{-}OCH_2CH_2N(C_2H_5)_2$; 2) $M{-}OCH_2CH_2N(CH_3)(CH_2{=}CH{-}CH_2)$; universal buffer solution with LiOH + LiCl (pH 7.4); 3) $M{-}OCH_2CH_2NHC(CH_3)_3$; 4) $M{-}OCH_2CH_2N(CH_3)_2$ ($M = CH_2{=}C(CH_3)C\genfrac{}{}{0pt}{}{\nearrow O}{\searrow}$ throughout).

An increase of the ionic strength of an alkaline solution (pH 12) leads[66] to a shift of $E_{1/2}$ towards less negative values (Fig. 2), as for esters with other uncharged alkoxy-groups[63]. The replacement of Li^+ by $(Alk)_4N^+$ in these solutions also greatly facilitates the reduction of the aminoalkyl esters (Fig. 3). The observed phenomena have been explained[66] by the increasing influence of reaction (III) [mechanism (4)] as a result of its acceleration due to the decrease of the absolute value of the Ψ_1 potential[79]. According to Eqn. (6), the change in the rate constant for the electrochemical stage k^0_{el} in solutions with $(Alk)_4N^+$ assumes a considerable importance.

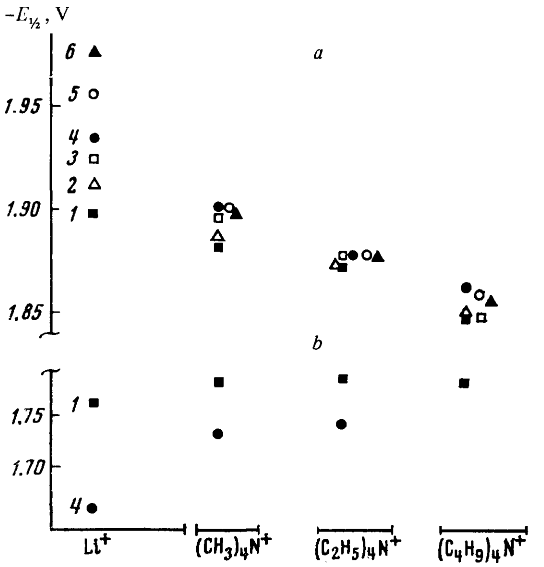

Figure 3. Variation of $E_{1/2}$ with the nature of the cation (Kt^+) of the supporting electrolyte[66]: *a*) 0.02 M KtOH; *b*) universal buffer solution with the corresponding KtOH (pH 7.4; ionic strength 0.02): 1) $M{-}OCH_2CH_2NHC(CH_3)_3$; 2) $M{-}OCH_2CH_2N(C_2H_5)_2$; 3) $M{-}OCH_2CH_2N(CH_3)C_4H_9$; 4) $M{-}OCH_2CH_2N(CH_3)_2$; 5) $M{-}OCH_2CH_2N(CH_3)CH_2{-}CH{=}CH_2$; 6) $M{-}OCH_2CH_2N(CH_2{-}CH{=}CH_2)_2$.

As in the case of methacrylates without an amino-group[64], the values of $E_{1/2}$ for aminoalkyl esters in a non-protonated form are displaced towards less negative values with increase in the size of the cation of the indifferent electrolyte (Fig. 3):

$$\underrightarrow{Li^+;\ (CH_3)_4N^+;\ (C_2H_5)_4N^+;\ (C_4H_9)_4N^+.}$$

This is qualitatively consistent with the corresponding shift of the Ψ_1 potential[80,81] but the displacement of $E_{1/2}$ exceeds the value expected as a result of the Ψ_1-effect[82] and depends to a considerable degree on the size of the substituent in the ester molecule. This has been explained[64] on the basis of the concept[79,83] of specific interactions of the organic depolariser in tetraalkylammonium salt solutions where the electrolyte cation is adsorbed (this leads to the formation of a cationic complex in the adsorption layer). As a result of this interaction, the depolariser is "drawn into" the double layer by the strongly adsorbed tetraalkylammonium cation, which leads to an additional acceleration of the electrode process and a positive shift of $E_{1/2}$.

When the pH approaches the value of pK_a, reactions (I) and (II) predominate [mechanism (4)] for partly protonated aminoalkyl esters, and, taking into account the quasidiffusional wave, $E_{1/2}$ is expressed by the following equation under these conditions[84]:

$$E_{1/2}=\frac{RT}{\alpha n_a F}\ln\frac{10^{-8}n\bar{S}Fk^0_{\mathrm{el}}}{K_{\mathrm{lim}}}+\Psi_1\left(\frac{\alpha n_a-1}{\alpha n_a}\right)+\frac{RT}{\alpha n_a F}\ln\frac{[\mathrm{H}^+]}{K_a+[\mathrm{H}^+]}\,. \tag{7}$$

It follows from Eqn. (7) that, when the nature of the aminoalkyl ester changes, $E_{1/2}$ begins to experience the opposite influence of K_a in addition to the influence of k^0_{el}. As a result of this, the plot of $-E_{1/2}$ against pK_a passes through a minimum[66] (Fig. 1).

For fully protonated aminoalkyl esters (pH ≪ pK_a), $E_{1/2}$ corresponding to the diffusional wave is described by the following equation[78] [reaction (II) in mechanism (4)]:

$$E_{1/2}=\frac{RT}{\alpha n_a F}\ln\frac{10^{-8}n\bar{S}Fk^0_{\mathrm{el}}}{K_{\mathrm{lim}}}+\Psi_1\left(\frac{\alpha n_a-1}{\alpha n_a}\right). \tag{8}$$

In this pH range, the half-wave potential $E_{1/2}$ virtually ceases to depend on the pH of the solution[66] (Fig. 4). The considerable positive shift of $E_{1/2}$ with decrease of pK_a (pH 7.4) (Fig. 1) can be explained by the polarising influence of the substituents in the protonated aminoalkyl esters, which becomes enhanced owing to the intramolecular hydrogen bond (see below).

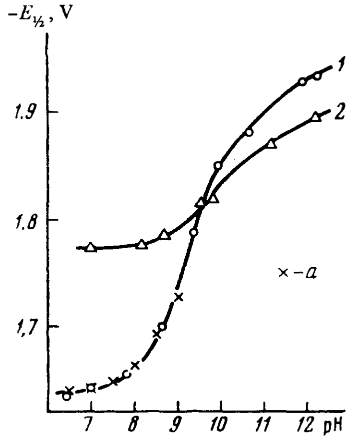

Figure 4. Variation of $E_{1/2}$ with pH of the universal buffer solution (LiOH) [66] [ionic strength 0.02 (+LiCl)]: 1) $M-OCH_2CH_2N(C_2H_5)_2$ (pK_a = 7.94); 2) $M-OCH_2CH_2.NHC(CH_3)_3$ (pK_a = 9.12); *a*) points calculated by Eqn. (7).

When Li^+ is replaced by $(Alk)_4N^+$ in the indifferent electrolyte in neutral buffer solutions at pH 7.4 (in contrast to alkaline solutions at a pH 12), $E_{1/2}$ for the aminoalkyl esters shifts towards negative values (Fig. 3),[66] which is consistent with Eqns. (7) and (8) (αn_a = 0.7–0.8). A similar influence of the indifferent electrolyte has been observed for an aminoalkyl ester with a quaternary nitrogen atom [$-CH_2CH_2N^+(CH_3)_3$], which is also consistent with the theory[80]. $E_{1/2}$ for protonated aminoalkyl esters[66] and the ester with a quaternary nitrogen atom[63] shifts in the same direction with increasing ionic strength [Eqns. (7) and (8)].

A tendency towards a negative shift of $E_{1/2}$ with increase of the molecular weight of methacrylates (methyl, ethyl, and butyl methacrylates) as been noted[61], which the authors explained by the positive inductive effects of the alkyl group, increasing from the methyl to the butyl group. This leads to an increase of electron density at the vinyl bond and hinders its reduction. This question has been examined qualitatively[63] on the basis of the correlation equation[85]

$$\Delta E_{1/2}=\rho^*_\pi\sigma^*_R, \tag{9}$$

where ρ^*_π is the constant defining the sensitivity of $E_{1/2}$ for the given group of compounds to the influence of the solvent and σ^*_R is the Taft constant. A satisfactory correlation has been obtained in the range of values of σ^*_R from −0.13 to 0.8, characterised by the following parameters: $\rho^*_\pi = 0.114 \pm 0.008$; $S = \pm 0.007$; $r = 0.977$. Since the ester with a non-protonated amino-group does not deviate from the general correlation, this permitted the conclusion[63] that the inductive effect of the non-protonated amino group has a dominant influence on the electrochemical activity of the aminoalkyl esters and made it possible to explain the small experimental negative shift[69,86] of $E_{1/2}$ following the introduction of an alkylamino-group into the alkoxy-moiety of acrylates and methacrylates.

$E_{1/2}$ for the ester derived from β-trimethylammoniumethanol was found to deviate[63] from the $E_{1/2}$–σ^*_R linear relation, which was explained by the electrostatic effect of the field.

It is interesting to note that, in an alkaline solution (pH 12), $E_{1/2}$ for the aminoalkyl esters is also satisfactorily correlated with the $\sigma^*_{R_i}$ constants of the substituents at the nitrogen atom in the alkylamino-group ($\rho^*_\pi = -0.110 \pm 0.006$; $S = \pm 0.002$; $r = 0.995$).[71] However, under these conditions ρ^*_π is negative, suggesting the dominant influence in this series of the nitrogen protonation stage, which is accelerated with increasing positive inductive effect of the alkyl substituent at the nitrogen atom.

It has been noted[57] that, on passing from acrylate esters to the corresponding methacrylate esters, $E_{1/2}$ for the esters shifts by 0.1–0.15 V towards more negative values owing to the positive inductive effect of the α-methyl group (Table 1).

III. THE KINETICS AND MECHANISM OF HYDROLYSIS

1. Kinetic Characteristics

The kinetics of the hydrolysis of the aminoalkyl esters of acids containing tertiary and certain secondary amino-groups in the alkoxy-moiety have been studied. The presence of a primary amino-group and in many cases also of a secondary amino-group leads predominantly to the O–N migration of the acyl group (see below).

Since in the acid pH range the rate of hydrolysis of aminoalkyl methacrylates is very low, data for the hydrolysis in neutral and alkaline pH ranges are mainly considered below.

The first most detailed information about the kinetics of the alkaline hydrolysis of esters of *N*-alkylaminoalcohols was reported by Agren et al.[87], Hansen[88], Zaslawsky and Fischer[89], and Higuchi et al.[90]. Isolated and conflicting data concerning the mechanism of this reaction are quoted in other communications[91-95] and the influence of the structure of the esters on their reactivity has been examined[96,97]. Later studies[98-103], on the one hand, confirmed and greatly expanded the available information concerning the kinetics of the alkaline hydrolysis of the aminoalkyl esters and, on the other hand, made it possible to treat this reaction from the standpoint of the nature of the interaction of the functional groups (the amino- and ester groups); despite the hypotheses put forward[93,104,105], this problem remained open for a long time.

Many studies of the kinetics and mechanism of the hydrolysis of the aminoalkyl esters were made by pH-stat[88,89,92,106] and spectrophotometric[87,90,98,101,102,107] methods; in a few instances chromatography[108] and colorimetry[107] were used. However, in the case of esters capable of being reduced at a dropping mercury electrode, the polarographic method proved to be the most convenient and promising[99] (see Section I). The reaction is then followed on the basis of the time variation of the limiting current, proportional to the concentration of the aminoalkyl ester. The only complication which may arise when the polarographic method is used to investigate the kinetics of the hydrolysis of esters on the basis of the wave for the initial ester is the possible influence of the hydrolysis product on this wave: adsorption or other effects. An appropriate test is therefore necessary in each instance. The hydrolysis products derived from the aminoalkyl esters of $\alpha\beta$-unsaturated acids considered in the present review did not influence the polarographic wave of the initial ester[99,100]. It is noteworthy that the polarographic method has been used successfully also in the study of the kinetics of the hydrolysis of many other esters[109-114].

Since, depending on the pH of the solution, the aminoalkyl esters can exist both as neutral molecules (RN) and as species protonated at the nitrogen atom (RNH⁺), in the general case the hydrolysis of such esters can be described by the sum of the following reactions[87,88,99]:

$$\mathrm{RN}\left|\begin{array}{l}\xrightarrow[k'_{\mathrm{OH^-}}]{\mathrm{OH^-(I)}}\\[2ex] \xrightarrow[k'_{\mathrm{H_2O}}]{\mathrm{H_2O(II)}}\end{array}\right. ;\qquad \mathrm{RNH^+}\left|\begin{array}{l}\xrightarrow[k''_{\mathrm{OH^-}}]{\mathrm{OH^-(III)}}\\[2ex] \xrightarrow[k''_{\mathrm{H_2O}}]{\mathrm{H_2O(IV)}}\end{array}\right. , \tag{10}$$

where k' and k'' are the rate constants for the reactions of the non-protonated and protonated forms of the esters respectively.

Bearing in mind that the rate of hydrolysis of the aminoalkyl esters is very low in the acid pH range[71,88], the influence of reaction (IV) [mechanism (10)] may be neglected at pH ⩾ 7.[99] Therefore the hydrolytic process to which mechanism (10) refers can be described by the following kinetic equation[87-89]:

$$-\frac{\mathrm{d}C_{\mathrm{est}}}{\mathrm{d}t}=\left(k'_{\mathrm{OH^-}}C_{\mathrm{OH^-}}\frac{K_a^0}{K_a^0+a_{\mathrm{H^+}}/f_{\mathrm{RNH^+}}}+k'_{\mathrm{H_2O}}\frac{K_a^0}{K_a^0+a_{\mathrm{H^+}}/f_{\mathrm{RNH^+}}}+\right.$$
$$\left.+k''_{\mathrm{OH^-}}C_{\mathrm{OH^-}}\frac{a_{\mathrm{H^+}}/f_{\mathrm{RNH^+}}}{K_a^0+a_{\mathrm{H^+}}/f_{\mathrm{RNH^+}}}\right)C_{\mathrm{est}}=k_{\mathrm{exp}}C_{\mathrm{est}}\ , \tag{11}$$

where $k'_{\mathrm{OH^-}}$, $k'_{\mathrm{H_2O}}$, and $k''_{\mathrm{OH^-}}$ are the corresponding rate constants, K_{a}^0 is the thermodynamic acid dissociation constant of RNH⁺ (since Tur'yan and coworkers[72,73] obtained K_{a} at a comparatively low ionic strength, in the calculations below it was assumed that $K_{\mathrm{a}}^0 \simeq K_{\mathrm{a}}$), $f_{\mathrm{RNH^+}}$ the activity coefficient of RNH⁺, k_{exp} = const. at a constant pH, and C_{est} is the analytical concentration of the ester. In relation to the polarographic method, when the limiting current $\bar{i}_{\mathrm{lim}}$ of the aminoalkyl ester is directly proportional to the sum of the concentrations of its protonated and non-protonated form, i.e. to C_{est}, Eqn. (11) becomes at a constant pH

$$\frac{\mathrm{d}\bar{i}_{\mathrm{lim}}}{\mathrm{d}t}=k_{\mathrm{exp}}\bar{i}_{\mathrm{lim}}\ . \tag{12}$$

The suitability of a pseudofirst-order equation [Eqns. (11) and (12)] for the description of the kinetics of the hydrolysis of the aminoalkyl esters has been confirmed in a number of studies[88,89,99,102]. On the other hand, the fact that the hydrolysis of the aminoalkyl esters constitutes the sum of the reactions of the protonated and non-protonated forms of the ester has not been always taken into account[97]. The experimental psuedo first-order rate constants k_{exp} can be found graphically on the basis of Eqn. (11) or (12).

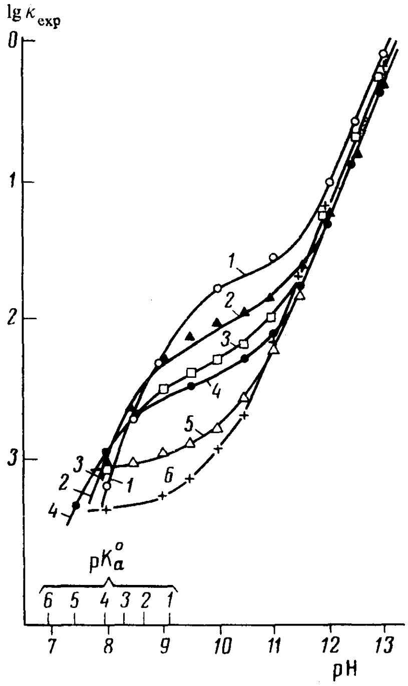

Figure 5. Variation of the experimental hydrolysis rate constant with pH.[99] Curves—experimental data; symbols—data calculated by Eqn. (13) (Table 3): 1) M–OCH₂.CH₂NHC(CH₃)₃; 2) M–OCH₂CH₂N(C₂H₅)₂; 3) M–OCH₂.CH₂N(CH₃)C₄H₉; 4) M–OCH₂CH₂N(CH₃)₂; 5) M–OCH₂.CH₂N(CH₃)CH₂–CH=CH₂; 6) M–OCH₂CH₂N(CH₂–CH=CH₂)₂.

The contribution of reactions (I)–(III) [mechanism (10)] depends on the pH of the medium in which the ester is hydrolysed and this determines the characteristic form of the lg k_{exp}–pH curves obtained[90,98,99] in studies of the rate of hydrolysis of the aminoalkyl esters over a wide pH range. These curves (Fig. 5) have two steep sections with an intervening low-slope section. Fig. 5 shows that, in the region where pH ≫ pK_{a}^0, reaction (I) predominates (the upper steep section represents the linear dependence of lg k_{exp} on pH with a slope close to unity): at pH values close to pK_{a}, the rate constant k_{exp} varies insignificantly with pH, which suggests a dominant contribution of either stage (II) or stage (III), since in both cases there should be a low-slope section of the $\lg k_{exp}$–pH relation, i.e. these stages are kinetically indistinguishable[88,99] [Eqn. (11)]. In agreement with experimental data and the theory[99] [Eqn. (11)], the low-slope section of the $\lg k_{exp}$–pH curves is displaced more towards lower values of k_{exp} and pH the lower the value of pK_a^0. At pH ≪ pK_a^0 the lower steep linear section is observed in the plot of $\lg k_{exp}$ against pH with a slope close to unity, which shows that stage (III) predominates in this instance [Eqn. (11)], provided that RN has been almost completely converted into RNH^+. For aminoalkyl esters with a low value of pK_a^0, it proved impossible to observe experimentally the lower steep section (Fig. 5).

Table 3. The rate constants for the alkaline hydrolysis of the aminoesters $CH_2{=}C(CH_3)COOCH_2CH_2R$ (H_2O; 25°C; ionic strength 0.5; polarographic method[99,100]).

$\overset{+}{N}(CH_3)_3$		35.9±0.3	—

---

* $E'_{act}(k'_{OH^-}) = 12.1 \pm 0.4$; $\lg A' = 7.6 \pm 0.5$ (E_{act} is the activation energy in kcal mole^{-1} and A is the pre-exponential factor).

** $E''_{act}(k''_{OH^-}) = 19.9 \pm 2.3$; $\lg A'' = 16.0 \pm 1.6$.

In the solution of the problem of the separate determination of the rate constants for the kinetically indistinguishable stages (II) and (III), it has been shown[88] on the basis of a comparison with the kinetics of the hydrolysis of 2-dialkylaminoethyl bromides that the influence of stage (II) may be neglected. Comparison of the rates of hydrolysis of acetylcholine, ethyl acetate, and diethylaminoethyl acetate in neutral and alkaline solutions also led to the qualitative conclusion[39] that stage (III) predominates. A similar conclusion has been arrived at by a more rigorous procedure (by analysing the influence of the ionic strength of the solution on the kinetics of the hydrolysis).[99] Thus in the general case the hydrolysis of the aminoalkyl esters is described by reactions (I) and (III) [mechanism (10)] and Eqn. (11) can be written as follows:

$$k_{exp} = k'_{OH^-}C_{OH^-}\frac{K_a^0}{K_a^0 + a_{H^+}/f_{RNH^+}} + k''_{OH^-}C_{OH^-}\frac{a_{H^+}/f_{RNH^+}}{K_a^0 + a_{H^+}/f_{RNH^+}}. \qquad (13)$$

The applicability of Eqn. (13) has also been confirmed[99] by comparing the experimental and calculated kinetic curves (Fig. 5).

The second-order rate constants, calculated by Eqn. (13) for aminoalkyl methacrylates[99,100], and most reliable data[87–89,92,101,102,115] for other aminoalkyl esters are listed in Tables 3–5.

One should note that, in the study of the kinetics of the hydrolysis of the aminoalkyl esters in buffer systems, general alkaline catalysis is sometimes possible. The effect of acetate and phosphate ions on the kinetics of the hydrolysis of choline esters and esters with a tertiary alkylamino-group has been investigated. However, in the case of choline esters[98,107,116,117] as well as esters with a tertiary amino-group[94,107] this effect could be observed only under conditions where the influence of more effective catalysts is slight (pH 5–6) and for esters with a tertiary amino-group the contribution of the catalytic effect of the components of the buffer mixture to the overall hydrolysis rate constant was insignificant[71,90,94,118,119].

Table 4. The rate constants and activation parameters for the alkaline hydrolysis of the aminoesters $C_6H_5.$ $.COOCH(R)(CH_2)_nNR'_2$ (60°C; 30 wt.% aqueous ethanol; ionic strength 0.1; spectrophotometric method[101,102]).

2. Hydrolysis of Aminoalkyl Esters in the Non-Protonated Form. The Influence of the Structure of the Ester

The introduction of an amino-group into the ethyl methacrylate molecule leads to an acceleration of the hydrolysis of the ester (Table 3). Such acceleration relative to analogues without an NR_2 group in the alcohol residue has also been observed for esters of azobenzene carboxylic[120], glycolic[96], acetic[88,89,96], and benzoic[87,93,101] acids. However, the influence of the amino-group on the reactivity of the esters is small and cannot be explained by the postulated[93,98,105] activation of the carbonyl bond by the intramolecular interaction of the

β-nitrogen atom with the carbonyl carbon atom, i.e. N: → C=O. It was concluded[88,89,99-101,103,121] that there is no nitrogen–carbonyl interaction and that the inductive effect of the non-protonated alkylamino-group predominates. This conclusion was based on the following characteristics of the influence of the structure: (1) as regards the general relation between lg k_{OH^-} and σ^*_{R} obtained for methacrylates with various alkoxy-groups, the aminoalkyl ester behaves in the nonprotonated form as an ordinary alkyl ester in accordance with the value of its σ^*_{R};[100] (2) a change in the basicity of the amino-group does not affect significantly the rate of hydrolysis of the non-protonated forms of the aminoalkyl esters, as shown by the absence[99,101] of an appreciable influence of the nature of the substituents at the nitrogen atom in the alkoxy-group (Tables 3 and 4); (3) the influence of the basicity of the carbonyl group on the reactivity of the non-protonated forms of aminoalkyl esters with a variable acid component and of the ethyl esters of substituted benzoic acids is approximately the same[103]; (4) studies on infrared spectra showed[121] that the frequencies and intensities of the band associated with the vibrations of the C=O bond in aminoesters and their analogues without an amino-group in the alkoxy-moiety do not differ appreciably from one another, while in the case of the postulated nitrogen–carbonyl interaction the differences should have been significant.

It is interesting to note that an appreciable variation of the activation energy with the number of methylene units and with the nature of the substituent at the nitrogen atom has been noted for esters of secondary benzyl alcohols containing a tertiary amino-group in the alkyl chain, in contrast to esters of primary aminoalkyl carbinols[101]. These data can be accounted for[101] by the nucleophilic catalysis by the amino-group, i.e. by the direct interaction of the amino- and ester groups. However, since spectroscopic evidence was not obtained for such interaction, the authors[101] suggested that the interaction is manifested mainly in the transition state and not in the initial state.

Other structural characteristics of esters in the non-protonated form which have been observed[101] include a distinct decrease of reactivity on passing from esters of primary aminoalcohols to those of secondary aminoalcohols and further to esters of tertiary aminoalcohols as well as a decrease of reaction rate with increase in the length of the hydrocarbon chain by a CH_2 group in the alcoholic component of the ester[88,96,101], which has been explained by steric hindrance[96].

3. Hydrolysis of Aminoalkyl Esters Protonated at the Nitrogen Atom. The Influence of the Structure of the Ester

It has been shown for esters of various acids[87-89,99,102,115] that the protonation of the amino-group increases the reactivity of the esters by 2–3 orders of magnitude compared with the initial non-protonated esters and their analogues without an NR_2 group in the alkoxy-moiety (Tables 3–5).

Such acceleration of the hydrolysis of the protonated ester can in general be a result of three effects: (a) the powerful inductive effect of the $+NHR'R''$ group via the chain of carbon atoms ($\sigma^* \simeq 3$);[122] (b) the electrostatic effect of the positive charge on the nitrogen atom (the interaction of N^+ with the C=O group); (c) the effect of the intramolecular hydrogen bond (IAHB) $^+NH\ldots O=C$.

These effects can be separated and their contributions to the overall acceleration of the hydrolysis can be estimated quantitatively with the aid of correlation analysis[123] using the principles described by Palm et al.[124] and assuming that each effect is independent of the structure of the acyl residue. In this case the inductive effect, calculated from the data of Ignat'eva et al.[100], accelerates the reaction by a factor of 4–5 and the electrostatic effect, determined for the $^+N(CH_3)_3$ group, accelerates it by a factor of 5–6. Bearing in mind that the values of σ^* and the electrostatic effects for the $^+NR_3$ and $^+NHR'R''$ groups are approximately the same, the difference by a factor of 15–40 between the values of k_{OH^-} for compounds with the $^+NR_3$ and $^+NHR'R''$ groups can be regarded as a result of the catalytic effect of the intramolecular hydrogen bond. The inductive effect and other factors have been shown by a computational procedure to exert their influence in the same order[88,100,102].

The hypothesis of the intramolecular interaction of the carbonyl and protonated amino-groups via hydrogen bonding, put forward for the first time by Shätzle et al.[93], has been used by many investigators[87,88,124-126] to explain the acceleration of the hydrolysis of the protonated forms of the aminoesters. However, convincing evidence for such interaction was obtained only in studies of the structural influences on the reactivities of the aminoesters[88,89,99,100,102,115,127].

The following characteristics of the influence of the structure confirm this hypothesis. (1) An increase of k''_{OH^-} with decrease of pK_a for the aminoester has been observed[88,99,102]. Since the energy of the hydrogen bond depends on the acidity of the dialkylammonium groups, it was natural to suppose that the decrease of pK_a should lead indirectly to an increase of the strength of the intramolecular hydrogen bond and hence to an enhancement of the catalytic effect of the $^+NHR'R''$ group, causing the increase of k''_{OH^-}. This has been confirmed by the linear variation of lg k''_{OH^-} with pK^0_a, observed by Tur'yan et al.[99]. It has been suggested[102] that, following the introduction of a phenyl residue into aminoethyl ester molecules (in contrast to aminopropyl esters, the $-I$ effect in the α-position of the alkoxy-group accelerates the reaction for the same reason, while the inductive effect of the C_6H_5 group on the carbonyl atom should be the same regardless of the length of the chain between the carboxy- and amino-groups. (2) The increase in the length of the chain between the nitrogen atom and the ester group by one CH_2 unit decreases k''_{OH^-} by a factor of 4–8, while the expected decrease due to the inductive effect is by a factor of 7–15.[102]. (3) The effect of the spatial proximity of the ammonium and ester groups, discovered by Babaeva et al.[127] on comparing the rates of hydrolysis of esters of the ethylene and acetylene series,

$$\Delta \lg k''_{\mathrm{OH}^-} = \lg k''_{\mathrm{OH}^-(\overset{+}{\mathrm{N}}\mathrm{HR'R''})} - \lg k_{\mathrm{OH}^-(\overset{+}{\mathrm{N}}(\mathrm{CH}_3)_3)},$$

is responsible for the increased reactivity of the protonated forms of the aminoester. When such proximity was hindered, the difference between the rate constants for the $^+NR_3$ and $^+NHR'R''$ derivatives was not greater than by a factor of 1.5–2. (4) The observed correlation[100] between $\Delta \lg k''_{\mathrm{OH}^-}$ ($\Delta \lg k''_{\mathrm{OH}^-(\overset{+}{\mathrm{N}}\mathrm{HR'R''})} = \lg k''_{\mathrm{OH}^-(\overset{+}{\mathrm{N}}\mathrm{HR'R''})} - \lg k_{\mathrm{OH}^-[\overset{+}{\mathrm{N}}(\mathrm{CH}_3)_3]}$) and the sum of the Taft constants $\Sigma\sigma^*_{\mathrm{R_i}}$ of the substituents at the nitrogen atom also constitutes significant confirmation of the influence of the

$^+$NHR′R″ group via intramolecular hydrogen bonding. The similarity of the values of ρ^* in the relations between $\lg k'_{\mathrm{OH}^-}$ and σ^*_{R} (for esters with a variable alkoxy-group) and between $\Delta \lg k''_{\mathrm{OH}^-}$ and $\Sigma\sigma^*_{\mathrm{R}}$ led to the conclusion[100] that the efficiences of the transmission of influences via the chain of carbon atoms and via the intramolecular hydrogen bond are approximately the same.

Thus the intramolecular interaction between the carbonyl and ammonium groups, transmitted via the hydrogen bond, is dominant in the acceleration of the hydrolysis of the protonated aminoester. However, the mechanism of this interaction between the functional groups cannot be accounted for by a change in the electron density at the carbonyl carbon atom, as suggested by some investigators[88,128]. The study of the activation parameters (activation energy and the pre-exponential factor)[71,102] showed that the acceleration of the reaction of the protonated aminoester owing to intramolecular hydrogen bonding is most probably associated with the interaction of the solvent with the initial and transition states in the reaction and that the main influence of the hydrogen bond is most probably manifested in the transition state, where it facilitates proton transfer from $\mathrm{N^+H}$ to $\mathrm{O^-}$ [see the process mechanism below; stage (II) in mechanism (17)], rather than in the initial state. The latter factor leads to a decrease of the degree of solvation of the transition state and hence to a change in solvation entropy. Data obtained in a study[103] of the infrared spectra in the region corresponding to the vibrational band of the C=O bond of aminoesters, characterising the initial state of the ester group, as well as the results of a ^{1}H NMR study[129] of the $\overset{+}{\mathrm{N}}\mathrm{H}\ldots\mathrm{O{=}C}$ interaction agree with the conclusion that there is no hydrogen bond in the initial state of the protonated aminoester[102]. Although the ^{1}H NMR data were obtained in chloroform and cannot be transferred mechanically to aqueous solutions in which the hydrolysis was studied, they also support the view that there is no intramolecular hydrogen bond in the initial state of the aminoester molecule (the earlier attempts at a direct determination of the strength of the hydrogen bond[130] were unsuccessful).

4. Kinetics of the Hydrolysis of the Aminoalkyl Esters in a Two-phase Water–Organic Liquid Emulsion

The study of the kinetics of chemical reactions in multiphase systems is of great theoretical and practical interest[131-133]. The theoretical and experimental principles of the application of the polarographic method in the study of the kinetics of chemical reactions in a two-phase emulsion system (water–benzene), including the study of the kinetics of the hydrolysis of aminoesters in such a system[135], were examined for the first time by Tur'yan et al.[134]. This type of system makes it possible to simulate to some extent the conditions of emulsion polymerisation[134] and this is very important from the practical point of view. On the other hand, owing to the rapid establishment of the equilibrium distribution of the components in the emulsion (large contact area), it is possible to test important theoretical relations for the kinetics of reactions in multiphase systems[134].

A polarographic study of the kinetics of the hydrolysis of aminoesters in a two-phase water–organic liquid emulsion has been made[135] and data have been obtained[135] for the equilibrium distribution of the aminoester between the aqueous and benzene phases, these being necessary for a theoretical interpretation of the kinetic measurements and for the development of a polarographic method whereby the aminoester can be determined (see below).

It has been shown[135] that in the general case the distribution of the aminoester between the aqueous and benzene phases is complicated by the dissociation of the protonated aminoester in the aqueous phase and, regardless of the pH of this phase, virtually only the non-protonated form of the aminoester is distributed in the water–benzene emulsion. These conclusions have been justified experimentally by the following findings: (1) the dependence of the partition coefficient $(K_\mathrm{c})_\mathrm{A}$ on the pH of the aqueous phase; (2) the suitability for the calculation of the partition coefficient of the expression

$$(K_c)_\mathrm{A} = \frac{(C_\mathrm{RN})_\mathrm{B}(K_a + a_{\mathrm{H^+}}/f_{\mathrm{H^+}})}{K_a\,(C^0_\mathrm{est})_{\mathrm{H_2O}}}, \tag{14}$$

where $(K_\mathrm{c})_\mathrm{A}$ is the ratio of the equilibrium concentrations of the non-protonated form of the aminoester in the aqueous and benzene phases. Eqn. (14) has been obtained taking into account the equilibrium between the protonated and non-protonated aminoester forms; the concentration of the latter is expressed in terms of the acid dissociation constant of the aminoester and its experimental overall concentration in the aqueous phase $(C^0_\mathrm{est})_{\mathrm{H_2O}}$. The partition coefficient calculated in this way (Table 6) was constant.

Table 6. The partition coefficient and the rate constants for the hydrolysis of diethylaminoethyl methacrylate in the water–benzene system at 25 °C (polarographic method)[135].

$(K_\mathrm{c})_\mathrm{A}$	k_1^{EM}, min^{-1} (expt.)	k_1^{EM}, min^{-1} (calc.)	$k_1^{\mathrm{H_2O}}$, min^{-1}
210±1.6	$9.9\cdot10^{-5}$	$9.3\cdot10^{-5}$	$1.1\cdot10^{-2}$

Alkaline hydrolysis of aminoesters in the emulsion at a constant pH is a pseudomonomolecular process and is described by the equation for first-order kinetics with respect to the aminoester[135].

A kinetic equation suitable for the polarographic study of the kinetics of chemical reactions in a two-phase system under the conditions of the equilibrium distribution of the components has been obtained[134] on the basis of the study of Abramzon and Kogan[133]. The equilibrium conditions are quite reliably realised in the case of an emulsion[134,135]. The above equation for the pseudomonomolecular alkaline hydrolysis of the aminoester in the emulsion (bearing in mind that the reaction proceeds virtually only in the aqueous phase and the concentration of $\mathrm{OH^-}$ ions in the benzene phase is insignificant) is of the following form[135]:

$$\lg \bar{i}_\mathrm{lim} = \mathrm{const} - \frac{1}{2.3}\,\frac{V_1 k_1^{\mathrm{H_2O}}}{V_1 + V_2 (K_c)_\mathrm{A}}\,t = \mathrm{const} - k_1^{\mathrm{em}} t, \tag{15}$$

where t is the duration of hydrolysis, V_1 and V_2 are the volumes of the aqueous and benzene phases respectively, and $k_1^{\mathrm{H_2O}}$ is the rate constant for alkaline hydrolysis in the aqueous buffer solution at the same pH and ionic strength as in the aqueous phase of the emulsion.

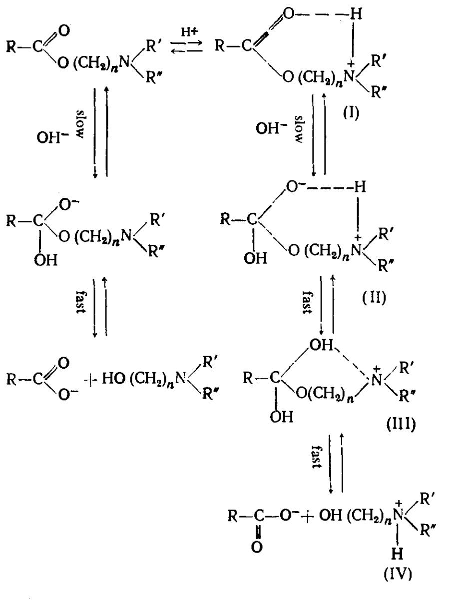
The sharp decrease of the effective rate constant in the emulsion (k_1^{em}),

$$k_1^{em} = \frac{1}{2.3} \cdot \frac{V_1 k_1^{H_2O}}{V_1 + V_2 (K_c)_A} \quad , \qquad (16)$$

compared with the aqueous medium (Table 6) has been explained by the redistribution of the reactants between the phases: the aminoester passes almost completely to the benzene phase [$(K_c)_A = 210$], while the hydrolysis proceeds in the aqueous phase. The validity of the theoretical postulates has been confirmed by the similarity of the experimental effective rate constant for the hydrolysis of the aminoester in the water–benzene emulsion and the value calculated by Eqn. (16).

5. The Mechanism of the Hydrolysis

The alkaline hydrolysis of the aminoalkyl esters (in both protonated and non-protonated forms) by hydroxide ions proceeds via a bimolecular $B_{AC}2$ mechanism (according to Ingold's classification)[136] and, when account is taken of the nature of the interaction of the functional groups discussed above, the overall reaction can be described by the following scheme[71,99,102]:



(17)

IV. THE KINETICS AND MECHANISM OF ISOMERISATION

1. Process Kinetics

In a series of acryl derivatives of aminoalkanols, aminophenols, and other compounds containing in the molecule both the hydroxy-group and primary or certain secondary amino-groups, the O–N migration of the acyl group is a well known phenomenon[95,105,137-144], but most studies on the latter have been qualitative or semiquantitative.

The results obtained at the beginning of the 1960s led to the conclusion that esters containing a primary or secondary amino-group can as a rule exist only in the protonated form, the free bases rearranging to the corresponding amides[95,105,139-144]. It has been established that the process is intramolecular, the dependence of the rate of reaction on the pH of the medium has been demonstrated, and the hypothesis has been put forward that an intermediate compound of the type of hydroxyoxazolidine is formed in the reaction.

A number of studies have been made on the reaction kinetics[52,126,145-147]. The kinetics of the O–N isomerisation of *O*-acetylethanolamine to *N*-acetylethanolamine have been studied by the pH-stat method in the pH range from 7.0 to 9.7.[126] Using a spectrophotometric method, the same reaction was studied in a buffer system at pH 7.9, 8.2, and 8.5.[146]

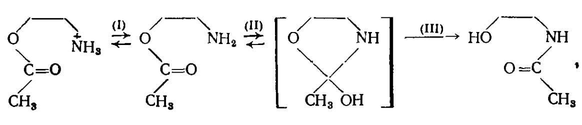
The O–N migration of the acyl group in a series of aminoalkyl methacrylates in the pH range 8.0–10.5 has been investigated in detail by the polarographic method[52,147]. This method proved to be the most promising when the aminoesters are capable of being reduced at a dropping mercury electrode (as in the study of their hydrolysis; see Sections I and III). The process in the buffer solution, where the aminoesters investigated give rise to polarographic reduction waves, was followed directly from the time variation of the limiting current, which is directly proportional to the concentration of the aminoester (the sum of the concentrations of the protonated and non-protonated forms).

The use of the polarographic method also made it possible to elucidate the influence of the simultaneous hydrolytic reaction, which was done using a different supporting electrolyte: a buffer solution at pH 4.75 containing 5% of formaldehyde[148-152]; the reduction wave of both the initial aminoester and of the hydrolysis product (the corresponding aminoalcohol) was observed in this solution[52,147]. Comparison of the results of the polarographic study in the presence and absence of formaldehyde in the solution led to the conclusion[52,147] that the hydrolysis has an extremely insignificant influence on the isomerisation kinetics. The same conclusion concerning 2-aminoethyl acetate was reached in another study[126] based on pH-stat data.

It has been noted[52,126,146,147] that the acyl group does not migrate in the protonated form of the aminoester, since nucleophilic attack by the protonated amino-group on the carbonyl carbon atom bearing a partial positive charge is unlikely. The reaction is both catalysed by hydroxide ions[52,126,146,147] and is subject to general base catalysis[146,147].

The isomerisation kinetics at constant pH are described by a first-order equation with respect to the aminoester[52,126,146,147]. Using the polarographic method, the experimental rate constants k_{exp} can be found by means of Eqn. (12) from a plot of $\lg \bar{i}_{lim}$ against t. Division by the coefficient $p = K_a/\{K_a + [H^+]\}$ (K_a is the acid dissociation constant of the aminoester), defined as the fraction of the non-protonated form of the aminoester, yields the rate constant referred to the non-protonated form.

The variation of $\lg(k_{exp}/p)$ with pH is illustrated in Fig. 6. On the basis of Hansen's experimental results[126], it has been shown[153] that the above relation has a similar form for the isomerisation of 2-aminoethyl acetate. The complexity of the dependence of the rate of rearrangement on the pH could not be accounted for by Hansen's mechanism[126]:



(18)

according to which stage (III) is catalysed by hydroxide ions and the rate-limiting stage varies with pH: stages (III) and (II) are rate-limiting at low and high pH values respectively.

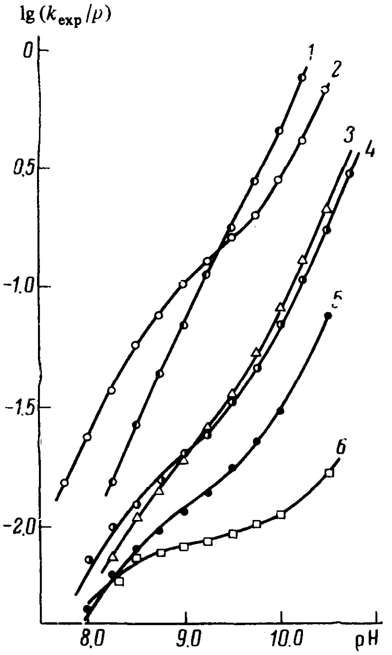


Figure 6. Variation with pH of the experimental isomerisation rate constant referred to the non-protonated form of the aminoester[52,147]. Symbols—experimental data; curves—calculated data: 1) $M-OCH_2CH_2NHCH_3$; 2) $M-OCH_2CH_2NH_2$; 3) $M-OCH_2CH_2NHC_2H_5$; 4) $M-OCH_2CH_2NHC_4H_9$-n; 5) $M-OCH_2CH_2NHC_4H_9$-iso; 6) $M-OCH_2CH_2NHC_3H_7$-iso.

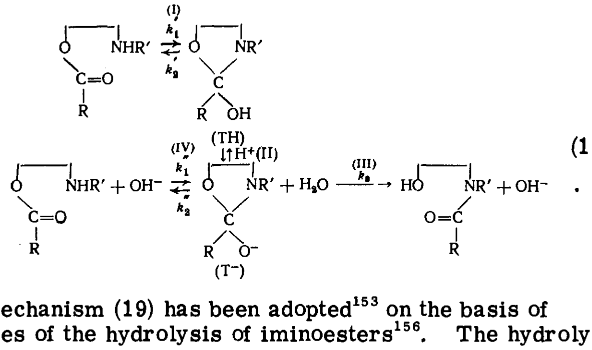
The most probable mechanism, which can account for the O-N migration of the acyl group[52,147,153] is analogous to the mechanism of the aminolysis of esters[153-155] and can be described by the following scheme[52,147]:



(19)

Mechanism (19) has been adopted[153] on the basis of studies of the hydrolysis of iminoesters[156]. The hydrolysis of iminoesters and the aminolysis of esters are accompanied by the formation and cleavage of the same types of intermediates.

In contrast to the studies by Hansen[126] and Martin et al.[146], in mechanism (19) account is taken of two forms of the intermediate—the undissociated form (TH) and the anion (T^-). It has been shown[153] that the undissociated form is not converted directly into the amide. Application of the method of steady states with respect to $[TH] + [T^-]$ in relation to the polarographic method yielded the following kinetic equation[52,147]:

$$\frac{d\bar{i}_{\lim}}{dt} = \frac{(k_1' + k_1''[OH^-])\,k_3\frac{K_1}{[H^+]}}{k_2' + (k_2'' + k_3)\frac{K_1}{[H^+]}}\,\frac{K_a}{K_a + [H^+]}\,\bar{i}_{\lim}, \tag{20}$$

where K_1 is the acid dissociation constant of TH; the rate constants k_2'' and k_3 include the concentration of water. k_1' includes not only the rate constant for the non-catalysed stage but also the kinetic terms associated with catalysis by the HPO_4^{2-} and CH_3COO^- ions of the universal buffer mixture[147]. At pH 8–10.5 these terms are almost independent of the pH, since the concentrations of the above ions change insignificantly in this range; therefore the rate constant k_1' can be referred to by convention as the rate constant of the non-catalysed stage. It has been shown[52,147] that the catalytic effect of the borate anion may be neglected.

Eqns. (12) and (20) with $[H^+]$ replaced by $[OH^-]$ yielded the relation describing the experimental rate constant for the migration of the acyl group in the non-protonated form of aminoalkyl methacrylates[147]:

$$\frac{k_{exp}}{p} = \frac{(k_1' + k_1''[OH^-])\,(k_3K_1/k_2'K_w)\,[OH^-]}{1 + \frac{(k_2'' + k_3)\,K_1}{k_2'K_w}[OH]^-}, \tag{21}$$

where K_W is the ionic product of water. In conformity with both experiment[52,147] and theory, k_{exp} = const. at constant pH. Eqn. (21) can be rearranged to the linear relation

$$\frac{k_{exp}}{p\,[OH^-]} = a + b\,[OH^-] - c\,\frac{k_{exp}}{p}, \tag{22}$$

where

$$a = k_1'\frac{k_3K_1}{k_2'K_w}; \tag{23}$$

$$b = k_1''\frac{k_3K_1}{k_2'K_w}; \tag{24}$$

$$c = \frac{(k_2'' + k_3)\,K_1}{k_2'K_w}. \tag{25}$$

Hence, taking into account mechanism (19), we have

$$k_1' = \frac{a^2}{ac - b}; \tag{26}$$

$$k_2'' = \frac{ab}{ac - b}. \tag{27}$$

The kinetic parameters of the O–N rearrangement of the acyl group in aminoalkyl methacrylates, including the rate constants k_1' and k_1'' (Table 7), have been calculated[147] on a computer from experimental data by Eqns. (22)–(27) (Fig. 6). Solution[153] of an equation of type (20) yielded k_1' = 0.13 min^{-1} and k_1'' = 1.08 × 10^4 litre $mole^{-1}$ min^{-1} for aminoethyl acetate.

Mikhlin et al.[147] (Fig. 6) and Schmir[153] showed that the calculated lg (k_{exp}/p)–pH curves agree satisfactorily with the experimental curves. Like the kinetic curves for the hydrolysis of aminoesters, these plots are characterised by three sections: the lower and upper sections (which are steeper and approach a straight line with a slope of unity) and the middle section (with a lower slope). This type of kinetic relation has been explained [mechanism (19)] [52,147] taking into account the different effects on the process, as a function of the pH, of the non-catalysed stage (I) and the simultaneous stage (IV) catalysed by OH^- ions and also taking into account the changes in the rate-limiting stage as a function of the pH.

Table 7. The kinetic parameters of the O–N migration of the acyl group in aminoalkyl methacrylates[147] $\mathrm{M{=}CH_2{=}C(CH_3)C}\begin{smallmatrix}\nearrow\!\!\!\!\nearrow O\\ \searrow\end{smallmatrix}$.

* The values of K_a were taken from Dokolina et al.[73]

2. The Rate of Isomerisation and the Influence of the Structure of the Aminoester

The influence of the structure of aminoalkyl methacrylates on k_1'' has been analysed on the basis of the results of Mikhlin et al.[147] It has been established that the nature of the alkyl substituents at the nitrogen atom has the opposite influence on the isomerisation rate constant compared with their influence on the nucleophilic reactivity of the nitrogen atom in the amino-group. This cannot be explained by hypothesis that the rate-determining stage involves the abstraction of a proton from the amino-group, based on the Taft inductive effect[157], because the compound with the allyl substituent deviates appreciably from the correlation, and, furthermore, the coefficient ρ^* is found to be unrealistically large.

This behaviour of the above compounds, as in other reactions of amines with electrophilic agents[158-160], can be explained by the influence of steric effects. It was noted previously[144] that the steric factor can have a decisive influence on the rate of the O–N migration of the acyl group and that aminoalkyl methacrylates with a t-alkyl group at the nitrogen atom of a secondary amino-group or with a primary amino-group at a tertiary carbon atom do not undergo isomerisation at all[161,162]. The ability of arylaminoalkyl methacrylates and acrylates to exist without O–N isomerisation can be accounted for by the steric effect in combination with the reduced nucleophilicity of the nitrogen atom in the secondary arylamino-group[164].

The use of Eqn. (28), which takes into account not only the Taft[157] steric effects[165,166] but also the steric effect of the "sixth" atom, revealed[52,247] a satisfactory correlation (Table 8) with respect to k_1'':

$$\lg k_1'' = \lg k_0 + \rho^*\sigma^* + \delta E_s^c + \gamma\Delta\sigma. \qquad (28)$$

Best results were obtained with E_s^c and E_s^0; the correlation with E_s was much less satisfactory.

A satisfactory correlation has also been obtained[147] using the Swain–Scott equation[165]:

$$\lg k = a + sn = (-18.4 \pm 3.9) + (4.2 \pm 0.8)\,n; \quad (r = 0.935;\ S = 0.252). \qquad (29)$$

The nucleophilicities in Eqn. (29) were taken from Hall's paper[166] for the corresponding primary amines. The aminoester with a primary amino-group deviates from the correlation.

The rate constant for the isomerisation of 2-aminoethyl methacrylate is higher than for 2-aminopropyl methacrylate, which can be explained by the more powerful influence in the former instance of the inductive effect of the amino-group via the chain of carbon atoms.

In conclusion one should note that the rate of migration of the acyl group in 2-aminoethyl methacrylate[147] is lower than the rate of the analogous reaction for 2-aminoethyl acetate[126,153] owing to the conjugation effect.

Table 8. The parameters of the correlation based on Eqn. (28).[147]

Steric constant	$\lg k_0$	ρ^*	δ	γ	r	S
E_s^c	3.63±0.06	−2.10±0.22	1.75±0.09	0.144±0.011	0.998	0.041
E_s^0	3.64±0.07	−1.98±0.29	1.99±0.13	0.166±0.015	0.997	0.055
E_s	3.20±0.26	−8.13±3,54	3.26±1.17	0,33±0.11	0.939	0.258

V. ANALYTICAL APPLICATIONS

The ability of aminoalkyl esters of $\alpha\beta$-unsaturated acids to be reduced at a dropping mercury electrode has been used in the development of polarographic methods for the analysis of the esters. The polarography is usually carried out with quaternary ammonium salts as the supporting electrolytes in non-aqueous solvents (methanol, ethanol, and dimethylformamide).

A polarographic method for the determination of monomeric aminoalkyl acrylates and methacrylates in the presence of their polymers and copolymers with *N*-vinylcarbazole has been proposed[68,69]; a 0.05 M solution of $(C_2H_5)_4NI$ in dimethylformamide was used as the supporting electrolyte.

The possibility of the polarographic determination of diethylaminoethyl methacrylate in a mixture with acrylonitrile using a 0.025 M solution of $(C_2H_5)_4NI$ in methanol as the supporting electrolyte has also been demonstrated[86]. A method for the determination of the residual monomeric diethylaminoethyl methacrylate in the latex has been described[65]; it is based on the extraction of the aminoester from the reaction mixture with benzene and its subsequent polarography in a solution of a tetraalkylammonium salt in a benzene–ethanol mixture. As stated above, owing to the high partition coefficient, quantitative extraction is simple and rapid[65].

In contrast to non-aqueous solutions of tetraalkylammonium salts, a more readily available electrolyte—the universal buffer solution (pH 7.5) in which NaOH has been replaced by LiOH in order to obtain a more distinct threshold of the wave—has been proposed[65] as the supporting electrolyte. The method is based on the selection of the optimum pH, concentrations of the buffer components, and the ionic strength of the supporting buffer solutions.

Application of the Mass Spectrometry of Negative Ions to Organic Chemistry

V.I.Khvostenko and G.A.Tolstikov

Experimental work on the dissociative capture of electrons by organic molecules is surveyed, and the main processes involved in the interaction between such molecules and electrons are discussed. Special attention is paid to the specificity of mass spectra. The mass spectrometry of negative ions not only supplements traditional mass spectrometry but also enables several novel problems to be solved. A list of 100 references is included.

CONTENTS

I. INTRODUCTION

The formation of negative ions by interaction between electrons and molecules has been less investigated than has the formation of positive ions, although experimental study of the capture of electrons by molecules with mass-spectrometric recording of the negative ions was begun as early as the 1930s, at the same time as study of the formation of positive ions. This was due to the absence of reliable methods for the mass-spectrometric investigation of negative ions and the experimental difficulties of working with such ions. However, discovery of the ability of negative ions to excite vibrational and rotational levels of molecules in radiation-induced reactions, by the elastic and inelastic resonant scattering of electrons, has caused the recent increase in the number of publications on the formation of negative ions.

The study of negative ions has shown a general tendency for increasingly complicated species to be investigated. Whereas in the 1950s simple diatomic and triatomic molecules were examined almost exclusively, at the present time increasing attention is being paid to complex molecules, including those of organic compounds. It is also planned to use mass spectra of negative ions to solve structural and analytical problems of organic chemistry.

Progress in the theory of resonances accompanying interaction between electrons and molecules[1-6], as well as development of electron-impact spectrometry[7], increased the interest taken in the capture of electrons by molecules with the formation of negative ions. At the same time advances in experimental technique promoted the development of improved methods of examining negative ions. The monochromatisation of electrons[8,9], enhancement of the sensitivity of the recording apparatus, and the development of objective methods for calibrating the scale of electron energies[10,11] have enabled reliable and reproducible values to be obtained for the appearance potentials of negative ions and the effective yield of ions from electron–molecule interaction.

Several monographs[12-15] and reviews[16,17], dealing broadly with the problems of studying negative ions, have appeared recently. However, they do not devote much space to organic compounds, although the negative-ion mass spectrometry of organic compounds is acknowledged to be a promising and important trend.

The present Review examines published work on the dissociative capture of electrons by organic molecules with the formation of negative ions. It does not cover the large group of publications on the mass spectrometry of negative ions[18-25] in which the experimental technique of the traditional mass spectrometry of positive ions is imitated. While recognising the importance of this work, we must note that the ambiguity in interpreting processes leading to the formation of negative ions in these cases diminishes the theoretical value of the results and prevents their practical exploitation.

II. FORMATION OF NEGATIVE IONS. RESONANCES IN SCATTERING CROSS-SECTIONS OF ELECTRONS WITH MOLECULES

The main processes involved in the formation of negative ions by single collisions can be expressed

$$1)\quad AB + e \rightarrow (AB)^{*} + e \rightarrow A^{-} + B^{+} + e$$

$$2)\quad AB + e \rightarrow (AB)^{-} \rightarrow \begin{cases} \left.\begin{array}{l} A^{-} + B \\ B^{-} + A \end{array}\right. \text{(dissociative electron capture)} \\ \left.\begin{array}{ll} (AB)^{*} + e & \text{inelastic} \\ (AB) + e & \text{elastic} \end{array}\right\} \begin{array}{l} \text{electron} \\ \text{scattering} \end{array} \end{cases}$$

The first process consists in dissociation of a molecule, excited by electron impact, into two fragments with opposite charges. The dependence of the effective yield of ions on the energy of the electrons is the same as for the formation of positive ions, i.e. a smooth increase in yield with increase in energy from the threshold at which ions appear to a maximum (when the energy of the electrons exceeds the threshold by a factor of 3–4), which is followed by a slow decrease in yield.

The second process–capture of an electron by the molecule with formation of a short-lived negative molecular ion $(AB)^-$—is a resonance process occurring within a narrow range of electron energies (0.01–2 eV). If the law of the conservation of energy permits, the molecular ion may dissociate into negative splinter ions: i.e. dissociative capture of electrons takes place. If dissociation is impossible, the existence of the negative molecular ion ceases with the ejection of the electron (autoionisation), and elastic or inelastic resonance scattering of electrons is observed†. Autoionisation (autodetachment of an electron) always takes place, whether or not accompanied by dissociation of the negative molecular ion (dissociative electron capture), and in the former case competes with the latter process. The mean lifetime of the negative molecular ion with respect to autoionisation τ is a characteristic of the process of electron capture by a molecule.

The mechanism of establishment of the temporary bond between molecule and electron may be that on impact the electron loses its energy in the electronic excitation of the target molecule and finds itself in a bound state which has an energy below that of the excited state of the target. The electron cannot be detached while the molecule remains in an excited state; the lifetime of the resonant state is relatively long, 10^{-13}–10^{-14} s. Such resonances have been termed "electronically excited Feshbach resonances"[4].

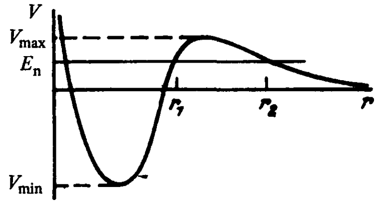

Figure 1. Typical interaction potential of electron and molecule (atom) for shape resonance: E_n is the energy of the trapped electron, and r_2–r_1 the range of effective action of the barrier.

Another mechanism for formation of temporary negative ions, without necessarily entailing excitation of the target molecule, involves the so called shape resonances (single-particle resonance, if electron capture takes place without excitation of the molecule, and electronically excited shape resonance). With shape resonance the bond between electron and molecule is established by the combined action of polarisation and exchange forces attracting the electron to the molecule and of the centrifugal force of repulsion when the incident electron possesses angular momentum relative to the target. The electron may be trapped in a quasi-discrete level of the potential well (Fig. 1) separated from the continuous spectrum by a centrifugal barrier. The reverse ejection of the electron takes place by tunnelling through the barrier. In contrast to Feshbach resonances, the parent state of the target has a lower energy, and ejection of the electron with transition of the molecule to the parent state (for the given resonance) is not energetically forbidden. The lifetime before autodetachment of the electron is determined for shape resonances by the width of the centrifugal barrier and the depth of the quasi-discrete level, and lasts 10^{-14}–10^{-15} s.

The so called vibrationally excited Feshbach resonance is due to electron capture at vibrationally excited levels of the molecular ion. If the electron affinity of the molecule is positive, the ground state of the negative molecular ion lies below that of the molecule. However, the vibrational energy of the negative ion can exceed the electron affinity of the molecule, and the vibrational levels of the ion will lie above the ground state of the molecule. An electron having positive energy may then be trapped at vibrationally excited levels of the ion. The kinetic energy of the electron is converted directly (without electronic excitation) into nuclear motion of the ion. Vibrationally excited Feshbach resonance is due to breakdown of the Born–Oppenheimer principle[4]. The lifetime before autoionisation of negative molecular ions formed with such resonance is extremely long in polyatomic molecules, reaching several tens of microseconds[15,16].

With vibrationally excited Feshbach resonance autoionisation of the negative ion may be prevented by a change in molecular configuration on conversion into the ion. A fairly long time would elapse before the configuration of the molecule–electron system would return to or approach the configuration before electron capture, from which autoionisation is possible.

Dissociative electron capture can thus be regarded as occurring in two stages: capture of an electron by a molecule with formation of a negative molecular ion (having a lifetime τ_a characteristic of a given process) is followed by dissociation along possible paths. According to O'Malley[3] the effective formation cross-section of negative ions in dissociative electron capture by diatomic molecules is given by the formula

$$\sigma = \mathrm{e}^{-\rho} C \frac{\Gamma_a}{\Gamma_d} \exp\left[\frac{{}^1\!/_2\Gamma_a^2 (E - E_0)^2}{{}^1\!/_4\Gamma_d^2}\right]; \quad \rho \approx \frac{\tau_d}{\tau_a},$$

where $\Gamma_a = \hbar/\tau_a$ is the so called autoionisation resonance width, τ_a the mean lifetime before autoionisation, Γ_d the observed width at mid-height on the peak effective yield of negative ions, τ_d the mean time of dissociation of the molecular ion into a negative ionic fragment and a neutral atom (radical), E the energy of the electron, E_0 the energy characteristic of the given process (closely similar to the energy corresponding to the maximum yield of ions), and $\hbar$ is Planck's constant.

This formula can be written $\sigma = \sigma_{cp}\mathrm{e}^{-\rho}$, where σ_{cp} is the cross-section for capture of the electron by the molecule and $\mathrm{e}^{-\rho}$ the probability of dissociation into a negative ion and a neutral fragment. The term $\mathrm{e}^{-\rho}$ is called the "survival factor", since it determines the proportion of molecular ions that have avoided autoionisation and have dissociated with the formation of stable (for the given experiment) negative ions. The dependence of τ_d on the reduced mass of the fragments that scatter on dissociation may be responsible for the so called isotope effect in

---

† Reverting to the mass spectrometry of negative ions by the technique used for positive ions (fixed electron energy 50–70 eV, no control of the energy distribution of electrons in the ion source), we note that two processes—dissociative capture of electrons by molecules and the dissociation of molecules into ion-pairs—yield negative ions under these conditions. Dissociative capture takes place with electrons that have lost part of their energy in collisions with the walls of the ionisation chamber and with electrons produced by secondary emission. The relative contributions by these two processes to the ion current depend on the material and the design of the ionisation chamber, i.e. on the experimental conditions, which are difficult to standardise. This explains the poor reproducibility of the mass spectra of negative ions obtained in this way[18,19,26].

the measurement of the formation cross-section of negative ions[3,27]. However, Γ_d also depends on the reduced mass, and the change in ion-formation cross-section on isotopic substitution is determined not only by the survival factor[3,28,29].

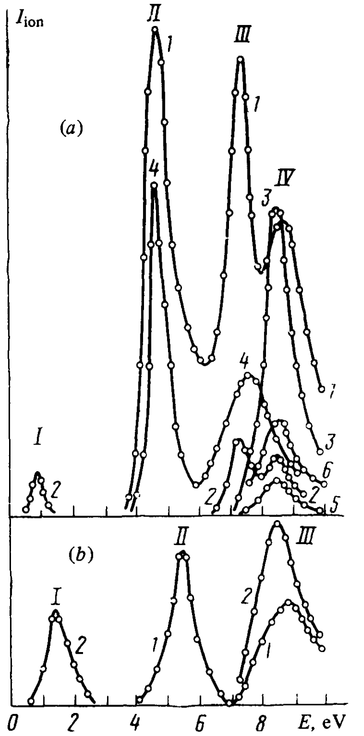

Figure 2. Curves of effective yields of negative ions for: (a) dimethyl sulphide: 1) S^-; 2) SCH_3^-; 3) SCH_2^-; 4) CH_3^-; 5) CH_2^-; 6) SH^-; and (b) di-isopropyl sulphide: 1) S^-; 2) $SC_3H_7^-$.

According to O'Malley[3] the above formula for σ is applicable also to polyatomic molecules, if all the quantities in it are assigned to separate normal vibrations of the molecule. A consequence of the multichannel breakdown of negatively charged polyatomic molecules is the formation of ions having different m/e ratios in the same resonance range of electron energies. While remaining within the same resonance region, the positions of the maximum yields of individual ions on the scale of electron energies $E_{\max}$ coincide neither with each other nor with the energy corresponding to maximum formation of the parent molecular ion. It follows from O'Malley's formula

$$E_{\max}=E_0-{}^1/_8\Gamma_d^2\left(\frac{d\rho}{dE}+\frac{1}{E}\right);\quad \frac{d\rho}{dE}>0$$

that $E_{\max}$ for each channel of formation of an ionic fragment depends on $d\rho/dE$, which in turn is determined by the direction of dissociation of the molecular ion ($\rho = \tau_d/\tau_a$).

Another reason for the difference in values of $E_{\max}$ for ionic fragments may be the formation of ions having different m/e ratios by consecutive decomposition of the type

$$(ABCD)^{\overset{\bullet}{-}} \xrightarrow{CD^{\dot{-}}} (AB)^{\overset{\bullet}{-}} \rightarrow A^- + B\ .$$

The AB^- ions are formed in a vibrationally excited state, and some of them, for which the energy of excitation exceeds the energy of the A–B bond, dissociate into A^- and B. With increase in the energy of the trapped electron (within the resonance range) the number of AB^- ions capable of dissociating increases: i.e. the maximum yield of A^- ions will shift to higher electron energies relative to the maximum yield of AB^- ions. This can be illustrated by the curves for the effective yield of $SC_3H_7^-$ and S^- ions from di-isopropyl sulphide[30] (Fig. 2); the latter ions are probably formed by the breakdown of excited $SC_3H_7^-$ ions. (Raising the temperature in the ionisation chamber, as would be expected, increases the yield of S^- ions.)

It is appropriate here to examine the energy balance of dissociative electron capture

$$AB + e \rightarrow (AB)^{\overset{\bullet}{-}} \rightarrow A^- + B\ .$$

Denoting the appearance potential of A^- ions by Aptl(A^-), the energy of dissociation of A–B by D(AB), and the electron affinity of an A atom (radical) by EA(A), we have

$$\text{Aptl}\ (A^-) = D\,(AB) + EA\,(A) + \varepsilon_{tr} + \varepsilon_{ie}$$

where ϵ_{tr} is the translational energy of the reaction products and ϵ_{ie} the energy of internal excitation of the fragments. The corresponding expression for B^- is

$$\text{Aptl}\ (B^-) = D\,(AB) + EA\,(B) + \varepsilon'_{tr} + \varepsilon'_{ie}).$$

In a series of papers Franklin et al.[31-33] obtained a formula linking the mean translational energy $\bar{\epsilon}_{tr} = \epsilon^*/\alpha N$ with the excess energy ϵ^* (the energy exceeding the threshold for dissociative electron capture: $\epsilon^* = \epsilon_{tr} + \epsilon_{ie}$) and the number of vibrational degrees of freedom of the molecule N, in which α is a semi-empirical parameter having the value 0.42 for such processes.

The chief experimental methods for studying resonances in the scattering of electrons by molecules are currently electron-impact spectroscopy and the mass-spectrometric investigation of resonant processes in the formation of negative ions. The former is characterised by relatively high energy-resolving power, which ensures accurate determination of the position of resonant levels and the possibility of recording short-lived negative molecular ions. The variety of experimental methods in electron-impact spectroscopy (each of which has its advantages) can be regarded as a virtue, permitting a flexible approach to solving a problem. Information on the energy levels of atoms or molecules is obtained by analysing the changes in momentum and energy of electrons in single collisions between electrons in the primary beam and atoms or molecules. A review has been published on electron-impact spectroscopy[7].

Negative-ion mass spectrometry involves a more reproducible technique: the rigid requirements of mass spectrometry do not permit wide variation in the design of the ion source or the experimental conditions. However, the mass analysis of the ionic fragments and the absence of a background of potential scattering (only resonance processes are recorded) make it possible to examine resonance phenomena in the interaction of electrons with complex molecules, as yet inaccessible to electron-impact spectroscopy.

Experimental procedure in mass-spectrometric investigations has been described repeatedly in reviews and monographs[12-17,34]. Study of dissociative electron capture by recording negative ions is undertaken with the usual mass spectrometers (static or time-of-flight). Changing to the registration of oppositely charged ions for the investigation of dissociative electron capture requires, of course, not only simple reversal of fields (electric and magnetic), but also several design modifications of the ion source (connected mainly with the need to monochromatise the electron beam and calibrate the electron-energy scale), and the sensitivity of the instrument must be improved. However, the conversion of commercial mass spectrometers into instruments suitable for investigating dissociative electron capture by molecules with the formation of negative ions is technically not a complicated task[11,35,36].

III. DISSOCIATIVE CAPTURE OF ELECTRONS BY ORGANIC MOLECULES

The studies considered in the present Section are not all equivalent with respect to the experimental technique used. Different workers employed apparatus of different sensitivities; different reference points were used for calibrating the electron-energy scale; and the energy distribution of the electrons was not strictly the same. In several studies attention was paid mainly to measuring the appearance potentials of the negative ions, without determining the positions of the maximum yields of ions on the electron-energy scale; in other cases the efficiency of the emission of ions was not determined[37,38]. Despite the differences in experimental technique, however, the values cited in the present Section from various publications are mutually comparable. The deviations (±0.2–0.3 eV for the positions of the resonance peaks on the energy scale, and ±20% for the relative intensities of the ions) are not so significant as to support the currently held view that data on dissociative electron capture by molecules show poor reproducibility[39-42].

1. Alkanes

Several papers have been published on dissociative electron capture by alkane molecules[37,39,43-45]. Methane exhibits two peaks representing the formation of ions having appearance potentials of 8.3 eV (H^-, CH_2^-) and 9.3–9.6 eV (H^-, CH^-, CH_2^-). Two peaks have been observed with ethane (8.3 and 9.2 eV), whereas the spectra of propane, n-butane, and isobutane contain one resonance peak corresponding to the formation of ions having appearance potentials of 7.6–7.8, 7.8, and 7.4–7.5 eV respectively[39]. The greatest probability of formation is found with H^- ions ($\sigma \simeq 10^{-19}$ cm^2). A comparatively large formation cross-section was noted for the ions CH_2^- and CH^- ($\sim 10^{-19}$ and $\sim 10^{-20}$ cm^2) from methane, CH_2^- from ethane, and CH_3^- from propane and isobutane ($\sim 10^{-20}$ cm^2). The formation cross-sections of C_2H^-, $C_2H_3^-$, and CH_4^- ions are of the order 10^{-21}–10^{-22} cm^2.[39]

In the spectrum of tetradeuteromethane the probability of formation of D^- ions is greater, while that of CD_2^- ions is smaller than those of the corresponding processes in methane[45,46]. The ratios of the formation cross-sections are $\sigma(H^-)/\sigma(D^-) = 0.8$ and $\sigma(CH_2^-)/\sigma(CD_2^-) = 25$.

2. Alkenes, Polyenes, and Alkynes

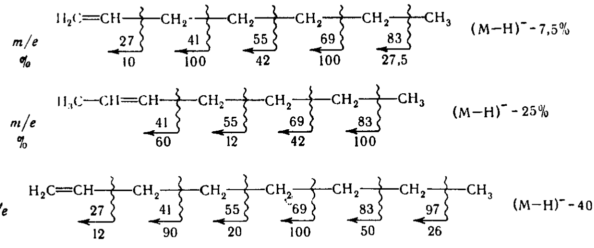
The effective-yield curves for negative ions resulting from the interaction of electrons with ethylene, propene, and isobutene molecules[39] indicate the existence of two resonance peaks of electron capture in the range of electron energies 7–13 eV. The ion-formation cross-section does not exceed 10^{-19} cm^2 in ethylene and isobutene, and 10^{-20} cm^2 in propene and but-1-ene (Table 1). The energy of excitation of the first Rydberg state ($^1B_{3u}$) of the ethylene molecules is 7.25 eV,[47] and peaks of negative ions from dissociative electron capture in ethylene can be assigned to the decomposition of $C_2H_4^-$ ions, which are formed by a mechanism of Feshbach resonances of Rydberg states of the molecules. The lowest state of the $C_2H_4^-$ ion recorded by transmitted-electron spectroscopy is responsible for the peak of resonant scattering of electrons with its maximum at 1.76 eV.[48] A molecular ion in this state breaks down without dissociation into ionic fragments. In propene a small peak due to C_2H^- ions (cross-section 10^{-21} cm^2) has been recorded with its maximum at 3.8 eV.[39]

Table 1. Appearance potentials (Aptl) of ions and their intensities*.

Ethylene			Propene			Isobutene		
ion	intensity	Aptl ± 0.3, eV	ion	intensity	Aptl ± 0.3, eV	ion	intensity	Aptl ± 0.3, eV
H^-	430	7.6;9.7	H^-	325	7.7	H^-	585	7.8
CH^-	174	7.3;8.7	CH_2^-	48	6.1;7.3; 7.8	CH^-	43.5	7.9
CH_2^-	131	8.8	CH_3^-	20	—	CH_2^-	130	7.8
C_2^-	60	10.4	C_2H^-	77	2.6;6.3; 7.6	CH_3^-	57.5	7.4
C_2H^-	520	7.1;10,0	$C_3H_3^-$	18	—	$C_3H_3^-$	58	5.8;7.6
$C_2H_3^-$	19.8	—	$C_3H_5^-$	250	5.9;7.6	—	—	—

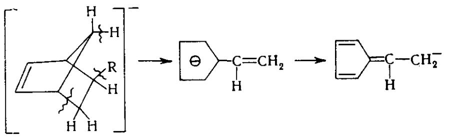
* Unit intensity corresponds to $\sigma = 10^{-22}$ cm^2.

The dissociative electron-capture mass spectra of hept-1-ene, hept-2-ene, and oct-1-ene are given below as schemes representing the rupture of the negative molecular ions together with the relative intensities at maximum effective yields of the ions, which correspond to electron-energies of ~8 eV:



These show that formation of ions is a consequence of the rupture of carbon–carbon bonds with addition of the electron to the fragment containing the double bond. However, the absolute formation cross-sections of the ions are small ($\sim 10^{-21}$ cm^2).[49]

Among 5-substituted bicyclo[2,2,1]heptene derivatives norbornene itself and 5-methylnorbornene have the simplest spectra[50,51], with three resonance peaks due to formation of the cyclopentadienyl anion $C_5H_5^-$ and one peak due to each of the ions $C_7H_7^-$, $C_4H_3^-$, and $(M - H)^-$. Formation of the $C_5H_5^-$ ion can be attributed to retrodiene decomposition, whereas the $C_7H_7^-$ ion is formed by the simultaneous rupture of carbon–hydrogen and carbon–carbon bonds:



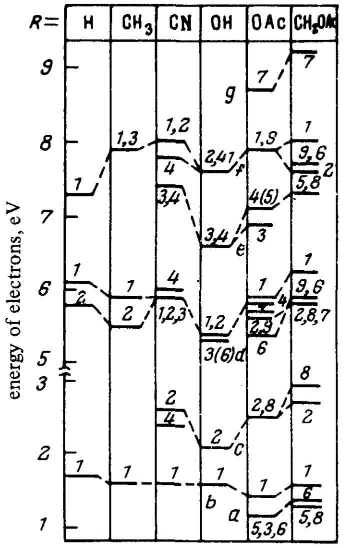


Figure 3. Positions of maximum effective yields of negative ions on scale of electron energies for interaction of electrons with norbornene and its 6-substituted derivatives: 1) $C_5H_5^-$; 2) $(M-H)^-$; 3) $RC_2H_2^-$; 4) R^-; 5) $COOCH_3^-$; 6) $COCH_3^-$; 7) C_2HO^-; 8) $(M - Ac)$; 9) $(M - OAc)$.

The process of lowest energy—emission of $C_5H_5^-$ ions at 1.6–1.7 eV—corresponds to the trapping of an electron in the first vacant π^* orbital. A second maximum, at 5.6–5.8 eV, can be assigned to Feshbach resonance involving the first triplet state of the molecules. The third peak, at 7.2–7.3 eV, is due to Feshbach resonance with excitation of Rydberg states of the molecule. Fig. 3 shows that the positions of maximum emission of ions vary with the substituent. For example, the low-energy peaks due to ions having m/e = 59.43 (levels *a*) are present in the spectra of molecules containing a CH_3COO group. The *a* level implies a single-particle resonance involving the lowest unoccupied orbital localised on the acetoxyl group. Levels *c* and *e* can be attributed to electron capture with $n \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ excitation: they are observed when the substituent contains a heteroatom with a lone pair of electrons. Thus data on the fragmentation of the negative molecular ions supplements the spectral characterisation of the molecule over a wide energy range.

Molecules of polyenes—5-methylhepta-1,3,6-triene, octa-1,3,7-triene, 6-methylnona-2,4,7-triene, 9-methylundeca-1,3,7,10-tetraene, and 3,8-dimethyldeca-1,4,6,9-tetraene—form negative ions on interaction with slow electrons, with three ranges of electron energies in which the trapping of electrons is followed by dissociation of the negative molecular ion[52,53]. The first two ranges, corresponding to maximum effective yields of ions at 2.5 and 6 eV, consist of three mass lines due to C_2H^- (m/e = 25), or $(M - H)^-$, and $(M - C_2H_3)^-$ ions, whereas in the third range, in which the maximum effective yields are grouped around 8 eV, the mass spectrum comprises six lines. The effective formation cross-section of ions corresponding to the maximum intensity is $\sim 10^{-20}$ cm^2.

It is significant that negative ions are formed predominantly by the simple rupture of bonds, without the rearrangements inherent in the breakdown of positive ions. As a consequence, the spectra of structural isomers are sharply differentiated, as is evident in the mass spectra of 5-methylhepta-1,3,6-triene and octa-1,3,7-triene (Table 2).

Table 2. Values of m/e and relative intensities (% of I_{max}) in mass spectra of negative ions of trienes.

m/e	107	81	67	55	53	51	41	27	25
5-Methylhepta-1,3,6-triene	28	76	—	42	100	80	14	57	80
Octa-1,3,7-triene	15	—	100	—	40	13	20	—	20

The formation of negative ions was interpreted as σ–π^* excitation with capture of the extra electron in an antibonding σ^*-orbital. This accompanied by β-cleavage relative to the double bond with retention of the negative charge on the fragment. Two electrons in σ^*- and π^*-orbitals form a new π^2-orbital of the negative ion, while the electron of the σ-orbital becomes a σ-electron of the neutral fragment:

$$\left[CH_2{=}CH{-}\overset{\overset{\displaystyle R_1}{|}}{C}H{-}R_2\right]^- \rightarrow CH_2{=}CH{-}\overset{\overset{\displaystyle R_1}{|}}{C}H^- + R_2\,.$$

$$\sigma\pi^*\sigma^* \rightarrow (\pi^2) + \sigma$$

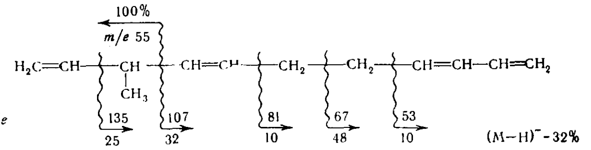
Such a process corresponds to ions of m/e 81 and 55 in the spectrum of 5-methylhepta-1,3,6-triene, and to ions 41 and 67 in that of octa-1,3,7-triene. The $\sigma\pi^*\sigma^*$-state of a negative molecular ion may lead to α-cleavage, when the negative charge will be concentrated on the fragment containing the double bond:

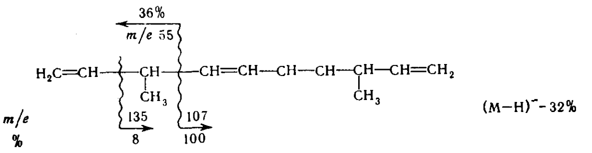
$$\left[CH_2{=}CH{-}\overset{\overset{\displaystyle R_1}{|}}{C}H{-}R_2\right]^- \rightarrow CH_2{=}CH^- + H^{\cdot}C\begin{smallmatrix}R_1\\R_2\end{smallmatrix}\,.$$

$$\sigma\pi^*\sigma^* \rightarrow (\sigma^2) + \pi$$

In the spectra of these trienes such cleavage corresponds to intense ions having *m/e* 53. In addition to the ions formed by α- and β-rupture, dissociation of a carbon–carbon bond with detachment of two hydrogen atoms results in ions with *m/e* 107, 51, and 25—$(M - H)^-$, $C_4H_3^-$, and C_2H^-. The intensity of the rearranged 41 peak in the spectrum of the methylheptatriene is low. The 67 peak is absent, although quite intense in the spectrum of the octatriene, whereas the latter contains no peak at 55. The corresponding ions cannot be formed by simple rupture of carbon–carbon bonds. The absence of an 81 peak from the spectrum of the octatriene is due to the fact that this fragment cannot be formed by either α- or β-cleavage: it would require either γ-rupture or α-rupture with transfer of the extra electron to the $\cdot CHR^1{-}R^2$ fragment, which obviously does not occur.

Three resonance ion-emission peaks are observed in dissociative electron capture by 9-methylundeca-1,3,7,10-tetraene and 3,8-dimethyldeca-1,4,6,9-tetraene. Their mass spectra can be represented by a scheme of α- and β-cleavage with the mass number and relative intensities (as percentages of the maximum intensity):





A characteristic feature of the spectra of negative ions of polyenes is the necessary presence of fragments containing an intact system of conjugated double bonds.

Fig. 4 shows the mass spectra of positive and negative ions of isomeric tetraenes. It is very significant that the slight differences in the mass spectra of positive ions of isomers bear no clear relation to the structure of the molecules. As a consequence, mass spectra cannot be used to assign a test material to a particular isomeric form. On the other hand, the mass spectra of negative ions resulting from dissociative electron capture by polyenes enable the structural formula to be determined without the use of other information.

Among compounds containing a triple bond only acetylene and propyne have been investigated. Their spectra reveal a large formation cross-section for $(M - H)^-$ ions ($\sim 10^{-18}$ cm^2).[37,39,44,53,54]

3. Benzene and its Derivatives

Electron-impact spectroscopy indicates[48,55,56] the capture of electrons by benzene molecules in the lowest unoccupied π^*-orbital (single-particle resonance, $^2E_{1u}$ state of $C_6H_6^-$) with electrons of energy 1.2–1.7 eV (various authors give differing values). The average lifetime of $^2\Sigma_{1u}C_6H_6^-$ ions is short ($<10^{-6}$ s), and the ions do not appear in the mass-spectrometric investigation of benzene. Sanché and Schulz[48] observed an additional peak, in the range 4–6 eV in the spectrum of electrons scattered by benzene molecules, and ascribed it to the capture of electrons in a b_{2g}-orbital of the molecule. Negative ions are not observed in this range of electron energies, although dissociation of $C_6H_6^-$ with the formation e.g. of $C_6H_5^-$ ions is energetically possible. Resonance peaks of negative ions are recorded at electron energies of 7–12 eV.[39,40]

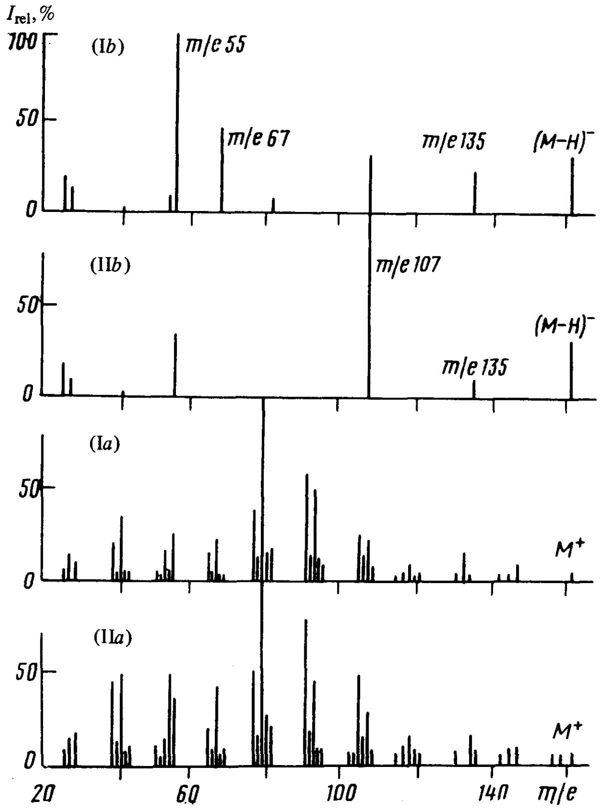


Figure 4. Mass spectra of: *a*) positive ions; *b*) negative ions of: I) 9-methylundeca-1,3,7,10-tetraene; II) 3,8-dimethyldeca-1,4,6,9-tetraene.

Table 3. Effective yields of negative ions (at maximum emissions of ions)*.[40]

Ion	Benzene	Toluene	Ethyl-benzene	Isopropyl-benzene	Butylbenzenes n-	s-	t-
$(M-H)^-$	100	46	24	23	41	22.2	15.7
$(M-2H)^-$	0.25	11	—	—	—	—	—
$(M-3H)^-$	1.1	0.3	2.0	—	2.0	—	—
$C_8H_9^-$	—	—	—	0.3	—	20	5.7
$C_8H_7^-$	—	—	—	4.6	2.2	—	0.3
$C_7H_7^-$	—	$(M-H)^-$	0,37	—	34	210	0.35
$C_6H_5^-$	$(M-H)^-$	0.9	6.7	21.6	6.1	15	70
$C_5H_5^-$	1.3	0.55	—	—	—	—	—
$C_4H_3^-$	7.8	0.74	—	—	—	—	—
C_2H^-	80	9.0	0.6	20.5	10.5	12	21
C_2^-	1.4	2.2	—	—	—	—	—
CH_3^-	—	—	—	—	—	—	52

* Unit intensity corresponds to $\sigma = 10^{-21}$ cm^2.

Table 3 shows that the main process in dissociative electron capture by benzene molecules is detachment of a hydrogen atom with localisation of the electron on the phenyl radical ($\sigma \simeq 10^{-19}$ cm^2 [39]). Formation of C_2H^- ions has a similar cross-section, whereas the effective yield of $C_2H_5^-$, $C_4H_3^-$, and C_2^- ions is one-tenth of this.

The minimum energy for the reaction $C_6H_6 + e \rightarrow C_6H_5^- + H$ to occur is 2.2 eV on the assumption that the electron affinity of the $C_6H_5^{\bullet}$ radical is 2.2 eV [57] and the energy of rupture of a carbon–hydrogen bond in benzene is $D(C_6H_5{-}H) = 4.4$ eV.[58] At the maximum yield of $C_6H_5^-$ ions (8 eV) the excess energy $E^* = 5.8$ eV is distributed between internal excitation of the $C_6H_5^-$ ion and translational energy of the reaction products. According to Franklin's formula $\bar{\epsilon}_{tr} = 5.8/0.42 \times 30 = 0.45$ eV, so that the total store of vibrational energy of the $C_6H_5^-$ ion is ~5.4 eV, which is 3.2 eV greater than the electron affinity of $C_6H_5^{\bullet}$. Even regarding this formula as a very crude approximation and bearing in mind the large excess energy of formation of the ion, we may conclude that $C_6H_5^-$ ions are formed in an autoionised state, i.e. with a sufficient store of vibrational energy for detachment of an electron.

Direct proof of the instability of $C_6H_5^-$ ions with respect to ejection of an electron has been obtained[59, 60] by measuring the mean lifetimes τ with respect to autoionisation of $C_6H_5^-$ ions from C_6H_6 and of $C_6D_5^-$ ions from C_6D_6 as respectively 47 ± 5 and 37 ± 5 μs. The effect of isotopic substitution on τ is probably due to a change in the overlap of the atomic vibrational wave-functions of the ion and of the corresponding neutral radical when hydrogen atoms are replaced by deuterium atoms. The C_2H^- ions were stable, which was not surprising, since their formation involved a lower excess energy, and part of the vibrational energy was associated with the neutral fragment. Two values were obtained for the isotope effect in the formation cross-section of the ions: $\sigma(C_6H_5^-)/\sigma(C_6D_5^-) = 1.18$ [61] and 5.4.[59] It is difficult to explain such a marked discrepancy, far exceeding possible experimental errors, but later work may reveal its cause.

Alkylbenzenes form negative ions[40] in the same range of electron energies as with benzene, though the maximum effective yields are slightly displaced (up to 0.3 eV) to higher energies. The maximum peaks in the dissociative electron-capture mass spectra of s- and t-butylbenzenes correspond to the ions $C_7H_7^-$ and $C_6H_5^-$ respectively. With the other alkylbenzenes investigated, the formation of $(M - H)^-$ ions is the most probable. The presence of an alkyl substituent changes the ways in which the molecular ion breaks down: thus $C_5H_5^-$, $C_5H_4^-$, $C_4H_3^-$, and $C_4H_2^-$ ions are present only in the mass spectra of benzene and toluene, but in alkylated benzenes both the formation cross-section of $(M - H)^-$ and C_2H^- ions and the total ion current at the maximum effective yield of ions have diminished. The latter does not apply to s-butylbenzene, with which the total ion current is increased by the large cross-section for formation of $C_7H_7^-$ ions, which exceeds that of $(M - H)^-$ ions from benzene by a factor of 2.1.

Study of dissociative electron capture by certain monosubstituted benzene derivatives has shown[51] ion-formation cross-sections of $\sim 10^{-19}$ cm^2, with the main processes of dissociation of the molecular ion coinciding with those in alkylbenzenes. The molecules C_6H_5X and C_6H_4XY, where X and Y respresent substituents possessing high electron affinities, exhibit effective cross-sections of dissociative electron capture larger by factors of 10^2–10^3, with several electron-capture resonance peaks. In chlorobenzene and bromobenzene the first peak with formation of halide ions is located at 0.6 eV; the capture of thermal electrons by iodobenzene molecules results in the appearance of iodide ions[62–64].

A long-lived negative molecular ion ($\tau = 40$ μs; energy of electrons ~0 eV) has been recorded in nitrobenzene[5]. The first peak in the electron-energy range 1–2 eV represents NO_2^- and $C_6H_5^-$ ions ($\sigma \simeq 2 \times 10^{-16}$ and 10^{-19} cm^2 respectively).[64, 65] Maximum yields of the ions— NO_2^- ($\sigma = 2 \times 10^{-16}$ cm^2), $C_6H_5NO^-$ (3×10^{-19}), $C_6H_4NO_2^-$ (2.5×10^{-18}), $C_6H_5^-$ (1.2×10^{-18}), CN^- (1.3×10^{-18}), NO^- (6×10^{-20}), $C_6H_5N^-$ (1.2×10^{-18}), and $m/e = 43, 42, 41$ (10^{-18} cm^2)—are obtained with electrons of energy 4 eV. Furthermore, peaks due to O^-, C_2H^-, and m/e 92 are situated with their maximum at 5 eV, and to OH^-, C_2H^-, and $(M - H)^-$ ions at 7 eV (cross-section $\sim 10^{-19}$ cm^2).

Two resonance peaks due to NO_2^- ions were observed in *o*- and *m*-nitrotoluenes[64]. It is interesting that the two peaks are of equal intensity in the *ortho*-isomer, but in *m*-nitrotoluene the intensity of the first peak with its maximum at 1.1 eV is only 15% of that of the second peak (maximum at ~3.3 eV). The energy of the resonant states has diminished by 0.3 eV in *o*-nitrotoluene. Molecular ions of *m*-chloronitrobenzene and *m*-iodonitrobenzene decompose along two channels with the emission of NO_2^-, Cl^-, and I^- ions[66]. In benzonitrile not only the molecular ion ($\tau \simeq 5$ μs) but also CN^- ions (two peaks) are observed with peaks due to $C_6H_4^-$ and $C_6H_4CN^-$ ions.

4. Fused-ring Aromatic Hydrocarbons

The only ionic fragment formed in naphthalene, fluorene, anthracene, and phenanthrene results from detachment of a single hydrogen atom from the negative molecular ion. Maxima on the effective-yield curves of $(M - H)^-$ ions from naphthalene and fluorene coincide with the corresponding maximum for benzene, but dissociative electron capture takes place over a wider range of electron energies than does the formation of $C_6H_5^-$ ions from benzene. Interaction of electrons with fluorene molecules gives rise to a further process of formation of $(M - H)^-$ ions with a maximum at 1.6 eV, which has been regarded[67] as corresponding to formation of a fluorenyl anion.

It is interesting that the dissociative electron-capture spectra of anthracene and phenanthrene are different. The effective-yield curve for $(M - H)^-$ ions from anthracene exhibits an inflexion, which is less strongly marked with phenanthrene. Furthermore, non-dissociative capture of electrons (having energies close to zero) is observed in anthracene. As a result, a negative molecular ion of anthracene is formed with a finite lifetime with respect to autoionisation ($\tau = 21$ μs). The formation cross-section of $(M - H)^-$ ions from anthracene and phenanthrene is $\sim 10^{-17}$ cm^2, and the cross-section of non-dissociative electron capture by anthracene molecules is 10^{-16} cm^2. Hence negative-ion mass spectrometry may be used to detect anthracene present as impurity (up to 0.5%) in other compounds, including phenanthrene.

5. Cyclopentadiene and Metallocenes

On interaction with electrons cyclopentadiene loses a hydrogen atom and is converted into a stable $C_5H_5^-$ anion, with a maximum probability for electrons of energy 2.05 eV.[41] A further resonance process is observed at 8 eV, leading to the formation of $C_5H_5^-$, $C_5H_4^-$, $C_5H_3^-$, $C_3H_3^-$, and

C_2H^- ions with respective intensities of 3.6%, 1.6%, 1.2%, 11%, and 20.5%. At 2.05 eV the intensity of the $C_5H_5^-$ peak reaches 100%.[41]

In dissociative electron capture by ferrocene, cobaltocene, manganocene, and nickelocene molecules[68] $C_5H_5^-$ ions are formed in the range of electron energies 0.5–1.0 eV, with widely varying formation cross-sections. Ferrocene and cobaltocene have the smallest cross-section (3×10^{-21} cm^2), that of nickelocene is larger by a factor of 25, and manganocene occupies an intermediate position. The effective formation cross-section for $C_5H_5^-$ ions is relatively small, that of $C_5H_5Co^-$ ions (at 0.7 eV) is 1.8×10^{-20} cm^2, and the non-dissociative capture cross-section of thermal electrons with formation of $CoC_{10}H_{10}^-$ ions is 6×10^{-18} cm^2.

Study of dissociative electron capture by dicyclopentadienyl dichlorides $M(C_5H_5)_2Cl_2$, where M = Ti, Zr, Hf, revealed in all cases the formation of molecular ions by the capture of thermal electrons, the probability of ion formation being greater the heavier the metal M.[69]

6. Five-membered Heterocycles

Five-membered heterocycles form negative ions in two ranges of electron energies, in both of which the mass spectrum contains a relatively large number of lines[41,70]. An exception is pyrrole, with which only $(M - H)^-$ ions are observed in the first, low-energy range. Table 4 reveals greater fragmentation of molecular ions in the second than in the first range, with an increase in the relative probabilities of formation of ions having low *m/e* values and a decrease in the yield of $(M - H)^-$ ions. The isotope effect in the cross-section for formation of the latter ions from thiophen is 1.4 and 12.1 in the first and second resonance peaks. In both resonance regions these $(M - H)^-$ ions are in autoionisation states, with $\tau(SC_4H_3^-)$ = 240 and 220 μs respectively.

Table 4. Effective yields of negative ions in two resonance peaks of selenophen, thiophen, furan, and pyrrole*.[26,70,41]

X Electrons, eV	Se 4.9–5.3	S 5.3–5.7	O 5.5	Se^{II} 7.8–8.1	S^{II} 8.3–8.5	O^{II} 9.8–10	NH^{II} 8.9–10.2

* Unit intensity corresponds to $\sigma = 10^{-21}$ cm^2.

Differences between the dissociation of negative molecular ions in the first and second ranges of electron capture have been examined[26] on α-deuterated thiophen and selenophen. It was found that $(M - H)^-$ ions of the first peak were formed by the detachment of either an α- or a β-hydrogen atom, with relative probabilities of 1 : 3. The same relative probabilities applied to the formation of C_2H^- ions.

In thiophen the decomposition channels of the molecular ion with formation of $(M - H)^-$ and SC_2H^- are independent in the sense that the degradation $(M - H)^- \rightarrow SC_2H^-$ does not take place. An isotope effect is observed in the formation cross-section of $(M - H)^-$ ions, but the yield of SC_2H^- ions is almost unaffected by deuteriation of the molecule[59]. Formation of SH^- ions takes place almost exclusively by migration of hydrogen atoms from the β-position. In the second peak the formation of $(M - H)^-$ and SC_2H^- ions also corresponds to two processes, involving detachment of hydrogen atoms from α- and β-positions, but the relative probabilities of the two processes are about the same as with the first peak.

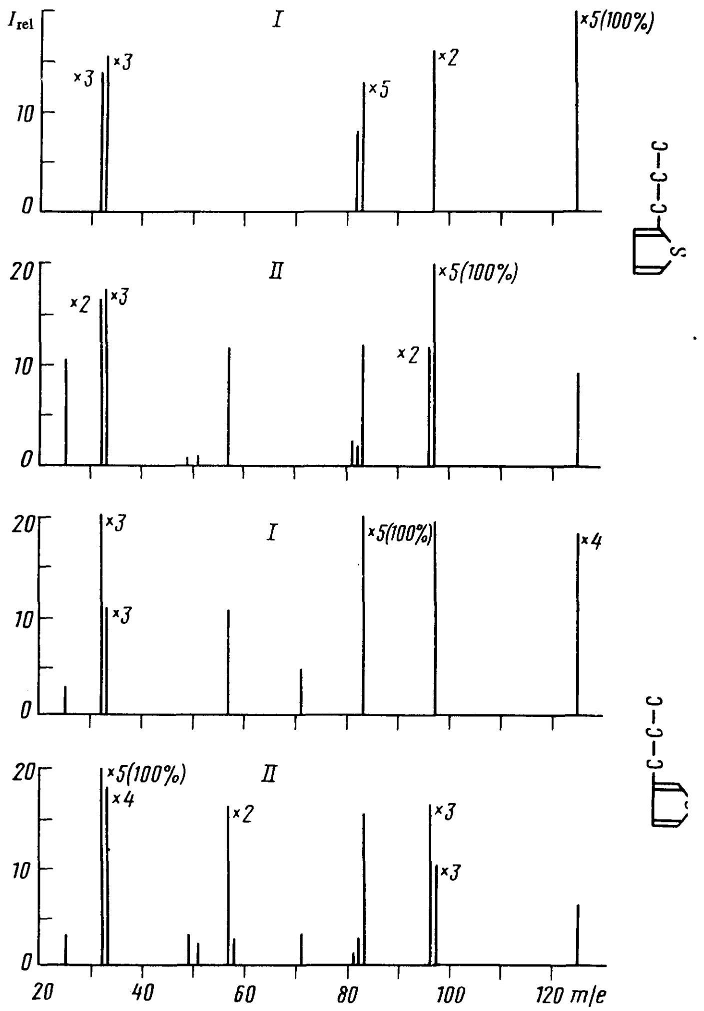

Figure 5. Mass spectra of negative ions of 2- and 3-propylthiophens: I) first range of electron capture (electrons of energy ~5 eV); II) second range (~8 eV).

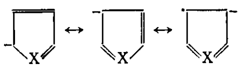
Breakdown of alkylthiophen molecular ions of the first peak (maximum yields of ions at ~5 eV) is closely similar to that of the corresponding molecular ion of thiophen. Substitution has little effect on the modes of decomposition of the molecular ion. For example, detachment of alkyl radicals from a β-position is more probable than the detachment of α-substituents, and the relative probabilities of formation of $(M - H)^-$, H^-, and C_2H^- ions in α- and β-alkylated thiophens can easily be interpreted qualitatively in terms of the relative probabilities of different modes of dissociation of the molecular ion of thiophen. In the second peak substitution has a more significant effect on the breakdown of molecular ions, which is apparent in the absence of consistency in the relative probabilities of individual modes of dissociation of molecular ions of thiophen and of alkylthiophens (Fig. 5).

While dissociative electron capture by five-membered heterocycles shows a general similarity, the most closely similar processes evidently occur with selenophen and thiophen. Formation of ions of the heteroatom does not occur in furan, although O^- ions are readily formed with other oxygen-containing compounds, and the line due to hydroxide ions is weak. Pyrrole does not exhibit NH^- ions at all. The vacant *d*-orbitals of sulphur and selenium enable the structures



to be included among those of the negative molecular ion. Such structures are impossible with furan and pyrrole. They are probably responsible for formation of the X^-, XH^-, XCH^-, and XC^- ions characteristic of thiophen and selenophen but absent from the dissociative electron-capture spectra of other five-membered heterocycles.

With indole and several alkylindoles the only negative ions that could be observed were $(M - H)^-$. Breakdown of the benzene ring, as found in fused aromatic hydrocarbons, does not occur on electron capture. The maximum effective yields of these ions from indole and 2,3,7-trimethylindole occur with electron energies of 1.55 and 1.65 eV respectively. Substitution at the nitrogen atom, as e.g. in 1,2,3,7-tetramethylindole and 1,7-propanoindole, eliminates this low-energy resonance formation of ions. From this it was deduced[41] that $(M - H)^-$ ions are formed from indole and from 2,3,7-trimethylindole as a result of rupture of the nitrogen–hydrogen bond.

7. Pyridines and their *N*-Oxides

The scattering of electrons by pyridine molecules reveals two states of short-lived molecular ions at electron energies of 1.2 and 1.6 eV,[71] or 0.84 and 1.3 eV according to other workers[56]. Single-particle shape resonances are probably involved, corresponding to electron capture at vacant π-orbitals of the molecule. Study of dissociative electron capture by pyridine and alkylpyridines[40] showed that, in contrast to benzene and alkylbenzenes, the two states of negative molecular ions break down with the formation of negative ionic fragments. The first resonance peak of ionic emission with maxima at ~4.5–4.6 eV corresponds to NC_3^-, C_2H^-, C_2^-, and in pyridine also $NC_5H_4^-$ ions. The mass spectrum of the second peak (at ~8 eV) contains more lines, and the modes of dissociation of the molecular ion are largely similar to those for benzene, only a large relative probability of formation of ions with destruction of the ring is observed (such ions as $^-N{:}CH.C{\vdots}CH$ and $^-N{:}C{:}CH_2$).

The isotope effect in the formation cross-section of $(M - H)^-$ ions from pyridine in the second peak is also closely similar to that in benzene: $\sigma(NC_5H_4^-)/\sigma(NC_5D_4^-) = 6 \pm 0.5$. The isotope effect is smaller in the first peak (3.1 ± 0.5). The probable reason is the shorter mean lifetime with respect to autoionisation of the molecular ion of pyridine produced by trapped electrons of energy 8 eV than by those of energy 4.5 eV. The $(M - H)^-$ ions are formed in an autoionised state, with $\tau(NC_5H_4^-) = 60$ μs (8 eV) but $\tau(NC_5D_4^-) = 68$ μs (8 eV): i.e. deuteriation increases the lifetime, in contrast to the case of benzene[60].

The Reviewers have investigated the mass spectra of the *N*-oxides of pyridine and of the three isomeric alkylpyridines. The oxygen atom has a substantial effect on processes involved in the dissociative capture of electrons, resulting both in the appearance of new excited states of the negative molecular ions and in a change in the possible channels of decomposition of the molecular ions. Five main states of excited molecular ions, denoted *a–e*, were distinguished by the positions of the maximum effective yields of ions on the electron-energy scale and by the modes of decomposition. The low-energy state *a* was represented in the spectrum of pyridine *N*-oxide by lines due to the ionic fragments $(M - H)^-$, $NC_3H_3^-$, $NC_3H_2^-$, and NC_3^-, with peaks of relatively low intensities, while the maximum efficiency of formation is observed with electrons of energy 0.2–0.5 eV.

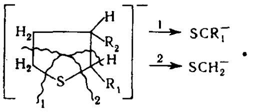
Molecular ions in state *b* break down with ejection of a C_2H_3 fragment (ions with *m/e* 68). The maximum of the resonance peak on the emission curve of $(M - C_2H_3)^-$ ions is located at 0.8 eV. The most intense peaks in the spectrum of pyridine *N*-oxide are due to ions formed by the dissociation of ions in state *c*, the maximum yield being observed at 3–3.2 eV. The breakdown of molecular ions in this state is represented by peaks due to $(M - H)^-$, $(M - OH)^-$, $(M - OCH)^-$, O^-, OH^-, and ions with $m/e = 64$. State *d* of molecular ions is apparent from the effective-yield curves for O^- ions, which show two poorly resolved peaks: the first (at 3.2 eV) corresponds to state *c*; the second peak (at 4 eV) indicates the existence of yet another state of molecular ions decomposing with the emission of O^-. Decomposition of molecular ions in the high-energy state *e* gives a mass spectrum rich in peaks, although their relative intensities are comparatively low. Besides the purely "pyridine" ions $NC_3H_2^-$, NC_3H^-, $NC_2H_2^-$, NC_2H^-, and C_2H^-, the fragments $(M - OH)^-$, $(M - CO)^-$, $(M - CHO)^-$, O^-, and OH^- are observed, as well as ions having *m/e* ratios of 41, 42, 49, and 68, whose maxima occur in the range of electron energies 8–9 eV. Replacement of hydrogen by methyl does not give rise to new states of the negative molecular ions, only some redistribution of the probabilities of different decomposition channels.

8. Sulphides

Sanché and Schulz[48] studied hydrogen sulphide molecules by transmitted-electron spectroscopy, and with electrons of energy 2 eV observed shape resonance (single-particle resonance) corresponding to capture of electrons in the lowest unoccupied $4a_1$ orbital of the molecules. Electronically excited Feshbach resonance with excitation of the lone pair of electrons on the sulphur atom takes place when the electron energy reaches ~4 eV. In the range of electron energies ⩾8 eV resonant states of H_2S^- are observed with two Rydberg electrons. The positive molecular ion H_2S^+ is the grandparent state for such states of negative ions.

Studies have been made[73-75] on dissociative electron capture by a large group of aliphatic sulphides, disulphides, and thiols. Fig. 2 illustrates effective-yield curves for negative ions of dimethyl sulphide. The resonance peaks of ion emission are denoted by Roman numerals in order of increasing energy. Peak (I) represents only SCH_3^- ions, the peak (II) CH_3^- and S^- ions. If peak (I) is assigned to single-particle resonance, and peak (II) to electronically excited Feshbach resonance with formation of a molecular ion in the $(b_1)(b_1^*)^2\ {}^2B_1$ state (point group C_{2v}, with b_1 the orbital occupied by electrons of the lone pair on the sulphur atom, and a_1 the first vacant orbital), it becomes clear why CH_3^- ions (${}^1A_1$) are absent from peak (II), since SCH_3^- ions (ground state ${}^1A$, point group C_{3v}) and the $CH_3^{\bullet}$ radical in the ground state ${}^2A_{1g}$ do not correlate with the B_1 state of the molecular ion. Peaks (III) and (IV) of dimethyl sulphide represent S^-, SCH_3^-, CH_3^-, CH_2^-, and $(M - H)^-$ ions, and probably result from the dissociation of resonant states, of the corresponding (by Feshbach resonance) Rydberg states of the molecule. Dissociative electron capture in the other dialkyl sulphides investigated is similar to that in dimthyl sulphide, but peaks (III) and (IV) are replaced by one broad resonance peak (Fig. 2).

In contrast to aliphatic sulphides, the negative molecular ions of cyclic sulphides (thiophans) have corresponding mass spectra containing intense lines due to $(M - H)^-$ ions, the relative yield of which increases with the length of the alkyl group. With electrons of energy 8 eV decomposition occurs according to the scheme[75]



.

Ions corresponding to single-particle resonance were not detected, which is fully explained by the fact that the energy available is insufficient to rupture two bonds on addition of an electron to the antibonding orbital of the sulphur–carbon bond.

Alkyl benzyl and phenyl sulphides are interesting in containing both a benzene ring and sulphur–carbon bonds, so that dissociative electron capture by their molecules can be compared with corresponding processes in benzenes and in dialkyl sulphides. Benzyl ethyl, methyl, and propyl sulphides, as well as butyl, ethyl, methyl, and propyl phenyl sulphides, have been studied[51]. With electrons of energy 0–10 eV three peaks can be distinguished, as in dialkyl sulphides. With alkyl benzyl sulphides the first peak (single-particle resonance) is characterised by a very large ion-formation cross-section ($\sigma \simeq 10^{-15}$ cm^2), and the ions SR^-, CH_3^- (in benzyl methyl sulphide), and $C_6H_5CH_2^-$ are observed in the second peak. The absence of $C_6H_5CH_2S^-$ ions indicates that the second peak is due to excitation of the lone pair of electrons on the sulphur atom. The large formation cross-section of SR^- ions in the second peak ($\sim 10^{-17}$ cm^2) is explained by formation of the benzyl radical in the ${}^2B_1$ state: $(C_6H_5CH_2SR)^{-*} \rightarrow C_6H_5CH_2^{\bullet}\ ({}^2B_1) + SR^-\ ({}^1A_1)$. The ions $(M - H)^-$, SH^-, S^-, SR^-, and $C_6H_5CH_2S^-$ are observed in the third resonance peak.

Thus the benzene ring in alkyl benzyl sulphides does not trap electrons, the overall pattern of dissociative electron capture being determined by the molecular orbitals of the sulphur–carbon bonds. The ion-formation cross-sections are larger than with dialkyl sulphides. The benzene ring has a more significant effect in alkyl phenyl sulphides, since processes characteristic of alkylbenzenes are observed (the ions C_2H^-, $C_4H_3^-$, $C_5H_5S^-$, and C_2H^- in the third peak—Fig. 6). Increase in size of the alkyl radical makes the mass spectrum more "sulphidic": thus the formation only of C_2H^- ions in the spectrum of butyl phenyl sulphide indicates the presence of the benzene ring; the other ions are formed by processes analogous to the fragmentation of dialkyl and alkyl benzyl sulphides.

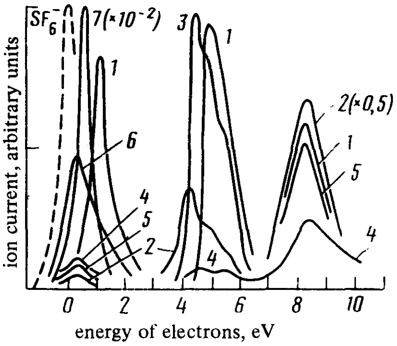


Figure 6. Effective-yield curves for negative ions from methyl phenyl sulphide: 1) S^-; 2) SCH_3^-; 3) CH_3^-; 4) $C_6H_5^-$; 5) SH^-; 6) SC_2H^-.

The existence in alkyl phenyl sulphides of a combined system comprising the ring π-electrons and the lone pair of electrons of the sulphur atom leads in the second peak to the appearance of complicated effective-yield curves, as would be expected. Fig. 6 shows that several closely spaced states of the molecular ion undergo decomposition, with the appearance of "bulges" and inflexions on the effective-yield curves of the ions.

9. Carbonyl Compounds

Study of the scattering of monoenergetic electrons on carbon monoxide have shown the existence of several Feshbach resonances in the range of electron energies 10–12.2 eV [76] and single-particle resonance at 1.7 eV. [77] The latter type of resonance has been observed also in acetaldehyde, acetone, acetophenone, benzophenone, and benzaldehyde (at 1.2, 1.2, 0.95, 0.75, and 0.72 eV). [78] In acetone it is not accompanied by formation of negative ions. When acetone molecules interact with electrons, negative ions appear as a broad peak resulting from the superposition of several resonance peaks over the range of electron energies 7–11 eV. [79,80]

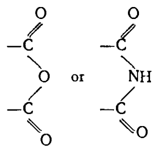
Formation of chloride ions in chloroacetone is energetically possible by dissociation of a single-particle resonant state. The maximum yield of Cl^- ions is situated at 0.6 eV. Capture of thermal electrons by hexafluoroacetone yields negative molecular ions that are long-lived with respect to autoionisation ($\tau > 10^{-6}$ s). The introduction of fluorine atoms evidently lowers the energy of the π-orbital of the carbonyl group to such an extent that the electron affinity of the molecule becomes positive.

The main processes producing negative ions in aldehydes and ketones are rupture of a β-carbon–carbon bond relative to the carbonyl group and the formation of homologous ions CH⁝C.O⁻ (*m/e* 41), CH_3.C⁝C.O⁻ (55), etc:

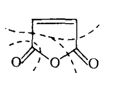
$$\left[R^1{-}\underset{\underset{O}{\parallel}}{C}{-}CH_2{-}R\right]^- \leftrightarrow R^1{-}\underset{\underset{O}{\parallel}}{C}{-}CH_2^- \leftrightarrow R^1{-}\underset{\underset{O^-}{|}}{C}{=}CH_2 \; .$$

Formation of the ions O^- and OH^- (with rearrangement of bonds), hydrocarbon ions CH_2:CH^- (*m/e* 27), and R_1–CO^- ions has also been observed[80].

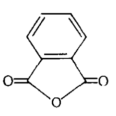
Two resonance peaks of ion emission have been found by Cooper and Compton[81] both in acetic anhydride and in acetyl peroxide. The first resonance peak represents CH_3COO^- ions (maximum yields at ~1 and at ~0 eV respectively), and the second peak CH_3^- and O^- ions (maxima at ~7 and at ~6.6 eV). These workers also investigated the capture of electrons by molecules containing the configuration



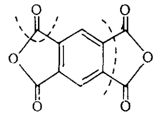
as part of a five- or six-membered ring. Unsaturated compounds



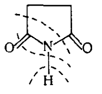
τ = 250 μs



τ = 330 μs

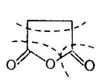


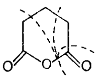
τ = 8000 μs

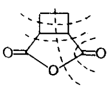


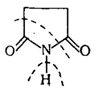
τ = 43 μs

trap thermal electrons with the formation of long-lived molecular ions (the mean lifetimes before ejection of the electron are indicated under the above structural formulae). In saturated compounds









only the formation of short-lived molecular ions is observed. The most probable process entailing dissociation negative molecular ions of the above compounds is ejection of carbon monoxide with formation of $RCOO^{-}$* ions, which are metastable with respect to detachment of an electron. Similarly metastable CO_2^{-}* ions are also observed, as well as O^-, CH_2CO^-, CO^-, and other ions corresponding to breakdown of the molecular ions in the ways indicated by the broken lines on the above structural formulae.

Dissociative electron capture by keten[82] and formaldehyde[83] has also been investigated.

10. Peroxides

The mass spectra of t-butyl and of its hydroperoxide are almost identical[84]. Over the range of electron energies 0–3 eV the ions $(CH_3)_3CO^-$, CH_2:$C(CH_3).O^-$, and CH_3^- are observed (100%, 13%, and 0.1% respectively), with a metastable-ion peak corresponding to the transition

$$(CH_3)_3CO^- \xrightarrow[\bullet]{-CH_4} CH_2{=}C(CH_3)O^- \; .$$

m/e 73 *m/e* 57

It was supposed that *m/e* 73 ions were formed by the direct capture of electrons by t-butoxy-radicals produced by thermolysis of the compounds in the ionisation chamber.

Investigation of dissociative electron capture by $R.C(CH_3)_2OOH$ molecules (where R = CH_3, C_2H_5, C_6H_5, $C_{10}H_7$) and by perbenzoic acid indicates[85,86] that the main process with all the compounds, when low-energy electrons are trapped, is the formation of $(M - OH)^-$ ions, in an autoionisation state, i.e. in an excited state with an average lifetime of $\sim 10^{-3}$ s before spontaneous ejection of an electron. The mass spectra contain a metastable-ion peak corresponding to the transition

$$R(CH_3)_2O^- \xrightarrow[\bullet]{-CH_4} RC(CH_2)O^- \; .$$

In the mass spectrum of perbenzoic acid the transitions

$$(C_6H_5CO{-}OOH)^- \xrightarrow[\bullet]{-OH} C_6H_5CO_2^- \xrightarrow[\bullet]{-CO_2} C_6H_5^-$$

are observed.

11. Nitro-compounds, Nitrites, [Nitrates,] and Nitriles

A relatively large number of papers have been published on the capture of electrons by nitromethane[65,87-90], whose negative molecular ion has six resonant states, which dissociate with the formation of negative ionic fragments[90]. Table 5 gives only ions from primary processes of electron capture, but $CH_2NO_2^-$ and $CHNO_2^-$ have also been observed, resulting from secondary reaction of O^- ions with nitromethane molecules, as well as OH^- and CH_2NO^- ions produced by an ion–molecule reaction involving NO_2^-.

Table 5. Negative ions from nitromethane (relative intensity of NO_2^- ions at 0.6 eV taken as 10 000).

Electrons, eV	Ion	Relative intensity	Electrons, eV	Ion	Relative intensity
0.6	NO_2^-	10 000	7.8–7.9	$CH_2NO_2^-$	37.5

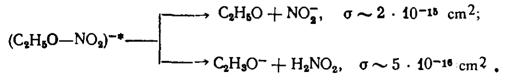
	CH^-	2.5		CN^-	10
5.6	O^-	250			
	OH^-	—			

A rather lower yield of negative ions is obtained in nitroethane[65] than in nitromethane, and the maxima on the effective-yield curves are displaced to higher energies (by a few tenths of an electron-volt).

Nitrites are characterised[65,91] by a large cross-section for ion-formation (~10^{-15} cm^2) on the capture of thermal electrons, by the reaction Alk.O.N:O^- → $AlkO^-$ + NO. The effective cross-section diminishes as the alkyl chain becomes longer. Formation of NO^- and NOH^- ions also occurs.

The ·O–NO_2 bond in ethyl nitrate also readily undergoes cleavage when the molecule traps an electron of energy close to zero:



$$(C_2H_5O{-}NO_2)^{-*} \begin{cases} \longrightarrow C_2H_5O + NO_2^-, & \sigma \sim 2\cdot 10^{-15}\ \text{cm}^2; \\ \longrightarrow C_2H_3O^- + H_2NO_2, & \sigma \sim 5\cdot 10^{-16}\ \text{cm}^2 \; . \end{cases}$$

Rupture of the O–NO_2 bond is also involved in the reactions

$$(C_2H_5O{-}NO_2)^- \longrightarrow \begin{cases} C_2H_5O^- + NO_2, & \sigma \sim 6 \cdot 10^{-17}\ \mathrm{cm}^2; \\ C_2H_4O^- + HNO_2, & \sigma \sim 2 \cdot 10^{-17}\ \mathrm{cm}^2. \end{cases}$$

Effective-yield curves have been obtained for the ions CN^-, $CHCN^-$, CHN^-, and CH_3CH^- from CH_3CN^- and $C_2H_5CN^-$.[38] Resonance peaks of negative-ion emission and their relative intensities have been recorded for the interaction of electrons with azoisobutyronitrile[92] and cyanonorbornene[50].

12. Peculiarities of the Formation of Negative Ions

In conclusion we make a general comparison of the dissociative electron-capture mass spectra with the mass spectra of positive ions, noting the most significant features of resonance processes.

Dissociative electron capture by molecules is characterised by a marked dependence of the effective ion-formation cross-sections on the functional groups present in the molecule. In alkyl benzyl and phenyl sulphides, nitrates, and hydroperoxides, for example, the effective cross-sections reach 10^{-14}–10^{-15} cm^2 (vibrationally excited Feshbach resonances and shape resonances); in alkenes and alkylbenzenes the cross-sections of formation of negative ions do not exceed 10^{-19} cm^2 (electronically excited Feshbach resonances)‡. Such marked differences in total ionisation cross-sections are not observed in the mass spectrometry of positive ions.

In contrast to the formation of positive ions, when most of the fragments may be positively charged, the extra electron can be retained only by fragments whose electron affinity is positive. For example, processes involving formation of N^- ions are excluded in nitrogen-containing compounds, since the electron affinity of the nitrogen atom is negative; this is probably why $C_2H_5^-$ ions are not formed, although detachment of $C_2H_5^{\cdot}$ radicals is observed in dissociative electron capture by molecules containing alkyl chains. The small number of lines in such mass spectra in comparison with those of positive ions undoubtedly is largely due to the fact that not all possible channels of decomposition of a negative molecular ion yield fragments having positive electron affinities. However, the existence of several resonant states of molecular ions to some extent compensates for the paucity of lines in the dissociative electron-capture mass spectra. In many cases we can speak of several such mass spectra of a given substance according to the number of resonances observed.

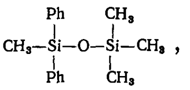
Dissociative electron capture via electronically excited Feshbach resonances usually involves a large excess energy, so that ionic fragments are likely to be formed in vibrationally excited states. Dissociation of the molecular ions thus occurs in ways leading to ionic fragments whose energy of vibrational excitation is less than some critical value, since a high energy of vibrational excitation may cause either further dissociation of the ionic fragment or ejection of the extra electron within times $\tau < 1$ μs (ions with such short lifetimes are not recorded by the mass spectrometer). Negative ions of energetically less advantageous structures are often formed preferentially precisely because of their lower energy of vibrational excitation[94]. It is noteworthy that, in the mass spectrometry of positive ions, the stability of the fragments formed plays an important role in determining the predominant direction of dissociation, where stability of the decomposition products implies mainly energetically favourable structures of the ion and of neutral fragments.

The finite lifetime of negative molecular ions before spontaneous detachment of an electron restricts the possible processes of dissociation. As a consequence, a smaller contribution is made by processes involving rearrangements, which require times comparable with that for detachment of the electron. For this reason negative ionic fragments are formed almost solely by simple cleavage of bonds in the molecular ion[86,94,95].

Table 6. Dissociative electron-capture mass spectra of isomers (I) and (II).

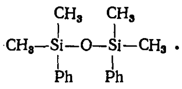
m/e	Relative intensity		*m/e*	Relative intensity		*m/e*	Relative intensity	
	I	II		I	II		I	II
285	100	8.0	211	13.0	—	135	—	2.0
269	25.0	6.0	207	60.0	100	89	32.0	5.0
213	13.0	—	151	—	7.5	73	16.0	2.4

For the above reasons the dissociative electron-capture mass spectra of structural isomers show marked differences. In contrast, the intensity of rearrangements makes the positive-ion mass spectra of structural isomers either completely identical or only slightly different (cf. e.g. the two types of mass spectra for polyenes and mass spectra of the former type for two isomeric propylthiophens—Figs. 4 and 5). Another illustration is provided[86] by the preparation of two isomers of molecular weight 286 and composition $Si_2O(CH_3)_4(C_6H_5)_2$ as shown by elementary analysis, infrared spectra, and positive-ion mass spectra. However, these mass spectra gave no indication of the isomeric structures, since they were almost identical for the two specimens. The dissociative electron-capture mass spectra (Table 6) make it easy to assign the structures



$$CH_3{-}\overset{\overset{Ph}{|}}{\underset{\underset{Ph}{|}}{Si}}{-}O{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{Si}}{-}CH_3,$$

(I)



$$CH_3{-}\overset{\overset{CH_3}{|}}{\underset{\underset{Ph}{|}}{Si}}{-}O{-}\overset{\overset{CH_3}{|}}{\underset{\underset{Ph}{|}}{Si}}{-}CH_3.$$

(II)

The great sensitivity of dissociative electron-capture mass spectra to variation in molecular structure follows from the conditions of dissociation of the parent molecular ion. The identification of isomeric structures may therefore be a possible field for the practical application of this type of mass spectrometry.

IV. SOLUTION OF SPECIAL PROBLEMS BY NEGATIVE-ION MASS SPECTROMETRY

1. Recording of Free Radicals in the Gas Phase

Iminoxyl radicals (di-t-butyliminoxyl and 2,2,6,6,-tetramethylpiperidinoxyl), on trapping thermal electrons, form negative molecular ions with $\tau = 16$ and 21 μs respectively,

---

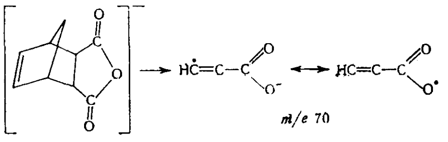
‡ Differences in the effective ion-emission cross-sections can be used to solve several problems in determining minor quantities of one substance in another[93].

the effective cross-section of the process being $\sim 10^{-17}$ cm^2.

Positive-ion mass spectrometry cannot record iminoxyl radicals, since their spectra contain no characteristic fragments, and in the presence of impurities it is impossible to isolate the spectrum corresponding to the radical[96] (the use of electron spin resonance spectra is applicable only to the liquid phase). The recording of iminoxyl radicals from the peaks of negative molecular ions is free from the problems of "background" and the superposition of peaks due to impurities, since the probability that the resonance peaks of ion emission for the radical and for the impurity molecules will coincide, with simultaneous coincidence of the mass numbers of the ions, is very slight[92, 97].

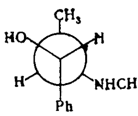
2. Stereoisomerism of Organic Compounds

Examination of the spectra of *endo*- and *exo*-5-cyanonorbornenes and of *endo*- and *exo*-norbornenedicarboxylic acids has shown that their differences can be used to identify stereoisomeric derivatives of norbornene and related bicyclic compounds. Thus the effective yield of *m/e* 70 ions from *endo*-norbornenedicarboxylic acid reaches a maximum with electrons of energy 6 eV, whereas with the *exo*-isomer the maximum is located at 4.7 eV. This means that $(H_2C_2CO_2)^-$ ions having *m/e* 70 can be formed, with maximum yields at 6 and 4.7 eV, by two resonance processes from both molecules

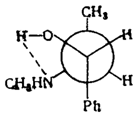


but the probability ratios of these processes are different. This applies also to the formation of ions with *m/e* 52, 91, 103.[95]

Ephedrine and pseudoephedrine exist predominantly as the respective conformers[98]



(I)



(II)

.

Considerable differences in the relative intensities of peaks due to ions of the two isomers are observed only with certain mass lines[99]. Fig. 7 shows the dependence of the total currents of negative ions of (I) and (II) on the energy of the electrons. Thus the stereochemical differences do not result in the appearance of new resonant states of the molecule–electron system. However, the absolute effective capture cross-sections of electrons change in all the resonance peaks other than the second, which is due to $(M - H)^-$ ions. The cross-sections for formation of negative ions of ephedrine in the resonance peaks *1* and *3* are somewhat lower than for pseudoephedrine, but at peak *4* they are almost double. Ephedrine is characterised by an increased relative probability of formation of ions having *m/e* 146, 133, and 117, whereas in pseudoephedrine the proportion of ions having *m/e* 17 and 30 increases. The effective-yield curves for ions from the two isomers differ markedly in the region of electron energies of ~6.5 eV. Many other quite significant differences between the spectra of ephedrin and pseudoephedrine have been discussed[97]. The positive-ion mass spectra of the isomers, obtained under standard conditions, are almost identical.

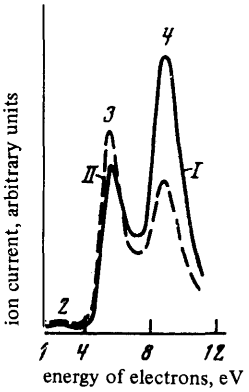


Figure 7. Dependence of total ion current on energy of electrons for: I) ephedrine; II) pseudoephedrine.

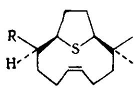
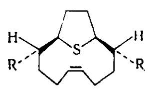
Study of the stereochemistry of 13-thiabicyclo-[8,2,1]tridec-*cis*-5-ene derivatives





has shown that, when R = H, no new states of the negative molecular ion appear in comparison with dialkylthiophans. The situation is greatly changed by the introduction of two acetoxy-groups ($R = OCOCH_3$). In particular, ions having *m/e* 119 are detected, with the empirical formula $(OCOCH_3)_2H^-$. Since peaks due to metastable and rearranged ions are absent from dissociative electron-capture mass spectra, it was concluded[100] that the negative molecular ions exist in an excited state for only a short time. From this point of view the formation of *m/e* 119 ions indicates the steric proximity of the acetoxy-groups in the thiabicycloalkane diacetate. Ions of type $(R_2H)^-$ are also detected in the spectra of thiabicycloalkanes with $R = OCH_3$, NO_2. These results have provided part of the evidence for the *cis*-arrangement of the substituents in 2,9-disubstituted derivatives of 13-thiabicyclo[8,2,1]tridec-*cis*-5-ene.

---oOo---

The results given in this Review of the mass spectra of negative ions in the dissociative capture of electrons by organic molecules cover little more than a hundred individual compounds belonging to 10–15 classes, incomparably fewer than the data on the mass spectra of positive ions. It is not surprising, therefore, that there remain many unsettled questions on the mechanism of dissociation accompanying the capture of electrons by molecules. It is indisputable that further work is needed on such problems as e.g. the structure of ions and neutral fragments, the internal energy of excitation of the resulting ions, and the classification of resonant states of the molecule–electron system.

Nevertheless, the material presented here is in our opinion evidence that even now we can regard such mass spectrometry of negative ions as a method which may be useful in solving several specific problems in organic chemistry.

Hydrogenation of Alkenes on Oxide Catalysts

Kh.M.Minachev, Yu.S.Khodakov, and V.S.Nakhshunov

A qualitative survey of available data has enabled pure oxides to be divided into five groups according to their catalytic activity. Zeolites are less active than oxides corresponding to their cationic forms. The activity of an oxide catalyst either increases continuously or passes through a maximum with increase in its temperature of ignition. This type of dependence is explained by the surface dehydroxylation model on the assumption that the activity is determined by the presence of electron-donating and electron-accepting sites situated side by side on the surface. The hydrogenation of alkenes involves stages of activation of the alkene and of hydrogen, with on most oxides appearance of a semi-hydrogenated form. A list of 91 references is included.

CONTENTS

I. INTRODUCTION

The problem of the hydrogenation of alkenes on oxide catalysts began to attract the attention of research workers only during recent years. Oxides, though less active than metals[1-3], may in several cases have the advantages of being less sensitive to certain catalytic poisons, more highly selective, and easily regenerated. In spite of the large number of experimental investigations, hardly any reviews have appeared covering this field of catalysis. A survey[4] of the conversion of alkenes on oxides contained a short list of references up to 1960.

In the present Review the problem of the hydrogenation of alkenes on oxide catalysts is considered from the points of view of the choice of catalyst, the nature of the catalytic activity, and the kinetics and mechanism of the hydrogenation of alkenes. Factual material is given illustrating the features of reactions on various oxides and on certain multicomponent systems.

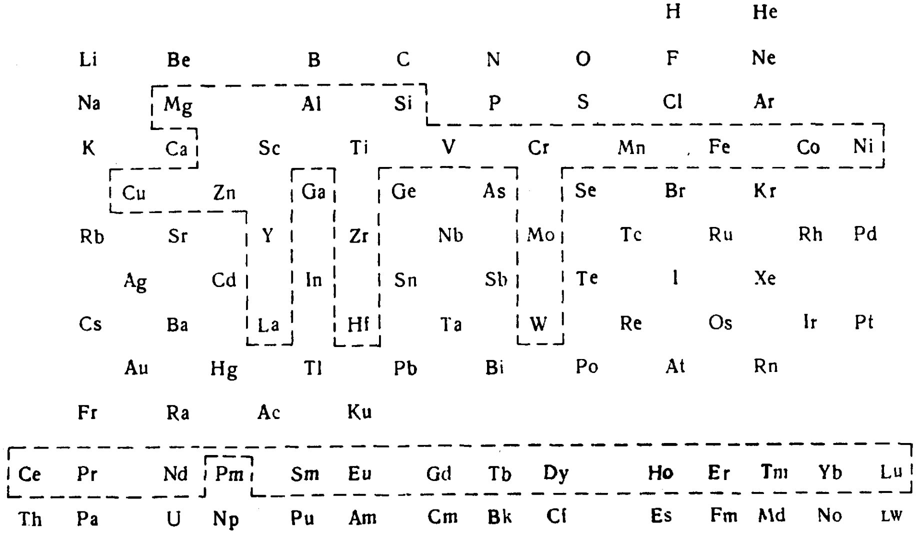
II. ACTIVITY OF OXIDE CATALYSTS

1. Individual Oxides

Thirty individual oxides (Table 1) and several mixed oxide systems have been examined as catalysts for the hydrogenation of alkenes. The largest number of investigations have been made on the oxides of zinc, aluminium, and chromium. The alkenes to be hydrogenated ranged from C_2 to C_8, most of the work being done on ethylene and propene.

Tables 2-4 give details of the conditions of preparation of the catalysts and the study of hydrogenating activity. Some 70% of the researches were made by a static method, and the remainder under flow conditions. The temperature range of the investigations was extremely wide, from −120°C for chromic oxide to 500–550°C with alumina, silica, and vanadium sesquioxide. The pressure of the

Table 1. Elements whose oxides have been investigated in the hydrogenation of alkenes.



reaction mixture under flow conditions was usually atmospheric, but in the static method it varied from 45 torrs to 60 atm. The molar ratio of hydrogen to alkene usually exceeded unity.

Table 2. Conditions of preparation and activation of oxide catalysts for the hydrogenation of alkenes.

It is evident from Tables 2-4 that quantitative comparison of oxides with respect to catalytic activity is difficult. Besides differences in methods of estimating activity, the oxides differed considerably in mode of preparation and conditions of activation. At the same time a cautious approach is necessary to assessing results obtained in individual investigations. Thus mutually different results were obtained in studies of the catalytic activity of aluminium oxide by six groups of workers[6-14,44]. Analogous differences are observed when a comparison is made of researches on the catalytic activity of the oxides of zinc[5,16,20,22-32] and vanadium[5,16,41]. Germain[45] remarks correctly that "the pretreatment of oxides is so important that some doubt must be cast on the significance of laws of hydrogenation". Another important factor determining the observed catalytic activity is the purity of the initial alkenes and hydrogen. The poisoning effect of water on the activity of oxides has now been proved. Nevertheless, the degree of purification of the gases was not indicated in the papers cited above. Thus the data in Tables 3 and 4 permit only certain qualitative conclusions on catalytic activities.

* In several cases the activity is expressed as the time τ required to reach a specified degree of conversion.

** Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tu, Yb, Lu.

From the above results it may be supposed that the oxides of titanium, iron, silicon, molybdenum, magnesium, and manganese are almost inactive, while those of aluminium, vanadium, and nickel exhibit slight activity. Cobalt and zinc oxides are moderately active. The most active are chromic oxide, rare-earth metal oxides, and the analogous yttria and scandia, which approach metals in their catalytic properties. Thus chromium and lanthanum sesquioxides are able to catalyse the hydrogenation of ethylene even at -120°C.[33]

A semiquantitative comparison is possible for three groups of oxides. Thus Lazier and Vaughen[5] used a recirculation method to compare the activities of magnesium, titanium(IV), vanadium(III), chromium(III), manganese(II), zinc, and molybdenum(III) oxides. The catalysts differed in method of preparation, but the conditions of activation—treatment with hydrogen at 400°C—were the same (Table 2). Chromic oxide was more active than the zinc and molybdenum oxides; the remaining oxides were inactive. On the whole these results agree with subsequent investigations. Other workers[16] have also found manganese(II) oxide to be inactive. However, varying the conditions of preparation and pretreatment has revealed some slight activity in titanium and vanadium oxides[16,41].

* Total pressure brought to 1 abs. atm with nitrogen or helium.

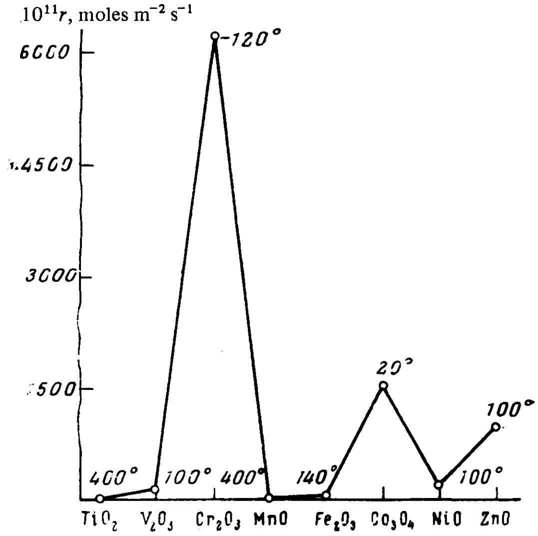

Figure 1. Catalytic activity of oxides of elements in the first transition series towards the hydrogenation of ethylene at various temperatures, where r is the reaction velocity.

Harrison et al.[16] examined the catalytic activity of oxides of transition elements in the fourth period (with the exception of scandium and copper oxides) towards the hydrogenation of ethylene. Comparison of the oxides was not altogether rigorous, for methods of preparation and conditions of activation varied considerably. Furthermore, initial rates of hydrogenation on these oxides were determined at different experimental temperatures. The two-peak pattern of catalytic activity obtained for this series of oxides (Fig. 1) was explained in terms of the electron configuration of the cations containing 3*d* electrons, in conformity with Dowden's ideas[46]. Increase in the coordination number of the cations Cr^{3+} and Co^{3+} from 5 to 6, in contrast to other cations, was accompanied by a greater gain in stabilisation energy of the crystal field. Hence adsorption or other stage accompanied by a change in coordination number was assumed to be the limiting stage. The two-peak pattern of variation in catalytic activity in the series of transition-metal oxides in the fourth period has been confirmed[47] in a study of the hydrogenation of propene by a pulse microcatalytic method.

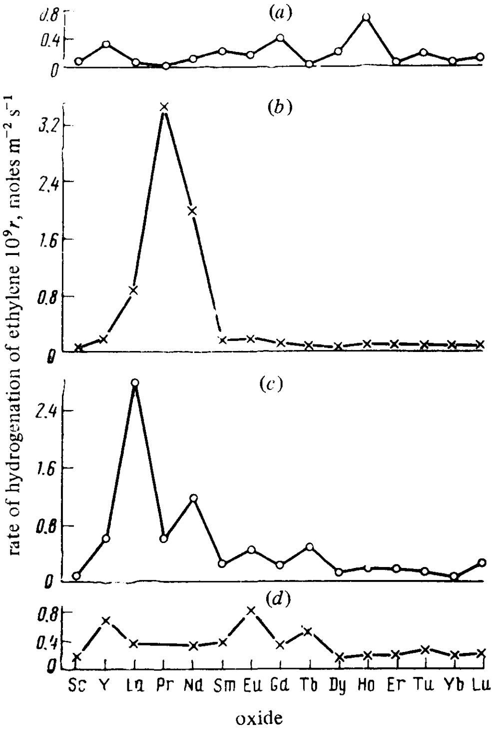

Figure 2. Catalytic activity of rare-earth sesquioxides at different temperatures (after ignition at different temperatures, °C): *a*) 20 (600); *b*) −78 (700); *c*) −78 (800); *d*) −78 (900).

An investigation has been made[33] of the catalytic activity of oxides of rare-earth metals from lanthanum to lutetium, as well as the oxides of scandium, yttrium, zirconium, hafnium, and chromium, towards the hydrogenation of ethylene. All the catalysts were prepared in the same way and were conditioned in a vacuum (to 10^{-5} torr) at various temperatures. Praseodymium, cerium, and terbium oxides were also hydrogenated and the reduced specimens were further conditioned in a vacuum at the same temperature.

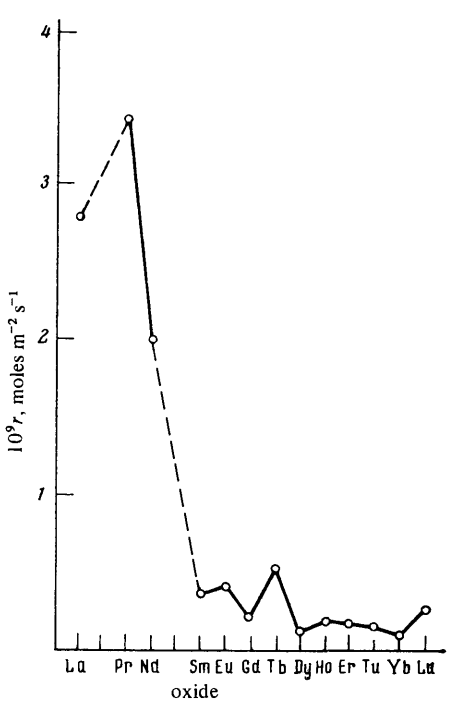

Figure 3. "Maximum" catalytic activity of rare-earth sesquioxides in the hydrogenation of ethylene at −78°C.

The catalytic activity of lanthanum, praseodymium, and neodymium oxides passed through a maximum with increase in the temperature of ignition; with all the other rare-earth sesquioxides the activity increased steadily. This feature of the behaviour of the three oxides was due to their ability to undergo a polymorphic transformation over the temperature range 600–900°C, from a body-centred cubic structure (*C*-form) to a hexagonal structure (*A*-form). It was therefore assumed that the accompanying increase in coordination number of the cation (from 6 to 7) diminished the catalytic activity. A similar conclusion follows also from results for non-stoichiometric oxides of cerium, terbium, and praseodymium. The dioxides of these metals have a fluorite structure with coordination number 8, and do not exhibit catalytic activity. The appearance of activity in the terbium and praseodymium oxides after ignition at 800°C is due to their partial decomposition, leading to a structure, derived from fluorite, with a certain number of vacancies in the oxygen sublattice and some cations having coordination number < 8.

Fig. 2 shows that the law of variation of specific catalytic activity in the series of rare-earth oxides is determined by the temperature of ignition. Thus the activity of lanthanum oxide is least after vacuum treatment at 600°C, and greatest after such treatment at 800°C.

Praseodymium and neodymium oxides exhibit maximum activity after ignition at 700°C, but many other oxides at 900°C. Thus these oxides require different ignition temperatures before they develop their maximum catalytic activity. The results indicate the difficulty of comparing the catalytic activities of oxide systems.

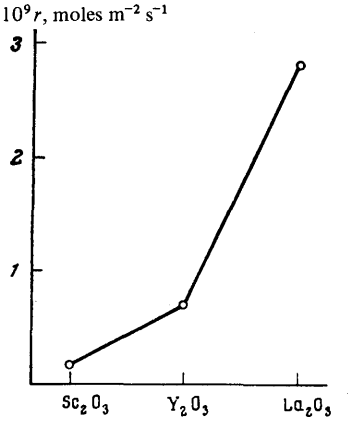

Figure 4. Activity of oxides of the scandium subgroup in the hydrogenation of ethylene at −78°C.

It has been suggested[33] that oxides should be compared after they have been ignited at temperatures ensuring maximum activity. Fig. 3 shows that such comparison gives for rare-earth oxides activities differing by factors of $10-10^2$. In this respect the rare-earth oxides differ significantly from those of transition elements in the fourth period, whose catalytic activities vary by factors of 10^2-10^3. The greatest variation in activity is observed in the series of oxides from lanthanum to gadolinium (cerium subgroup); the remaining oxides (yttrium subgroup) show a less marked variation. It is interesting that the fundamental chemical properties also show greater variation in the former than in the latter subgroup. Scandium and yttrium oxides were closely similar in catalytic activity (Fig. 4), as in many other chemical properties, to oxides of the yttrium subgroup.

Table 5. Hydrogenating activity of oxides (rate of hydrogenation of ethylene at −78°C) and electron configuration of cations.

Oxide	Configuration	$10^9 r$, mole m^{-2} s^{-1}	Oxide	Configuration	$10^9 r$, mole m^{-2} s^{-1}
Sc_2O_3	$3d^0$	0.16	La_2O_3	$4f^05d^0$	2.8
TiO_2		0.0 (Refs.5, 16)	CeO_2		0.0
Y_2O_3	$4d^0$	0.6	Lu_2O_3	$4f^{14}5d^0$	0.25
ZrO_2		0.0	HfO_2		0.01

Comparison of the activities of a few pairs of oxides (Table 5) indicates that catalytic activity does not depend solely on the electron configuration of the cation. Theoretical views suggested[46] that the activity of scandium oxide would be low, which is inconsistent with recent results[33].

The fall in catalytic activity of the oxides observed from lanthanum to lutetium and from lanthanum to scandium (Figs. 3 and 4) correlates with the decrease in their basicity[48]. This correlation explains also certain other experimental results: (i) acidic oxides—the dioxides of cerium, praseodymium, terbium, zirconium, and titanium—are not active catalysts for the hydrogenation of ethylene; and (ii) acidic impurities—oxides of nitrogen, carbon dioxide, and water—are catalytic poisons.

2. Multicomponent Oxide Catalysts

Study of a chromium–alumina catalyst in the hydrogenation of butene revealed[49] that it was relatively unstable and highly sensitive to traces of moisture, oxygen, and the treatment conditions. The butene was 5–50% hydrogenated over the temperature range 220–340°C. Hydrogenation of ethylene on this type of catalyst[50] gives yields of ethane reaching 80–90% with an equimolecular mixture of ethylene and hydrogen having a space velocity of 1000 h^{-1} at 400–470°C. The hydrogenation of propene on a potassium–chromium–alumina catalyst has been studied[51] by a pulse method at 450–600°C.

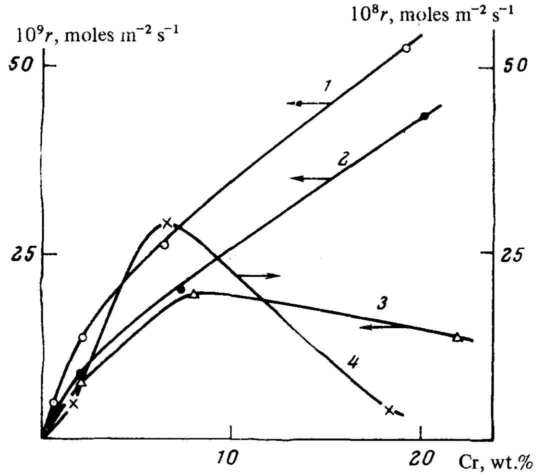

Figure 5. Rate of hydrogenation of ethylene at −78°C on alumina–chrome catalysts obtained by the impregnation with chromium trioxide of: 1) boehmite; 2) bayerite; 3) γ-alumina; 4) hydrargillite.

A circulatory static method, with an equimolecular mixture of hydrogen and ethylene at an initial pressure of 60 torrs, has been used[52] to investigate the effect of method of preparation on the activity of these types of catalyst in the hydrogenation of ethylene at −78°C. The catalysts can be divided into two groups according to the dependence of the activity on the chromium content (Fig. 5). One group includes chromium–alumina catalysts based on boehmite and bayerite (curves *1* and *2*); catalysts prepared from hydrargillite and from γ-alumina belong to the second group. Catalysts of the first group become more active with increase in the chromium content, whereas the activity of the others passes through a maximum at 7–10 wt.% of chromium.

The difference observed between the two types of chromium–alumina catalysts was explained by differences in the distribution of chromic oxide on the carrier surfaces. This involved the postulate that, with boehmite and bayerite catalysts, the proportion of Cr^{3+} ions in the surface layer increased continuously with the concentration of chromic oxide. With catalysts based on hydrargillite and γ-alumina a similar relation is observed only at low concentrations of chromic oxide. With further increase the fine crystals (or clusters) of the oxide become larger, which may lead to a decrease in the surface concentration of Cr^{3+}, and hence in catalytic activity. Catalysts based on hydrargillite are the most active: with 6–8% of chromium their activity is about tenfold that of any other chromium–alumina catalyst, and they are only slightlv inferior to chromic oxide, for which the reaction velocity under the same conditions is 50×10^{-8} mole m^{-2} s^{-1}. The introduction of potassium into a boehmite chromium–alumina catalyst diminishes the activity (Table 6).

Table 6.

Potassium, wt.%	0	0.5	1.0	2.0	4.0
$10^9 r$, moles m^{-2} s^{-1}	27	25	23	19	17

Fig. 6 illustrates the degree of conversion of ethylene into ethane on a chromium–alumina catalyst as functions of the partial pressures of water, pyridine, ammonia, and thiophenol. The toxicity of these substances towards catalysts varies in the same sequence as their acidity, which reveals the basic nature of the active centres.

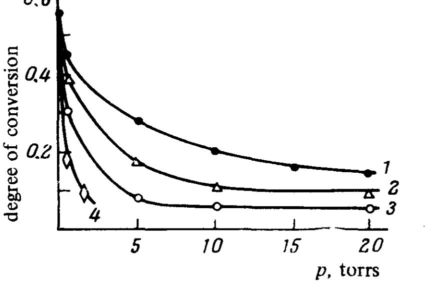

Figure 6. Kinetic isotherms for the poisoning of an alumina–chrome catalyst in the hydrogenation of ethylene at 420°C by: 1) ammonia; 2) pyridine; 3) water; 4) thiophenol.

In the presence of a zinc chromite catalyst[22] ethylene was hydrogenated at 215–250°C. On an $MoO_3.Al_2O_3$ catalyst[53], after activation with hydrogen at 500°C, ethylene was hydrogenated over roughly the same temperature range as on chromic oxide catalysts. A vanadium–aluminium catalyst is active[41] in this hydrogenation at 400–450°C. Komarevsky et al.[54–56] found that this catalyst, reduced with hydrogen at 400°C, catalysed the hydrogenation of butene, hexene, octene, butadiene, and acetylene; under 115 atm at 475°C even benzene could be 27% hydrogenated.

The hydrogenation of heptenes is strongly catalysed by $CoO.MoO_3.Al_2O_3$ over the range 250–275°C.[57] Parravano et al.[58] reported that ethylene can be hydrogenated on an aluminosilicate at 345°C, a result qualitatively confirmed by Topchieva et al.[59] According to these workers aluminosilicates catalyse the hydrogenation of propene only after pretreatment with hydrogen at 550°C. An aluminosilicate containing 0.01% of sodium was more active than a specimen containing a larger quantity. The rate of hydrogenation of ethylene diminishes with increasing acidity of aluminosilicate catalysts[60].

Table 7. Activity (measured by rate of hydrogenation) of neodymium compounds.

Compound	$10^3 r$, mol. s^{-1} Nd^{3+} ion^{-1}
Nd_2O_3, *A*-form	0.15
Nd_2O_3, *C*-form	1.2
74 mole % Nd_2O_3-CeO_2	1.2
37 mole % Nd_2O_3-CeO_2	0
$7Nd_2O_3.9SiO_2$	0.022

Several neodymium compounds have been compared with the *A*- and *C*-forms of the oxide in the hydrogenation of ethylene at −78°C (Table 7).[61] Analysis of the results revealed a relation between the activity and the coordination number of neodymium. The *C*-form of the oxide and a solid solution of 74 mole % of the oxide with cerium dioxide, containing Nd^{3+} in octahedral coordination, had similar activities per cation. The corresponding 37 mole % solid solution was catalytically inactive and contained cations only with coordination number 8. The orthosilicate $7Nd_2O_3.9SiO_2$ contained two types of cations, the relative proportions of which with 7 and 9 coordination were 2 : 5. If it is postulated that the latter cations are inactive, recalculation for cations of coordination number 7 yields a value (8×10^{-5} mol. s^{-1} ion^{-1} Nd^{3+}) very close to the activity of the *A*-form of neodymium sesquioxide with Nd^{3+} ions in the same coordination.

3. Zeolite Catalysts

Until recently few studies had been made of the influence of zeolites on hydrogenations. The activity of γ-type zeolites in the hydrogenation of ethylene was first established by Minachev et al.[62] for the neodymium, calcium, and decationised forms. Hydrogenation took place with a space velocity of 2000 h^{-1} at 78–150°C. With the conditions adopted for regeneration (treatment with air at 500°C for 2 h) the activity of the catalysts diminished from experiment to experiment. The zeolite containing neodymium was more active than the calcium and decationised forms; the sodium form was inactive. It is significant that the hydrogenation of ethylene in the presence of neodymium γ-zeolite was promoted by oxygen, which was later found to activate the hydrogenation of ethylene also with alumina[63].

Results obtained by Topchieva et al.[59,64] using a pulse method indicated that sodium, yttrium, and chromium-zeolites were active in the hydrogenation of propene at

200°C. The activity of the yttrium form depends on the temperature of pretreatment with hydrogen (200–640°C), reaching a maximum after activation at 350°C. Exchange of sodium for yttrium exceeding 50% produces sharply diminished selectivity of hydrogenation. Thus, whereas propane was the only product with yttrium γ-zeolite at a degree of exchange of 46%, the selectivity of the reaction with a specimen having 77% exchange did not exceed 30%. Similar results were obtained with the chromium form (degrees of exchange 4% and 11%). At 200°C the degree of hydrogenation on chromium γ-zeolite reached 23–50%. All specimens rapidly lost their activity. The initial activity of the sodium form was lower than those of the yttrium and chromium forms.

Table 8. Catalytic activity of zeolites and oxides in the hydrogenation of ethylene.

Catalyst	Temperature, °C		Reaction velocity, 10^3r, mol. s^{-1} ion^{-1}

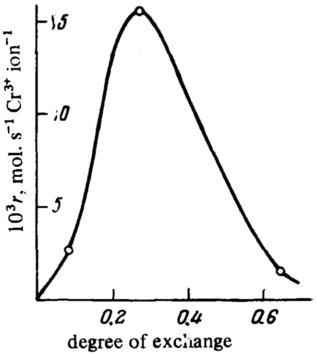

Figure 7. Dependence of activity of CrNa Y-zeolite in the hydrogenation of ethylene at 20°C on the degree of exchange of Na^+ for Cr^{3+}.

A detailed comparative investigation of the catalytic properties of various cation-exchange forms of γ-type zeolites in the hydrogenation of ethylene as functions of the type of cation, degree of exchange, and ratio of silicon to aluminium has been made[65,66] by a circulatory static method with an equimolecular mixture of hydrogen and ethylene at an initial pressure of 60 torrs. This has shown that, after vacuum treatment (10^{-5} torr) over the range 400–700°C (in steps of 100 deg), the sodium, copper, barium, calcium, and decationised forms of the zeolites were inactive from –78 to 400°C. Only zeolites containing tervalent cations—chromium, lanthanum, neodymium, and iron—were active (Table 8). With increase in the fraction of chromium exchange cations from 0.08 to 0.65 the catalytic activity passes through a maximum at a degree of exchange of 0.27 (Fig. 7).

Increasing the ratio of silicon to aluminium from 2.1 to 2.5 (cf. 0.8 CrNa and 0.65 CrNa Y-zeolites [Table 8]) leads to a change in catalytic activity. These results suggest non-uniformity of the active centres, probably due to differences in the distribution of cations among several possible sites[67]. Table 8 indicates also that the chromium form of the zeolite acquires its maximum activity after being heated in a vacuum at 500°C, which was the optimum temperature also for other cationic forms. Ignition at temperatures above 600°C caused irreversible loss of activity, although the zeolites retained their crystalline structure. This peculiarity of behaviour can be attributed to migration[67,68] of cations from large to small cavities, so that ion-exchange cations may form part of the active centres of hydrogenation. This hypothesis is supported by the qualitative analogy between the catalytic properties of oxides and zeolites. Oxides of tervalent elements form the activity sequence

$$Cr_2O_3 > La_2O_3 > Nd_2O_3 \gg Fe_2O_3,$$

which on the whole is consistent with that of the zeolites

$$\mathrm{CrNaU} > \mathrm{NdNaU} > \mathrm{LaNaU} \gg \mathrm{FeNaU}.$$

The activation energies for the hydrogenation of ethylene on oxides and zeolites are roughly equal at 3–6 kcal mole^{-1}. The lower activity of zeolites than of oxides may evidently be attributed to steric inaccessibility of some of the ion-exchange cations.

Table 9.

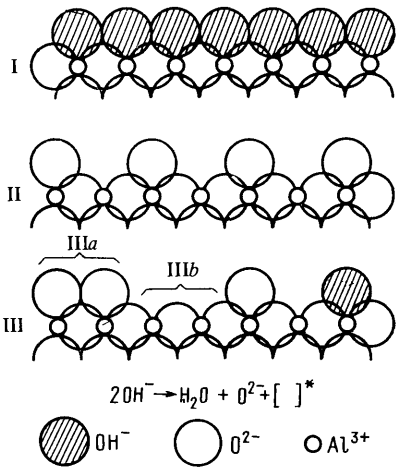
Zeolite	NaM	LiM	KM	CaM	MgM	ZnM	CdM	HM
Cyclohexane, %	98.3	87.7	11.0	98.6	69.4	59.7	17.4	19.7

Cationic forms of mordenite were first shown by Minachev et al.[69-71] to catalyse the hydrogenation of ethylene and benzene. Under the conditions adopted—$4H_2 + C_2H_4$ with space velocity 750 h^{-1} under 1–30 atm at 215–235°C—ethylene was completely hydrogenated in the presence of NaM zeolite; with the potassium form hydrogenation was 20–92% complete. Table 9 gives the yields of cyclohexane from the hydrogenation of benzene (C_6H_6 + $5H_2$ at 1 h^{-1} under 30 atm at 250°C).

III. NATURE OF THE CATALYTIC ACTIVITY

Despite the differences in approach by different authors and the use of an extremely wide range of methods, only a limited number of hypotheses have been made on the nature of the catalytic activity: (i) many workers suppose that coordinatively unsaturated cations are present in the active centre; (ii) in several papers catalytic activity was associated with ions of metals in a certain valency state; and (iii) several investigators assume that an active centre contains not only cations but also oxygen ions.

The first hypothesis provided an explanation for the many experimental data on the influence of heat-treatment conditions and the reversible poisoning effect of water vapour on the catalytic activity of oxides of aluminium[6,7], zinc[24,25,28,29], chromium[16-20], rare-earth metals[33-35], and silicon[15], as well as that of zeolites[66]. On this hypothesis the reason why oxides must be ignited for catalytic activity to develop is that, under the usual conditions of storage, the surface becomes hydrated by contact with atmospheric moisture, and contains no coordinatively unsaturated ions. The increase in activity as the temperature of ignition of the oxides is raised is attributed to increase in the number of such cations. The activity of zeolites passes through a maximum as this temperature is raised, which could be explained[66] by two factors: the activity of the zeolites is increased by the appearance of coordinatively unsaturated cations at high temperatures; on the other hand, the number of cations accessible to reactant molecules diminishes because of their migration into small cavities. Incorporation of cations into active centres follows also from the identity of the activity sequences of oxides and corresponding cationic forms of zeolites.



* Anionic vacancy on surface.

Figure 8. Diagram of cross-section through surface of aluminium oxide at various stages of dehydroxylation, with the surface: I) completely hydrated; II) completely dehydroxylated; III) partly dehydroxylated.

However, no quantitative comparison between the number of cations in a certain coordination environment and catalytic activity was made in the above studies. Such comparison is now possible for alumina, whose ability to catalyse the hydrogenation of ethylene at 250–450°C appears only after heat-treatment at 450°C,[6,7] when at least 30% of the surface aluminium ions change their coordination from 6 to 5.[72] Yet according to Weller and Hindin[7] the number of active centres does not exceed 1–2% of the total number of surface ions, since at this particular coverage with water the catalytic activity of alumina is completely lost. Raising the temperature of ignition from 450 to 550°C increases the number of coordinatively unsaturated cations only by 30%, while the catalytic activity increases by a factor of 20! Thus no direct functional dependence is present between the total number of coordinatively unsaturated cations and catalytic activity.

This conclusion suggests the non-uniformity of such cations, which is clearly illustrated by Peri's model of dehydroxylated aluminium oxide[72]. The partly dehydroxylated surface (Fig. 8) contains a disordered layer of ions: at some sites (III*a*) oxygen ions accumulate in direct contact, and at others (III*b*) coordinatively unsaturated cations are situated side by side. Catalytic activity towards hydrogenation could then probably be related to sites of the latter type. Their ability to catalyse migration of the double bond in butenes had earlier been proved by Peri[73]. The number of such sites (Fig. 8—II and III) and hence also the catalytic activity of the oxide should pass through maxima with increase in the degree of dehydroxylation (and in the ignition temperature). This conclusion is consistent with results for chromic oxide[33] and zinc oxide[23].

The relation between catalytic activity and the valency state of the cations has been discussed. Chromic oxide, CrNa Y-zeolite, and chromium–alumina catalysts strongly catalysed the hydrogenation of ethylene in the absence of Cr^{2+} ions[74]. Catalysts containing a considerable quantity of Cr^{5+} and Cr^{6+} ions were inactive, which allows us to reveal the catalytic activity of Cr^{3+} ions. With cerium, praseodymium, and terbium the sesquioxides also possessed catalytic activity, but the dioxides were almost inactive. Under the experimental conditions[74] ions of bivalent rare-earth metals were not formed, and hence the activity of these elements was due to the tervalent cation.

It was postulated in most of the above papers that ethylene underwent hydrogenation on a centre containing not only a cation but also an oxygen ion, but no evidence was given. Such evidence includes[33] the relation found between catalytic activity and basicity, which may be governed[75] by the oxygen ions.

IV. KINETICS AND MECHANISM OF THE HYDROGENATION OF ALKENES

The mechanism of the hydrogenation of alkenes (mainly ethylene) has been studied most thoroughly on the oxides of aluminium, zinc, chromium, and rare-earth metals. Kinetics, infrared spectroscopy, thermal desorption, and other methods enabling the reactivity of adsorbed species to be estimated have been used. In a few cases a tracer technique was applied. Since a kinetic method has been used most frequently, we begin with an account of the principal results obtained in studies of the kinetics of hydrogenation.

Table 10 shows that many kinetic equations have been suggested. One example indicated that the reaction velocity is almost independent of the partial pressures of the components[22]. According to others[23-26,35,38,39,77] the rate is determined solely by the pressure of hydrogen or ethylene. Two formulae[41,39] were of the first order with respect to the initial reactants, and in three cases[9,48,53] equations of the type $r = kP_{H_2}P_{C_nH_{2n}}^{0.5}$ were found. Thus inspection of Table 10 indicates that the kinetic orders with respect to hydrogen and the alkene usually vary from first to zero. The rate of the reaction is unaffected by the pressure of alkanes, except in experiments with silica and $CoO.MoO_3.Al_2O_3$ catalysts. The form of the kinetic equation depends on the chemical composition of the specimen, the conditions of pretreatment, and the temperature range of the investigation (cf. *2* and *3*, *9–11*, *13* and *14* in Table 10). The activation energy of the reaction varies over a wide range, from 0 to 24 kcal mole^{-1}, probably being a function of temperature. With the oxides of aluminium, zinc, and rare-earth metals the activation energy falls to zero with rise in temperature.

Table 10. Kinetic equations and activation energies of hydrogenation of alkenes on oxides.

No.	Catalyst	Equation	Activation energy, kcal mole^{-1}	Temp. range, °C	Ref.
1	Al_2O_3	$r = kP_{H_2}P^{0,5}_{C_2H_4}$	9 0	120—180 300—430	9

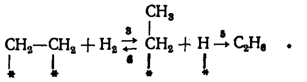
18	$MoO_3\cdot Al_2O_3$	$r = kP_{H_2}P^{0,5}_{C_2H_4}$	4	150—450	53
19	$CoO\cdot MoO_3\cdot Al_2O_3$	$r = kP_{H_2}(P_{C_nH_{2n}}/P_{C_nH_{2n+2}})$	22.5—24.5	250—375	57
20	Y_2O_3, La_2O_3, Ho_2O_3	$r = kP_{H_2}$	5—6	—22--22	77

* Experiments conducted in a stream of hydrogen after preliminary adsorption of ethylene, where $\theta_{C_2H_4}$ is the degree of surface coverage with ethylene.

The kinetic results can equally well be explained by the ideas of Eley and Rideal, who assume activation of only one of the reactants (hydrogen or alkene), and by those of Langmuir and Hinshelwood, who regard the interaction of adsorbed species as the limiting stage. In most of the papers cited it is assumed that the catalytically active surface is homogeneous. Nevertheless, the kinetic equations with fractional powers of reactant partial pressures (Table 10) can be explained also by energetic non-uniformity of the active centres.

Sinfelt[9] explained the kinetics of the hydrogenation of ethylene on aluminium oxide by means of Twigg's mechanism[78], involving a stage of interaction between hydrogen adsorbed by van der Waals forces and chemisorbed ethylene:

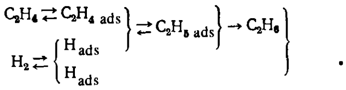
$$C_2H_4 \underset{2}{\overset{1}{\rightleftarrows}} \underset{*}{CH_2}-\underset{*}{CH_2}\ ,$$



$$\underset{*}{CH_2}-\underset{*}{CH_2} + H_2 \underset{4}{\overset{3}{\rightleftarrows}} \underset{*}{\overset{CH_3}{CH_2}} + \underset{*}{H} \xrightarrow{5} C_2H_6\ .$$

A comparative study of the catalytic activity of aluminium oxide towards the hydrogenation of ethylene and of hydrogen–deuterium exchange data suggested[6,7] that activation of ethylene was the limiting stage. Lucchesi et al.[79] detected by infrared spectroscopy the adsorbed ethylene and ethyl assumed in Twigg's mechanism.

Amenomiya and Cvetanovic[80] used thermal desorption to examine the mechanism of the hydrogenation of ethylene on aluminium oxide, and established the presence of two types of adsorption centres, differing in energy of bonding with ethylene. These centres occupy 2.8% of the alumina surface; 60% of them have an activation energy of desorption of 26.8 kcal mole^{-1}, and 40% an activation energy of 36.4 kcal mole^{-1}. Hydrogenation of ethylene occurred more readily on centres of weak adsorption. Ethylene sorbed on them gave with deuterium 1,2-dideuteroethane, which was regarded as indicating hydrogenation by Twigg's scheme. Interaction of the firmly bound ethylene with deuterium gave a mixture of all possible deuteroethanes, which was explained by a mechanism analogous to that suggested by Horiuti and Polanyi[81]:



$$\left.\begin{matrix}\left.\begin{matrix}C_2H_4 \rightleftarrows C_2H_{4\,ads}\\ H_2 \rightleftarrows \left\{\begin{matrix}H_{ads}\\ H_{ads}\end{matrix}\right.\end{matrix}\right\} \rightleftarrows C_2H_{5\,ads}\end{matrix}\right\} \rightarrow C_2H_6\ .$$

This involves a stage of dissociative chemisorption of hydrogen on centres with weak bonding of ethylene, and the formation of ethane via a semi-hydrogenated state.

An attempt[7] at a geometrical interpretation of the activation of ethylene on aluminium oxide suggested two possible mechanisms—adsorption of ethylene on two neighbouring aluminium ions in the corundum structure or two-point adsorption on an aluminium ion and an oxygen ion—the length of the aluminium–carbon bond being taken as 1.8 Å in both cases (as in aluminium alkyls). The activation of ethylene on vanadium sesquioxide was assumed[18] to involve adsorption on two vanadium cations.

Interesting results were obtained in studies of the mechanism of the hydrogenation of ethylene and propene on chromic oxide, which showed[19,20] that hydrogenation with deuterium at −78°C did not involve exchange with the hydrogen of the hydrocarbons. The hydrogenation of ethylene with an equimolecular mixture of gaseous hydrogen and deuterium gave[20] ethane, deuteroethane, and dideuteroethanes. Conner and Kokes[20] therefore assume dissociative chemisorption of hydrogen and successive addition of hydrogen atoms. A similar conclusion concerning the mechanism of the hydrogenation of ethylene on cobalt oxide between −78 and 30°C was drawn by some Japanese workers[42] from a study of reaction velocities and product compositions for the four systems

1. $C_2H_4 + H_2$
2. $C_2H_4 + D_2$
3. $C_2H_4 + C_2D_4 + H_2$
4. $C_2H_4 + H_2 + D_2$.

The largest number of investigations on the mechanism of hydrogenation have been made with zinc oxide. Teichner et al.[23-26,82], on the basis of a kinetic study, suggested a mechanism involving interaction between associatively adsorbed ethylene and dissociatively sorbed hydrogen. In contrast to the Horiuti–Polanyi scheme[81], all stages were assumed to be in equilibrium. This scheme was made somewhat more detailed. Catalytic activity was found[23,24] to be independent of the concentration of electrons in the conduction band. This was regarded as indicating a covalent form of chemisorption of hydrogen, as was confirmed also by infrared spectroscopy.

On the basis of infrared spectra Dent and Kokes[28] consider that hydrogen is chemisorbed on coordinatively unsaturated zinc and oxygen ions:

$$H_2 + \text{—}\overset{|}{Zn}\text{—}\overset{|}{O}\text{—} \rightleftarrows \text{—}\overset{H}{\overset{|}{Zn}}\text{—}\overset{H}{\overset{|}{O}}\text{—}\quad .$$

An analogous conclusion was reached by Eischens et al.[83] In the view of the former workers[84] the chemisorption of ethylene is a consequence of π-electron interaction with oxygen ions. Hydrogenation of adsorbed ethylene takes place by the successive addition of hydrogen atoms bound to zinc and oxygen atoms. In the first stage π-adsorbed ethylene becomes detached from oxygen and bound in its semi-hydrogenated form to a zinc atom. The truth of this mechanism is confirmed[85] by the detection, in the infrared spectra, of the compound $Zn-C_2H_5$, which on treatment with hydrogen disappeared at a rate closely similar to the rate of hydrogenation. Krause[86] also supposes that the hydrogenation of ethylene on zinc oxide involves an intermediate semi-hydrogenated form adsorbed on zinc atoms. In contrast to Dent and Kokes[28,84], he assumes that the π-adsorbed ethylene is attached only to zinc atoms.

Table 11. Results for the mechanism of the hydrogenation of ethylene on dysprosium sesquioxide at −55°C.

No.	Initial compound	Reaction products
1	$OH_{surf} + D_2$	HD found only at ⩾ 120°C
2	H_{ads} (w + s)*** + D_2	HD *in minor quantity*
3	H_{ads}(s) + D_2	HD not detected
4	H_{ads}(w + s) + C_2D_4	$C_2H_2D_4$ not detected
5	$C_2D_{4,\,ads} + H_2$	$C_2H_2D_4$
6	$C_2H_4 + H_2$	C_2H_6; $r = 0.46 \times 10^{-9}$*
7	$C_2H_4 + D_2$	99% $C_2H_4D_2$; $r = 0.30 \times 10^{-9}$
8	$C_2D_4 + H_2$	97% $C_2D_4H_2$; $r = 0.42 \times 10^{-9}$

10	$C_2H_6 + D_2$	HD, $C_2H_{6-x}D_x$—not detected
11	$H_2 + D_2$	HD, $r = 0.38 \times 10^{-9}$
12	$C_2H_4 + H_2 + D_2$ (1.7 : 1 : 1)	47% C_2H_6, 21% C_2H_5D, 32% $C_2H_4D_2$; HD**

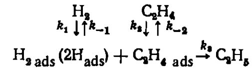
* Rates of reaction for 50% conversion r, mole m^{-2} s^{-1}.

** Detected only after ethylene had been completely hydrogenated.

*** Weakly (w) and strongly (s) adsorbed.

Baranski and Cvetanovic[30] have been able by means of thermal desorption to study the reactivity of five forms of adsorbed hydrogen and two forms of ethylene. They found that only the most weakly bound forms of hydrogen and ethylene take part in hydrogenation. The heat of adsorption of such ethylene is 4–6 kcal $mole^{-1}$. The yellow colour of tungsten oxide does not vanish when ethylene undergoes hydrogenation on the oxide. This suggested[40] that the reaction does not involve atomic hydrogen, and that ethane is formed by Twigg's scheme of interaction of physically adsorbed hydrogen with chemisorbed ethylene.

The mechanism of the hydrogenation of ethylene and propene on rare-earth oxides has been studied by both kinetic and isotope methods. Kinetic investigations by Topchieva et al.[35,38,39] established for the temperature range 130–190°C a mechanism of hydrogenation analogous to that of Polanyi and Horiuti[81], with interaction between the adsorbed alkene and dissociatively chemisorbed hydrogen assumed to be the limiting stage. The mechanism of the low-temperature hydrogenation of ethylene on dysprosium sesquioxide has been examined by isotope and thermal-desorption methods[33,87–89]. A series of reactions which might hypothetically occur in the ethylene–hydrogen–oxide system was studied (Table 11). It is evident for reaction *1* that the hydrogen of surface hydroxyls is not exchanged, and is probably not involved in hydrogenation, under the conditions of catalysis (−55°C). In conformity with reactions *2* and *3* it was established that the two different forms of chemisorbed hydrogen differed in reactivity. These results suggested that firmly sorbed hydrogen played no part in hydrogenation. Reactivity of adsorbed ethylene was shown in reaction *5*. The hydrogenation of ethylene (reactions *7* and *8*) gave only simple addition products. These results indicate absence of dissociative adsorption of ethylene or the ethane formed, which is supported by the investigation of reactions *9* and *10*, when the hydrogen of the hydrocarbons (ethane and ethylene) is not exchanged. Yet in the hydrogenation of ethylene with a mixture of protium and deuterium (reaction *12*) the products of simple addition—ethane and dideuteroethane—were accompanied by deuteroethane C_2H_5D, although H_2-D_2 exchange does not take place under the conditions of hydrogenation. Thus the above investigation shows that the reaction may occur via a semi-hydrogenated form:



$$\begin{matrix} H_2 & & C_2H_4 & & & & \\ {\scriptstyle k_1}\downarrow\uparrow{\scriptstyle k_{-1}} & & {\scriptstyle k_2}\downarrow\uparrow{\scriptstyle k_{-2}} & & & & \\ H_{2\,ads}(2H_{ads}) & + & C_2H_{4\,ads} & \xrightarrow{k_3} & C_2H_{5\,ads} & \xrightarrow{k_4} & C_2H_6, \end{matrix}$$

where stage 3 is irreversible.

Comparison of rates of hydrogenation of ethylene by reactions *6* and *7* revealed a kinetic isotope effect $r_H/r_D = 1.5$. Yet rates of hydrogenation of deuteriated and ordinary ethylene (reactions *6* and *8*) were almost the same. Hydrogen–deuterium exchange and the hydrogenation of ethylene took place at closely similar rates. Furthermore, the activation energies of the two reactions are also equal at ~ 5 kcal $mole^{-1}$. These results suggest that the hydrogenation of ethylene is limited by the activation of hydrogen. Nevertheless, such an assumption does not mean that hydrogenation can take place e.g. by the interaction of chemisorbed hydrogen with physically sorbed ethylene, according to Jenkins and Rideal's mechanism[90]. In the presence of oxide catalysts migration of the double bond in butenes is considerably more rapid than hydrogenation[66,91]. The sequences of catalytic activity of oxides for these reactions were closely similar, which suggested that active centres for activation of the double bond and for hydrogenation were analogous in nature. The mechanism of catalytic hydrogenation should therefore involve both stages—chemisorption of the alkene and chemisorption of hydrogen.

V. CONCLUSION

The information reviewed above shows that oxide catalysts are more complicated than metallic catalysts[1–4]. Work on the latter has developed several methods for obtaining pure and crystallographically uniform surfaces, which has permitted the comparison of metals according to their specific catalytic activity. With oxide catalysts such comparison encounters several difficulties, primarily because of the significant dependence of catalytic activity on conditions of pretreatment. This dependence is not always due solely to the desorption of impurities, as with metals, but is connected with surface oxidation, reduction, and dehydroxylation. Changes in chemical composition are often accompanied by crystallographic changes, which may also influence catalytic activity. This was shown quite clearly by the catalytic properties of oxides of rare-earth metals.

Existing data indicate that, with rise in the temperature of ignition, the activity of an oxide catalyst per square metre of surface increases to a certain limit or else passes through a maximum. The present Reviewers have therefore proposed comparing the "maximum" activities of oxides. However, the effect of ignition temperature on the activity of several oxides has not been studied, so that this approach does not lead to a quantitative comparison of all the catalysts studied.

Qualitative consideration of the data enables oxides to be divided into four groups

(1) very active—Cr_2O_3, La_2O_3, Pr_2O_3, Nd_2O_3

(2) active—Sc_2O_3, Y_2O_3, Sm_2O_3, Eu_2O_3, Gd_2O_3, Tb_2O_3, Dy_2O_3, Ho_2O_3, Er_2O_3, Tu_2O_3, Yb_2O_3, Lu_2O_3

(3) moderately active—Co_3O_4, ZnO

(4) relatively inactive—V_2O_3, NiO, Fe_2O_3, Al_2O_3, SiO_2, HfO_2.

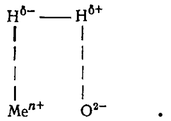
The oxides—ZrO_2, MoO_{2-x}, MgO, MnO, TiO_2, CeO_2, Pr_6O_{11}, and Tb_4O_7—exhibit hardly any activity.

It follows from the above enumeration that hitherto no study at all of catalytic activity has been made on the oxides of gallium, indium, thallium, germanium, tin, lead, niobium, tantalum, antimony, bismuth, tellurium, alkali metals, transuranium elements, and certain other elements intermediate in properties between metals and non-metals. No data are available on the catalytic properties of oxides of the platinum subgroup.

The lack of data for many oxides and the limited study made of others are probably among the main factors preventing any general approaches to the prediction of catalytic activity. The ideas of Dowden, who discussed the energetics of the interaction of an adsorbed particle with a coordinatively unsaturated cation, provide a partial understanding of the variation of activity in oxides of the first transition series. In order to explain the catalytic properties of rare-earth oxides the Reviewers suggested that activities were determined by interaction of an adsorbed molecule with a basic centre. This hypothesis provided a qualitative explanation also of the decrease in activity on passing from oxides to zeolites and silicates.

Thus the development of approaches to the forecasting of catalytic action depends on elucidation of the chemical nature and the structure of the active centre. However, an exact solution of the problem is impossible without elucidation of the chemical nature of the adsorbed species interacting on the surface and the mechanism of the reaction. Despite the abundance of kinetic papers, the mechanism of hydrogenation remains little studied. In experiments with butenes not only can hydrogenation be followed but the main laws governing migration of the double bond, which requires activation of the latter, can be determined. A series of oxides shows analogous variation in activity towards hydrogenation and towards migration of the double bond, which suggests that the active centres for activation of the alkene and for its hydrogenation are the same in nature. Migration of the double bond always occurs under milder conditions and at higher rates than does hydrogenation, which leads to the postulate that activation of hydrogen is the limiting stage. This conclusion has been proved experimentally in a study of the mechanism of the hydrogenation of ethylene on dysprosium oxide.

In spite of the differences in systems studied and in methods of investigation, most workers now consider that the active centre contains an ion-pair comprising a coordinatively unsaturated cation and an oxygen ion, which adsorb a polarised hydrogen molecule:



$$\begin{array}{ccc} H^{\delta-} & \text{—} & H^{\delta+} \\ \vdots & & \vdots \\ Me^{n+} & & O^{2-} \end{array} .$$

This mechanism of activation of the hydrogen molecule suggests that a correlation will exist between catalytic activity and the polarising effect of the ion-pair, which on the whole is apparent. Published information indicates that oxides of trebly charged cations are the most active, whereas those containing doubly and quadruply charged cations either are relatively inactive or do not catalyse hydrogenation at all. It follows also from the above mechanism that easily polarisable substances will act as poisons of catalytic hydrogenation. The relation found between the toxicity of poisons and their ability to abstract a proton supports the hypothesis that catalytic activity is due to an ion-pair. Metals, on the other hand, are not poisoned by most of the substances that are highly toxic to oxides (e.g. water, pyridine, alcohols, ketones).

In the case of alumina, detailed investigation has shown that not all coordinatively unsaturated ions are catalytically active. Centres of catalytic activity may be two adjacent segments of the surface (electron-donating and electron-accepting), respectively aggregates of coordinatively unsaturated cations and of oxygen ions. The diminished catalytic activity of oxides after ignition at high temperatures can be explained in terms of such a model by a redistribution of surface oxygen ions leading to a regular surface structure.

The absence of sufficiently accurate models of the surface for most oxides is currently a serious obstacle to confirming or refining existing views on the nature of active centres.

Liquid-phase Oxidation of Aldehydes

S.A.Maslov and E.A.Blyumberg

Published information on the kinetics and the mechanism of the low-temperature liquid-phase oxidation of various classes of aldehydes–aliphatic, aromatic, unsaturated–is surveyed, and the mechanism of the elementary stages under various conditions –with thermal and photochemical initiation, in the presence of catalysts, in various solvents–is discussed. The mechanism of the concerted oxidation of aldehydes with other organic compounds is also reviewed. Numerical data on these reactions are given in tables. Applications of the oxidation of aldehydes in chemical technology are described. A list of 134 references is included.

CONTENTS

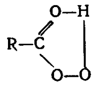
I. INTRODUCTION

The liquid-phase oxidation of organic compounds, the scientific principles of which were developed by Emanuel'[1], is used in many processes of modern chemical technology, in particular in the manufacture of acetic acid and acetic anhydride from acetaldehyde. The oxidation of aldehydes to peroxy-acids, as well as the concerted oxidation of aldehydes and alkenes, shows great practical promise[2]. The oxidation of aldehydes is also of considerable theoretical interest, since they serve as convenient model subjects for study of the kinetics and the mechanism of slow chain reactions with degenerate branching.

The first kinetic studies of the gas-phase oxidation of aldehydes[3,4] belong to the early period when Semenov was establishing the theory of chain reactions[5]. The first and later publications[6,7] give data on the rate of change of pressure and the accumulation of oxidation products of acetaldehyde in the region of slow oxidation and under conditions of cold and hot ignition; the reaction mechanism is also discussed.

Systematic investigations of the kinetics and the mechanism of the gas-phase oxidation of acetaldehyde made by Emanuel' and his coworkers[8-13] were summarised in a review[14]. Oxidation at 125–185°C was found to involve two consecutive chain reactions—(i) oxidation of acetaldehyde with its quantitative conversion into an intermediate hydroperoxide and (ii) interaction of acetyl hydroperoxide with acetaldehyde to form the final products—acetic acid, carbon dioxide and monoxide, ethylene, and water. The surface state of the reaction vessel had a considerable influence on both stages of the process. A discovery of great interest for the modern theory of chain reactions was the existence[9-15] of acyl hydroperoxides (peroxy-acids) in two states with a reversible transition between them as the temperature was varied; the heat of transition was 8 kcal $mole^{-1}$. On rapid cooling ("quenching") of the reacting gaseous mixture of aldehyde and oxygen, the peroxy-acid present passes into a state of enhanced reactivity, apparent in a fall in the ignition temperature when the mixture is reheated after quenching.

The change in the reactivity of peroxy-acids is due to the formation of an intramolecular hydrogen bond with transfer of the acidic proton from one oxygen atom to another.



followed by rearrangement of the valency bonds in the molecule[14,15].

The direct recording of acylperoxy-radicals $AlkCOOO^{\cdot}$ by electron spin resonance has yielded fresh information on the kinetics and the mechanism of the gas-phase oxidation of acetaldehyde at 230–350°C. Peracetic acid is formed by the interaction of acetylperoxy-radicals at $CH_3COOO^{\cdot}$ with acetaldehyde, is the chief intermediate responsible for degenerate chain branching in the oxidation of acetaldehyde, and decomposes mainly heterogeneously on the surface of the reaction vessel.

The oxidation by molecular oxygen of aldehydes in the liquid phase takes place under far milder conditions than in the gas phase. An increasingly large number of papers have appeared on the kinetics of these reactions. There are a few reviews[17-19], but they were published about twenty years ago, and furthermore pay insufficient attention to the elementary mechanism of the process. The present Review covers work on the kinetics and the mechanism of the liquid-phase oxidation of aldehydes by molecular oxygen† completed mainly during recent years. The numerical data obtained in these investigations—bond lengths, equilibrium constants, rate constants and activation energies of individual stages—are given in Tables 1 and 2.

The first experimental confirmation of the radical-chain mechanism of the oxidation of aldehydes was the abnormally high quantum yield (up to 15 000) obtained in the photochemical oxidation of heptanal and benzaldehyde[20].

---

† Henceforward the term "oxidation" will be used to imply liquid-phase oxidation by molecular oxygen.

Chain oxidation of aldehydes is effected both thermally and in the presence of various initiators and catalysts. The bonding energy $E_{C(O)-H}$ is relatively small (77–79 kcal mole^{-1}) in aldehydes[21], so that thermal initiation of oxidation is always very significant. In view of the ready oxidisability of aldehydes the value ~80 kcal mole^{-1} seems more justified than 87 kcal mole^{-1} [22,23] (furthermore, it should be the same for different types of aldehydes—acetaldehyde, benzaldehyde, and acrylaldehyde). Values of 74 and 88 kcal mole^{-1} have been published[24] for benzaldehyde and acetaldehyde respectively. It is beyond the scope of the present Review to discuss the accuracy of the values obtained for $E_{C(O)-H}$. If the chain-propagation rate constant k_2 is taken to be a measure of this bonding energy, however, such a large difference between the values for benzaldehyde and acetaldehyde is unjustified. Furthermore, this bonding energy should be smaller in acrylaldehyde than in acetaldehyde[25], which is also inconsistent with the above results[22,23].

Table 1. Length of chain in the oxidation of aldehydes.

Aldehyde	Initiation	Chain length	Temp., °C	Ref.
Benzaldehyde	$h\nu$	15 000	5	20
Heptanal	$h\nu$	4 000	5	17
Acetaldehyde	$h\nu$	10 000	5	1
Benzaldehyde	O_3	50 000	5	1
Butyraldehyde	O_3	200 000	5	1
Decanal	azoisobutyronitrile	8 450	25	1
Benzaldehyde	azoisobutyronitrile	1 050	25	1
Methacrylaldehyde	thermal oxidation	590	26	76
Benzaldehyde	»	450	45	76
Benzaldehyde	»	500	25	38
Heptanal	»	198	43	30
Heptanal	$h\nu$	150	10	35
Isobutyraldehyde	$h\nu$	1 200*	10	35
Isobutyraldehyde	thermal oxidation	250	20	29

* At low partial pressures of oxygen.

II. UNCATALYSED OXIDATION

The general scheme of the liquid-phase oxidation of organic compounds consists[1] of consecutive and parallel elementary stages of chain initiation, propagation, branching, and termination. We shall examine data on each of these stages for the liquid-phase oxidation of aldehydes.

Initiation of Chains

Chains may be initiated in liquid-phase oxidations by the reactions

$$RCHO + O_2 \xrightarrow{k_0} H\dot{O}_2 + RCO^{\cdot}; \quad (1)$$

$$RCHO + RCHO + O_2 \xrightarrow{k_{0'}} H_2O_2 + RCO^{\cdot}; \quad (2)$$

$$RCHO + RCHO \xrightarrow{k_{0''}} 2\,RCO^{\cdot} + H_2 \quad (3)$$

Table 2. Kinetic parameters of elementary stages in the oxidation of aldehydes (subscripts as in text).

Parameter	Aldehyde	Numerical value	Temp., °C	Solvent	Ref.

* Calculated from authors' data.
** Cobalt acetate as catalyst.
***Copper and iron phthalocyanines as catalyst.

From published bonding energies in reactant and product molecules the negative heats of reactions (1)–(3) for aldehydes having $E_{C(O)-H} \simeq 80$ kcal mole^{-1} can be estimated as 35, 20, and 55 kcal mole^{-1} respectively. Thus the termolecular reaction (2) is energetically the most favourable. In experimental kinetic investigations, however, various workers have observed both bimolecular and termolecular initiation. Reaction (2) has been established in the oxidation of acetaldehyde[26], decanal[27,28], and benzaldehyde[34]; initiation by reaction (3) occurs in the oxidation of isobutyraldehyde[29], benzaldehyde[30], α-alkylacrylaldehydes, and crotonaldehyde[31]. The pre-exponential factor of reaction (2) for saturated aldehydes is 10^3–10^5 M^{-2} s^{-1}; that of reaction (3) for unsaturated aldehydes is 10^3–10^4 M^{-1} s^{-1}, with E = 15–17 kcal mole^{-1}. In the oxidation of isobutyraldehyde initiation occurs mainly by reaction (3), the pre-exponential factor is 6×10^8 M^{-1} s^{-1}, and E = 19.5 kcal mole^{-1} (calculated from the Reviewers' experimental results).

The rate constant of initiation in the oxidation of benzaldehyde exceeds those for aldehydes of other types by factors of 10^2.[30] Available experimental results do not enable any unambiguous relation to be established between the structure of an aldehyde and the mechanism of the initiation of oxidation chains.

Initiation of the oxidation of aldehydes may occur also by the reaction[33]

$$RCH_2CHO + O_2 \rightarrow R\dot{C}HCHO + HO_2^{\cdot} \tag{4}$$

whose negative heat of reaction should be 25–30 kcal mole^{-1}. The radical $\cdot$CHR.CHO may give rise to formic acid, small quantities of which are present among the products of the oxidation of aldehydes containing two or more carbon atoms. It is formed as a result of decomposition of the hydroperoxide:

$$\mathrm{RCH(OOH){-}CHO \rightarrow OH^{\cdot} + RCH(\dot{O}){-}CHO \rightarrow RCHO + HCO^{\cdot};}$$
$$\mathrm{HCO^{\cdot} + OH^{\cdot} \rightarrow HCOOH.}$$

Abstraction of hydrogen from a methylene or a methyl group in an aldehyde is promoted by the presence of a catalyst[34].

Chain Propagation

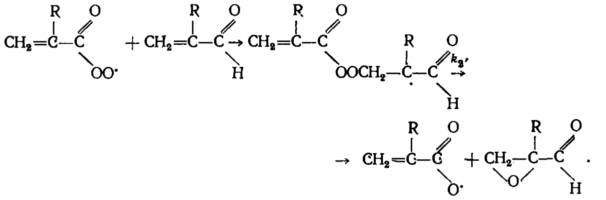
A chain is propagated by addition of an oxygen molecule to an acyl radical and abstraction of hydrogen from an aldehyde molecule by the acylperoxy-radical formed:

$$\mathrm{RCO^{\cdot} + O_2 \xrightarrow{k_1} RCOOO^{\cdot};} \quad (5)$$
$$\mathrm{RCOOO^{\cdot} + RCHO \xrightarrow{k_2} RCOOOH + RCO^{\cdot}.} \quad (6)$$

Reaction (5) is exothermic (~ 20 kcal mole^{-1}) and is very rapid, with rates of 10^7–10^8 M^{-1} s^{-1} and almost zero activation energy (E_1 = 2.0 ± 1.5 kcal mole^{-1} was given[35] for the oxidation of heptanal). Reaction (6), leading to the formation of peroxy-acids, is also exothermic, but less strongly so than reaction (5). The activation energy E_2 = 4–6 and 3–5 kcal mole^{-1} respectively for saturated aliphatic[27,29,35] and unsaturated[31] aldehydes, the corresponding pre-exponential factors being 10^5–10^6 and 10^3–10^4 M^{-1} s^{-1}, so that rates of chain propagation are higher in the oxidation of saturated aldehydes (by factors of 10–10^2). In the oxidation of benzaldehyde E_2 has the values 1–2 and 6–8 kcal mole^{-1} in the absence of a catalyst[28,30,36] and in the presence of cobalt acetate respectively[37,38]; the pre-exponential factor is 50 000 M^{-1} s^{-1}.[28] Values differing almost tenfold have been given[28,39] for the rate constant k_2 for benzaldehyde, the lower of which is fivefold the rate constant k_2 for decanal[27] and coincides with those obtained[39] for saturated aliphatic aldehydes. According to these measurements[39] k_2 for benzaldehyde is almost tenfold those for aliphatic aldehydes, e.g. acetaldehyde. Thus values of k_2 determined by different workers vary by almost a whole order of magnitude. The lower rate of chain propagation (and hence of the overall oxidation) with unsaturated aldehydes can be explained[25] by features of the intermediate complex formed in reaction (6) with compounds having conjugated double bonds. The hypothesis that reaction (6) involves the intermediate complex $[\mathrm{RO_2^-} : \dot{\mathrm{H}}\ \overset{+}{\mathrm{R}}{}']$ was put forward[40] for the oxidation of substituted aromatic ethers.

It can now be accepted that the rates of oxidation of unsaturated aldehydes are substantially lower than those of the corresponding saturated aldehydes[31]. This is probably due not only to different rates of chain propagation but also to the rate of initiation.

The mechanism of the oxidation of unsaturated aldehydes (α-alkylacrylaldehydes) involves not only reaction (6) but also another chain-propagating reaction, between an acylperoxy-radical and the double bond of the aldehyde[41]:



(7)

Occurrence of this reaction is supported by the presence of α-alkylepoxypropionaldehydes among the oxidation products from α-alkylacrylaldehydes.

Chain propagation in the oxidation of aldehydes may involve not only RCOOO$\cdot$ radicals but also acyloxy-radicals RCOO$\cdot$ formed by cleavage of peroxy-acids at the RCOO–OH bond:

$$\mathrm{RCOO^{\cdot} + RCHO \xrightarrow{k_{2''}} RCOOH + RCO^{\cdot}.} \quad (8)$$

This reaction, leading to the formation of acids, competes with decomposition of the acyloxy-radicals[42,43], which occurs at 20–70°C with considerable rapidity. At sufficient aldehyde concentrations reaction (8) predominates. This is confirmed by experiments on the decomposition of acetyl peroxide in the presence of 3 M acetaldehyde in benzene solution at 70°C, in which the yield of acetic acid per mole of peroxide decomposed exceeded fourfold the yield of carbon dioxide[44]. The rate constant $k_{2''}$ was not estimated.

Branching of Chains

Degenerate branching of chains probably plays a less significant role in the liquid-phase oxidation of aldehydes than in the oxidation of hydrocarbons. This may be deduced from a comparison of the rate of thermal initiation by reaction (2) with the rate of radical decomposition of peroxy-acids

$$\mathrm{RCOOOH \xrightarrow{k_3} RCOO^{\cdot} + OH^{\cdot}.} \quad (9)$$

The activation energy of reaction (9) for peracetic and perbenzoic acids is[45–47] 30–33 kcal mole^{-1} (which corresponds to the energy of the oxygen–oxygen bond in a peroxy-acid). The pre-exponental factor is 10^{13}–10^{14} s^{-1}, which is fully consistent with the unimolecular reaction (9): the factor would have been considerably smaller for induced decomposition of the peroxy-acids. The rate constant of reaction (9) at 70°C is $k_3 = 10^{13} = \exp(-30\,000/RT) = 10^{-6}$ s^{-1}. When the concentration of the peroxy-acid is 0.2 M, the rate of degenerate chain branching by reaction (9) is 2×10^{-7} M s^{-1}. Yet the rate of chain initiation by reaction (2) in the oxidation of acetaldehyde under these conditions is 1.05×10^{-6} M s^{-1} [48] (or 3.6×10^{-7} M s^{-1} [44]). Thus the rate of degenerate branching (9) is even somewhat smaller than the rate of initiation (2). A similar conclusion was reached[30] from a comparison of the rates of decomposition of perbenzoic acid and of thermal initiation of chains in the oxidation of benzaldehyde. Peroxy-acids can evidently decompose also by a bimolecular reaction

$$\mathrm{2RCOOOH \rightarrow RCOOO^{\cdot} + RCO^{\cdot} + H_2O}$$

analogous to the reaction for hydroperoxides. The rate constant of this reaction for peroxy-acids has not been measured. In the oxidation of hydrocarbons $k_3 = 10^6$ M^{-1} s^{-1} at 40–60°C.[1]

A possibility in the low-temperature oxidation of aldehydes is that chain branching may occur by breakdown of an addition product of peroxy-acid and aldehyde (henceforward termed for brevity an "adduct")[49]. Addition of a small quantity of the adduct (1-hydroxyethyl peracetate) to a solution of acetaldehyde in acetic acid eliminated the induction period and accelerated considerably oxidation of the aldehyde at 18°C. Under the experimental conditions this peroxy-compound broke down mainly by a molecular mechanism, but a small fraction (~0.1%) of the peroxide decomposed into radicals. Unfortunately, the paper did not contain sufficient data for the rate of initiation to be estimated, and only the actual fact of the initiating action of the adduct at low temperatures can be established. With rise in temperature the importance of this mode of degenerate chain branching will probably diminish because of a shift in the adduct equilibrium towards formation of the corresponding peroxy-acid and the aldehyde.

Termination of Chains

In the liquid-phase oxidation of aldehydes termination is effected by the recombination of radicals:

$$RCO^{\cdot} + RCO^{\cdot} \xrightarrow{k_4} \text{Molecular products} \qquad (10)$$

$$RCO^{\cdot} + RCOOO^{\cdot} \xrightarrow{k_5} \text{Molecular products} \qquad (11)$$

$$RCOOO^{\cdot} + RCOOO^{\cdot} \xrightarrow{k_6} \text{Molecular products} \qquad (12)$$

The relative rates of these reactions are directly dependent on the concentration of dissolved oxygen: at low concentrations termination occurs predominantly by reaction (10); with excess of oxygen, because of the higher rate of reaction (5) than of (6), the system contains almost solely RCOOO· radicals, the only termination reaction is (12), and the rate of oxidation becomes independent of the oxygen concentration. The dependence of the rate of oxidation on the concentrations of the starting materials is given by the formula

$$W = W_{\infty}\left[1 + \frac{k_5}{k_6}\frac{k_2[\mathrm{RH}]}{k_1[\mathrm{O_2}]} + \frac{k_4}{k_6}\left(\frac{k_2[\mathrm{RH}]}{k_1[\mathrm{O_2}]}\right)^2\right]^{-1/2},$$

where

$$W_{\infty} = \frac{k_2}{k_6^{1/2}}[\mathrm{RH}]W_i^{1/2},$$

in which W_i is the rate of initiation.

Experimental results for the dependence of the rate of oxidation of acetaldehyde in benzene solution on the concentration of dissolved oxygen[50] are well reproduced by this formula. The rate becomes independent of the oxygen concentration when the latter reaches 0.2 M.[50]

A similar dependence of reaction velocity on partial oxygen pressure was obtained[35] for the oxidation of benzaldehyde. At low oxygen concentrations, when $[C_6H_5CHO]/p_{O_2} \geqslant 0.01$ M mm^{-1}, the rate of reaction is linearly dependent on the partial pressure, but with ratios $\leqslant 0.002$ M mm^{-1} (which corresponds to 0.1 M oxygen) it is independent of the oxygen pressure. The intermediate range of $[C_6H_5CHO]/p_{O_2}$ ratios is characterised by a fractional kinetic order with respect to molecular oxygen. It is interesting that the limiting oxygen concentration (0.1–0.2 M) at which the rate of oxidation of the aldehyde ceases to depend on the oxygen pressure far exceeds the values usual for the oxidation of hydrocarbons (e.g. $\sim 10^{-5}$ M for ethyl linoleate[51] and tetrahydronaphthalene[1]). An explanation offered[50] for this was that the rate constant of reaction (10), in competition with reaction (5), is greater for acyl radicals RCO· than for alkyl radicals R·.

In practice the oxidation of aldehydes is almost always conducted under conditions such that chain termination occurs solely by reaction (12). It was usually considered that no activation energy was involved, but values E_6 = 1–3 and 4 kcal mole^{-1} were obtained in the oxidation of unsaturated aldehydes[31] and of isobutyraldehyde[29] respectively. The pre-exponential factors of reaction (12) are 10^4–10^5, 10^6–10^7, and 10^8 M^{-1} s^{-1} for unsaturated aldehydes, saturated aliphatic aldehydes, and benzaldehyde. The difference in these factors for different groups of aldehydes remains difficult to understand (especially the low values for unsaturated aldehydes[31]). The activation energy of chain termination also requires further experimental study. In the oxidation of unsaturated aliphatic aldehydes[41] termination may occur also by means of the radical $CH_2:\dot{C}R.CO.O.O.CH_2.CR(CHO)^{\cdot}$, whose transformation leads to formation of the polyperoxide

$$CH_2{=}C(R){-}C(O){-}OO{-}CH_2{-}\overset{\overset{\displaystyle R}{|}}{C}(CHO){-}OO{-}CH_2{-}\overset{\overset{\displaystyle R}{|}}{C}(CHO){-}OO{-}\cdots$$

Only fragmentary data are available on the nature of the molecular products of chain termination in the oxidation of aldehydes. For example, butane-2,3-dione, formed by the recombination of acyl radicals, has been identified[52] among the oxidation products from acetaldehyde in benzene solution with low concentrations of oxygen at 70°C. The oxidation of benzaldehyde in acetic acid[53] yields benzoyl peroxide, perhaps because of chain termination by reaction (12). Acetic anhydride among the oxidation products of acetaldehyde was attributed[54] to chain termination by the reaction RCO· + RCOO·, but no experimental results were given in support.

Because of the great length of the chain, products of termination are formed in very small quantities, and cannot always be identified. Table 1 gives data on the length of the chain in the oxidation of aldehydes.

Mechanism of Formation of Molecular Products

Molecular products may be formed both from the radicals responsible for the chain process and from valency-saturated molecules. The RCOO· radicals formed at the stage of degenerate branching by decomposition of peroxy-acids readily undergo decarboxylation:

$$RCOO^{\cdot} \xrightarrow{k_7} R^{\cdot} + CO_2. \qquad (13)$$

However, if an aldehyde is present in the system, competition by reaction (8) noted above results in formation of a far smaller quantity of carbon dioxide than from decomposition of the peroxy-acid in an inert solvent. Thus addition of acetaldehyde in the decomposition of acetyl peroxide in benzene solution at 70°C lowered the yield of carbon dioxide from 80 to only 25 mole % of the peroxide decomposed[44].

Carbon dioxide may be formed also from acylperoxy-radicals:

$$RCOOO^{\cdot} \rightarrow RO^{\cdot} + CO_2. \qquad (14)$$

However, no experimental results have been published on this reaction. It has merely been postulated[55] among other hypothetical reactions possible in the oxidation of acrylaldehyde.

The formation of carbon dioxide in the oxidation of acetaldehyde by air was studied[56] in benzene solution under 50 atm at 60°C. Hardly any carbon dioxide was formed in a glass reaction vessel, which indicated that reaction (14) occurs predominantly by a heterogeneous mechanism. This is confirmed by the increased yield of carbon dioxide produced by increasing the ratio of surface to volume of the reaction vessel.

Carbon monoxide is probably formed by the decomposition of acyl radicals[57]:

$$RCO^{\cdot} \xrightarrow{k_8'} CO + R^{\cdot} \qquad (15)$$

Acids are formed in the oxidation of aldehydes as a result of reaction between the aldehyde and the peroxy-acid:

$$\mathrm{RCOOOH} + \mathrm{RCHO} \overset{K_9}{\rightleftarrows} \mathrm{X}, \qquad (16)$$

$$\mathrm{X} \xrightarrow{k_{9'}} 2\,\mathrm{RCOOH}. \qquad (17)$$

It was suggested[58] that this reaction involves the intermediate formation of a compound X (an "adduct") having the structure R.CH(OOH)–O.CO.R. A detailed study was made of the kinetics of the formation of acetic acid in the oxidation of acetaldehyde[28]. The experimental results were fully described by the kinetic scheme involving intermediate formation of the adduct. The equilibrium constant K_9 for acetaldehyde is 0.1–0.3 M at 25°C [55,58-60], and E_9 = 5.5 kcal mole^{-1}.[59] Values of the rate constant $k_{9'}$ obtained by several workers[49,61,62] for decomposition of the adduct showed satisfactory agreement. Activation energies $E_{9'}$ = 19 and 15 kcal mole^{-1} were obtained[61,17]. The many independent determinations and the good agreement among the results indicate that K_9 and $k_{9'}$ may well be among the most reliably determined elementary constants in the oxidation of aldehydes.

There is considerable disagreement as to which classes of aldehydes form an adduct. This was regarded[55,58,63,64] as occurring only in the oxidation of aliphatic aldehydes, whereas aromatic aldehydes underwent direct oxidation

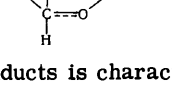
$$\mathrm{RCOOOH} + \mathrm{RCHO} \xrightarrow{k_{9''}} 2\mathrm{RCOOH}. \qquad (18)$$

Infrared spectroscopy did not reveal formation of an adduct in the oxidation of benzaldehyde[65], but the opposite conclusion was reached from kinetic[66,67] and spectroscopic[68] data. Formation of an adduct was stated[25,69] to occur in the oxidation of acrylaldehyde, but the same authors gave a scheme[57] from which the adduct was absent. The present Reviewers consider that unambiguous evidence of the existence of an adduct would be its isolation in pure form from the reaction mixture at low temperatures. This method was adopted[70] in studying the oxidation of acetaldehyde and butyraldehyde. Isolation of an adduct had been achieved earlier[71] in the oxidation of another saturated aliphatic aldehyde, undecanal. The question of the formation of an adduct in the oxidation of aromatic and unsaturated aliphatic hydrocarbons cannot be regarded as settled.

In the early investigations by infrared spectroscopy[72] a hydroperoxide form of adduct was assumed to be present. Examination of the nuclear magnetic resonance spectra of products of the low-temperature oxidation of acetaldehyde led to the conclusion[70] that the adduct could have two possible structures

$$\underset{(a)}{\mathrm{CH_3C(O)}\text{—}\mathrm{OO}\text{—}\mathrm{CH(OH)}\text{—}\mathrm{CH_3}};\quad \underset{(b)}{\mathrm{CH_3}\text{—}\overset{\mathrm{O—O}}{\mathrm{C}}\text{—}\mathrm{O}\text{—}\mathrm{CH(OH)}\text{—}\mathrm{CH_3}},$$

of which (*a*) was the more probable. Almost all authors who postulated formation of an adduct during oxidation assumed a similar structure. Kinetic study of the decomposition of adducts from acetaldehyde and butyraldehyde established[70] that decomposition occurred mainly by a molecular mechanism via a cyclic intermediate complex of type



.

The presence of adducts is characteristic of the low-temperature of oxidation of acetaldehydes. The quantity of adduct in the mixture is considerably diminished by raising the temperature merely to 10–20°C, and the main oxidation product becomes acetic acid[73].

Carboxylic acids may be formed in the oxidation of aldehydes not only by breakdown of an adduct but also directly from peroxy-acids as a result of their molecular decomposition:

$$\mathrm{RCOOOH} \rightarrow \mathrm{RCOOH} + \frac{1}{2}\mathrm{O_2} \ . \qquad (19)$$

This reaction was postulated on the basis of results obtained by several workers[26,30,74,75] in kinetic studies of the decomposition of peroxy-acids. An almost 100% yield of carboxylic acid was obtained based on the peroxy-acid decomposed, and evolution of molecular oxygen was observed. The fact that inhibitors and initiators of radical reactions had no effect on the decomposition of peroxy-acids was further evidence of molecular decomposition. The activation energy of reaction (19), 16–24 kcal mole^{-1}, is less than for the radical decomposition of peroxy-acids. Decomposition of peracetic acid is a first-order reaction with respect both to this acid and to acetic acid[76].

III. PHOTOCHEMICAL OXIDATION—INITIATION OF CHAINS

In the photochemical oxidation of aldehydes the reaction mixture is usually exposed to ultraviolet radiation of wavelength 2500–4000 Å. On absorbing a quantum the aldehyde molecule passes into an excited singlet state S_1, from which a radiationless transition can occur to a metastable triplet state T_1.

At sufficient aldehyde concentrations the excited molecules are deactivated by interaction with aldehyde molecules in the ground state, while free radicals are produced, and initiate the chain process. Since the lifetime of the T_1 state greatly exceeds that of S_1, radicals are most probably formed by autodeactivation of the T_1 state. In the gas phase, e.g. with benzaldehyde, the lifetimes of S_1 and T_1 states are 1.6 μs and 2 ms respectively[77]. In the photochemical oxidation of benzaldehyde the initiation of chains was regarded[78] as resulting mainly from reaction between an aldehyde molecule in the triplet state and an unexcited molecule:

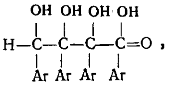
$$\mathrm{C_6H_5CHO} + h\nu \rightarrow \mathrm{C_6H_5\dot{C}H\text{—}\dot{O}};$$

$$\mathrm{C_6H_5\dot{C}H\text{—}\dot{O}} + \mathrm{C_6H_5CHO} \rightarrow \mathrm{C_6H_5\dot{C}O} + \mathrm{C_6H_5\dot{C}HOH}.$$

This quite widely held view on the mechanism of chain initiation in the photochemical oxidation of aldehydes[79,80] is contradicted by results obtained at low partial pressures of oxygen (54–450 mm) in an investigation[81] of the oxidation of decanal in decane solution with λ = 3130 Å at 10°C. It was concluded[81] that at low oxygen pressures radicals are initiated mainly by reaction between an oxygen molecule in an S_1 state and an unexcited aldehyde molecule. At higher pressures both S_1 and T_1 are involved in radical formation.

It has been recommended that special additives which readily produce free radicals under the influence of light, e.g. butane-2,3-dione, be introduced in the oxidation of heptanal[35], in order to improve the efficiency of photochemical initiation. On absorption of a quantum (λ = 4358 Å) the dione passes into an excited singlet state, which is converted almost quantitatively into a triplet state. The latter is deactivated mainly by reaction with molecular oxygen, and free radicals are formed. With this method of initiation the rate of generation of chains is constant during oxidation.

Photochemical initiation is an efficient method of intensifying oxidation which finds practical application for obtaining oxidation products of aldehydes. In photochemical oxidation the above reactions of chain termination (10)–(12) are probably accompanied by destruction of radicals on the molecules of certain oxidation products. This may explain in particular why the oxidation of aldehydes gradually slows down with time. Thus it was suggested[82] that the compound



$$\mathrm{H{-}C(OH)(Ar){-}C(OH)(Ar){-}C(OH)(Ar){-}C(OH)(Ar){=}O}$$

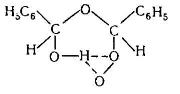
, об-

formed in the liquid-phase photolysis of benzaldehyde, may act as an inhibitor. Preliminary photolysis of heptanal in an oxygen-free medium lowers the rate of a subsequent oxidation[17]. The oxidation of benzaldehyde slows down at a time when considerable quantities of aldehyde are still present in the mixture[30]. Some quantities (1–2%) of salicylaldehyde and phenol, which are inhibitors, have been shown to be present.

A study of the photochemical oxidation of benzaldehyde in the presence of quinol as inhibitor established that the absorption of one quantum by an aldehyde molecule initiates only one reaction chain[78]. Since the act of initiation produces two radicals, $C_6H_5CO\cdot$ and $C_6H_5CH(OH)\cdot$, this result was explained by the destruction of one of the radicals according to the scheme

$$\mathrm{C_6H_5\dot{C}HOH + C_6H_5CHO \rightarrow C_6H_5CH(OH){-}O{-}\dot{C}H{-}C_6H_5 \xrightarrow{+O_2}}$$
$$\mathrm{\rightarrow C_6H_5CH(OH){-}O{-}CH(O\dot{O}){-}C_6H_5}\ .$$

It is assumed that the rate of this reaction in pure benzaldehyde will be comparable with the rate of the reaction between $C_6H_5CH(OH)\cdot$ and molecular oxygen. The resulting radical tends to form intramolecular hydrogen bonds



which is responsible for its characteristic reactivity.

The phenomenon of autoinhibition noted in papers on photochemical oxidation has been observed also in the thermal oxidation of benzaldehyde. This can be attributed both to the inhibiting effect of certain oxidation products and to possible deactivation of the catalyst in the later stages of catalytic oxidation[83]. Thus phenol has been detected in the thermal oxidation of benzaldehyde[66], and is formed as secondary product of the reaction between benzaldehyde and perbenzoic acid[63], its quantity being greater the more strongly electron-donating is the *para*-substituent in a substituted benzaldehyde.

IV. CATALYSED OXIDATION

Catalysts, mainly compounds of metals of variable valency, are widely employed to increase the rate and the selectivity of the oxidation of aldehydes. Published information relates mainly to homogeneous catalysts, but considerable interest has recently been taken in the use of heterogeneous catalysts. Introduction of a catalyst leads to a significant change in the mechanism of the process.

Initiation of Chains

Initiation may result from interaction of the catalyst with a molecule of a peroxy-acid or an aldehyde, which can be represented schematically

$$M^{n+} + \mathrm{RCOOOH} \xrightarrow{k_{3'}} M^{(n+1)+} + \mathrm{OH}^- + \mathrm{RCOO}^{\cdot}; \tag{20}$$

$$M^{(n+1)+} + \mathrm{RCHO} \xrightarrow{k_{3''}} M^{n+} + \mathrm{H}^+ + \mathrm{RCO}^{\cdot}; \tag{21}$$

$$M^{(n+1)+} + \mathrm{RCOOOH} \xrightarrow{k_{3'''}} M^{n+} + \mathrm{H}^+ + \mathrm{RCOOO}^{\cdot}. \tag{22}$$

Reaction (20), involving oxidation of the catalyst ion, is usually far more rapid than (21) and (22). Its rate depends on the nature of the metal ion[38,84], but for the most commonly used homogeneous catalysts—cobalt, copper, and manganese salts—its rapidity leads to the presence of the catalyst ions almost entirely in the state of higher valency during the reaction. The oxidised form of the ion may generate free radicals as a result of reaction with the initial aldehyde or with the peroxy-acid. The rates of these reactions were measured[38], and the rate of (21) for benzaldehyde was determined by independent measurements in a mixture of acetic and sulphuric acids. The rate constant obtained agreed satisfactorily with that of chain initiation determined from the consumption of inhibitor during the oxidation of benzaldehyde.

From this it was concluded that reaction (21) was responsible for chain initiation in the oxidation of benzaldehyde in the presence of a catalyst. This view was fairly widespread in the literature until quite recently, but it can hardly be accepted as soundly based. Firstly, the consumption of inhibitor can be related only to the total rate of interaction with radicals, whereas free radicals are formed primarily by the uncatalysed reaction (2) or (3). After a certain quantity of peroxy-acid has accumulated, radicals are formed by reactions (21) and (22). Considerable inaccuracy is due also to the fact that the measured[38] rate of reaction (21) is far too high, because the rate constant obtained in sulphuric-acid medium exceeds significantly its value in an inert solvent[37]. Moreover, the same work[38] gave $k_{3''} = 0.05$ M s^{-1}, and the rate constant of reaction (22) as 0.8 M s^{-1}, which contradicts the authors' statement that reaction (21) predominated in the initiation of chains. Measurements of the rates of reactions (21) and (22) in acetic-acid medium during the oxidation of benzaldehyde gave values of 8×10^{-11} and 7×10^{-7} M s^{-1} at 30°C.[37] The rate of the uncatalysed initiation (2), determined under the same conditions for comparison, was 1.3×10^{-8} M s^{-1}. A similar ratio of rates of (21) and (22) has been observed[85] in the oxidation of *p*-tolualdehyde.

Thus the main reaction responsible for the formation of free radicals in the catalytic oxidation of aldehydes is interaction of an oxidised form of a metal ion with a hydroperoxide. This reaction probably cannot be regarded as the elementary stage described by Eqn. (22). It must be remembered in particular that, in the presence of a catalyst, decomposition of the peroxy-acid induced by free radicals is possible. Such induced decomposition has been observed e.g. in the presence of cobalt and iron salts[86].

As shown for the oxidation of hydrocarbons[87], it is assumed that free radicals are generated in the oxidation of aldehydes through formation of an intermediate complex between the catalyst and an aldehyde or a peroxy-acid molecule. Kinetic evidence of the formation of complexes with the catalyst has been obtained for perbenzoic acid[83], benzaldehyde[37], peroxypropionic acid[75], and peroxyacrylic acid[57]. It was shown[57] by spectroscopic methods that, when complex compounds are used to catalyse the oxidation of acrylaldehyde, an aldehyde molecule takes the place of one of the ligands, being coordinated through its carbonyl group with the central atom of the catalyst. The same views on the entry of an aldehyde molecule in hydrated form into the coordination sphere of the Co^{3+} ion have appeared[88] in a study of the oxidation of pyridinecarbaldehyde in aqueous medium. An oxygen molecule may enter the intermediate catalytic complex[89,90]. On the whole, however, the question of the existence and the role of catalytic complexes in chain initiation has been developed in considerably less detail than for the oxidation of hydrocarbons, where the decisive role of such complexes in the breakdown of hydroperoxides has been proved unambiguously by both kinetic and physical methods[91,92].

In the presence of a catalyst chains can be initiated not only by reactions (20)–(22) but also by detachment of hydrogen from the alkyl group[34,93]:

$$RCH_2CHO + Mn^{3+} \rightarrow R\dot{C}HCHO + Mn^{2+} + H^+. \qquad (23)$$

Acyl radicals are then formed by a secondary reaction:

$$R\dot{C}HCHO + RCH_2CHO \rightarrow RCH_2CHO + RCH_2CO^{\cdot} \qquad (24)$$

This mechanism of initiation was supported by the isotope effect $k_H/k_D = 5.5$–6.0 obtained for α-deuterated acetaldehydes, whereas no isotope effect was present when the carbonyl hydrogen was replaced by deuterium. Additional evidence for reaction (23) is the detection in the mixture, on addition of an alkene, of products formed by addition of $\cdot CHR.CHO$ radicals to the double bond of the alkene[93].

In the homogeneous catalysis of the oxidation of aldehydes, as in the uncatalysed ocidation, chain-initiating reactions may involve either the free peroxy-acid or its addition product with the aldehyde (an "adduct"). The relative concentrations of adduct and free-peroxy acid, and hence their contributions to the generation of free radicals, depend mainly on the temperature and the aldehyde concentration. Cobalt salts accelerate decomposition of the adduct at temperatures above 10°C. A molecular reaction has been postulated[94] leading to oxidation of the cobalt by interaction between the catalyst and the adduct:

$$CH_3C(O)OOCH(OH)CH_3 + 2Co(OOCCH_3)_2 + CH_3COOH \rightarrow 2Co(OOCCH_3)_3 + CH_3CHO + H_2O.$$

Another postulate[95,96] is radical decomposition of the adduct:

$$Co^{2+} + CH_3CH(OH)-OO-C(O)CH_3 \rightarrow Co^{3+} + CH_3CH(\dot{O})OH + CH_3COO^- \ .$$

These reactions become more important at high aldehyde concentrations, when the equilibrium between the peroxy-acid and the adduct is displaced towards formation of the latter. With decrease in the aldehyde concentration reaction (20) becomes the main process converting the metal ion to a higher valency state. The oxidised form of the metal is obviously able to interact not only with the peroxy-acid but also with the adduct to form free radicals.

Decomposition of Peroxy-acids

In the presence of a catalyst a peroxy-acid may undergo decomposition not only by reactions (20) and (22) but also by homolysis of the oxygen–oxygen bond, as has been proved[57,97,98] by the formation of carbon dioxide (resulting from decarboxylation of $RCOO\cdot$ radicals—products of the cleavage of peroxyacrylic and peroxytoluic acids at the peroxy-bond).

In the presence of catalysts peroxy-acids undergo not only radical but also molecular decomposition with formation of the corresponding carboxylic acids. Molecular breakdown has been established for peroxyacrylic[57], peroxypropionic[57], and peroxybutyric[90] acids. It is significant that this process is observed mainly when carboxylic acids are used as solvents. In the presence of a heterogeneous catalyst—silver oxide—decomposition of peracetic acid in the presence of acetic acid takes place by a molecular mechanism at temperatures of 20–40°C.[26] When the temperature is raised to 70°C, a small proportion of the peroxy-acid breaks down into radicals at the oxygen–oxygen bond. The rate of decomposition of the peroxy-acid diminishes with increase in the concentration of silver oxide.

Chain Propagation

In both catalysed and uncatalysed oxidation the chain-propagating reaction leads to formation of a peroxy-acid as primary molecular product. Involvement of the catalyst in propagation has been shown in the oxidation of hydrocarbons[99], but direct experimental evidence has not been obtained for aldehydes. However, the tenfold increase in the ratio $k_2/k_6^{\frac{1}{2}}$ obtained for the oxidation of benzaldehyde in the presence of a manganese salt relative to the uncatalysed process[100] suggests that the catalyst does affect the chain-propagating reaction. The heterogeneous catalyst Ag_2O may take part in propagation in the oxidation of aldehydes in the presence of unsaturated compounds[26].

Little information has been published on the effect of catalysts on the formation of molecular oxidation products. An acyl radical $RCO^{\cdot}$ may form a complex with the catalyst[57], and thus react more readily with oxygen than it decomposes into $R^{\cdot} + CO$. As a consequence, use of a catalyst leads to a decrease in the quantity of carbon monoxide among the reaction products. A decrease in the yield of carbon dioxide in the oxidation of acetaldehyde has been observed in the presence of silver oxide[101]. The probable reason is that radicals attached to a heterogeneous catalyst are unlikely to break down with the formation of carbon dioxide.

The equilibrium constant of adduct formation K_9 is unaffected by the catalyst[58,60]. No data have appeared on the effect of the catalyst on decomposition of the adduct into carboxylic acids ($k_{9'}$). However, it is known that ions of metals of variable valency may take part in the decomposition of carboxylic acids. Thus Mn^{3+}, Co^{3+}, and Ce^{4+} ions react at 50–100°C with carboxylic acids[102–105]:

$$RCOOH + M^{(n+1)+} \rightarrow M^{n+} + \dot{R} + CO_2 + H^+ \ . \qquad (25)$$

Another possible reaction is[106–108]

$$CH_3COOH + M^{(n+1)+} \rightarrow M^{n+} + \dot{C}H_2COOH + H^+. \qquad (26)$$

Intermediate formation of an adduct and its decomposition

$$Co^{3+} + 2C_6H_5COOH \overset{K_{15}}{\rightleftarrows} [Co^{3+} \cdots 2C_6H_5COOOH] \xrightarrow{k_{15}} Co^{2+} + C_6H_5COOO^{\cdot} + C_6H_5COOH + H^+ \qquad (27)$$

have been discussed[37]. A peculiar feature of the action of salts of metals of variable valency in oxidising processes is the dual function of the catalyst—accelerating at low concentrations of the metal salt in the reaction mixture, and inhibiting at high concentrations.

Chain Termination

Since it was first shown that the catalyst may be involved in the termination of chains[109,110], there are indications that this occurs also in the oxidation of aldehydes. Thus the oxidation of benzaldehyde[84] in the presence of a sufficiently high concentration (~10^{-3} M) of cobalt(II) acetate as catalyst has an induction period directly proportional to the catalyst concentration and inversely proportional to the initial aldehyde concentration. Completion of the induction period coincides with complete conversion of cobalt(II) into cobalt(III). This was explained by the presence of an unpaired electron in cobalt(II) compounds, which (at high concentrations) play a considerable part in the destruction of radicals, whereas cobalt(III) contains no unpaired electrons and does not interact with free radicals.

Chains may be terminated by interaction of the benzoylperoxy-radical $C_6H_5COOO^\cdot$ with cobalt(II) acetate or its dimer. However, data given[84] on the inhibiting action of ions of other metals are fairly contradictory and require further refinement. It was stated[84] in particular that copper(II) even in high concentrations does not bring about an induction period in the oxidation of benzaldehyde. Yet copper(II) at concentrations of ~0.05 M strongly inhibits the oxidation of hydrocarbons[110].

Experimental results on the oxidation of *p*-tolualdehyde in the presence of cobalt salts[85] are reported on the hypothesis that chain termination takes place on acyl radicals $RCO^\cdot$. Similarly[54] chain termination by reaction (10) with the formation of butane-2,3-dione has been established in the oxidation of acetaldehyde catalysed by cobalt acetate. The formation of considerable quantities of this dione (up to 10% on the acetic acid formed) may indicate that the catalyst accelerates recombination of acyl radicals, making it competitive with the chain-propagating reaction (5). Nevertheless, reaction (10) does not strictly involve termination, since the butanedione formed can itself undergo further oxidation by a radical–chain mechanism[112]. The ratio of the rate of accumulation of carbon dioxide to that of acetic acid in the oxidation of butane-2,3-dione is respectively 0.3 and 0.5 in the presence and in the absence of a catalyst[54,112]. This indicates that the catalyst enhances the selectivity of oxidation of the dione to acetic acid.

V. EFFECT OF SOLVENT

Studies of the liquid-phase oxidation of aldehydes have hitherto not included a systematic investigation of the influence of the solvent on the elementary stages. Results obtained in individual researches are qualitative in character and relate mainly to the effect on the overall rate of oxidation.

Current views distinguish two types of solvation—non-specific and specific—of reactant species[113]. Non-specific solvation occurs in all solutions and is due to interaction of the solute with the field of the solvent molecules. One of the main forms of non-specific solvation is caused by electrostatic interaction of reactant species with the medium. The relation between the reaction rate constant k and the dielectric constant of the medium ϵ is expressed by Kirkwood's equation

$$\ln k = \ln k_0 - \frac{1}{kT}\,\frac{\varepsilon-1}{2\varepsilon+1}\left(\frac{\mu_A^2}{r_A^3}+\frac{\mu_B^2}{r_B^3}-\frac{\mu_{\neq}^2}{r_{\neq}^3}\right),$$

in which μ is the dipole moment, r is the effective radius of the dipole, and the subscripts A, B, and $\neq$ denote respectively the starting materials and the activated complex. Plots of ln k against $(\epsilon - 1)/(2\epsilon + 1)$ based on published data for the oxidation of aldehydes[26,69,114,115] either are not linear at all or show many points lying outside a linear relation. They suggest that non-specific solvation is not the main factor governing the effect of the solvent on the oxidation of aldehydes.

Specific solvation is due to the formation of various types of complexes between the reactant species and the solvent, e.g. involving hydrogen bonding and π-complexes. The hydrogen bond between a solvent molecule and a peroxy-acid formed by oxidation of an aldehyde may probably either accelerate or retard decomposition of the acid. The selectivity of oxidation of the aldehyde to the peroxy-acid is correspondingly changed.

An increase in the yield of acrylic acid from the oxidation of acrylaldehyde has been observed when water[76], butyric acid, or valeric acid[69] is used as solvent. Water also increases the yield of carboxylic acids from the oxidation of C_2–C_5 saturated aldehydes[116,64]. In the oxidation of isobutyraldehyde water increases the yield of the acid only when present in quantities exceeding 10%; with about 4% of water the yield of the peroxy-acid is increased[64]. In contrast to the above results, acetic acid lowers the yield of peracetic acid obtained by the oxidation of acetaldehyde[26]. Increase in the yield of peroxy-acids in the presence of compounds capable of forming a hydrogen bond has been observed in the oxidation of butyraldehyde in the presence of chloroform and dichloroethane[115], and in the oxidation of acetaldehyde in water and in acetic acid[117].

When benzene, which is able to form π-complexes[118], is used as solvent, carboxylic acids are obtained as the main product of the uncatalysed oxidation of butyraldehyde[115] and benzaldehyde[65]. However, a benzene medium tends to increase the yield of perbenzoic acid from the catalytic oxidation of benzaldehyde[119] and of peracetic acid from that of acetaldehyde[26].

The dependence of the total rate of oxidation of aldehydes on the nature of the solvent can probably be attributed to the effect of the latter not only on the reactivity of the acylperoxy-radicals $RCOOO^\cdot$ in chain propagation but also on chain initiation, as well as on the molecular reactions (16) and (17).

The lower rate of oxidation of acetaldehyde in a carboxylic acid than in acetone can be explained[114] by hydrogen bonding between the acylperoxy-radical and the solvent. The rate of oxidation of benzaldehyde is lower in benzene than in acetone[119], which may be due either to the lower dielectric constant of the solution or to diminished reactivity of peroxy-radicals as a result of "adhering" to the benzene. A similar situation is found[26] for the rate of oxidation of acetaldehyde in various solvents, decreasing in the sequence

$$\text{acetone} > \text{benzene} > \text{acetic acid}\ .$$

The rate of oxidation of acetaldehyde is much lower in cyclohexanone than in other solvents. The solvent effect in this case also may be due to deactivation of peroxy-radicals by hydrogen bonding, since the keto–enol tautomeric equilibrium is displaced considerably further towards the enol with cyclohexanone than with acetone[120]. However, it remains obscure why the decrease in reaction velocity is considerably more marked with cyclohexanone than with other solvents capable of forming hydrogen bonds. The maximum rate of oxidation of acrylaldehyde was found[57] to decrease in the sequence of solvents

carboxylic acids $\geqslant$ aromatic hydrocarbons $>$ aliphatic hydrocarbons $>$ water

The retarding effect of water on the oxidation of aldehydes in the presence of homogeneous catalysts may be due[37] to its ability to form complex hydrates with the catalyst, thereby preventing the latter from taking part in the initiation of chains.

It is quite clear that solvents have a considerable effect on the oxidation of aldehydes, which comprises the aggregate of its effects on the individual stages in the composite process. In order to elucidate the elementrary mechanism of the solvent effect, therefore, separate investigations are required for every elementary stage.

In the oxidation of aromatic and unsaturated aldehydes the solvent may also have a specific influence depending on the structure of the oxidisable substrates. Thus in the later stages of the oxidation of benzaldehyde[66] the effect of the solvent is largely due to its ability to accelerate the formation of autoinhibitors of chain oxidation that may be formed in the oxidation of benzaldehyde, or on the other hand to prevent their formation. In the oxidation of acrylaldehyde[57] the solvent effect is largely governed by the influence on polymerisation of the initial aldehyde and of the resulting acid. Rates of radical polymerisation are considerably higher in non-polar than in polar media. The resulting polymer is able to deactivate the catalyst, with a consequent decrease in the rate of the process.

VI. USE OF THE OXIDATION OF ALDEHYDES TO OBTAIN CERTAIN OXYGEN-CONTAINING COMPOUNDS

The liquid-phase oxidation of aldehydes forms the basis for the preparation of various oxygen-containing compounds, including processes of industrial value, mainly the oxidation of acetaldehyde. Considerable interest has recently been taken in the liquid-phase oxidation of unsaturated aldehydes—predominantly acrylaldehyde and methacrylaldehyde—and also in the combined (concerted) oxidation of aldehydes and unsaturated compounds as a method for obtaining acids and alkene oxides at the same time.

Preparation of Acids

The liquid-phase oxidation of acetaldehyde is a most important method for the manufacture of acetic acid[121]. The process is usually conducted at about 60°C in the presence of manganese acetate, which is an efficient catalyst also for the preparation of acids by the oxidation of other aldehydes[122,123].

An important problem of chemical technology is to develop an effective method for the direct oxidation of methacrylaldehyde to methacrylic acid in the liquid phase. Large quantities of this acid are required for the production of polyesters, and the existing method of obtaining it from acetone[124] is unable to satisfy the rapidly growing demands of industry.

Several attempts have been made to obtain methacrylic acid from methacrylaldehyde in the presence of homogeneous catalysts, but the results show poor reproducibility and evidently cannot be regarded as reliable. This is indicated also by the fact that manufacture of the acid from the aldehyde has not yet been realised. Thus, when methacrylaldehyde was oxidised with oxygen in benzene medium at 40°C in the presence of copper and nickel acetates as catalysts[125], the selectivity of formation of methacrylic acid was 99% with 60% conversion of the aldehyde. The yield of the acid did not exceed 40%, and a large quantity of polymeric products was formed. However, these results could not be repeated by workers[126] who proposed to obtain methacrylic acid by oxidising the aldehyde in alkaline medium in the presence of silver oxide. Nevertheless, despite the great selectivity of formation of the acid, this process, requiring the use of alkaline solutions, can hardly find industrial application. Conducting the oxidation in the presence of such catalysts as cobalt and manganese acetates and acetylacetonates, as well as vanadium compounds, gave the best results[127] with cobalt acetate (the same catalyst as before[125]), when the yield of methacrylic acid reached 80%.

The above results show that, with the exception of the classic catalyst of liquid-phase oxidation—cobalt acetate—sufficiently effective specific catalysts for the oxidation of methacrylaldehyde are not yet available. A promising approach to the problem is thus to develop new catalytic systems based on heterogeneous catalysts, which possess high selectivity and, in contrast to homogeneous catalysts, do not result in contamination of the product with metal compounds.

VII. CONCERTED OXIDATION OF ALDEHYDES WITH OTHER ORGANIC COMPOUNDS

Concerted oxidation provides a highly effective method for obtaining valuable oxygen-containing products, one of which is the carboxylic acid corresponding to the initial aldehyde. The available oxygen of the acylperoxy-radicals and the intermediate products (peroxy-acids) is used to oxidise the second component of the pair. This method was suggested in 1962[2,128,129], when methyloxiran and acetic acid were obtained simultaneously by the concerted oxidation of propene and acetaldehyde. The efficiency of the process has since been improved considerably[101,130] by the use of heterogeneous catalysts, in particular silver oxide. The process is conducted in air compressed to 30-50 atm at 60-100°C.

In the catalytic process the required products are rapidly obtained in high yields—1300 kg of acetic acid and 800 kg of methyloxiran per tonne of acetaldehyde that has reacted—respectively 97 and 60 mole %. The catalytic action of the silver oxide can be explained by involvement of the heterogeneous catalyst in chain propagation[26]:

$$[\mathrm{CH_3COOO} \cdots \mathrm{Ag_2O}]^{\cdot} + \mathrm{C_3H_6} \rightarrow \mathrm{C_3H_6O} + \mathrm{CH_3COO^{\cdot}} + \mathrm{Ag_2O} \ .$$

Concerted oxidation with aldehydes can be used for the epoxidation not only of propene but also of other unsaturated compounds, e.g. allyl chloride[131,132], as well as for introducing oxygen into other classes of organic compounds, including saturated compounds. Thus amines of the piperidine series can be converted by concerted oxidation with benzaldehyde into the corresponding stable iminoxyl radicals[26].

Acetic Anhydride

An important industrial product of the oxidation of acetaldehyde is acetic anhydride[43,96], for which the best catalyst is a mixture of copper and cobalt acetates. The reason is that Co^{3+} and Cu^{2+} ions react readily with an acyl radical:

$$\mathrm{CH_3CO} + \mathrm{Cu^{2+}} \rightarrow \mathrm{CH_3\overset{+}{C}O} + \mathrm{Cu^{+}} \ .$$

This competes with reaction (5) (addition of oxygen to the acyl radical) and ultimately results in formation of an anhydride:

$$CH_3\overset{+}{C}O + CH_3COOH \rightarrow CH_3C(O)O{-}C(O)CH_3 + H^+ \ . \qquad (28)$$

The chief difficulty in the industrial production of acetic anhydride is its ready hydrolysis. This is prevented by the use of high concentrations of the catalyst, which permit short times of contact and relatively low temperatures (~40°C).

Preparation of Peroxy-acids

Peroxy-acids are formed in the act of chain propagation in the oxidation of aldehydes. In order to diminish their reactivity in subsequent transformations and increase their concentration in the mixture the oxidation is conducted at comparatively low temperatures (0–30°C). Furthermore, many publications, mainly patents, give a selection of solvents and catalysts. Data on the effect of the former is fairly contradictory, and it can be stated with some certainty only that ethyl acetate and benzene are among the best solvents for this purpose. Very many catalysts have been proposed. Thus, in order to obtain peracetic acid, the use has been suggested of cobalt(II) nitrate[133] and acetate[114], a mixture of iron monophenoxide and 2,4,6-trinitroresorcinol, a mixture of the latter and cobalt naphthenate, a mixture of cobalt(II) and iron(III) nitrates with concentrated hydrochloric acid, a mixture of cobalt and iron salts of dicarboxylic acids having pK_a = 4.6, and also additions of 60% nitric acid[134]. Manganese compounds—e.g. manganese salts in the presence of water[117] or manganese naphthenate mixed with selenium dioxide—are used as catalysts. The oxidation of acetaldehyde catalysed by iron citrate and naphthenate yields peracetic acid with nearly 100% selectivity. When malonic acid is used as catalyst, the oxidation of acetaldehyde (at 25–30°C) gives a mixture of peracetic acid and its adduct with the aldehyde, in relative amounts depending on the catalyst concentration. Use of the heterogeneous catalyst Ag_2O produces a considerably higher yield of peracetic acid than obtained in the uncatalysed process[101]. Photochemical initiation is also used to increase the concentration of peroxy-acids.

Prebiological Synthesis of Aminoacids and the Search for them in Meteorites and Lunar Rocks

A.T.Soldatenkov and I.A.Sytinskii

New data on various prebiological syntheses of aminoacids and the detection of very small amounts of aminoacids in meteorites and lunar rocks are reviewed. Data are presented concerning the possible precursors of these aminoacids. The hitherto obscure problem of the mechanisms of the formation of aminoacids under the conditions of prebiological synthesis is considered.

The bibliography includes 156 references.

CONTENTS

I. INTRODUCTION

By 1974 fifty years had elapsed since Academician A. I. Oparin's theory of the origin of life was proposed[1]. The Soviet biochemist was the first to formulate a hypothesis concerning the nature of the primary atmosphere on Earth and the possibility of forming complex compounds such as proteins and nucleic acids from the elements as a result of chemical and physicochemical processes in the atmosphere and in the ocean. These processes would have occurred spontaneously under the influence of ultraviolet radiation from the sun, the energy of electric discharges, volcanic heat, and the ionising radiation from terrestrial radioactive rocks. Oparin's idea, subsequently supported by Haldane[2], received the first experimental confirmation after 30 years as a result of the studies carried out by Miller, who succeeded in simulating the formation of biologically important molecules in a non-living system imitating Earth's primitive atmosphere[3,4].

Sciences such as organic and bio-organic chemistry, biochemistry, cosmochemistry, astrophysics, selenology, and others have played an appreciable role in the elaboration and development of the theory of the origin of life. The fundamental studies in this field are being prosecuted in two directions. The first direction, involving synthetic research, was initiated about 20 years ago. Theoretical and experimental investigations led to the accumulation of an enormous amount of data on the synthesis of aminoacids, polypeptides, purine and pyrimidine bases, porphyrins, and monosaccharides under the conditions of the primitive planet as reproduced in the laboratory[5-9]. The development of this research was stimulated afresh by recent radioastronomical observations, which indicate the presence in interstellar matter of molecules important for chemical evolution, such as those of ammonia, water, hydrogen cyanide, cyanoacetylene, acetaldehyde, and others[10].

The second direction involves analytical research. Here studies in the last 5-7 years have been concentrated on the analysis of the carbonaceous material in meteorites and lunar rocks, as well as interstellar matter. Exceptionally important results have been obtained in this field, which permit an answer to the questions whether or not organic compounds of extraterrestrial origin exist, what is their composition, and how they have been formed.

Both prebiological synthesis and analysis of aminoacids are considered in the present review. Recently, all the protein and a number of non-protein aminoacids have been successfully synthesised by non-biological methods or have been detected in objects of extraterrestrial origin (lunar rocks, meteorites), but the mechanisms of formation of these aminoacids have still been little studied.

II. AMINOACID PRECURSORS. THE SEARCH FOR AMINOACIDS IN METEORITES AND LUNAR ROCKS

Cosmic Space

The initial elements required for the synthesis of organic compounds (H, C, O, and N) are formed on a cosmic scale in the central regions of stars at very high temperatures. Diffusional and convective processes displace them towards the surfaces of stars. In stellar atmospheres at relatively low temperatures diatomic and triatomic species such as C_2, C_3, CH, CH_2, CN, CO, CO_2, NH, OH, and CH_4 may be synthesised. Astronomical observations have shown that various stellar processes probably lead to the ejection of these and other compounds as well as atoms into the space around the stars and the interstellar space[11]. Among processes of this kind, one may include the explosion of novae and supernovae, stellar pulsations, flares, and winds, and the migration of mass as a result of the pressure difference between the hot surfaces of stars and the cold interstellar space.

Oró[10], who considered the relative abundances of certain chemical compounds and their stability with respect to heat and light, concluded that stable species of the type CO, CN, CH, C_2, C_3, and others, which are ejected into interstellar space, are subsequently hydrogenated and hydroxylated with formation of organic molecules: CH_2O, CH_3OH, HCOOH, HCN, $HCONH_2$, CH_3CHO, HC_2CN, etc.

The following species have been detected by optical measurements in the gaseous components of interstellar clouds and gas nebulae: CH, CN, CH^+, H_2, and CO.[12] Following the development of microwave spectroscopy, it became possible to extend greatly the knowledge of the composition of interstellar matter. Between 1968 and 1970, compounds such as ammonia[13], water[14], formaldehyde[15] (the first organic molecule discovered in interstellar space), and hydrogen cyanide[16] (the second organic molecule found in space) were detected. Turner[17] observed in 1970 an emission spectrum which corresponded to cyanoacetylene. The above five polyatomic molecules discovered in the interstellar space are probably the most important aminoacid precursors; formaldehyde is most widely distributed in space and is frequently called the "cosmic molecule". Together with hydrogen and hydroxy-radicals, it is probably a normal constituent of many regions of the Milky Way[10].

Table 1. Certain chemical compounds detected by radiospectroscopy in cosmic space.

Year of discovery	Compound	Formula of compound	Wave-length, mm	Concn. of cpd.*	References
1968	Ammonia	NH_3	13	$1 \cdot 10^{-7}$	12.13
1968	Water	H_2O	13	—	14
1969	Formaldehyde	CH_2O	62	—	15
1970	Carbon monoxide	CO	2.6	$1 \cdot 10^{-3}$	12.18
1970	Cyanyl radical	CN	2.6	—	19
1970	Hydrogen cyanide	HCN	3.4	$1 \cdot 10^{-7}$	12,16
1970	Cyanoacetylene	$HC{\equiv}C{-}CN$	33	—	17
1970	Methanol	CH_3OH	360	$1 \cdot 10^{-7}$	12.20
1970	Formic acid	HCOOH	180	—	21
1971	Formamide	$CHONH_2$	65	—	22
1971	Methylacetylene	$HC{\equiv}C{-}CH_3$	3.5	—	24
1971	Acetonitrile	CH_3CN	2.7	—	23
1971	Acetaldehyde	CH_3CHO	280	—	10
1971	Thioformaldehyde	CH_2S	95	—	10
1972	Hydrogen sulphide	H_2S	1.7	—	10
1972	Methyleneimine	CH_2NH	56	—	10

*The concentration of hydrogen was adopted as unity.

By the beginning of 1974, 27 cosmic molecules had been discovered (Table 1). The data in Table 1 show that interstellar matter includes all the initial compounds which may serve for the synthesis of biochemically important substances. The problem of the ways in which these initial compounds are synthesised remains open. There exist two hypotheses concerning the formation of interstellar molecules. The first claims that they may be synthesised under the influence of cosmic rays on the surface of dust particles of interstellar nebulae or meteorites from the CO and H_2 adsorbed on them by a mechanism close to that of the familiar Fischer–Tropsch synthesis[25]. The other (ionic) hypothesis presupposes a homogeneous synthesis of complex cosmic molecules as a result of collisions between ions or simple molecules in the gas phase. Thus it is believed that formaldehyde may be formed in space via the following mechanism[12]:

$$H_2^{\bullet} + H_2 \rightarrow H_3^{\bullet} + H;$$

$$H_3^{\bullet} + CO \rightarrow H_3CO^{*};$$

$$H_3CO^{*} \rightarrow H_2CO + H^{*}.$$

According to this mechanism, one may expect the existence in space of HCO^+ ions, which are formed in another decomposition reaction: $H_3CO^* \rightarrow HCO^* + H_2$. Indeed, Buhl and Snyder[26] detected this ion in 1970 at a wavelength of 3.4 mm.

Comets

The primary compounds may have appeared on Earth's surface in different ways. For example, they might have been introduced when the planets of the solar system passed through interstellar clouds and gas nebulae. One cannot rule out the possibility that the organic substances in comets and meteorites may have served as the sources of the simplest aminoacid precursors on Earth. For example, it is believed that the isotopic composition of the carbon in comets is similar to that on Earth[27].

The orbits of certain comets adjoin Earth's orbit and may even intersect it. This suggests the possibility that a certain amount of the material from comets may reach our planet by a direct collision between the comet and Earth or following the incidence on Earth of meteor streams (showers) and other residues from the comet. Comets contain significant amounts of organic compounds. The nucleus of the comet probably includes H_2O, HCN, NH_3, CO, C_2N_2, CH_4, and C_2H_2.[27] The central body of the comet is surrounded by a rarefied atmosphere (an envelope of vaporised molecules), which emits a beam of rays (the tail) in the direction away from the sun. The main component of the gaseous envelope (the "coma") is atomic hydrogen[28]. Other species are also present: H_2, OH, OH^+, O, CN, C_2, C_3, CH_2, CH, CH^+, CO^+, NH, NH_2, etc.[27]; the presence of C_2H radicals is also possible. CO^+, N_2^+, CO_2^+, CH^+, OH^+, and CN have been detected in the comet's tail. These chemical species may arise on photodissociation or ionisation of stable initial molecules. It is also possible that they are formed as a result of chemical reactions occurring on the surface of the nucleus (for example, under the influence of the solar wind).

Meteorites

Meteorites frequently contain the so called carbonaceous material. Carbonaceous chondrites are particularly rich in this material (up to 5 wt.%).[29] It has been established that the carbonaceous material consists of volatile and involatile organic compounds. In this connection, carbonaceous chondrites are of particular interest for the investigation of aminoacid precursors. Data on the nature of the organic compounds in meteorites have been fully reviewed by Vdovykin, who surveyed scientific data which have accumulated on this problem since 1806.[30] Studies in recent years have shown that meteorites contain not only aminoacid precursors (for example, alkanes ranging from C_1 to C_{26})[30,31] but also aminoacids themselves.

Aminoacids were found previously in many carbonaceous chondrites, but until 1970 the majority of investigators held the view that these aminoacids are probably of terrestrial biological origin and that they are present in the material of the meteorite as a result of contamination[32]. The aminoacid composition of the mixture closely resembled that of human fingerprints. Furthermore, it was shown that aminoacids detected in two meteorites had mainly the L-configuration[33].

Indeed, the problem of biological contamination continues to arise at various stages of experiments on specimens of extraterrestrial origin. Biological impurities can completely distort the true qualitative and quantitative composition of the aminoacid mixture[32,34]. If criteria were available for distinguishing between molecules of biological and non-biological origin, it would be possible to detect reliably biological impurities in the aminoacid mixtures analysed. The general approach to the solution of this problem is based on the differences between the distributions of the enantiomers in the mixtures, between the molecular structures of the individual aminoacids, and between their relative amounts[35,36]. The value of this approach in determining the aminoacid source is somewhat reduced by the racemisation processes[37-41] and the presence in certain micro-organisms (a possible source of contamination) of aminoacids having the D-configuration[42].

The distribution of protein aminoacids in man and bacteria[43] shows that, on contamination by material of human origin, one may expect approximately the following proportions of the four commonest aminoacids, namely glutamic acid : aspartic acid : glycine : leucine = 1.0 : 0.70 : 0.70 : 0.6, while on bacterial contamination we have 1.0 : 0.8 : 0.4 : 0.4.

One should note that aminoacid mixtures obtained in the analysis of contaminations by human fingerprints contain, apart from all the protein aminoacids, also citrulline and ornithine—the metabolic products of the urea cycle[44], which can also be used for the identification of impurities.

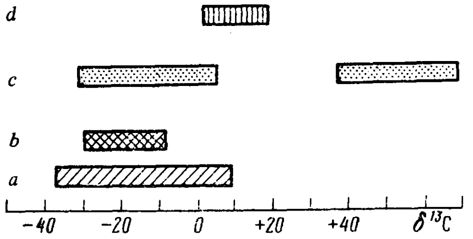

Figure 1. Isotope composition of terrestrial [*a*) total; *b*) biospheric], meteoritic (*c*), and lunar (*d*) carbon.

In the search for aminoacids of extraterrestrial origin, the study of isotopic composition may be of decisive importance. It is known[45] that most of the carbon in Earth's biosphere has an isotope composition† ranging from −29 to −8‰ [of carbon-13] (Fig. 1). The content of the heavy isotope in meteoritic carbon reaches up to +70‰.[46] Such an isotope ratio does not obtain in any of the known sources of carbon on Earth. Consequently these data might indicate indirectly the extraterrestrial non-biological origin of the aminoacids in carbonaceous chondrites. The organic substance in meteorites is also greatly enriched in deuterium[29].

The recent fall of the Murchison meteorite (in 1969) made it possible to obtain specimens with minimal biological contaminations. This carbonaceous chondrite contains 2.0 wt.% of carbon and 0.16% of nitrogen[47]. Studies on the Murchison meteorite carried out in three laboratories[47-50] established the presence of aminoacids of non-biological origin. In two investigations[47,48], the meteorite specimen was treated with water and the solution was hydrolysed and separated on an aminoacid analyser. Part of the aminoacid mixture was analysed in the form of 2-butyl-D-esters of *N*-trifluoroacetylaminoacids on a gas–liquid chromatograph combined with a mass-spectrometer[51-54].

The analysis led to the determination of six protein aminoacids with approximately equal proportions of the enantiomers and 12 non-protein aminoacids (Table 2). Gas–liquid chromatography (GLC) showed that nine aminoacids gave rise to separable diastereoisomeric derivatives (Fig. 2). They all probably exist in the form of racemic mixtures. The presence of many non-protein aminoacids in the Murchison meteorite (2-methylalanine and sarcosine, which are very rarely encountered in biological systems), the presence of all the isomers with two and three crabon atoms, and almost all the isomers with four carbon atoms, as well as the high degree of racemisation of the optically active aminoacids indicates a low probability of biological contamination of the meteorite and suggest that non-biological synthesis has been the source of the aminoacids. This conclusion is confirmed by measurements of the isotope ratio $^{13}C/^{12}C$, which show that the carbon of the Murchison meteorite ($\delta^{13}C$ = +4.4 − +5.9‰) differs appreciably from the carbon of Earth's biosphere (between −8 and −29‰).

The maximum concentrations of the protein aminoacids of the Murchison meteorite were those of glycine (6 μg g^{-1}), alanine (3 μg g^{-1}), glutamic acid (3 μg g^{-1}), valine (2 μg g^{-1}), and proline (1 μg g^{-1}). A similar distribution of aminoacids in this meteorite was found by another group of investigators[49], who analysed it by a highly sensitive and rapid ion-exchange chromatographic method. They also analysed the Murray and Allende carbonaceous meteorites, the results for the former being analogous to those for the Murchison meteorite, while in the latter no aminoacids were detected (the specimens contained only 0.007% of nitrogen).

The total amounts of 10 aminoacids in the Murchison and Murray meteorites were 22 and 21.5 μg g^{-1} respectively[49]. The amount of each of the 8 aminoacids of the non-protein type was smaller than that of the protein aminoacids, with the exception of α-aminoisobutyric acid, the concentration of which was at the level of those of the protein aminoacids. A more detailed analysis of the Murray meteorite[55], carried out by the method used in the studies of Kvenvolden and coworkers[47,48], established that this meteorite contains at least 18 aminoacids. The ratios of the D- and L-isomers of some of them are analogous to the ratios in the Murchison meteorite (Fig. 2). It has recently been established by the same analytical techniques[56] that one of the oldest carbonaceous chondrites (the Orgueil chondrite which fell in France in 1864) also contains aminoacids, some of which are probably of non-biological origin, since they are present in the form of racemic mixtures (Table 2).

The Moon

The analyses of lunar rocks supplied by Soviet and American spaceships are of undoubted interest. The search for aminoacid precursors in these rocks revealed the presence of hydrocarbons, carbides, and other compounds. For example, the experiments of Abell et al.[57], who treated lunar dust with deuterated acids (a 38% solution of DCl in D_2O and a 20% solution of DF in D_2O), led to the discovery of methane and ethane as well as carbides. The specimens of lunar rocks brought by the Apollo 11 and 12 expeditions evolved hydrocarbons on treatment with hydrofluoric, orthophosphoric, or sulphuric acid, one of the main components of which was methane[58,59]. Grinding the lunar rocks in glass ball mills also resulted in the evolution of methane which was probably present in a free state as inclusions (gas bubbles) in the solid rock.

Lunar rocks obtained by the recent Apollo 16 and 17 expeditions contained approximately the same amount of

total hydrogen as the specimens brought by the earlier expeditions—between 4 and 206 parts per million[60]. Aminoacid precursors were detected at the level of several parts per 1000 million. Nitrides, carbides, water, carbon dioxide, hydrogen, and various metals and their oxides were found in lunar materials[61]. Hopeful results have now been obtained, suggesting that these materials contain organic products, including aminoacids of non-biological origin. After extraction with cold water in two laboratories of the lunar rocks supplied by the astronauts of the Apollo 11 expedition, aminoacids were not detected[62,63]. All other groups of investigators extracted the specimens with hot water and did discover aminoacids[64-67]. The identification of glycine (32 μg per kg of lunar dust) and alanine (36 μg kg^{-1}) in aqueous non-hydrolysed extracts has been reported[64,67]. Fox and coworkers[65,66] used extraction with hot water followed by hydrolysis. Analysis on an ultrasensitive ion-exchange chromatograph detected glycine and alanine in the same amounts as those obtained by other investigators[64], but threonine, serine, and aspartic and glutamic acids were also found. It has been shown[64,66] that aminoacids are present in lunar rocks mainly as polymers.

A scheme for the complete analysis of organic substances of different classes in lunar materials supplied by the crew of the Apollo 11 spaceship has been described[58,68,69] (Fig. 3). It was developed on the basis of numerous investigations of organic compounds in old rocks and meteorites. In this scheme, organic substances of different classes are extracted in succession from a single large specimen with minimal transfer of materials. Such consecutive tests of lunar specimens did not prove to be

Figure 2. sufficiently effective and were not used in subsequent analyses. However, this unique scheme may be useful in the study of geological and extraterrestrial specimens available in limited amounts.

Yet another scheme has been proposed[70] for the analysis of organic substances in lunar specimens. Here it is suggested that a closed extraction apparatus be used, whereby one can carry out the extraction (with the aid of ultrasound), evaporation, separation on columns with adsorbents, and the collection of fractions in a closed system. Solvents and solutions are transferred from one apparatus to another by the pressure of pure helium. However, the nature of the carbon-containing compounds in lunar rock precluded the application of this scheme. Nevertheless, there is hope that this idea may prove useful in designing an apparatus for the remote investigation of the organic substances present on other planets.

The techniques used in the extraction and hydrolysis of the lunar specimens supplied by the Apollo 11 and 12 expeditions have been described in detail also in other reports[71-73], which likewise confirm that schemes in which provision is made for the isolation of any one class of compounds are the most rational.

Thus in the analysis of the first lunar specimens use was made of three methods involving extraction by aqueous and non-aqueous solvents: boiling in open and closed systems, Soxhlet extraction, and extraction with the aid of ultrasound[59]. It has been shown that aminoacids and their precursors may be most effectively sought by extraction with hot water followed by acid hydrolysis of the aqueous extract[65]. Extraction with non-aqueous solvents and direct acid hydrolysis of the lunar specimens do not yield positive results[59,62,63]. Direct hydrolysis of the lunar specimen with 6 *N* HCl is accompanied by the formation of a very large amount of salts, which greatly impair the extraction process. It may be that treatment of lunar rocks with hot hydrochloric acid leads to the decomposition of aminoacids[59,74]. Extraction with water

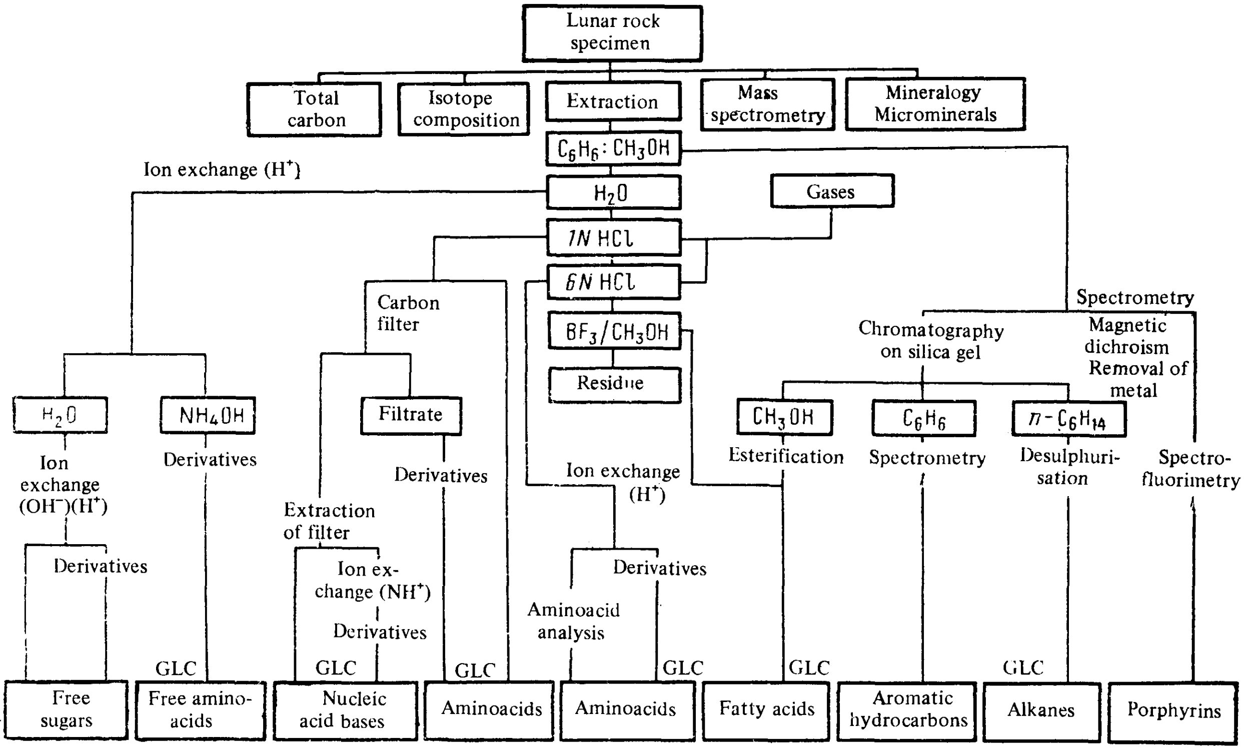

Figure 3. A scheme for the complete analysis of organic compounds in lunar rocks[65].

followed by the hydrolysis of the extract (indirect hydrolytic scheme) has been rapidly adopted and used to search for aminoacids in other specimens of lunar rocks and in meteorites.

Together with a detailed description of the analytical technique for lunar rocks provided by the Apollo 11, 12, and 14 expeditions, the paper by Fox et al.[34] presents also the qualitative and quantitative compositions of the aminoacids detected in such rocks (Table 2). The results in Table 2 show that the same aminoacids were identified in almost all instances.

Analysis of lunar specimens revealed the presence of aminoacids in very small amounts (20–70 parts per 1000 million)[44,65]. It was therefore of interest to test for the presence in these specimens of biological contaminations of terrestrial origin. Comparison of the analytical results for lunar specimens on an ultrasensitive aminoacid analyser with the aminoacid content in fingerprints suggests the absence of such contaminations (Fig.4).[44] A blank experiment demonstrated the absence of aminoacids from the reagents employed.

The possibility that the aminoacids detected might have been formed on oxidation of the rocket fuel (1,1-dimethylhydrazine) on the surface of the Moon was tested directly on a lunar specimen[75]. The specimen was taken from beneath the lunar module of the Apollo 15 expedition after it had been acted upon by the exhaust gases of the engine of the descent apparatus. The results of the analysis of the hydrolysates of this specimen revealed a lower overall amount of aminoacids than in the specimens investigated previously[34,75]. Their qualitative composition proved to be the same. It follows from this that the rocket fuel oxidation products do not contaminate lunar soil with aminoacids. It is possible that the hot exhaust gases actually decompose the lunar aminoacids. Furthermore, oxidation of 1,1-dimethylhydrazine under laboratory conditions does not lead to the synthesis of aminoacids[66].

The study of the isotope composition of lunar carbon also indicates the absence of terrestrial contaminations. The isotope composition of the carbon in lunar rocks, collected in the Sea of Tranquility, varies from +2.2 to +10.8‰ (breccia) and from +15 to +20‰ (lunar powder)[62,76,77]. The distribution of carbon isotopes in the lunar powder specimens supplied by the Apollo 16 expedition varied from +9.4 to +16.1‰ for a total amount of carbon of 88–206 parts per million[61]. Thus, one may assume that lunar carbon is anomalously heavier compared with terrestrial carbon (Fig.1).

The analytical data show that the aminoacids in lunar rocks are present in a bound form and are not terrestrial contaminations or rocket fuel combustion products. The low concentration of aminoacids suggests that they might have appeared on the Moon as a result of the incidence of organic compounds from interstellar matter[78], comets' tails[79], solar wind[60], and meteorites[48]. Interstellar matter probably makes the smallest contribution to the formation of aminoacids on the Moon's surface[80] and solar wind the highest.

The Planets

Data concerning the composition of the atmospheres of the planets in the solar system are very important for the determination of aminoacid precursors (Table 3). Table 3 shows that Earth differs strongly from the other planets in the composition of the atmosphere, which is probably due to the presence of life on Earth. The exact composition of the primary terrestrial atmosphere is unknown. Oparin assumed that Earth was formed by a cold process and its atmosphere might therefore have contained hydrogen, methane, and the inert gases[1]. This reducing atmosphere was gradually enriched in the gases evolved from the Earth's core—methane, hydrogen sulphide, and ammonia. It probably also contained water vapour. An atmosphere having this composition might have served as a source of various organic substances on Earth. Numerous subsequent experiments confirmed the possibility of the synthesis of aminoacids under the reducing conditions of the primary terrestrial atmosphere. Experiments simulating Jupiter's atmosphere[82] also demonstrated the possibility of the synthesis of organic compounds which are precursors of biologically important molecules.

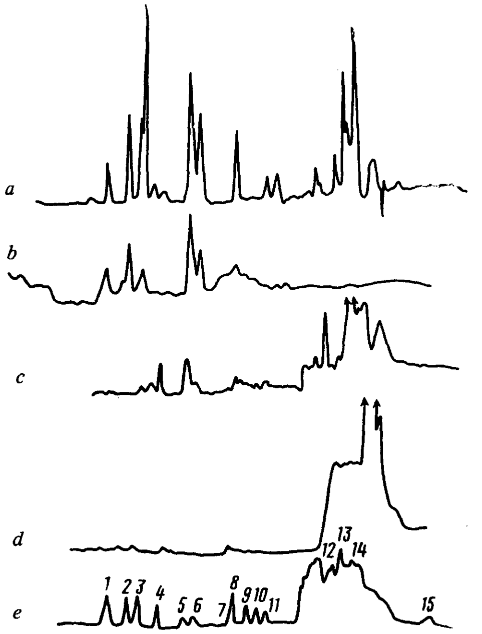

Figure 4. Chromatograms of aminoacid mixtures obtained in separation on an ion-exchange analyser[44]: *a*) contaminations by human fingerprints; *b*) hydrolysate of the aqueous extract of lunar dust (Apollo 11); ditto (Apollo 12); *d*) aqueous solutions in a blank experiment; *e*) mixture of standard aminoacids [1) aspartic acid; 2) threonine; 3) serine; 4) glutamic acid; 5) glycine; 6) alanine; 7) cysteine; 8) valine; 9) methionine; 10) isoleucine; 11) leucine; 12) histidine; 13) lysine; 14) ammonia; 15) arginine].

Some investigators believe that the atmosphere of the primitive Earth was not entirely reducing[83]. The primitive atmosphere might have been formed from the gases evolved from the Earth's mantle and core. Methane, carbon dioxide, and a number of radicals (C_2, C_3, CH_3, CN, etc.) are formed at present in the Earth's mantle and were probably formed during the cooling of the fused Earth[84,85]. The primary atmosphere might have been close in composition to that of volcanic gases. The gases which are ejected by volcanoes at the present time contain largely CO_2, CO, CH_4, H_2, N_2, and possibly HCN.[86-88] In 1973 Soviet investigators succeeded in confirming that volcanic gases contain hydrogen cyanide—a most important aminoacid precursor[89]. Its concentration in the gases evolved by the incandescent lava (at 900°C) of the volcano Alaid in the Kuril islands is about 0.01 mg $litre^{-1}$. Aminoacids and their precursors have been obtained from gases having a composition close to that of volcanic gases (see the next Section). The data presented show that, during certain periods of evolution, the atmosphere of the primitive Earth might have had a composition resembling that of the atmospheres of Jupiter and Saturn (the "fossil" planets) or Venus and Mars.

Table 3. The compositions of the atmospheres of the planets in the solar system[13,81] (the components are listed in order of decreasing concentrations).

Planet	Components
Venus	CO_2,CO, HCl, HF, H_2O (O_3?), (N_2?)
Earth	N_2, O_2, H_2O, Ar, CO_2, Ne, He, CH_4, Kr, N_2O, H_2, O, O_3, Xe
Mars	CO_2, CO, H_2O, O_2, (CH_4?), (NH_3?), (N_2?)
Jupiter	H_2, CH_4, NH_3
Saturn	H_2, CH_4, (NH_3?)
Uranus	H_2, CH_4
Neptune	H_2, CH_4

When an oxidising atmosphere is simulated (a mixture of CO_2, H_2O, N_2, and O_2), it is impossible to synthesise important aminoacid precursors such as HCN, CH_3CHO, CH_3NH_2, etc.[90] Thermodynamic calculations have shown that, under the conditions of a reducing atmosphere (a mixture of NH_3, H_2, H_2O, and CH_4), the enthalpies of formation of these compounds are an order of magnitude lower than in an oxidising atmosphere.

The principal ways in which the most important aminoacid precursors (methane, hydrogen cyanide, cyanoacetylene, the simplest aldehydes, and others) are synthesised have been thoroughly examined[5,8,9]. For example, it is known that hydrocarbons may be formed at an elevated temperature from carbon and hydrogen, a mixture of carbon monoxide or dioxide with hydrogen, and also when metal carbides are acted upon by water. Hydrogen cyanide is obtained in electric discharges between carbon electrodes in an atmosphere of nitrogen and hydrogen, nitrogen and methane, or carbon monoxide and hydrogen. Under the same conditions, cyanoacetylene may be formed. Lower aldehydes may be synthesised by the action of ultraviolet radiation or an electric discharge on CO_2-H_2O, $CO-H_2O$, CH_4-H_2O, and even $CO-H_2$ mixtures.

Thus the most varied primary compounds, which are of interest as aminoacid precursors, might have existed in the atmosphere or hydrosphere of the primitive Earth. To some extent, they might have been brought to Earth from space in one way or another or they might have arisen spontaneously from the simplest organic and inorganic substances present on Earth itself. During chemical evolution, these compounds, particularly methane, ammonia, water, formaldehyde, and hydrogen cyanide, served as the starting materials in the non-biological syntheses of various biologically important substances, particularly aminoacids.

III. PREBIOLOGICAL SYNTHESIS OF AMINOACIDS

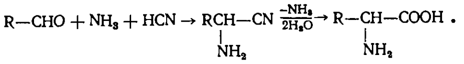
The majority of the syntheses of aminoacids require the expenditure of energy. Under the conditions of the primitive Earth, the following different energy sources might have existed: ultraviolet radiation from the Sun—570.0 cal cm^{-2} per year ($\lambda < 250$ nm); electric discharges (atmospheric lightning)—3.9 cal cm^{-2} per year; radioactive emission from the Earth's core (at depths down to 1 kilometer)—0.8 cal cm^{-2} per year; volcanic heat (as a result of magmatic activity)—0.13 cal cm^{-2} per year; cosmic rays—0.0015 cal cm^{-2} per year [91].

a. Synthesis in Electric Discharges

Aminoacids were obtained for the first time under laboratory conditions by Miller [3,4,92] when a mixture of gases simulating the atmosphere of the primitive Earth were subjected to the action of electric discharges. Miller's apparatus consisted of a 5-litre flask (fitted with two electrodes), through which a mixture of water vapour, methane, ammonia, and hydrogen circulated. A potential of 60 kV was applied to the electrodes and the arc was struck.

After incubation for a week, it was found that HCN, HCHO, CH_3CHO, aminoacids, hydroxyacids, carboxylic acids (Table 2) urea, and *N*-methylurea had been synthesised. Altogether 11 aminoacids were found, glycine, α-alanine, β-alanine, and α-aminobutyric acids being obtained in amounts sufficient for identification on the basis of the melting points of their derivatives.

Miller [34,92] suggested two possible pathways to the synthesis of aminoacids: (1) their generation in the gas phase from the radicals and ions formed in the electric discharges from mixtures of methane, ammonia, and water; (2) the formation in the gas phase of only the simplest aldehydes and nitriles, which are then converted into aminoacids in the liquid phase. The secondary pathway appears to be more likely. Analysis of the gas phase reveals the presence of HCN, HCHO, and CH_3CHO, their amount increasing to a maximum at the beginning of the reaction and then falling. These observations enabled Miller to suggest the occurrence of the Strecker reaction in the synthesis of aminoacids and hydroxyacids in the liquid phase. Aminonitriles should have been formed as intermediates:



$$R{-}CHO + NH_3 + HCN \rightarrow \underset{\displaystyle NH_2}{RCH}{-}CN \xrightarrow[2H_2O]{-NH_3} R{-}\underset{\displaystyle NH_2}{CH}{-}COOH\ .$$

To confirm the proposed mechanism, Miller carried out the alkaline hydrolysis of a synthetic mixture of RCHO, HCN, and NH_3. This also yielded glycine, α-alanine, and α-aminobutyric acid. The last two aminoacids were obtained in much greater amounts than in the experiment with an electric discharge. An important confirmation of this mechanism is provided by the detection in the liquid phase of the corresponding hydroxyacids (glycolic, lactic, and α-hydroxybutyric) in approximately equal proportions together with the aminoacids (glycine, α-alanine, and α-aminobutyric acid). This finding suggests that the acids are synthesised simultaneously with equal thermodynamic and kinetic probabilities. The detection of a large amount of formic acid also confirms the importance of the role of hydrocyanic acid as an intermediate in prebiological synthesis.

Some workers believe [86,93,94] that the content of ammonia in the primitive atmosphere of Earth was not more than 10^{-5} atm. This does not, however, diminish the important role which ammonia might have played in the prebiological synthesis of organic compounds in the ocean. In their latest studies Miller and coworkers [95,96] investigated in detail the synthesis of aminoacids in electric discharges in mixtures of methane, nitrogen, and water containing traces of ammonia. They detected 28 aminoacids by ion-exchange chromatography and gas chromatography combined with mass spectrometry (Table 2). Their overall yield was 15.5% (with respect to carbon).

It is noteworthy that previously many investigators found a wide variety of protein and non-protein aminoacids in analogous syntheses. However, the reliable detection in a single experiment of 20–30 aminoacids at once, when these are present in very small amounts, became possible only recently as a result of the great sophistication of analytical techniques.

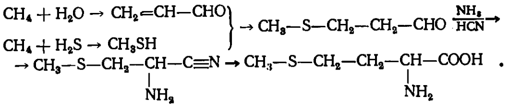
It has been suggested [96] that, when a mixture of methane, nitrogen, and water is subjected to the action of electric discharges, aminoacids are formed mainly via nitriles and aminonitriles. The high content of hydrocyanic acid in the aqueous phase and the fact that the presence of γ-amino-α-hydroxybutyric, $\alpha\gamma$-diaminobutyric, and $\alpha\beta$-diaminopropionic acids and serine is associated with nitrile precursors support this hypothesis. The absence of ammonia from the initial mixture probably rules out the Strecker synthesis in the present instance.

According to Miller, aspartic and glutamic acids are formed by the Strecker reaction via α-cyanoacetaldehyde and β-cyanopropionaldehyde. This is confirmed by the detection in the electric discharges of cyanoacetylene [97], which may be regarded as a precursor of cyanoacetaldehyde.

The mechanism of the synthesis of aspartic acid via diacetylene, which is always present in the gases formed by the electrocracking of hydrocarbons, also appears to be likely [98,99]. At elevated temperatures diacetylene may combine with two ammonia molecules with formation of succinodinitrile. Radical amination of the latter and hydrolysis of the aminodinitrile lead to aspartic acid. Glutamic acid can also be synthesised from diacetylene by the addition of ammonia and water with intermediate formation of β-cyanopropionaldehyde.

By subjecting various hydrocarbons to high temperatures or electric discharges, it is possible to synthesise phenylacetylene [100], which is readily hydrated to phenylacetaldehyde. The yield of the aldehyde increases when the reaction proceeds via the nucleophilic or radical addition of hydrogen sulphide followed by the hydrolysis of the thioaldehyde [101]. Next ammonia and hydrogen cyanide add on by the Strecker reaction with formation of the nitrile of phenylalanine and then of phenylalanine itself. In the radical addition of hydrogen sulphide to phenylacetylene, a low yield of tyrosine was obtained. The above sequence of reactions probably determines the mechanism of the synthesis of these aminoacids in the presence of hydrogen sulphide. However, previously investigators [102,103] detected phenylalanine in mixtures synthesised nonbiologically in the absence of hydrogen sulphide.

The prebiological synthesis of methionine has been achieved [104] by exposing a mixture of methane, nitrogen, ammonia, water, and hydrogen sulphide (or thiomethanol) to an electric discharge. It is believed that acrolein, which has been detected in the resulting mixture, is an intermediate in this reaction:



$$\left.\begin{array}{l} CH_4 + H_2O \rightarrow CH_2{=}CH{-}CHO \\ CH_4 + H_2S \rightarrow CH_3SH \end{array}\right\} \rightarrow CH_3{-}S{-}CH_2{-}CH_2{-}CHO \xrightarrow[HCN]{NH_3}$$

$$\rightarrow CH_3{-}S{-}CH_2{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}{-}C{\equiv}N \rightarrow CH_3{-}S{-}CH_2{-}CH_2{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}{-}COOH\ .$$

The authors note that acrolein may be a precursor not only of methionine, but also of homocysteine, glutamic acid, homoserine, and $\alpha\gamma$-diaminobutyric acid. This is possible when hydrogen sulphide, hydrogen cyanide, water, or ammonia add to its double bond.

Experiments[105] analogous to the first experiment carried out by Miller revealed an acceleration of the synthesis of aminoacids. Exposure to electric discharges for the first 20 h led to the formation of two aminoacids, four aminoacids were detected after 100 h, and 12 aminoacids after 200 h. Abelson[106] subjected to the action of electric discharges mixtures of gases with different concentrations of H_2, CH_4, CO_2, CO, H_2O, NH_3, N_2, and O_2. He demonstrated that aminoacids are synthesised only in a reducing atmosphere (oxygen inhibits their formation) and emphasised the role of hydrogen cyanide as an intermediate in these syntheses.

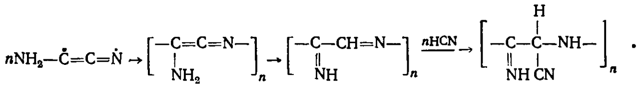
Pavlovskaya and Pasynskii[107] obtained the same set of aminoacids as Miller[3,4] when they exposed to spark discharges a different mixture, which, however, was of a reducing type (CH_4, NH_3, CO, and H_2O). A thermodynamic assessment of the pathway followed in this synthesis showed that aminoacids are formed with a decrease of free energy ($\Delta G_0 = -5.9$ kcal mole^{-1}), while in Miller's model mixtures the free energy increases ($\Delta G_0 = +62$ kcal mole^{-1}), i.e. the conditions are less favourable. The main conclusion reached in this important study involves the hypothesis that the loss of hydrogen from the terrestrial atmosphere could not have been a major obstacle to the synthesis of aminoacids.

Electric discharges have also been used to treat mixtures of methane, ammonia, and water vapour[108]; 45% of the products formed were found in the aqueous phase where the concentration of hydrocyanic acid was highest. After the hydrolysis of the aqueous phase (6 N HCl, 100°C, 24 h), glycine, alanine, aspartic and glutamic acids, threonine, serine, isoleucine, and phenylalanine were found by ion-exchange and gas chromatography. Hydrolysis of the polypeptides, detected in the reaction mixture, yielded the same aminoacids. In the reaction mixture, aminoacids are present in a free state only in trace amounts. It was concluded that, in the presence of a condensing agent (cyanamide), the aminoacids synthesised are converted into polypeptides in the aqueous phase.

Ponnamperuma and Woeller[109], who subjected an anhydrous equimolecular mixture of methane and ammonia to the action of spark discharges (4 kV, 0.5 mA), demonstrated the formation of nitriles and aminonitriles in the gas phase in the absence of aldehydes, which are necessary for Strecker condensations. Only the simplest aminonitriles (aminoacetonitrile and aminopropionitrile) were detected in the reaction gases. After the hydrolysis and esterification of the involatile liquid fraction in an analogous experiment[110], glycine, alanine, sarcosine, β-aminoisobutyric acid, diethylaminomalonic acid, etc. were detected.

These experiments indicate a different mechanism for the formation of aminonitriles—the direct precursors of aminoacids. At the high temperatures of the electric discharge, there is an equilibrium system consisting of molecular acetylene, hydrogen, and many radicals: C_2H, CH, CH_2, CH_3, NH, NH_2, CN, H, etc. When the temperature is reduced, the radicals recombine with formation of molecular compounds: acetylene and its homologues, hydrogen cyanide, cyanoacetylene, nitriles, and aminonitriles. Hydrolysis of the aminonitriles formed in this way yields the corresponding aminoacids.

Having determined the molecular weights of the liquid fractions obtained in similar experiments, Ponnamperuma and coworkers[109-111] concluded that the heavy fractions consist mainly of polymers (M from 2.4×10^2 to 1.4×10^3). The synthesis of these polymers can be accounted for on the basis of polymerisation of hydrogen cyanide[112-114], which is formed in the electric discharges from methane and ammonia. In the gas phase, hydrogen cyanide dimerises spontaneously in the presence of ammonia, forming the aminocyanomethylene biradical $H_2N{-}\dot{C}{=}C{=}\dot{N}$.[115,116] The latter polymerises rapidly and the resulting polymer tautomerises to polyiminoketimine, which interacts with hydrogen cyanide to form polyiminomalononitrile:



$$nNH_2{-}\dot{C}{=}C{=}\dot{N} \rightarrow \left[\begin{array}{c}{-}C{=}C{=}N{-}\\ | \\ NH_2\end{array}\right]_n \rightarrow \left[\begin{array}{c}{-}C{-}CH{=}N{-}\\ \| \\ NH\end{array}\right]_n \xrightarrow{nHCN} \left[\begin{array}{c} H \\ | \\ {-}C{-}C{-}NH{-}\\ \|\quad | \\ NH\ CN\end{array}\right]_n .$$

Hydrolysis of such compounds can lead to the formation of polypeptide chains, which are subsequently decomposed to aminoacids. In this mechanism, hydrogen cyanide is the main precursor of aminoacids, giving rise in an anhydrous gaseous phase to a number of nitriles and imino- and amino-compounds, which are starting materials for the synthesis of aminoacids and polypeptides.

The experiments of Toupance et al.[90] also emphasised the role of the nitrile group in the syntheses of aminoacid precursors from methane–ammonia mixtures in electric discharges (200 V, 100 mA). The infrared spectra (712 cm^{-1}) of the reaction mixture revealed a rapid increase of the concentration of hydrogen cyanide during the first seconds of the experiment. Subsequently its concentration remained unchanged.

Thus the following three pathways to the synthesis of aminoacids are possible under the influence of electric discharges through gases simulating the reducing atmosphere of the primitive Earth: (1) via aldehydes (with subsequent Strecker condensation); (2) via aminonitriles; (3) via nitrogen-containing polymers. It is extremely likely that non-biological synthesis included simultaneously all three mechanisms, particularly since in virtually all of them the principal role is assigned to acetylene and nitrile groups.

b. The Influence of Ultraviolet Radiation

Ultraviolet light has also been used to synthesise aminoacids. Groth and Weyssenhof[117] irradiated for a week with ultraviolet light from a low-pressure mercury lamp (4×10^{18} photons s^{-1}) a mixture of ammonia, methane, and water containing mercury vapour as the sensitiser. However, aminoacids were not detected in the subsequent analysis of the reaction mixture by paper chromatography. In this instance there was probably no direct photolysis of methane in the given wavelength ranges of the radiation and the probability of photosensitisation was low. The radicals and atoms obtained on photolysis or photosensitisation of ammonia (NH_2 + H) are energetically relatively unreactive towards methane at the experimental temperature (50°C). Their reactivity begins to be manifested above 300°C. However, the replacement of CH_4 by C_2H_6 in this experiment led to the formation of aminoacids (the yields are indicated in brackets): glycine (32×10^{-6} M), α-alanine (23×10^{-6} M), and α-aminobutyric acid (0.5×10^{-6} M) as well as carboxylic acids: formic (72×10^{-6} M), acetic (203×10^{-6} M), and propionic (17×10^{-6} M). In the absence of a photosensitiser, the amount of aminoacids synthesised was lower.

When a methane-containing mixture was subjected to the shorter-wavelength radiation of the xenon lamp (147 nm and 129.5 nm, 4×10^{16} photons s^{-1}), aminoacids were also synthesised. In this case very small amounts of glycine and α-alanine were detected. Terenin and coworkers[118,119] achieved the photochemical synthesis of aminoacids from gaseous and liquefied mixtures of methane, ammonia, carbon monoxide, and water. They used a powerful hydrogen lamp whose radiation in the short-wavelength range ($\lambda \geqslant 130$ nm) was closer to the ultraviolet spectrum of the Sun. α-Alanine, α-aminobutyric acid, valine, and norleucine were detected in the synthesis products. Thus, short-wavelength radiation might have been sufficiently effective in the photolysis of mixtures of ammonia, methane, hydrogen, and water. This conclusion was confirmed by their ionisation potentials and quantum yields[120].

The photochemical synthesis of aminoacids from aldehydes and ammonium salts was developed in greatest detail by Pavlovskaya and coworkers[102,121–123]. Aqueous solutions of formaldehyde and ammonium nitrate were irradiated with ultraviolet light at a wavelength of 253.7 nm and 40°C in the course of 20–355 h. The aminoacid fractions, obtained by separation on ion-exchange resins, were analysed by paper and thin-layer (silica gel) chromatography. Serine, glycine, alanine, threonine, and basic aminoacids were detected. The qualitative and quantitative composition of the aminoacids changes somewhat following the irradiation of the initial solutions in the presence of natural adsorbents and catalysts: kaolinite, bentonite, limonite, and quartz. Numerous aminoacids are formed when acetaldehyde is irradiated instead of formaldehyde. In this case lysine, ornithine, arginine, glutamic acid, tyrosine, valine, leucine, and isoleucine were also found (Table 2).

The mechanism of the synthesis of aminoacids when gaseous mixtures of methane, ammonia, and other components are acted upon by ultraviolet radiation has been less thoroughly investigated. Presumably photolysis results in the formation of radicals analogous to those examined previously. For example, the photodissociation of methane does not stop at the stage involving the formation of the CH_3 radical, but very probably proceeds further to CH_2 and CH.[124] The quantum yield of ammonia reactions such as $NH_3 \rightarrow NH + H_2$ and $NH_3 \rightarrow N + H_2 + H$ increases with decrease of wavelength[125]. The recombination of various radicals can lead to the formation of aminonitriles.

Sidorov[126] and Pavlovskaya and coworkers[123] proposed a mechanism for the synthesis of aminoacids from aldehydes and ammonium salts under the influence of ultraviolet radiation. In the presence of formaldehyde, the $CH\dot{O}$ radical is formed initially, its recombination giving rise to glyoxal. The latter is converted under the influence of a light quantum into glyoxalic acid, which in the presence of ammonia and hydrogen gives rise to the simplest aminoacid—glycine. In the presence of higher aldehydes, other intermediate products are possible (ketoacids), which are transformed into more complex aminoacids.

The non-biologically synthesised aminoacids can themselves undergo interconversions. Thus, when valine is irradiated with ultraviolet light in the presence of metal oxides (ZnO and V_2O_5), glycine, threonine, and alanine are formed[127]. Alanine and glycine have been obtained from leucine under these conditions. In aqueous aminoacid solutions without metal oxides, new aminoacids are not formed. It is interesting that in the presence of MoO_3 irradiation of alanine or leucine leads to the formation of more complex aminoacids, for example, aspartic acid[128]. However, such acids are not formed from glycine. The photolysis of phenylalanine in the presence of polyphosphoric acid leads to its decomposition and hydroxylation, which results in the formation of tyrosine, alanine, and glycine[129]. In addition to the new aminoacids, ammonia, aldehydes, and carboxylic acids are formed under the conditions of the experiments.

c. Thermal Syntheses

The heat necessary for chemical synthesis on Earth might have been provided by early volcanic activity, which was probably much greater than at the present time. The wide distribution of regions in which thermal waters emerge on the surface suggests that the heat derived from thermal sources might have been important for the formation of aminoacids.

In order to investigate the possibility of the formation of biologically important compounds from gases evolved by magmatic rocks, Harada and Fox[130] heat-treated a mixture of methane, ammonia, and water. The initial gaseous products were passed at a high rate through a quartz tube heated to 900–1000°C. The tube was filled with silica gel, alumina gel, or volcanic lava. The reaction products were absorbed with aqueous ammonia and then hydrolysed (4 *N* HCl). Aminoacid analysis demonstrated the formation of a large proportion of protein aminoacids, including aromatic aminoacids, namely, aspartic and glutamic acids, threonine, serine, proline, glycine, alanine, valine, leucine, isoleucine, tyrosine, and phenylalanine. β-Alanine and certain other non-natural aminoacids were also detected.

This experiment aroused interest among investigators and was frequently repeated for a detailed investigation of the conditions of the synthesis and the composition of the aminoacids. Thus, Taube et al.[131] largely confirmed the results of Harada and Fox. Apart from the compounds indicated above, they identified lysine in the reaction mixture by electrophoresis. Oró[132,133], who carried out a similar experiment in the absence of a catalyst, showed that the same set of aminoacids is formed. Glycine and alanine had the highest concentrations in the mixture (Table 2). The reaction mixtures obtained under the conditions of the experiments of Harada and Fox[130] were recently analysed[134] by gas chromatography and mass spectrometry. It was shown that aminoacids are formed in low yields (0.007%) and fewer were found than in the experiment of Harada and Fox[130]. The authors note that β-aminoacids predominate in the mixtures.

Comparison of the experiments with the effect of electric discharges and heat on gaseous mixtures showed that the simplest aminoacids (glycine and alanine) are formed in maximum amounts regardless of the type of energy used.

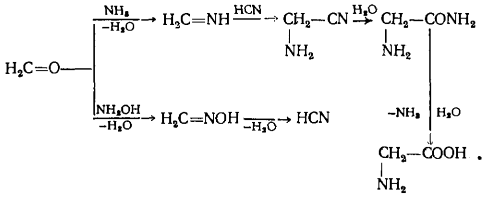
Aspartic and glutamic acids have been obtained in high yields by the thermal method. Reactions involving the isomerisation of the hydrocarbon chain (valine, leucine, and isoleucine are present in the mixture), cyclisation (tyrosine, phenylalanine, and proline), and hydroxylation (threonine, serine, and tyrosine) are more characteristic of thermopyrolysis. An increase of temperature favours these reactions[132,133]. Reactions involving the formation of unbranched chains (aminobutyric acid, sarcosine, and methylalanine) are more probable in electropyrolysis. It is noteworthy that the action of heat leads to the formation of mainly natural aminoacids.

It has been established that non-biological synthesis takes place at the present time and might have occurred in the remote past in the film on the edge of thermal sources and in the eruption of volcanoes[85,135]. Fox[136] analysed lava specimens collected with sterile steel rods in the eruption of Mauna Loa volcano (Hawaian Islands). The lava temperature during sampling exceeded 1000°C. The specimens were treated with hot water and the aqueous extract was hydrolysed (6 *N* HCl). Aminoacid analysis revealed the presence of 16 aminoacids (Table 2) with an overall yield of about 30×10^{-9} mole/g of lava. Glutamic (27%) and aspartic (12.5%) acids as well as glycine and alanine (16.8 and 10.0% respectively) were present in largest amount. It is interesting that a sulphur-containing aminoacid (methionine) was also detected in the mixture. The cooled lava had a bubble structure and consequently contained gas. Fox believes that the aminoacids were synthesised from the gases during their cooling.

Non-biological aminoacid mixtures can be obtained from CO, H_2, and NH_3 under the conditions of a modified Fischer–Tropsch process[25,137–139]. The initial mixtures of gaseous products were heated to 150–700°C in the presence of a wide variety of catalysts (montmorillonite, alumina gel, or silica gel). The resulting mixture contained a large proportion of protein aminoacids, including structurally complex aromatic and heterocylic aminoacids (Table 2), the yield of which was 0.01–0.1%.

Bakh was one of the first to use formaldehyde and hydrocyanic acid in thermal synthesis of non-biological aminoacids and polypeptides[9]. By heating (80–100°C) aqueous mixtures of hydrocyanic acid and ammonia or formaldehyde and hydroxylamine, it is possible to obtain the following aminoacids[133]: glycine, alanine, aspartic and glutamic acids, serine, threonine, leucine, isoleucine, arginine, α-amino-n-butyric and $\alpha\beta$-diaminopropionic acids, and β-alanine. In the latter mixture, a considerable amount of glycine is formed. When hydroxylamine is replaced by hydrazine, certain aminoacids are again synthesised. Simple heating of an aqueous solution of formaldehyde with ammonia (3 : 1) followed by acid hydrolysis (185°C, 8 h) led to the formation of a mixture of aminoacids[140,141], which qualitatively differed little from the mixture obtained by Pavlovskaya and coworkers[121,122]. The quantitative proportions of the aminoacids are indicated in Table 2. Their overall yield was 0.007%. Hexamethylenetetramine was detected in the reaction product. The reaction has also been achieved in the presence of lunar dust[136]. After hydrolysis, six aminoacids were detected, the amounts of glycine and glutamic acid being greatest.

The synthesis of aminoacids on heating formaldehyde and ammonia[140,141] proceeds via hexamethylenetetramine[142], the formation of which from these starting materials was first demonstrated by Butlerow[43]. The acid hydrolysis of hexamethylenetetramine also yielded all the aminoacids synthesised from CH_2O and NH_3.[142] Oró[144] suggests that aminoacids are formed in thermal syntheses from a mixture of formaldehyde, hydroxylamine, and water via oximes, hydrocyanic acid, and aminoacid amides. For example, the following reaction mechanism is possible in the case of glycine:



The high reactivities of aminonitriles, which are important aminoacid precursors, has been noted in the literature. Thus Moser and Matthews[145] reported that certain α-aminoacids are formed on neutral or alkaline hydrolysis of aminoacetonitrile. They believe that aminoacids are synthesised via the decomposition of aminoacetonitrile to HCN and NH_3, the polymerisation of HCN, and subsequent hydrolysis of the polymer to various aminoacids.

In the presence of CH_2O, aminoacetonitrile can give rise to methyleneaminoacetonitrile, which is also readily formed from CH_2O, HCN, and NH_4OH.[146] This compound is converted on mild hydrolysis (110°, pH 5.5–10) into glycine, serine, hydroxymethylserine, alanine, sarcosine, and di- and tri-glycine. It has been suggested that glycine and formaldehyde are the products of the direct hydrolysis of methyleneaminonitrile, while serine and hydroxymethylserine are obtained on *C*-hydroxymethylation of the reactive methylene group of the initial compound (or of the glycine formed) by formaldehyde. Alanine is probably formed from serine via dehydroalanine.

In order to elucidate the mechanism of the synthesis of complex aminoacids, it is quite justifiable to attempt to use as starting materials the simplest aminoacids or their derivatives, which are obtained in high yields in most non-biological syntheses. Thus, the synthesis of valine and isoleucine, aminoacids with branched hydrocarbon chains, is probably based on the fairly high yield of the nitrile of glycine formed on cyanide polymerisation[112]. The nitrile gives rise to the required aminoacids in the presence of acetone or ethyl methyl ketone (40°C, 21 days)[147]. The yield of valine is 0.3% and that of isoleucine is lower by an order of magnitude. Ketones are believed to be the products of non-biological syntheses, since they can be obtained from the corresponding acetylene homologues.

The possibility of the formation of serine by the reaction of glycine with formaldehyde (60–100°C, phosphate buffer) has been demonstrated[147]. It was shown that formaldehyde exhibits catalytic activity. Apart from serine, hydroxymethylserine, sarcosine, alanine, and iminodiacetic acid may be obtained from dilute alkaline solutions of glycine and formaldehyde[148]. The introduction of acetaldehyde or benzaldehyde leads to the synthesis of threonine or β-phenylserine respectively.

The most complex aminoacid (tryptophan) was obtained by the Michael reaction (60–100°C, 8–53 days) from indole and dehydroalanine employed in the form of a peptide to increase its stability[147]. The yield of tryptophan was between 0.01 and 0.5%. Indole, formed in small amounts in electric discharges from hydrocarbons and ammonia, can also be regarded as a precursor of tryptophan.

d. Other Syntheses

There have been fewer studies in which prebiological syntheses of aminoacids under the influence of ionising radiation were investigated. However, they confirm to a large extent the results obtained by the procedures discussed above. Palm and Calvin[149] irradiated with fast electrons in a linear accelerator (5 MeV, overall dose 10^9 rad, 6 ms pulses at a frequency of 30 Hz) a gaseous mixture of CH_4, NH_3, and H_2O, which was kept over an ammonia solution of magnesium and iron silicate or ammonium phosphate; the experimental temperature was 30–80°C. Analysis of the liquid phase by ion-exchange and paper chromatography demonstrated the formation of a multiplicity of products: aminoacids (glycine, alanine, and aspartic acid), hydrocyanic and lactic acids, urea, C_3–C_6 sugars, etc. Unfortunately, the gas phase was not analysed.

Studies by Oró[133] confirmed and extended these experiments. A similar mixture was irradiated under identical conditions and the same aminoacids were detected by paper radiochromatography. In addition, glycine amide was identified. Oró also reported a novel method for irradiating with fast electrons a solid mixture of CH_4, NH_3, and H_2O at the liquid nitrogen temperature. The aim of the experiment was to simulate the irradiation of the nucleus of a comet in space. Similar aminoacids were detected in the aqueous phase[149], but their radiochemical yields could not be found owing to the lack of analytical data for the gaseous phase.

Choughuley and Lemmon[150] demonstrated the possibility of synthesising sulphur-containing aminoacids on irradiation of a mixture of CH_4, NH_3, H_2O, and H_2S with fast electrons. Nevertheless, it was difficult to obtain them in satisfactory yields under such conditions owing to the ease of oxidation of the mercapto-groups by the water radiolysis products.

Studies on the synthesis of aminoacids from a mixture of gases (CH_4, NH_3, H_2O, N_2, and CO_2) under the influence of low-intensity X-rays have been carried out[151]. Electrophoretic analysis of the aqueous extracts of the radiolysis products demonstrated the formation of neutral and acid aminoacids as well as amines. In subsequent similar investigations[152], glycine, alanine, and aspartic acid were found. The radiochemical yields of the aminoacids were low owing to the low selectivity of the process. Furthermore, one may note that the radioactivity might possibly have supplied energy for the synthesis of aminoacids mainly on the surface of the primitive Earth and not in the atmosphere.

Aminoacids can also be obtained in the field of ultrasonic waves[153]. Aqueous solutions of organic acids, formed by the Miller electrosynthesis[3], saturated with molecular nitrogen or a nitrogen–hydrogen mixture served as the starting materials. The formation of aminoacids was also observed following the exposure of ammonium chloride solutions containing urea or hydroxylamine to ultrasound. Experiments have been carried out recently using the energy of a shockwave[154–156]. Similar conditions are likely to have occurred on collision of meteorites with Earth's atmosphere. A number of aminoacids obtained from the gaseous mixture were identified in these experiments.

The aim of the studies considered in this section was to investigate mainly the possibility of the prebiological synthesis of protein aminoacids, i.e. to investigate one of the first steps in chemical evolution on Earth. Considerable advances have been made in this field. Almost all the protein aminoacids and a series of non-protein aminoacids have been synthesised. It is interesting that, regardless of the type of energy employed, various methods of non-biological synthesis lead to the formation of similar sets of aminoacids, in which there are many protein aminoacids. The analytical procedure developed recently makes it possible to detect a very large number of aminoacids present simultaneously in the mixtures synthesised.

The data quoted suggest that the problem of determining the principal pathways in the prebiological synthesis of aminoacids under laboratory conditions may be regarded as to a large extent solved. The possible discovery of new non-biological methods for their formation will confirm yet again the wide variety of natural pathways to the origin of life on Earth. The mechanism of the chemical conversion of simple starting materials into aminoacids, products with a highly developed polyfunctional structure, has many aspects, which are still unelucidated despite the large number of studies carried out. This applies particularly to the reactions occurring under the influence of ionising radiation, ultraviolet light, and heat, although in each case, including reactions under the influence of electric discharges, the excitation, activation, and ionisation processes have much in common, which is confirmed by the similarity of the products synthesised. In this connection, consistent efforts of investigators in the field of non-biological syntheses will probably be directed to a more systematic elucidation of the mechanisms of the formation of aminoacids.

It is interesting that all the protein and non-protein aminoacids discovered in the Murchison meteorite have been identified in a single experiment using electric discharges. There is a similarity not only between the qualitative but also the quantitative compositions of the products obtained in the laboratory experiment and discovered in the meteorite. One must emphasise yet again that the carbonaceous material in meteorites contains both aminoacids and their precursors—formaldehyde, hydrogen cyanide, and cyanoacetylene, i.e. compounds which are obtained in various non-biological syntheses. Together with the results of the analysis of lunar rocks, these data constitute evidence for universality of the prebiological pathways to the formation of aminoacids.

Condensed Tetrazoles

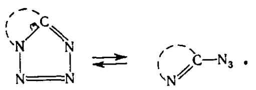
V.Ya.Pochinok, L.F.Avramenko, T.F.Grigorenko, and V.N.Skopenko

The present review surveys the literature on the methods of synthesis and chemical properties of condensed tetrazoles. The bibliography includes 125 references.

CONTENTS

I. INTRODUCTION

During the last 15 years, numerous studies dealing with the structure and properties of condensed tetrazoles have been published, the reason being that the tetrazole ring condensed via the $N_{(1)}-C_{(5)}$ bond with other rings exhibits a number of characteristic features in relation to non-condensed 1,5-disubstituted tetrazoles. Conversions into isomeric 2-azido-derivatives of nitrogen-containing heterocycles, which frequently occur on heating solutions of the test substance and sometimes in the crystalline state after prolonged storage, are characteristic of such condensed systems:



An equilibrium is then frequently established between the isomeric tetrazole and azido-forms, the position of which depends on the electronic nature of the condensed ring and its substituents, the polarity of the solvent, the pH of the medium, the reaction temperature, and the nature of the reagent employed[1].

Certain methods for the synthesis and the properties of individual examples of this interesting type of compound have been described in reviews dealing with the azide–tetrazole tautomerism[1-6], but a review in which methods for the synthesis of condensed tetrazoles and the relations between their properties and structures are surveyed and described systematically is lacking. The literature data on this problem are discussed in the present article (including publications in 1973).

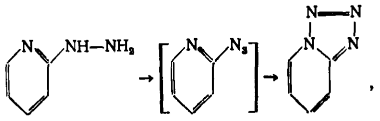
II. METHODS FOR THE SYNTHESIS OF CONDENSED TETRAZOLES

The majority of the reactions leading to condensed tetrazoles proceed via the formation of isomeric α-azido-derivative of nitrogen-containing heterocycles as intermediates. In this case the group

may be compared with the azidoazomethine group $R_2-N=\underset{R_1}{\underset{|}{C}}-N_3$ in linear systems, which isomerises irreversibly to the thermodynamically more stable tetrazole ring. Calculations carried out by Roberts[7] have shown that an appreciable expenditure of energy is not required for the formation of the tetrazole ring on formation of a bond between the azido-group and a nitrogen atom in an open chain or a ring.

If the azidoazomethine group is part of a heterocycle, the formation of a bond between the azido-group and the nitrogen atom of the heterocycle and the consequent formation of a condensed system do not always occur. Depending on the nature of the nitrogen-containing ring and the electronic nature of the substituents, the reaction product may be isolated in the form of a condensed tetrazole isomeric with the azido-derivative or in the form of an equilibrium mixture of both tautomeric forms.

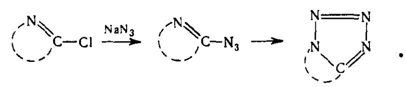
One of the most widely used methods for the synthesis of condensed tetrazoles involves the interaction of α-hydrazino-derivatives of nitrogen-containing heterocycles with nitrous acid. Tetrazolo[5,1-*a*]pyridine (I) was obtained for the first time by this procedure in 1915[8]:



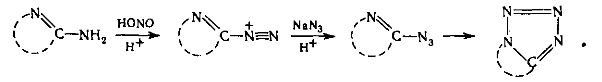
(I)

and subsequently compounds were synthesised in which the tetrazole ring is condensed with isoquinoline[9], quinoxaline[10-12], *s*-triazine[13], pyrimidine[14-18], phthalazine[19-22], naphthothiazole[23], pyridazine[24-26], pyrazine[26], pyridine[27], naphthyridine[28-35], uracil[36], quinoline[37,38], quinazoline[10,39,40], purine[41,42], thiazole[43-45], and benzoselenazole[46,47].

Condensed tetrazoles are frequently obtained by the interaction of α-chloro-derivatives of nitrogen-containing heterocycles with nitrous acid or sodium azide in a solvent (alcohol, acetonitrile, dimethylformamide). α-Chloroderivatives of benzothiazole[48], pyridine[49-53], quinoline[54], pyridazine[25,26,55-57], pyrimidine[14,15,58,59], quinazoline[14,22,40,60-62], phthalazine[19-22], quinoxaline[10,19], pyrazine[63], triazine[26], and naphthyridine[30,32] have been introduced into this reaction:



A convenient modification of this method involves the diazotisation of *α*-amino-derivatives of nitrogen-containing heterocycles followed by treatment of the resulting diazonium salts with sodium azide in an acid medium[48,64-66]:

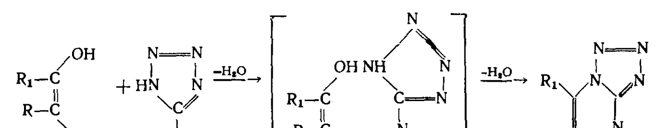


Although the yield of tetrazoles is lower in this case than in the synthesis by the procedures described above, the amino-derivatives are sometimes more readily available than the chloro- or hydrazino-derivatives. Furthermore, certain condensed tetrazoles cannot be formed at all by the first two methods. Thus, instead of the expected thiazolo[2,3-*e*]tetrazole, the interaction of 2-hydrazinothiazole with nitrous acid led to the isolation of 2,2′-dithiazolyltriazene[14]. On the other hand, the required product can be readily obtained from 2-aminothiazole[67]. Consequently this method was later used by Carboni and coworkers to synthesise tetrazolonaphthyridines[31,35].

Condensed tetrazoles can also be obtained by carrying out the Schmidt reaction with cyclic ketones. 1,5-Pentamethylenetetrazole[68], adamantane derivatives[69], methylcyclohexanone and camphor derivatives[70-72], and others[69] have been obtained by this method. Ruzicka and coworkers applied this reaction to higher cyclic ketones—cyclopentanone, cyclooctanone, cyclopentadecanone, and civetone[73,74]. The reaction of nitrous acid with 2-methoxy-Δ^1-pyrroline, as a result of which a compound which is probably trimethylenetetrazole was isolated, has been reported[75].

By treating 3,3-dihalogenoazocycloalkan-2-ones with phosphorus pentachloride and subsequent treatment of the resulting intermediate iminochlorides with nitrous acid, 8,8-dichloro- and 8,8-dibromo-tetrahydrotetrazolo[1,5-*a*]pyrimidines, 9,9-dichloro- and 9,9-dibromo-6,7,8,9-tetrahydro-5*H*-tetrazolo[1,5-*a*]azepines, and 10,10-dichloro-5,6,7,8,9,10-hexahydrotetrazolo[1,5-*a*]azocine have been obtained[76].

Several examples of the synthesis of condensed tetrazoles using non-condensed tetrazoles as the starting materials have been described. Derivatives of tetrazolo[1,5-*a*]pyrimidine (II) have been obtained by the reaction of 5-aminotetrazole with *β*-diketones or *β*-keto-acids[77]:



(II)

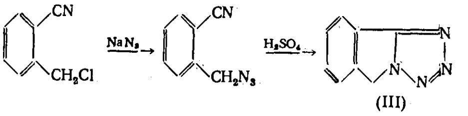
where

$R = H,\ R_1 = CH_3,\ R_2 = OC_2H_5;$
$R = H,\ R_1 = R_2 = CH_3;\ R = H,\ R_1 = C_6H_5,\ R_2 = CH_3,$
$R = R_1 = R_2 = CH_3.$

The mechanism of this reaction has been studied by Temple and Montgomery[16], who showed that the intermediate may be isolated as the sodium salt. Other tetrazolopyrimidines have been obtained by the same procedure[17,78,79].

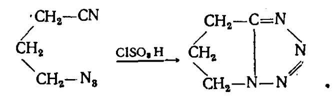
A series of chemical transformations led to the conversion 1-(*o*-carboxyphenyl)-5-phenyltetrazole into 1-(*o*-aminophenyl)-5-phenyltetrazole, which yields tetrazolophenanthridine on treatment with nitrous acid[54]. Certain tetrazolopyridines and isoquinolines have been synthesised by the dehydrogenation of 1-(*α*-pyridyl)-3-aryltriazine with tribromophenyl bromide in acetic acid at room temperature[36].

When azidonitriles are treated with concentrated acids, condensed tetrazoles are also formed[80-82]. Thus 5*H*-tetrazolo[1,5-*a*]isoindole (III)[82] has been obtained by the reaction of *o*-chloromethylbenzonitrile with sodium azide in aqueous alcoholic medium followed by the treatment of the resulting *o*-azidomethylbenzonitrile with concentrated sulphuric acid while cooling the mixture:



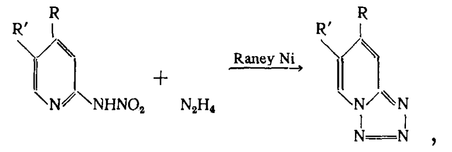
(III)

When chlorosulphonic acid is allowed to react with *γ*-azidobutyronitrile, trimethylenetetrazole is formed[81] (IV):



(IV)

A method has been proposed for the preparation of substituted hydrogenated derivatives of (I) from nitraminopyridines and hydrazine in the presence of Raney nickel[83]:



$R = R' = H;\ R = CH_3,\ R' = H;\ R = H,\ R' = CH_3.$

III. THE PROPERTIES OF CONDENSED TETRAZOLES

The reactions in which condensed tetrazoles participate may involve the condensed tetrazole ring or the isomeric azidoazomethine group, the heterocycle with which the tetrazole ring is condensed, or a substituent in the heterocycle.

The chemical properties of condensed tetrazoles depend on the stability of the tetrazole ring, the type of reactant, and the reaction conditions. The first stage of these reactions frequently involves the opening of the tetrazole ring and the formation of the isomeric azidoazomethine derivative under the influence of heat, the solvent, or another reactant. The condensed tetrazole then reacts like an aromatic or heterocyclic azide. The reaction may be accompanied by the evolution of nitrogen and the subsequent recombination of the nitrene radicals formed (photolysis and thermolysis). Interaction with nucleophilic reagents leads to the substitution of the azido-group (reactions with sodium cyanide and organometallic compounds). Reactions which proceed via the cycloaddition of the azido-group formed have also been described.

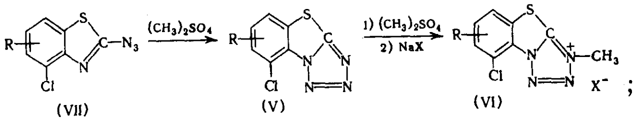
If the tetrazole ring shows no tendency towards isomerisation or is stabilised under the reaction conditions, it is preserved.

1. The Effect of Inorganic Acids and Alkylating Agents

The effect of inorganic acids on condensed tetrazoles depends on the nature of the nitrogen-containing heterocycle with which the tetrazole ring is condensed. Strong inorganic acids and trifluoroacetic acid at room temperature sometimes increase the stability of the tetrazole ring and displace the azide–tetrazole equilibrium towards the cyclic form. At the same time the electron-accepting tetrazole ring is protonated.

Thus Pochinok and coworkers[84] showed that tetrazolo-[5,1-*b*]-benzothiazole (V), thiazolo[3,3-*e*]tetrazole, and their derivatives with electron-donating substituents dissolve in concentrated sulphuric acid without decomposition, the dissolution being accompanied by protonation. When the solution is diluted with water, the initial tetrazoles are recovered almost quantitatively. Furthermore, when certain isomeric 2-azido-derivatives, for example 2-azido-4-chloro-benzothiazole, are dissolved in inorganic acids, they isomerise to condensed tetrazoles with subsequent protonation of the resulting ring[84]. The increase of the stability of the tetrazole ring of tetrazolo[5,1-*a*]pyridine (III) in an acid medium has also been reported by Boyer et al.[85] This compound does not decompose even on heating in concentrated acid up to 120°C.

When tetrazolo[5,1-*b*]benzothiazoles (V) react with dimethyl sulphate or triethyloxonium fluoroborate, the condensed tetrazole ring is alkylated with formation of quaternary tetrazolium salts (VI) and not the isomeric azidinium salts[84]. For example, alkylation of 2-azido-4-chlorobenzothiazole (VII) proceeds via the preliminary isomerisation to the 8-chloro-derivatives (V) under the influence of polar dimethyl sulphate:

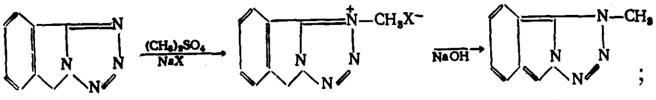


(VII) (V) (VI)

$X = I, ClO_4$.

By subsequent treatment with a saturated alcoholic solution of sodium iodide or sodium perchlorate, the *N*-methyltetrazolium methyl sulphates were converted into the corresponding methiodides or methoperchlorates.

Under analogous conditions compound (III) has been converted into a quaternary salt, from which the base (VIII) was obtained on treatment with alkali[82]:

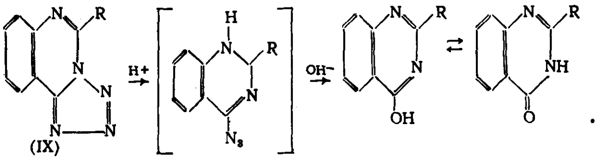


(III) (VIII)

$X = ClO_4, I$.

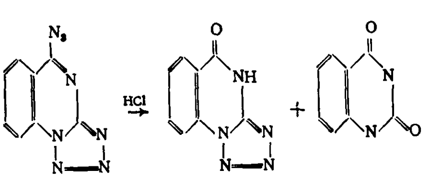
If the nitrogen-containing heterocycle can be protonated, electrons are withdrawn from the tetrazole ring, the stability of the latter decreases sharply, and the azide–tetrazole equilibrium in the system is displaced towards the isomeric azido-form[15,16,26,31,34,52,85] in which the azido-group plays the role of the electron donor.

On heating in acids, the azido-group produced is hydrolysed and replaced by the hydroxy-group. Postovskii and coworkers showed[40,56,62] that heating of 5-substituted tetrazolo[1,5-*c*]quinazolines (IX) in hydrochloric acid leads to the formation of 2-substituted 4-quinazolinones. This process can be assumed to involve a stage in which the condensed tetrazole ring is opened with subsequent hydrolytic abstraction of the azido-group via a nucleophilic mechanism:



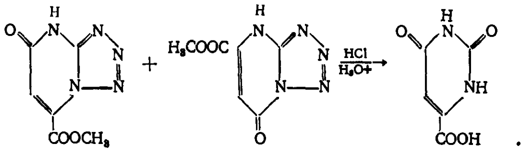
(IX)

When the 5-azido-derivative (X), in which the tetrazole ring is somewhat more stable, is heated in hydrochloric acid, a mixture of tetrazolo[1,5-*a*]quinazolin-5-one (XI) and quinazoline-2,4-dione (XII) is formed:



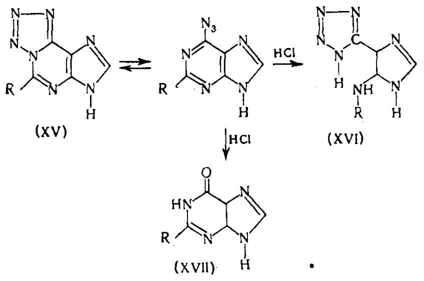
(X) (XI) (XII)

It has been found[87] that, when a mixture of the isomers of methoxycarbonyloxodihydrotetrazolo[1,5-*a*]pyrimidine (XIII) is refluxed with hydrochloric acid, 1,5-dipolar opening of the tetrazole ring also takes place with subsequent nucleophilic substitution of the azido-group and the formation of 6-carboxy-2,4-dioxo-1,2,3,4-tetrahydropyrimidine (XIV):



(XIII) (XIV)

Temple et al.[42] found that the unsubstituted 6-azidopurine system (XV, R = H) is converted preferentially into 5-substituted tetrazole (XVI) on treatment with concentrated hydrochloric acid:



(XV) (XVI) (XVII)

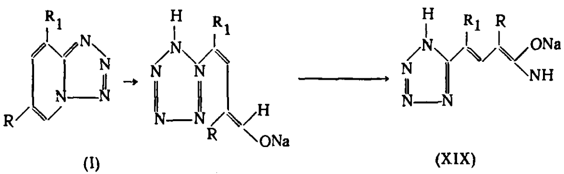
When an amino- or chloro-group is present in the 2-position [compounds (XV, R = NH_2 or Cl)], the system is resistant to the action of hydrochloric acid at room temperature, but hydrolyses on heating to guanine or xanthine (XVII).

2. The Effect of Alkalis and Alkoxides

Condensed tetrazoles, which as a rule readily undergo ring opening under the influence of acids, are more stable in alkalis and do not interact with them[31,34]; the nitrogen-containing heterocycle is cleaved[16,42,88,89].

Carboni and coworkers[31,34] showed that in the hydroxy- and amino-derivatives of substituted tetrazolo[1,5*a*][1,8]-naphthyridines (XVIII) the tetrazole formed is stabilised by alkalis. When the acetamido-derivative (XVIII) is hydrolysed with sodium hydroxide, the amino-derivative is formed in satisfactory yield, the tetrazole ring being unaffected[29–33].

Derivatives of tetrazolo[5,1-*a*]pyridine (I) with electron-donating substituents in the 6- and 8-positions readily dissolve in alkalis, alkoxides, or organic bases[88]. The pyridine ring is then opened with formation of the 5-substituted tetrazole (XIX) and its subsequent *cis-trans* isomerisation:

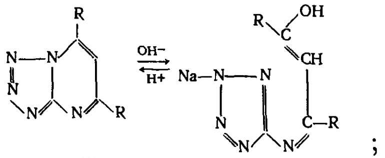


(I) (XIX)

R=NO$_2$.

The cleavage of the nitrogen-containing heterocycle in condensed tetrazoles under the influence of alkali has been described for tetrazolo[1,5-*a*]pyrimidines[16] (II), tetrazolo[1,5-*a*]quinazolines (X)[89], and the 6-azidopurine (XV) system[42].

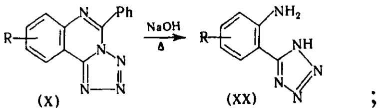
When compound (II) or its dimethyl derivative is dissolved in 0.1 *N* aqueous solution of alkali, the product is an equilibrium system which is reconverted into (II) on cautious acidification[16]:



(II)

R=H, CH$_3$.

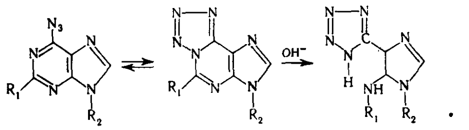
Golomolzin and Postovskii[89] described the alkaline cleavage of 5-phenyl-7(9)-R-tetrazolo[1,5-*c*]quinazolines (X), which results in the formation of 5-[2-amino-3′(5′)-R-phenyl]tetrazoles (XX):



(X) (XX)

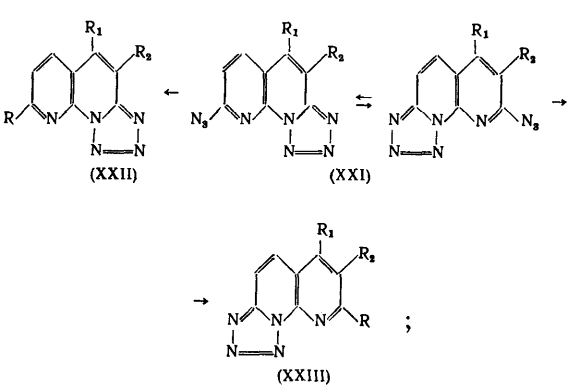
R=H, OCH$_3$, CH$_3$, Cl, Br.

The pyrimidine ring is opened similarly when the system (XV) substituted in the 2-position is treated with aqueous solutions of alkali[42]:



(XV) (XVII)

The tetrazole ring is also retained in the azido-derivatives of condensed tetrazoles 6-azidotetrazolo[1,5-*b*]pyridazine[25], 6-azidotetrazolo[1,5-*a*]phthalazine[99], 6-azidopyrido[2,3-*d*]tetrazolo[5,1-*b*]pyridazine[91], 6-azidopyrido[3,2-*d*]tetrazolo[1,5-*a*][naphthyridine[29-33], 6-azidopyrazino[2,3-*d*]tetrazolo[4,5-*b*]pyridazine[92], and 5-azidotetrazolo[1,5-*a*]quinazoline[62] on heating with aqueous or alcoholic solutions of alkalis, alkoxides, ammonia, and organic bases. The azido-group is activated under the influence of the electronegative tetrazole ring and readily becomes involved in a nucleophilic substitution reaction, which results in the formation of the corresponding hydroxy-, alkoxy-, amino-, and hydrazino-derivatives of the condensed tetrazoles. Mixtures of the isomeric hydroxy- and alkoxy-derivatives (XXII) and (XXIII) are formed from substituted 8-azidotetrazolo[1,5-*a*][1,8]-naphthyridines (XXI), which exist in solution in the form of two isomeric species in equilibrium[29-33]:



(XXII) (XXI)

(XXIII)

R=OH, OC$_2$H$_5$, NH$_2$

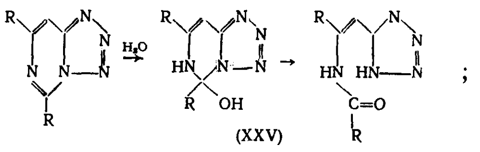
R$_1$=R$_2$=H; R$_1$=CH$_3$, R$_2$=H; R$_1$=C$_6$H$_5$, R$_2$=H;

R$_1$=H, R$_2$=CH$_3$.

3. Covalent Hydration

The condensation of the electron-accepting tetrazole ring with pyrimidine, purine, or quinazoline leads to the withdrawal of electrons from the carbon atom in the 5-position as a result of which there is a possibility of the formation of covalent hydrates involving the N$_{(6)}$–C$_{(5)}$ bond. The covalent hydration process competes with the cleavage of the nitrogen-containing ring, leading to the formation of 5-substituted tetrazoles, the former process predominating. The stability of covalent hydrates is greatly influenced by the pH of the medium, the electronic nature of the substituents in the nitrogen-containing heterocycle, and temperature.

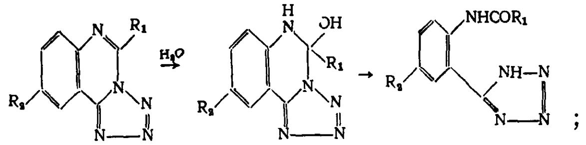
Thus it has been shown[58] that tetrazolo[1,5-*c*]pyrimidine (XXIVa) readily reacts with water to form the covalent hydrate (XXVa), which cannot be dehydrated even on heating *in vacuo* to 120°C. The 5,7-dimethyl derivative (XXIVb) forms a covalent hydrate even at room temperature, but this involves the opening of the pyrimidine ring and the formation of the substituted tetrazole (XXVIb)[15]:



(XXIV) (XXV) (XXVI)

(a) R=H; (b) R=CH$_3$.

A similar process involving (XXIV) proceeds in an alkaline medium with formation of a salt. The 2-azidopurine system (XV) also undergoes covalent hydration[42]. It has been shown in a series of studies by Postovskii and coworkers[93-97] that the covalent hydration of tetrazolo-[1,5-*c*]quinazolines (X) takes place in a weakly acid medium, since the protonation of the N$_{(6)}$ heteroatom promotes an increase of δ^+ on the C$_{(5)}$ atom[96] and the yield of such interaction depends on the nature of the substituents. The unsubstituted tricyclic compound (Xa) is hydrated more readily than the 5-methyl derivative (Xb), while the 5-phenyl analogue (Xc) is not hydrated at all:



(X) (XXVI)

(a) $R_1=R_2=H$; (b) $R_1=CH_3$, $R_2=H$; (c) $R_1=C_6H_5$, $R_2=H$;
(d) $R_1=\gamma$-pyridyl , $R_2=H$; (e) $R_1=C_6H_5$, $R_2=COOH$;
(f) $R_1=C_6H_5$, $R_2=Br$.

It may be that the steric hindrance associated with the phenyl group also plays a role here. The 5-γ-pyridyl derivative (Xd) behaves similarly[95,96]. The introduction of a carboxy- or bromo-group, which increase the positive charge on $C_{(5)}$, into the 9-position of compound (Xc) makes possible the hydration of compounds (X,e and f)[93,97]. The product of the hydration of (Xf) has the structure of 5-(2-acylamino-5-bromophenyl)tetrazole (XXVII) in the crystalline state[94].

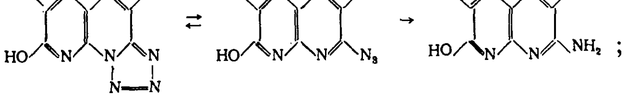
When the covalent hydrates are heated in 2 *N* hydrochloric acid, acid hydrolysis takes place with formation of 5-(2-acylaminophenyl)tetrazoles[95,96].

4. Reduction

The resistance of the condensed tetrazole ring to the action of reducing agents or catalytic hydrogenation depends in many respects on the reaction conditions, particularly on the pH of the medium. Boyer et al.[85], who investigated the catalytic hydrogenation of tetrazolo[5,1-*a*]pyridine (I), showed that in an acid medium, where the tetrazole form (I) is stabilised, only the pyridine ring is hydrogenated. 2-Aminopyridine is formed in an alkaline medium. In a neutral medium the reaction proceeds in two ways with formation of a mixture of products. They also observed that, when the 6-methyl-4-nitro-derivative of (I) is treated with stannous chloride in hydrochloric acid, only the nitro-group is reduced.

In those cases where a second nitrogen heteroatom in the nitrogen-containing heterocycle is protonated, the stability of the condensed tetrazole ring is reduced and acids and bases are found to have the opposite effects on the mode of catalytic hydrogenation.

Carboni and coworkers[31,34] showed that, in the case of the isomeric hydroxy-derivatives of 5(6)-phenyltetrazolo-[1,5-*a*][1,8]naphthyridine (XXVIII), the azido-form is stabilised (as a result of protonation) by acids and the tetrazole form is stabilised by alkalis. Accordingly, during the catalytic hydrogenation of (XXVIII, a – d) in acetic acid, amino-derivatives of naphthyridine (XXIX) are formed in acetic acid in 75–78% yield. After hydrogenation in an alkaline medium, the initial compounds (XXVIII), a – d) were recovered in an almost quantitative yield:

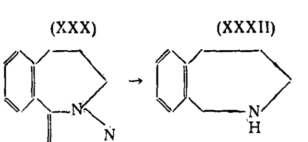


(XXVIII) (XXIX)

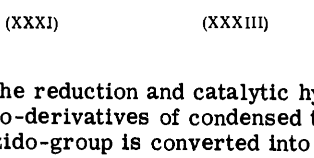
(a) $R_1=C_6H_5$, $R_2=R_3=R_4=H$; (b) $R_1=R_3=R_4=H$; $R_2=C_6H_5$;
(c) $R_1=R_2=R_4=H$, $R_3=C_6H_5$; (d) $R_1=R_2=R_3=H$, $R_4=C_6H_5$.

Tetrazolo[1,5-*a*]pyrimidines behave similarly on hydrogenation in acetic acid[98].

The reduction of pentamethylenetetrazole (XXX) and 6,7-dihydro-5*H*-tetrazolo[4,5-*a*]benzo[*c*]azepine (XXXI) with lithium aluminium hydride in isopropyl ether, leading to the formation of the perhydroazepine (XXXII) and 1,2,3-tetrahydrobenzo[*c*]azepine (XXXIII) has been described[72]:



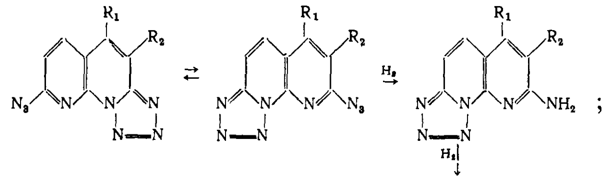
(XXX) (XXXII)



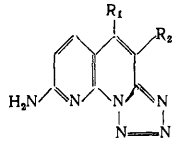
(XXXI) (XXXIII)

The study of the reduction and catalytic hydrogenation reactions of azido-derivatives of condensed tetrazoles has shown that the azido-group is converted into the amino-group much more readily than the condensed tetrazole ring. Thus, hydrogenation, treatment with hydrogen sulphide, or heating in ethylcellosolve of 6-azidotetrazolo-[1,5-*b*]pyridazine[22,25] and heating of 6-azidotetrazolo-[1,5-*a*]phthalazine in tetralin[22] leads to the formation of the corresponding aminotetrazoles.

Catalytic hydrogenation of the unsubstituted 8-azidotetrazolo[1,5-*a*][1,8]naphthyridine (XXIa) results in the formation of the 8-amino-derivative and a very small amount of the 8-hydroxy-analogue[29]. Under these conditions, the 5-methyl and 5-phenyl derivatives (XXI, b and c) are preferentially converted into the corresponding amines (XXXIV, b and c) and their 4-methyl and 4-phenyl analogues (XXI, d and e) are converted into the amines (XXXV, d and e)[31-34]:



(XXI) (XXXIV)

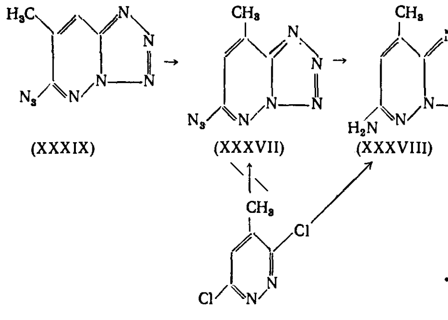


(XXXV)

(a) $R_1=R_2=H$; (b) $R_1=CH_3$, $R_2=H$; (c) $R_1=C_6H_5$, $R_2=H$;
(d) $R_1=H$, $R_2=CH_3$; (e) $R_1=H$, $R_2=C_6H_5$.

It has been shown that, when 3,6-dichloro-4-methylpyridazine (XXXVI) is treated with sodium azide in ethylene glycol, the 8-amino-derivative (XXXVIII) is formed as a result of the reduction of the azido-group instead of the expected 6-azido-8-methyltetrazolo[1,5-*b*]pyridazine

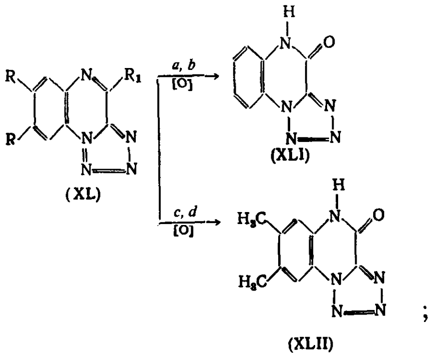
(XXXVII).[91] When 6-azido-7-methyltetrazolo[1,5-*b*]pyridazine (XXXIX) is heated in ethylcellosolve, it isomerises with subsequent reduction to the amino-derivative (XXXVIII):



5. Oxidation

Like 1,5-disubstituted tetrazoles, the condensed tetrazole ring sometimes exhibits an appreciable resistance to oxidation. Thus the oxidation of quinolino[1,2-*e*]tetrazole with a solution of potassium permanganate leads to the formation of tetrazole and the quantitative evolution of carbon dioxide[54]. Tetrazolo[1,5-*a*][1,8]-naphthyridines behave similarly[29,39].

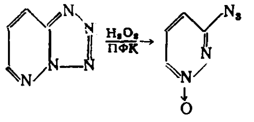
Postovskii and coworkers[11] studied the action of various oxidants on tetrazolo[1,5-*a*]quinoxalines (XL), which resulted in the isolation of the tetrazolo[1,5-*a*]quinoxalinones (XLI) and (XLII):



(a) $R=R_1=H$; (b) $R=H$, $R_1=CH_3$; (c) $R=CH_3$, $R_1=H$; (d) $R=R_1=CH_3$.

Oxidants decompose the tetrazole ring when the ring carbon atom carries a nitrogen-containing substituent. For example tetrahydrotetrazolo[1,5-*a*]quinazoline is oxidised by potassium permanganate to adipic acid and ammonia[99]. When 6-methyltetrazolo[1,5-*b*]benzothiazole and 9-methyl-5-phenyltetrazolo[1,5-*c*]quinazoline react with aqueous solutions of potassium permanganate, the methyl group is oxidised to the carbonyl group[67,93].

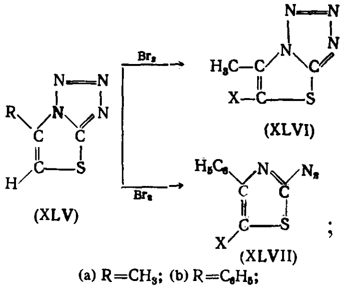
Treatment of tetrazolo[1,5-*b*]pyridazine (XLIII) with hydrogen peroxide in polyphosphoric acid leads to the simultaneous *N*-oxidation and opening of the tetrazole ring with formation of 3-azidopyridazine N-oxide (XLIV)[57]:



6. Electrophilic Substitution Reactions

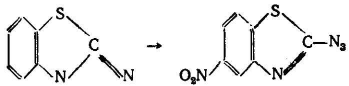
The structure of the products of electrophilic substitution reactions involving condensed tetrazoles depends in many respects on the stability of the tetrazole ring and on the electronic nature of the substituent introduced into the nitrogen-containing heterocycle. Powerful electron-accepting substituents or substituents with a negative inductive effect destabilise the condensed tetrazole ring and promote the formation of reaction products having the azide structure.

It has been shown that bromination and the introduction of thiocyanato-groups into 6-methylthiazolo[2,3-*e*]tetrazole (XLVa) take place in the 5-position of the condensed system with formation of the corresponding 5-bromo- and 5-thiocyanato-derivatives (XLVI). The reactions with the 6-phenyl-substituted derivative (XLVb) proceed similarly in the 5-position, but, owing to the lower stability of the tetrazole ring, the isomeric azido-derivatives (XLVII) are formed in this case[84,100]:



(a) $R=CH_3$; (b) $R=C_6H_5$; X=Br, CNS.

The sulphonation, chlorosulphonation, and nitration reactions of compound (XLVb) also involve the 5-position. The introduction of strong electron-accepting substituents promotes the opening of the tetrazole ring at the $N_{(1)}-N_{(2)}$ bond with formation of the isomeric 2-azido-derivatives[66,84]. Tetrazolo[5,1-*b*]benzothiazole is nitrated in the 7-position of the condensed system and the nitration product has the structure of 2-azido-5-nitrobenzothiazole (XLVIII):

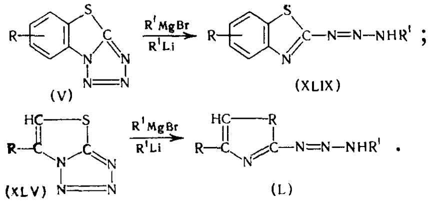


It has been observed[84] that the tetrazole ring is protonated in electrophilic substitution reactions carried out in the presence of inorganic acids and the tetrazolium salt reacts. In a concentrated acid, the reaction product retains the structure of the tetrazolium salt. When the reaction mixture is diluted with water, the salt is hydrolysed and the condensed tetrazole isomerises to the 2-azido-derivative in consequence of the introduction of an electron-accepting substituent into the thiazole or benzothiazole ring.

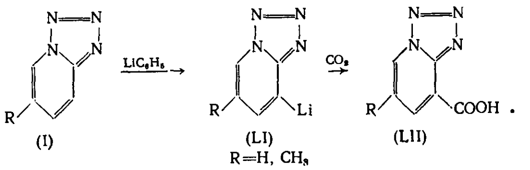
Sasaki et al.[86] showed that tetrazolo[5,1-*a*]pyridine (I) is nitrated and brominated in the 6-position with formation of the 6-nitro- and 6-bromo-derivatives.

7. Reactions with Organometallic Compounds and Sodium Cyanide

It has been shown for derivatives of tetrazolo[5,1-*b*]benzothiazole (V) and thiazolo[2,3-*e*]tetrazole (XLV) that the course of the reactions with organomagnesium bromide and organolithium derivatives depends on the position of their azide–tetrazole equilibrium and the nature of the organometallic reagent[48,64,101,102]. In contrast to the 4-methyl derivative (V) and the 6-methyl derivative (XLV), which do not react with such organometallic reagents, compound (V) and its 6-methyl, 6-chloro-, 6-methoxy-, and 4-chloro-derivatives as well as the 6-phenyl derivative of compound (XLV) give rise respectively to benzothiazol-2-yl-triazenes (XLIX) and thiazol-2-yltriazenes (L)[48,64,101,102]. It is interesting that compound (V) and its 6-methyl- and 6-chloro-derivatives are converted into triazenes only in reactions with phenylmagnesium bromide and phenyl-lithium:

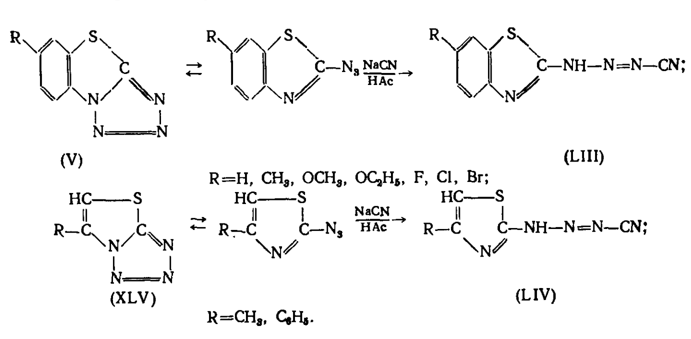


When tetrazolo[5,1-*a*]pyridine (I) and its methyl derivative are treated with phenyl-lithium, the pyridine ring is metallated, while the tetrazole ring remains unchanged. The lithio-derivatives (LI) obtained in this way were then converted into carboxylic acids (LII):



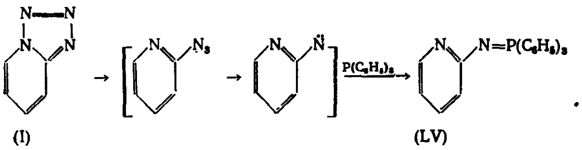
The reaction of the tetrazole ring with organometallic compounds probably requires a definite degree of electron-accepting capacity of the substituents in the condensed tetrazole and of the organic group linked to the metal.

Like aromatic azides, the tetrazoles (V) and (XLV) readily react with sodium cyanide, forming benzothiazol-2-ylcyanotriazenes (LIII) and thiazol-2-ylcyanotriazenes (LIV) respectively[64,102]:

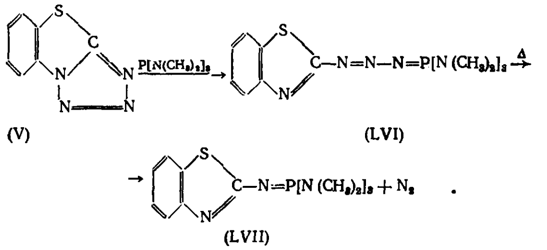


8. Reactions with Organophosphorus Compounds

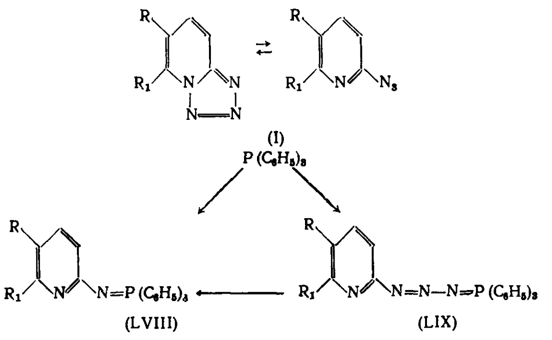
Aromatic azides are known to form aryliminophosphoranes on reaction with triphenylphosphine[103]. The interaction of condensed tetrazoles with triphenylphosphine was described for the first time by Sasaki and Kanematsu[107] with tetrazole (I) as an example. It is believed that under the reaction conditions the tetrazole isomerises to the azido-derivative, which is followed by a thermally induced loss of nitrogen and the interaction of 2-pyridylnitrene with triphenylphosphine, the product being 2-triphenylphosphazopyridine (LV):



Zhmurova et al.[105] studied this reaction with certain tetrazolo[5,1-*b*]benzothiazoles (V) and thiazolo[2,3-*e*]-tetrazoles (XLV). Since the reaction proceeds under mild conditions (in benzene at 50–60°C), the formation of benzothiazol-2-yl- and thiazol-2-yl- nitrenes as intermediates is doubtful. The authors suggested that the reaction of these tetrazoles with triphenylphosphine is due to the presence in the solution of azido-forms and that it involves the usual oxidative imination of tertiary phosphines by organic azides. This hypothesis was confirmed indirectly by the isolation of the intermediate phosphazide (LXI) in the reaction of compound (V) and phosphorous hexamethyltriamide. The phosphazide subsequently decomposes with formation of the phosphazo-compound (LVII):

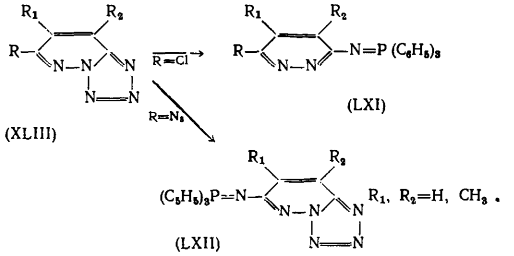


Sasaki et al.[106] investigated the interaction of compound (I) and some of its derivatives with triphenylphosphine in various solvents and at different temperatures. They showed that the reaction is of second order and that its rate and mechanism depend on the electronic nature of the ring substituents, on the type of solvent, and temperature. Thus, substituents promoting ring opening and the formation of the isomeric azido-form accelerate the formation of the iminophosphoranes (LVIII) via the intermediate triazenophosphoranes (LIX). A decrease of solvent polarity and an increase of reaction temperature act in the same direction.



In the absence of the reactive azido-form from the solution, the reaction involves the $N_{(1)}$ or $N_{(3)}$ atoms of the tetrazole ring, after which the ring is cleaves with subsequent loss of nitrogen and the formation of compound (LVIII).

Tetrazolodiazines[107], i.e. tetrazolo[1,5-*b*]pyridazine (XLIII) and tetrazolo[1,5-*a*]pyrazine (LX) and their derivatives, also form iminophosphoranes on reaction with triphenylphosphine. Electron-accepting substituents in the pyridazine and pyrazine rings facilitate this reaction, while electron-donating substituents stabilise the tetrazole ring and preclude the reaction:



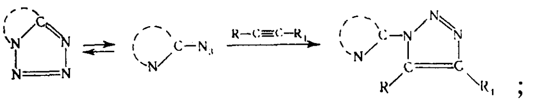
(XLIII) (LXI) (LXII)

Thus, the unsubstituted compound (XLIII) and its 5-methoxy-derivative do not interact with triphenylphosphine even on refluxing in chlorobenzene, while the 5-chloro-derivatives form the corresponding iminophosphoranes.

The 5-azido-derivative (XLIII) reacts with an excess of triphenylphosphine only via the azido-group, forming monoiminophosphoranes (LXII). Evidently, the iminophosphorane group formed behaves as an electron-donating substituent and stabilises the tetrazole ring. The reaction mechanism depends on the position of the azide–tetrazole equilibrium in solution also in the case of tetrazolopolyazines. If only the tetrazole forms (XLIII, R = Cl) and (LX) are present, the $N_{(1)}$ and $N_{(3)}$ atoms of the tetrazole ring are subjected to nucleophilic attack by triphenylphosphine. If only the azido-isomer of the 5,6-diphenyl derivative of compound (LX) is present in acetic acid under the reaction conditions, the reaction involves the formation of triazenophosphorane. When both tautomeric forms of compound (LX) are present in the reaction mixture in chloroform, the reaction proceeds in both ways.

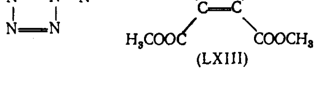
9. Cycloaddition Reactions and Others

It has been shown that tetrazolo[5,1-*a*]pyridine (I)[108] and its 5-chloro-, 6-bromo-, and 6-nitro-derivatives[86], 5,7-dimethyltetrazolo[1,5-*a*]pyrimidine[108], and 7,8-diphenyltetrazolo[1,5-*a*]pyrazine[26] undergo cycloaddition reactions with propiolate and acetylenedicarboxylate esters and diphenylacetylene, forming the corresponding substituted triazoles:



R = H, R₁ = COOCH₃; R = R₁ = COOCH₃; R = R₁ = C₆H₅ .

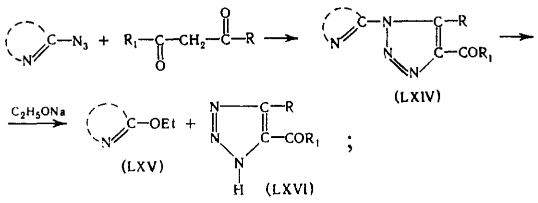
All these reactions proceed via the preliminary isomerisation to the azido-form and the yield of the triazole under the reaction conditions depends on the rate of isomerisation. It has been noted[26] that even in boiling toluene 6-azidotetrazolo[1,5-*b*]pyridazine reacts with dimethyl acetylenedicarboxylate only via the azido-group, forming the product (LXIII):



(LXIII)

while the tetrazole ring does not react. On the other hand, 7,8-diphenyltetrazolo[1,5-*a*]pyrazine takes part in this reaction at a temperature as low as 62°C in chloroform, which indicates a greater tendency of the tetrazole ring towards isomerisation in the latter compound.

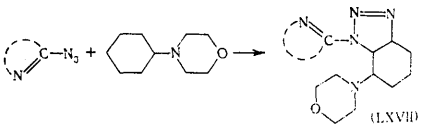
Triazoles are not always the final products of such reactions. Several instances have been described where cycloaddition with formation of triazoles is an intermediate stage. Under the reaction conditions, the triazoles may be cleaved, which leads to the formation of secondary reaction products. Thus it has been reported[109] that the interaction of tetrazolo[5,1-*b*]benzothiazole and tetrazolo[1,5-*b*]1,2,4-triazine with compounds of the type $R-\overset{\overset{O}{\|}}{C}-CH_2-COR$ (where R = CH_3 or C_6H_5) proceeds with formation of the corresponding cycloaddition products (LXIV), which are relatively unstable under the reaction conditions and are cleaved at the C–N bond between the heterocyclic rings with formation of 2-ethoxy-derivatives of the corresponding heterocycles (LXV) and substituted triazoles (LXVI):



R = CH₃, R₁ = C₆H₅; R = R₁ = CH₃ .

When the same tetrazoles react with ethylbenzoyl acetate, the stable sodium salt of the corresponding cycloaddition product may be isolated; on acidification with hydrochloric acid, the sodium salt is hydrolysed with evolution of nitrogen and carbon dioxide and formation of 2-aminobenzothiazole and ω-chloroacetophenone.

Fusco et al.[110] found that, like azides, condensed tetrazoles react with *N*-(α-cyclohexenyl)morpholine, also forming 1,2,3-triazole derivatives (LXVII):

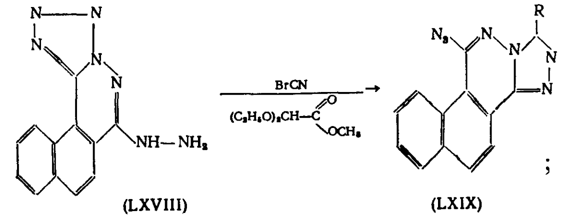


(LXVII)

The cycloaddition of 4,5-dimethyltetrazolo[1,5-*a*]pyrimidine and tetrazolo[5,1-*a*]pyridine to norbornene proceeds in a similar manner[108]. The interactions of these tetrazoles with cyclohexene, 1,2-dihydronaphthalene, indene, *trans*-stilbene, 1,1-diphenylethylene, and dimethyl maleate and fumarate have been investigated[108] and it has been found that the cycloaddition products are the corresponding triazoles, which are cleaved under the reaction conditions with subsequent formation of enamines and the evolution of nitrogen.

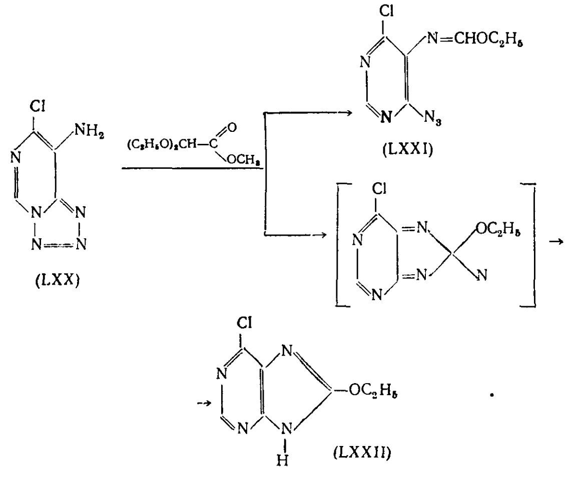
Stanovnik and Tišler[20,21] studied the interaction of 6-hydrazino-7,8-dihydrobenzo[*h*]tetrazolo[5,1-*a*]phthalazine (LXVIII) with diethoxymethyl acetate or bromocyanogen and found that this involves the destabilisation and opening of the tetrazole ring with formation of the azido-derivative. As a result, a new condensed triazole ring

(LXIX) is formed, destabilising the tetrazole ring and converting it into the azido-form:

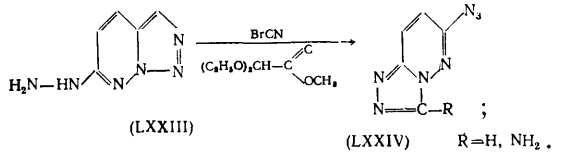


(LXVIII) (LXIX) R=H, NH₂ .

The interaction of diethoxymethyl acetate with 8-amino-7-chloro-tetrazolo[1,5-*c*]pyrimidine (LXX) at room temperature, leading to the formation of the corresponding ethoxymethylene derivative (LXXI), has been described[111]. The tetrazole ring is ruptured in this process. On heating in anisole, 6-chloro-8-ethoxypurine (LXXII) is formed:



The attempts to obtain a tricyclic derivative by treating 6-hydrazinotetrazolo[1,5-*b*]pyridazine (LXXIII) with diethoxymethyl acetate or bromocyanogen led to the opening of the tetrazole ring and the formation of 3-R-6-azido-*s*-triazolo[4,3-*b*]pyridazine (LXXIV)[20,21]:



(LXXIII) (LXXIV) R=H, NH₂ .

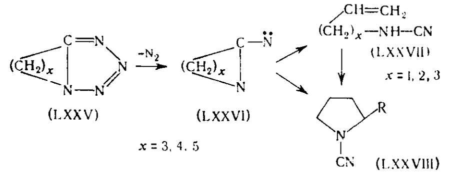
10. Thermolysis and Photolysis

Many condensed tetrazoles are known to be converted into the isomeric azido-derivatives even at room temperature or on slight heating. Therefore it was to be expected that even condensed tetrazoles which do not exhibit a tendency towards the azide–tetrazole tautomerism might be converted into azides at high temperatures and might undergo thermal decomposition of the azide type.

The behaviour of condensed tetrazoles on heating has been investigated for polymethylenetetrazoles[112], tetrazolo[5,1-*a*]pyridine[51,52,86,88,113-117], tetrazolo[5,1-*a*]quinoline[60], tetrazolo[1,5-*a*]pyrimidine[113,118-120], tetrazolo[1,5-*c*]pyrimidine[119], tetrazolo[1,5-*a*]quinoxaline[60], tetrazolo[1,5-*a*]pyrazine[26,119], tetrazolo[1,5-*a*]pyridazine[26,53,119,121], tetrazolophenanthridine[60], tetrazolo[1,5-*c*]quinazoline[60], and certain others.

The reactions were carried out in the gas phase or in solvents, sometimes using copper acetylacetonate as the catalyst, which made it possible to reduce the thermolysis temperature (evolution of nitrogen) by approximately 100°C. In all the cases investigated the first stage of the thermolysis is the cleavage of the condensed tetrazole ring at the $N_{(1)}-N_{(5)}$ bond and the formation of the isomeric α-azido-derivative. The azide formed then loses nitrogen and gives rise to a nitrene radical, which is subsequently stabilised via several mechanisms, depending on the reaction conditions (solvent, temperature).

One important pathway to the stabilisation of the nitrene is its conversion into the corresponding α-amino-derivative as a result of the abstraction of hydrogen from the solvent and the formation of secondary amines as well (reaction with a neighbouring reactive group). Nitrenes can also undergo cycloaddition reactions with aromatic hydrocarbons, stilbenes, and nitriles. The cleavage of the ring and the formation of various unsaturated cyano-compounds or their polymerisation products are also possible (particularly at high temperatures in the gas phase). Ring contraction and the formation of various nitrogen-containing heterocyclic cyano-derivatives containing one carbon atom less frequently take place in the gas phase. It has been suggested that the latter process proceeds via the formation of ring cleavage products as intermediates with participation of nitrene nitrogen[115] or via the formation of bicyclic systems. Dimers are sometimes formed[60]. Thus polymethylenetetrazoles (LXXV), which do not exhibit a tendency towards isomerisation, under thermal decomposition in the gas phase at 450–675°C with formation of the nitrene (LXXVI), which then recombines with formation of alkenylcyanamides (LXXVII) (on ring opening) and 1-cyanopyrrolidine (LXXVIII) or its alkyl derivatives (on ring contraction[112]):



(LXXV) (LXXVI) (LXXVIII)

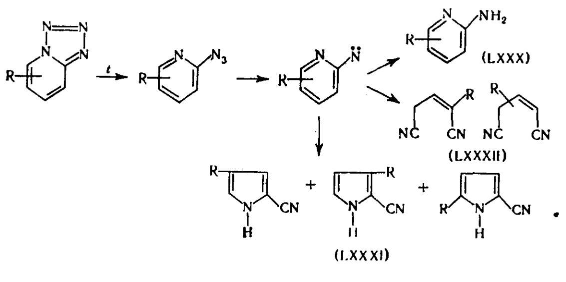
x = 3, 4, 5

In the reaction involving trimethylenetetrazole, the propenylcyanamide formed evolves nitrogen and gives rise to poly-*N*-cyanoformamidine (LXXIX):

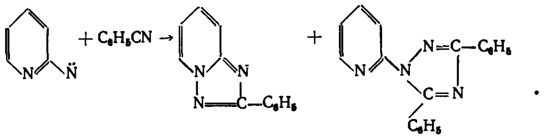
$$CH_2{=}CH{-}NH{-}CN \rightarrow CH_2{=}CH_2 + \cdots -\underset{CN}{\underset{|}{N}}-CH_2-\underset{CN}{\underset{|}{N}}-CH_2-\cdots$$

(LXXIX)

It is known that tetrazolo[5,1-*a*]pyridine (I) is not converted into the isomeric 2-azidopyridine even on heating to 120°C. However, under more severe conditions in the gas phase or in the presence of a catalyst, isomerisation does take place with formation of 2-pyridylnitrene accompanied by the evolution of nitrogen. The process also involves the formation of 2-aminopyridine (LXXX), 2-cyanopyrroles (LXXXI) on ring contraction, and the nitrile of glutaconic acid (LXXXII) on ring opening[26,113,117,118]. It has been shown[115-117] that 2-pyridylnitrene is converted into 2,7-diazatropylidene in the gas phase with ring expansion, the product being subsequently converted into a cyanoazole following ring contraction. In the presence of a catalyst (copper acetylacetonate), there is no ring expansion with formation of diazepines:

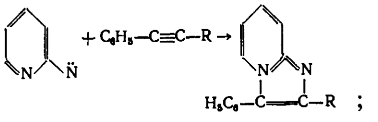


The thermolysis of tetrazolo[5,1-*a*]pyridine and its 6-bromo-, 6-nitro-, 8-nitro-, and 8-bromo-derivatives in solvents without a catalyst or in the presence of copper acetylacetonate[51,52,86,113] is accompanied by the interaction of 2-pyridylnitrene with solvents. In these cases the pyridine ring is preserved. The structure of the reaction products depends on the type of solvent. Thus, when the reaction is carried out in cyclohexane, cyclohexene[113], and toluene[86] in the presence of copper acetylacetonate, the main reaction product is 2-aminopyridine. In benzonitrile [3 + 2] cycloaddition takes place and 2-phenyl-3-triazolo[1,5-*a*]pyridine (LXXXIII) is formed with 2-(3,5-diphenyl-1,2,4-triazolyl)pyridine (LXXXIV) as an admixture[113]:



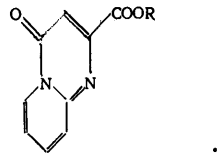
(LXXXIII) (LXXXIV)

Thermolysis in the presence of dienophiles (ethyl phenylpropiolate, diphenylacetylene) involves 3 + 2 cycloaddition of alkynes with formation of imidazopyridine derivatives (LXXXV):



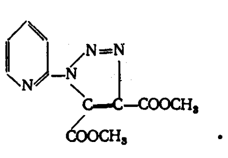
(LXXXV)

$R=C_6H_5$, $COOC_2H_5$;



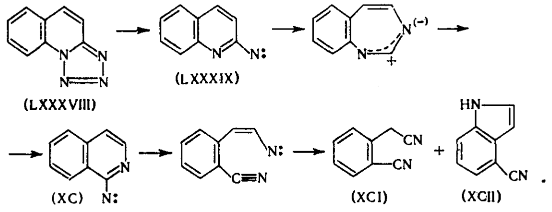
(LXXXVI)

Cycloaddition to fumaric acid[114] proceeds with formation of the analogous product (LXXXVI). However, in the presence of dimethyl acetylenedicarboxylate, compound (LXXXVII) is formed[86]:



(LXXXVII)

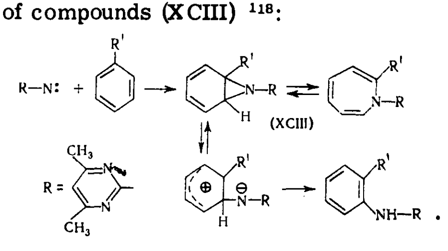
It has been shown[60] that the 2-quinolinylnitrene (LXXXIX) formed in the gas-phase thermolysis of tetrazolo[5,1-*a*]quinoline (LXXXVIII) is converted into 1-isoquinolinylnitrene (XC), possibly via preliminary ring expansion to azatropylidene followed by ring opening and the formation of compounds (XCI) and (XCII):



The thermolysis of tetrazolo[5,1-*a*]isoquinoline proceeds similarly[60].

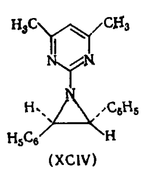
The thermolysis of tetrazolo[1,5-*a*]pyrimidine and tetrazolo[1,5-*c*]pyrimidine in the gas phase also involves isomerisation to the azido-derivatives, the loss of nitrogen, and the formation of pyrimidin-2-yl- and pyrimidin-4-yl-nitrenes. Subsequently pyrimidin-2-ylnitrene and its derivatives are converted via ring contraction into 1-cyano-3-R-5-R′-pyrazoles and 2-amino-4-R-6-R′-pyrimidines[119]. The 1-cyanopyrazoles formed can split off HCN with formation of pyrazoles (at 500°C), while under more severe conditions (at 700°C) nitrogen is split off with formation of cyanopenta-2,4-dienes[120]. Under still more severe conditions, the unsubstituted 3*H*-pyrazole gives rise to cyanoallene and tetrolonitrile in proportions of 1 : 3.

On gas-phase pyrolysis, tetrazolo[1,5-*c*]pyrimidine gives rise to cyanoimidazoles only[119]. The pyrolysis of tetrazolo[1,5-*a*]pyrimidines in solvents (cyclohexane, isobutane, naphthalene, anthracene, phenanthrene, mesitylene, and anisole[118,122]) involves the formation of 2-aminopyrimidine, secondary 2-aminopyrimidines, or a mixture of both. Furthermore, pyrimidin-2-ylnitrene can take part in cycloaddition reactions with aromatic hydrocarbons via the following mechanism involving the formation of compounds (XCIII)[118]:

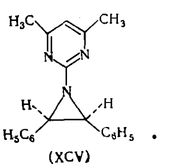


7-Methyl-5-methylthiotetrazolo[1,5-*c*]pyrimidine gives rise to 1-cyano-4-methyl-2-methylthioimidazole on pyrolysis in organic solvents, i.e. ring contraction can occur also in solvents; in addition, amino-derivatives are produced[122].

The pyrolysis of tetrazolo[1,5-*a*]pyrimidines in the presence of *trans*-stilbene without a catalyst (160°C) or in the presence of a catalyst (copper acetylacetonate, 120°C), leading to the formation of derivatives of *trans*- and *cis*-aziridines (XCIV) and (XCV) (40% and 3% respectively) has also been described[113]:



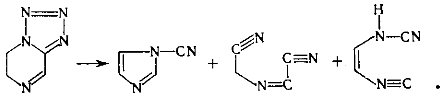
(XCIV)



(XCV)

The pyrolysis of 8-phenyltetrazolo[1,5-*c*]pyrimidine in dichlorobenzene[123] proceeds with formation of indole in 50% yield. When the above tetrazole was refluxed in trifluoroacetic acid, mainly the initial product, which failed to react, was isolated. On gas-phase pyrolysis, tetrazolo[1,5-*a*]quinoxaline and tetrazolo[5,1-*c*]quinazoline form identical products. Ring contraction results in the formation of 2-cyanobenzimidazole and ring opening gives rise to *N*-cyanoanthranilonitrile[60].

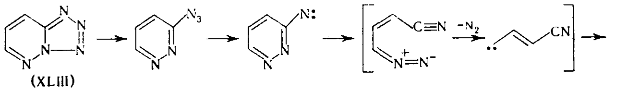
The pyrolysis of tetrazolo[1,5-*a*]pyrazine (XCVI) in the gas phase[19,122] involves ring contraction and the formation of compound (XCVII) and the ring cleavage products (XCVIII) and (XCIX):



(XCVI) (XCVII) (XCVIII) (XCIX)

In organic solvents (cyclohexane) the thermolysis proceeds with formation of 2-aminopyrazine[122], which confirms the formation of a nitrene and 1-cyanoimidazole as a result of ring contraction. On heating in acetic acid, the 5,6-diphenyl derivative of compound (XCVI)[8] gives rise to a mixture of 2,5-diphenylimidazole (56%) and 1-acetyl-5-diphenylimidazole (3%). Wentrup's studies[122] have shown that the formation of these products can be readily accounted for by the primary contraction of the nitrene ring.

In the thermolysis of tetrazolo[1,5-*b*]pyridazine (XLIII)[119], one of the most stable of the condensed tetrazoles, ring opening results in the formation of cyanoallene (C), tetrolonitrile (CI), propargyl cyanide (CII), and 2-cyanocyclopropene (CIII):

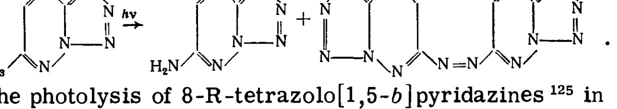


(XLIII)

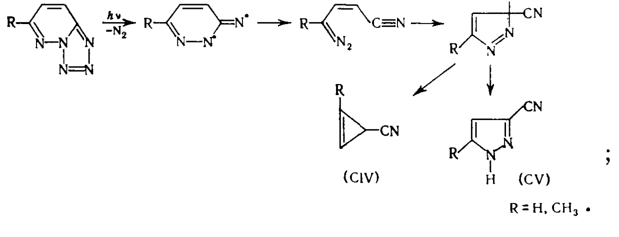
(C) (CI) (CII) (CIII)

When 9,10-tetrazolophenanthridine is heated to 500°C, a nitrene dimer is formed and then 9-cyanocarbazole and 4-cyanocarbazole (possibly as a result of ring opening and recyclisation[60]).

The photolysis of 6-azidotetrazolo[1,5-*b*]pyridazine in alcoholic solution for 20 h leads to the formation of a mixture consisting of 95% of 6-aminotetrazolo[1,5-*b*]pyridazine, 3% of the corresponding azo-compound, and 2% of a polymer[124]:



The photolysis of 8-R-tetrazolo[1,5-*b*]pyridazines[125] in methanol or methylene chloride results mainly in the formation of 3-cyano-R-cyclopropenes (CIV) in 20–25% yield and 3-cyano-5-R-pyrazoles (CV) in 0.1% yield. In acetone the yield of compounds (CIV) decreases to 5%, while compounds (CV) are not formed:

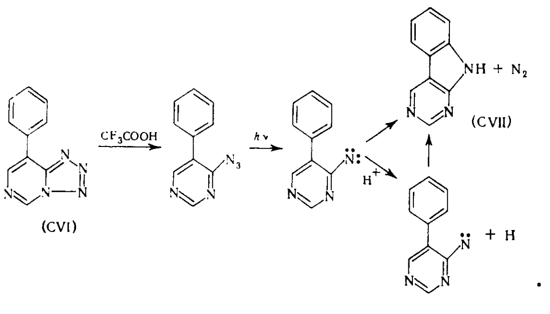


(CIV) (CV)

R = H, CH$_3$.

7,8-Diphenyltetrazolo[1,5-*a*]pyrazine decomposes photolytically in acetic acid in the course of 32 h with formation of 4,5-diphenylimidazole (10%) and benzoic acid (7%).[26]

The photolysis of 8-phenyl-, 8-*p*-tolyl-, 8-*p*-methoxyphenyl-, and 8-*p*-chlorophenyl-tetrazolo[1,5-*c*]pyrimidines (CVI) in trifluoroacetic acid leads to the corresponding 2*H*-pyrimido[4,5-*b*]indoles (CVII)[123], which are formed in a high yield. This process can be used as a method for the synthesis of indoles. In a non-polar medium, photolysis takes place slowly and with low yields. The quantum yield of the photolysis of the 8-phenyl derivative is 0.5:



(CVI) (CVII)

o0o

The properties of condensed tetrazoles, the mode of various reactions in which they are involved, and the structures of the reaction products are directly related to the distribution of electron density in the molecule. The latter is in turn determined by the electron-accepting properties of the tetrazole ring and of the nitrogen-containing heterocycle and by the electronic nature of the substituents.

The distribution of electron density influences the stability of the condensed tetrazole ring and its capacity for being opened at the $N_{(1)}$–$C_{(5)}$ bond with formation of the isomeric azidoazomethine derivatives of the nitrogen-containing heterocycles. The protonation, alkylation, electrophilic substitution, covalent hydration, and reduction reactions as well as reactions with alkalis depend on the electron-accepting properties of the tetrazole ring.

The stability of the tetrazole ring determines the mode and rates of reactions with nucleophilic agents, cycloaddition reactions, thermolysis, photolysis, and reactions with organometallic, organophophorus, and other compounds.

Present State of the Theory of Homogeneous Nucleation

A.A.Lushnikov and A.G.Sutugin

The present state of the theory of the spontaneous condensation of a supersaturated vapour is discussed, and modern methods for calculating the free energy of nuclei of the new phase are examined, especially in the light of the resolution of the Lothe-Pound paradox. Reasons for the differences between the best known formulae for the rate of nucleation ara analysed. The limits of applicability of the existing theory to practical calculations are deduced from a consideration of a large quantity of experimental data, and specific problems that have not yet been completely solved are mentioned. A list of 179 references is included.

CONTENTS

I. INTRODUCTION

Many theoretical and experimental studies have been made on nucleation in a supersaturated vapour, both because of the fundamental importance of the kinetics of phase transitions of the first kind and because of the need to establish methods for engineering calculations on bulk condensation, which are required in many branches of technology. During recent years considerable progress has been made in this direction. In the theory of nucleation inaccuracy has been revealed in the Lothe–Pound concept, new methods have been established for calculating the bonding energy of small nuclei, and the mathematics of the theory has been improved significantly. New methods have appeared for studying nucleation–molecular beams, improved diffusion cells, and apparatus for investigating condensation during turbulent mixing—and laser techniques have been widely employed for tracing the growth of the disperse phase. Condensation from the vapour has been studied on a greater range of substances. New methods for calculating bulk condensation have been developed. The present Review summarises and analyses these achievements.

II. KINETICS OF FORMATION OF A NEW PHASE IN A SUPERSATURATED VAPOUR—GENERAL APPROACH

Almost all current theories of the formation of a new phase from a supersaturated vapour are based on the so called Szillard model, according to which a supersaturated vapour comprises a mixture of monomeric molecules and molecular aggregates (clusters) containing different numbers of molecules. Clusters are able either to vaporise or to grow by adding molecules and finer clusters. The mathematical description of this model is based on the so called quasi-chemical approximation, which regards clusters of each size as chemical compounds characterised by definite free energies of formation from the monomer. Such an approach is rather unsound logically since, as will be shown later, calculation of the free energies of formation of clusters requires that the partition function of the system shall be expressed as a combination of small partition functions written for clusters of each size. Yet statistical thermodynamics should describe a system in a state of true—not metastable—equilibrium, and its application to a system whose parameters of state represent a region lying between the binoidal and the spinodal should give Maxwell's phase rule, as was demonstrated by Kac et al.[1] The statistical-mechanical formulation in current nucleation theory is therefore largely arbitrary and approximate, with the closeness of its approximation diminishing as the system moves from the binoidal towards the spinodal.

The purpose of nucleation theory is to preduct the rate I of formation of stable particles of the condensed phase per unit volume of the supersaturated vapour under given external conditions, and also to determine the size at which these particles become stable. The free energy of formation of clusters ΔG_g increases with size for very small clusters, then passes through a maximum, and decreases to negative values. Clusters of size corresponding to the maximum free energy are said to be "critical", and are equally likely to grow or to vaporise. Nuclei characterised by negative free energies are completely unstable and capable only of growth. Such a system, corresponding to the Szillard–Farkas scheme, can be described by an infinite series of differential equations:

$$\frac{\mathrm{d}f_g}{\mathrm{d}t}=\frac{1}{2}\sum_{k=1}^{g-1}\beta_{g-k,k}f_{g-k}f_k+\sum_{k=g+1}^{\infty}\alpha_{k-g}^{k}f_k-f_g\left(\sum_{k=1}^{\infty}\beta_{gk}f_k+\frac{1}{2}\sum_{k=1}^{g-1}\alpha_{g-k,k}^{g}\right), \quad (1)$$

where f_g is the concentration of clusters comprising g molecules, β_{ij} is the probability of formation of a cluster of size g by the collision of i and j molecules, and α_{ij}^{g} is the probability that a cluster of size g will break down into clusters of sizes i and j.

It is useful for the subsequent discussion to distinguish two extreme cases of nucleation, which, following Gerlach[2], we shall term "rapid" and "slow" nucleation. Contemporary literature refers more often to condensation at high and at low supersaturations of the vapour S, but this seems less appropriate, since it is difficult to choose a criterion for assessing supersaturation. The absolute supersaturation means nothing by itself, since for different substances and under different conditions the same supersaturation may correspond to rates of nucleation, i.e. rates of formation I of nuclei of supercritical size, differing by several powers of ten. Nor can the critical supersaturation S_{cr}, corresponding to $I = 1$, be regarded as significant, since it may vary over a similarly wide range as the temperature changes from the absolute zero to the critical point, with the character of nucleation at a constant rate I also varying with temperature. It is advisable to use the degree of reversibility of migration of a cluster along the size (g) axis as a measure of the rapidity of condensation. White showed[3] that under steady-state conditions the mean time required for a cluster to pass from the point $g = 1$ into the supercritical region is f_1/I. A dimensionless parameter for the rapidity of nucleation can be obtained by dividing this quantity by the time of collision between molecules of the vapour at zero time $\beta_1 f_1^0$. The resulting parameter $\theta^* = f_1^2\beta_1 I^{-1}$ has values of 10^{22}–10^{28} for the condensation of water or alcohol vapour in Wilson cloud chambers (typical cases of slow nucleation) and only 10^3–10^4 for the condensation of the highly dilute vapours of inorganic substances.

Rapid condensation is characterised by small (<10) critical nuclei, a sharp decrease in the free energy of formation of clusters in the supercritical region (so that the addition of one molecule to a critical cluster is equivalent to falling into a trap), and a considerable role of collisions between clusters. In slow condensation the critical nucleus contains several tens of molecules, and clusters grow by adding single molecules of the monomer (provided that the vapour is not already associated in the unsaturated state). It is significant also that processes of the rapid type overlap in time with the coagulation of supercritical particles, whereas slow processes are separated in time from subsequent coagulation. Slow nucleation usually occurs in relatively dense vapours (and partial pressures >0.1 mmHg), but rapid nucleation at low vapour densities, since in the latter case condensation during supersaturation is unable to diminish its extent significantly. Difficulties are involved in describing both types of processes. Thus with rapid nucleation the free energy ΔG_g cannot be expressed in terms of parameters of macroscopic quantities of the condensed phase, since such processes are usually accompanied by change in the external conditions. Slow nucleation takes place at a temperature comparable with the critical point, leading to thickening of the interfacial layer on the nuclei and making it difficult to describe their properties. The concentration ratio of the carrier gas to the vapour is far greater in rapid than in slow nucleation, which ensures the isothermal character of the process and the relaxation of the distribution of energy between degrees of freedom of the cluster in the time intervals between successive collisions between it and molecules of the vapour.

The greatest attention has hitherto been paid to slow nucleation in a monomolecular vapour with the concentration of the monomer maintained constant. A considerable number (>30) of formulae have been suggested for the rate I under steady-state conditions, which makes it difficult to choose an expression for the analysis of experimental results or for engineering calculations. We shall therefore repeat the deduction of the formula for the rate of nucleation, incidentally mentioning the sources of discrepancies between the results of different authors and examining individual attempts to improve the theory.

The migration of nuclei along the size axis, caused by the addition or the evaporation only of individual molecules, is described by the equation

$$\frac{\mathrm{d}f_g}{\mathrm{d}t} = I_{g+1} - I_g, \tag{2}$$

where I_{g+1} is the number of nuclei passing in unit time fro from the point g to the point $g + 1$, which can be expressed

$$I_g = \beta_{g-1} f_1 g_{g-1} - \alpha_g f_g. \tag{3}$$

The set of equations (2) in principle enables the distribution $f_g(t)$ to be determined at any time provided that formulae are known for α_g and β_g.

We shall now make certain general statements, whose validity is independent of the specific form of α_g and β_g. Firstly we consider the steady-state process, when f_g is independent of t, so that I is independent of g. We rewrite (3) in the form

$$I = -\alpha_{g-1} f_{g-1} + \beta_g f_g f_1 \tag{5†}$$

which represents a set of inhomogeneous linear equations in f_g. In order to find I, we first solve the homogeneous equation

$$\alpha_{g-1} c_{g-1} - \beta_g f_1 c_g = 0 \tag{6}$$

when we have

$$c_g = \prod_{j=2}^{g-1} \frac{\alpha_{j-1}}{\beta_j}. \tag{7}$$

Supposing that $I \neq 0$, we find $f_g = A_g c_g$, where A_g is determined from (5) by the recurrence relation

$$A_g = -I \sum_{s=2}^{g} (\beta_s f_1 c_s)^{-1}. \tag{8}$$

If we put $g = 2$, we have $A = f_1$, so that

$$f_g = c_g \left[f_1 - I \sum_{s=2}^{g} (\beta_s f_1 c_s)^{-1} \right]. \tag{9}$$

The next problem is to find I, which usually involves the assumption that sufficiently large clusters are removed from the system, i.e. that $f_G = 0$ at some point G. From (5) and (9) we then have

$$I = \left[\sum_{s=1}^{G-1} (f_1 \beta_s c_s)^{-1} \right]^{-1}. \tag{10}$$

Combining (9) and (10) gives

$$f_g = c_g I \sum_{s=g}^{G-1} (f_1 \beta_s c_s)^{-1}. \tag{11}$$

Formulae (10) and (11) relate I and f_g to the coefficients α_g and β_g.

The next step should be to express I and f_g in terms of parameters defining the state of the vapour and the properties of the substance, and to transform the sums occurring in these expressions. This would require that the concentrations c_g, which would be maintained in the vapour in the absence of a flux of nuclei along the g-axis, should be identified with the equilibrium concentrations determined from the condition of equality

$$\mu_g = g\mu_1. \tag{12}$$

of the chemical potentials μ_g of the same quantities of substance included in clusters of different sizes. We again recall that this is strictly valid only for equilibrium association in an unsaturated vapour: the soundness of such identification becomes increasingly dubious with deeper penetration into the region of metastable states. Since μ_g can be written as the sum of the standard chemical potential μ_g^0 and the concentration-dependent term $kT \ln c_g^*$ (where c_g^* is determined by some concentration adopted as standard), c_g can be expressed in terms of f_1 and the Gibbs free energy of formation of the cluster $\Delta G^* = \mu_g^0 - g\mu_1^0$:

$$c_g = f_1 \exp(-\Delta G^*/kT). \tag{13}$$

The Kelvin–Gibbs equation is usually employed to express ΔG^* in terms of the surface tension σ and the density ρ of the condensed phase. Logical difficulties associated with this step will be discussed later. Replacing the summation in formula (10) by integration, we obtain for the rate of nucleation

$$I = \left(\int_0^G \frac{\mathrm{d}g}{f_1 \beta_g c_g} \right)^{-1}, \tag{14}$$

(where G is the size of the clusters for which $f_g = 0$), which can be used for the direct calculation of I.

Frenkel'[4] and Zel'dovich[5] replaced the set of difference equations (3) by the equation of diffusion along the g-axis in order to calculate the rate of nucleation. Becker and Döring[6] resorted to direct replacement of the sum (10) by the integral, using the equation $\alpha_{g^*} = \beta_{g^*}$ instead of (6), which entailed an inaccuracy from disregard of the change in surface area of the particle on the vaporisation from it of one molecule, and led to a result differing from that of Frenkel' and Zel'dovich by a factor of $g^{-2/3}$. As shown both by Barnard[7] and by Petrovskii and Amelin[8], when the correct condition (6) is used, the Becker–Döring procedure gives a result identical with that of Zel'dovich and Fenkel'. It may be mentioned here that the difference between Barnard's[7] and the Becker–Döring results is due to the retention by the former, after replacing the sum $\Sigma g^{-1/3}$ by the integral

$$\int g^{-1/3}\,\mathrm{d}g = \frac{3}{2} g^{2/3} - 1 \tag{15}$$

of unity, which undoubtedly improves the accuracy, since replacing a sum by an integral by itself introduces an inaccuracy of the same order. Indeed, White's deduction[3], based on a consideration of discrete migrations along the g-axis and not involving replacement of summation by integration (or other approximate operations), gives precisely the same numerical values of I as do Frenkel'–Zel'dovich calculations. The final calculated result (for steady-state conditions) can be written

$$I = [f_1 \exp(-\Delta G^*/kT)]\,[f_1 \beta_{g^*}]\,Z, \tag{16}$$

where the three factors in square brackets are the equilibrium concentration of nuclei of critical size c_{g^*}, the rate of condensation of the vapour on the critical nuclei, and the so called Zel'dovich factor, which allows for the fact that the concentrations f_g do not reach the equilibrium values c_g. All three quantities are expressed in terms of phenomenological parameters. For ΔG^* we have

$$\Delta G^* = 4\pi r^{*}\sigma, \tag{17}$$

---

† The Russian version contains no Eqn. (4) (Ed. of Translation).

where the radius r^* of a critical nucleus is found from the condition $d\Delta G/dr = 0$:

$$r^* = \frac{2\sigma M}{kT\rho N \ln S}; \ \Delta G^* = \frac{16\pi\sigma^3 M^2}{3\,(kT\rho N)^2 \ln^2 S} \tag{18}$$

in which M is the molecular weight, N Avogadro's number, and S the supersaturation. The rate of growth is found by combining (18) with Knudsen's formula:

$$\beta_{1g}f_1 = \frac{\gamma_g f_1 kT}{(2\pi mkT)^{1/2}} \cdot 4\pi r^{*2}, \tag{19}$$

where γ_g is the condensation coefficient and m the mass of the molecule. Finally, for Z we have

$$Z \equiv (f_g/c_g) = (\Delta G/3kT\pi g^{*2})^{1/2} = \frac{\rho \ln^2 SN}{8\pi M}\left(\frac{kT}{\sigma}\right)^{1/2} \tag{20}$$

from which it follows that $Z \simeq 0.01$. Substituting (18)–(20) in (16) yields the Frenkel'–Zel'dovich formula for the rate of nucleation:

$$I = 9.6 \cdot 10^{25} \frac{\gamma}{S\rho} f_1^2 \left(\frac{2M\sigma}{\pi N}\right)^{1/2} \exp\left[\frac{16\pi}{3}\left(\frac{\sigma}{kT}\right)^3 \left(\frac{M}{\rho \ln S}\right)^3\right]. \tag{21}$$

The same (or very similar) expressions were obtained by independent methods by Gerlach[2], by Deryagin[11,12], and in papers already cited[8,9]. Equation (21) is based on the hypothesis that clusters can be regarded as spherical droplets possessing the macroscopic density and surface tension. Some inaccuracy, slight in the case of slow nucleation, is introduced by the use of Knudsen's formula, while the β_{1g} should be expressed as coefficients of the frequency of collision between gas molecules (since clusters must be regarded as molecules of a Lorentzian gas).

Equation (16) applies also to rapid nucleation when occurring under steady-state conditions, and the expressions for Z obtained from a consideration of discrete migrations along the g-axis are equally applicable to the two types of nucleation. Accurate calculations[9,10] show that Z for rapid nucleation is close to unity and in any case at least 0.5. The difference from unity can safely be neglected because of the relative inaccuracy of the determination of ΔG. However, proof of the validity of the formulae for Z in the case of rapid nucleation is essentially of value merely to illustrate the possibility of a common approach to the description of nucleation, since rapid nucleation is usually accompanied by rapid changes in the temperature and the concentration of the vapour, which makes the use of steady-state solutions impossible. The description of nucleation must then be based on the numerical solution of equations of type (2) by means of an electronic computer[13,14].

It must be noted here that with rapid nucleation the cluster concentrations may differ very markedly from the equilibrium values for the instantaneous temperature and monomer concentration. This may be because for small g the condensation coefficient may be strongly dependent on the cluster size and change significantly when g decreases even by unity. According to Gerlach[2] it is sufficient that

$$(\Delta G_{g^*} - \Delta G_{g^*-1}))/kT > 3 \tag{22}$$

in order that Z should be close to unity (disregarding the dependence of γ on g). This condition (22) becomes insufficient when $\gamma(g-1) \ll \gamma(g)$. However, another simplification is possible in this case: with $Z \ll 1$ the possibility of the vaporisation of molecules from the clusters can be neglected, which removes the necessity of solving the complicated problem of determining the free energies of small clusters.

The Reviewers' numerical calculations on rapid condensation[15,16] showed that, after some time θ^* ($\sim 10^3$ in $\beta_1 f_1^0$ units), the monomer becomes completely exhausted, and the subsequent course of the size distribution of condensed particles is governed by coagulation. An asymptotic regime is established, in which the particle concentration decreases with time according to a $t^{-6/5}$ law, as was predicted by Lai et al.[17], and also by Lushinkov[18] for purely coagulation processes (i.e. for systems in which every collision of monomeric particles results in their association with 100% probability).

The quantity θ^* depends on the type of relation between γ and g or on the free energy of formation of the clusters, but never exceeds 10^4 for rapid condensation: independently of its value, the subsequent evolution of the coagulating system follows the same $t^{-6/5}$ variation, with the mean particle size depending unambiguously on the dimensionless time

$$\theta = \beta_{11} f_1^0 t. \tag{23}$$

If the temperature of the system and the concentration by weight of the vapour vary, this quantity is given by[19]

$$\theta = \beta_1 f_1^0 \int_0^t F(t')\, T^*(t')\, dt', \tag{24}$$

where

$$F(t') = \Sigma g f_g / f_1^0$$

is the time variation of the concentration of the condensing substance and

$$T^*(t') = \sqrt{T(t')/T_0};\ T_0$$

in which T_0 is the temperature at zero time. Knowledge of θ permits immediate determination of the number concentration, the preceding particle size, and the size distribution[17-19].

Ultimately, of course, the existence of any gas-disperse system always ends in coagulation, but with slow nucleation the quantity θ^* usually exceeds greatly the lifetime of the system.

III. GROWTH AND VAPORISATION OF CLUSTERS

Following the ideas of Gibbs, the classic theory of nucleation assumes that the free energy of formation of a cluster can be written

$$\Delta G = 4\pi r^2\sigma - kT \ln S = ag^{2/3} - (\mu_v - \mu_l)\, g, \tag{25}$$

where μ_v and μ_l are the chemical potentials of the vapour and of the condensed phase. The second term in (25) can be expressed in terms of σ by means of the well known Kelvin–Gibbs formula

$$kT \ln S = \frac{2M\sigma}{N\rho r}, \tag{26}$$

which also gives an expression[18] for ΔG. This was used for many years in the theory of nucleation, until a few years ago the criticism by Lothe and Pound[20-23] and also by their successors[24-26] cast doubt on the hitherto orderly set of ideas. The arguments of these authors changed from paper to paper under the influence of counter-arguments, but the general sense of the proposed revision of the classic theory was invariably that formula (25) describes the free energy of a drop having a fixed centre of mass, but not that of a nucleus endowed with external degrees of freedom and undergoing thermal motion in the space occupied by the condensing system.

In order to examine this question in detail, we must pass to the statistical-mechanical description of a multicomponent gas comprising a mixture of monomeric molecules and molecules aggregates of various sizes. The phase integral for such a mixture can be written

$$Q=\frac{1}{N!h^{3N}}\int \mathrm{d}^{3N}\boldsymbol{P}\int \mathrm{d}^{3N}\underline{r}\exp\left\{-\beta\left[\sum_i \frac{P_i^2}{2m}+U(r_1\ldots r_N)\right]\right\}, \qquad (27)$$

where P is the momentum of the molecule, U is the potential energy of interaction among all the molecules present, and $\beta = kT^{-1}$. We now express (27) in terms of the configurational partition functions for the individual nuclei, in which integration with respect to the coordinates is performed only over some bound region C, where each nucleus exists as a single bound group of particles:

$$q_g=\frac{(2\pi mkT)^{3g/2}}{g!h^{3g}}\int\limits_C \exp\left[-\beta U_g\right]\mathrm{d}^{3g}x, \qquad (28)$$

in which U_g is the energy of interaction of the molecules in a cluster.

The change to integration over bound regions itself causes discrepancies and, in the opinion of several authors, should be accompanied by the introduction of correction factors. However, the chief source of discrepancies is the mode of expressing q_g in terms of ΔG_g. If the chemical potential of a nucleus can be expressed

$$\mu = kT\left[\ln(q_g/N)-\ln(c_g/N)\right], \qquad (29)$$

it follows from the smallness of the difference between the Gibbs and the Helmholtz free energies that

$$c_g = q_g \exp(g\mu_1/kT). \qquad (30)$$

According to Lothe and Pound the quantity

$$\lambda_g = \exp(-G_g/kT);\ G_g = \Delta G + g\mu_1, \qquad (31)$$

is not identical with q_g but is a partition function for a spherical volume isolated in the massive liquid, occupied by g molecules, and provided with an interface. If in (30) we then use λ_g instead of q_g, we must introduce the correction factor

$$\Gamma=\frac{1}{N}\left\{\frac{q_g^{tr}q_g^{r}}{\lambda_g^{tr}\lambda_g^{r}}\right\}, \qquad (32)$$

termed[20-23] the "replacement factor", in which q^{tr} and q^{r} are the partition functions for the collective rotational and translational motion respectively of the nucleus, and λ^{tr} and λ^{r} are the corresponding partition functions for the spherical volume regarded as a drop with a fixed centre of mass. (The term "replacement factor" is sometimes applied to the product $\lambda_g^{tr}\lambda_g^{r}$.) Estimates of Γ based on reasonable values for the vibrational spectral parameters of the molecules in the liquid and for the moments of inertia of the nuclei give a correction of $\sim 10^{17}$ to the rate of nucleation.

Reiss and his coworkers[27-29], Lin[30], Stillinger[31], and also Rusanov and Kuni[32,33] correctly pointed out that the volume of liquid cannot be regarded as a drop with a fixed centre of mass, and that it is more correct to regard it as a drop having fixed boundaries. Because of the ability of the centre of mass of such a drop to fluctuate within its boundaries the replacement factor decreases to comparatively low values depending on the method used to estimate these fluctuations. On the basis of the earlier general theory of equilibrium in polydisperse systems[32] Rusanov and Kuni[33], as well as Parlange[34], showed that the difference between the free energies of formation of a freely moving drop and of a drop having fixed boundaries is almost equal to the difference between those of a mobile nucleus and of a drop having a fixed centre of mass. Certain analogies that can be drawn between the concepts of nucleation theory and those of nuclear physics indicate that the two models—a drop with fixed boundaries and a free nucleus--are in general identical, i.e. that $\Gamma = 1$. The model with fixed boundaries is indeed analogous to the shell model of the atomic nucleus, while the model of a free nucleus is analogous to the drop model. The identity of these models of the atomic nucleus has been demonstrated[35], at least at high temperatures.

In order to obtain agreement between calculated and experimental equations of state[36,37] the value of σ corresponding to the free energy of a planar surface per molecule must be replaced in (18) by values about 10% larger. Thus the surface tension must be correspondingly overstated in isolating the contribution of the collective motion of the cluster.

In the case of a fixed centre of mass ($\lambda_g^{tr} = 1$) the introduction of a replacement factor (allowing only for translational motion) is equivalent to multiplying q_g by $h^3/(2\pi gmkT)^{3/2}$. This view was most clearly expressed by Abraham[23], who, having isolated in the Hamiltonian of the nucleus the components corresponding to the collective translational and rotational motion, diminished by six the number of internal degrees of freedom over which the summation was made. From the equality of molecular momenta in gaseous and liquid phases at a given temperature Bashkirov and Sutugin have shown[38] that the restriction $\Sigma P_g = P$ is imposed on the range of integration in the evaluation of the phase integral over the components of the collective momentum from the momenta of the individual molecules constituting the cluster. The isolation in q_g^{tr} of a factor exceeding $g^{9/2}$ times the partition function for three internal degrees of freedom should then entail the division by $g^{9/2}$ of the partition function for the internal degrees of freedom. It is noteworthy that this approach was made by Frenkel' (though without comment) when, speaking of the need to allow for external degrees of freedom of the clusters, he replaced g by $g-2$ in both terms of Eqn. (25). The Lothe–Pound approach is equivalent to substituting $g-2$ only in the volume term. The equality of molecular momenta in liquid and gaseous phases in general supports the identity of the partition functions of the cluster and of a volume isolated from a liquid and provided with a surface: i.e. it indicates that formula (25) reproduces correctly the free energy of formation of a cluster whose physical properties coincide with those of a drop. However, several authors consider[31,39,40] that the configurational parts of the phase integrals for the cluster and for the volume isolated from the liquid differ somewhat, and there is also no unanimity on the magnitude of this difference. As already stated, however, the replacement factors obtained from the estimated configurational integrals are by no means so large as in the papers by Lothe and Pound.

A final comment on the replacement factor is that the Lothe–Pound approach leads to the conclusion that the concentration of free clusters in equilibrium with a given monomer concentration should far exceed the concentration of drops having a fixed centre of mass. Hence isothermal distillation of matter should take place from stationary to moving drops, which is obviously inconsistent with the law of the conservation of energy. The same argument can be used also in refutation of the identity of a cluster and a volume isolated from the liquid[38].

It is interesting[29,41] that in one case the replacement factor may indeed differ markedly from unity—in the formation of rigid spherical nuclei and molecules possessing non-degenerate rotation—when the factor should by less than unity. The possibility of the formation of solid, not supercooled liquid, nuclei from the vapour has not yet been proved; moreover, an aggregate of 20–90 molecules cannot be regarded as a smooth, rigid sphere.

The immense values of the Lothe–Pound replacement factor gave rise to many hypotheses on the nature of clusters to explain the discrepancy between the theory and experiment[42–47]. Since the Lothe–Pound theory is now obviously untenable, we shall not discuss these hypothesis further.

Two sources of uncertainty arise in connection with the coefficients β_g. Firstly, the density of clusters would be smaller than the macroscopic value ρ (see Section IV), so that the surface area of a cluster should be greater. Secondly, information is lacking on the coefficient of condensation $\gamma(g)$ on small clusters. It has been stated repeatedly that γ may diminish appreciably with decrease in size of the clusters. As long as we consider isothermal condensation (i.e. suppose that all the heat evolved in the system is immediately absorbed by the thermostat), however, it follows from the principle of detailed balancing that condensation and evaporation coefficients are equal. This implies that a decrease in γ should not affect the steady-state rate of nucleation, since from Eqns. (3), (5), and (6) we have

$$f_g = \frac{\beta_1\beta_2 \ldots \beta_{g-1}}{\alpha_2\alpha_3 \ldots \alpha_g} c_g, \tag{33}$$

and such coefficients occurring in β and α cancel out. Under completely isothermal conditions the decrease in γ with small clusters can affect only the time required to attain a steady state after the instantaneous establishment of supersaturation in a system comprising monomeric molecules. In practice the removal of heat of condensation is never instantaneous, which would influence significantly the course of elementary processes involving the smallest clusters, as the efficiency of collisions between vapour molecules and clusters drops sharply. Since the evaporation coefficient is an intrinsic property of the actual cluster, it is unaffected by non-isothermal conditions, and with small values of g the decrease in γ will lead to a decrease in I_0. These effects will be discussed in detail in Section VI.

Okuyama and Zung[48] tried to obtain an analytical expression for the dependence of γ on g. They started from the fact that γ should decrease with increase in the positive curvature of the surface, since the condensation of a molecule on a drop must involve work to increase the surface of the latter. However, one of the Reviewers has pointed out[49] that this is already taken into account by the Kelvin–Gibbs formula, and the Okuyama–Zung result is incorrect. The erroneousness of the latter formula is readily illustrated by applying it to condensation on a concave meniscus, when values of γ exceeding unity are obtained.

IV. PROPERTIES OF SMALL CLUSTERS

The evident doubt as to the applicability of phenomenological parameters, relating to major quantities of the condensed phase, to express the free energy of formation of clusters has stimulated a search for other methods of determining this function. The first attempts of this kind were based on the use in expressions for ΔG of surface tensions for a curved surface. A considerable number of such papers, reporting essentially modifications of Tolman's theory of surface tension, were surveyed in a previous review[50].

The one-sided character of these attempts was shown[51–54] by the demonstration that the decrease in tension of the curved surface of a cluster is accompanied by an increase in thickness of the interfacial layer with a consequent decrease in density of the droplets. Study of the asymptotic behaviour of the configurational integral of liquid droplets showed[55–57] that the free energy of a cluster cannot in general be written in the form $ag + bg^{2/3}$ and that expressions for ΔG should contain terms proportional to $g^{-1/3}$, $\ln g$, and—what is especially important—a term representing the contribution by capillary waves. It was also revealed[57] that the theory of the tension tensor in the interfacial layer, usually employed to determine the dependence of σ on surface curvature, is completely unable to reproduce the significant properties of clusters.

Decrease in the size of a cluster is not simply accompanied by a decrease in its density: the radial distribution of density in a cluster depends on its previous history and on the degree of saturation of the vapour—a conclusion reached by Strickfaden and de Sobrino[58], who calculated the density profile as a solution of the diffusion equation for molecules in the self-consistent field of the cluster.

Considerable efforts were concentrated on attempts to express ΔG in terms of the parameters of the intermolecular interaction potential for the molecules forming the cluster. Regarding a cluster as a polyatomic molecule, we can write

$$q_g = q_{tr}q_rq_vq_0, \tag{34}$$

where q_{tr}, q_r, and q_v are the translational, rotational, and vibrational partition functions respectively, while $q_0 = \exp(-U_0/kT)$, in which U_0 is the minimum potential energy of the cluster. If the cluster comprises polyatomic molecules, a factor must be included to allow for the contribtuion by intramolecular degrees of freedom. The main difficulties in solving such a problem are to determine moments of inertia, the set of frequencies, and the bonding energy. It is first necessary to assign a definite structure to the cluster; thus this approach is applicable only to crystalline nuclei. Yet several workers consider that direct formation of crystal nuclei from a vapour is impossible, since clusters are amorphous according to Ostwald's rule, and are able to crystallise only when they have become much larger than the critical size[59,60].

The first reported determination of q_g was made by Reed[61], who calculated it for nitrogen clusters on the assumption that the interaction of molecules in a cluster is described by a Lennard–Jones potential with clusters of each size existing in the most stable configuration (as dumbbells, regular triangles, tetrahedra, double tetrahedra, and cubes respectively). This method was modified by Andres[62] for clusters up to $g = 12$. Later papers specified only the lattice type, and interatomic distances were determined by finding the minimum potential energy.

Such calculations were made for argon clusters by Burton[63–65] and by McGinty[66], who both calculated the rate of nucleation by means of formula (14) and obtained agreement with calculations based on the classical theory and the surface tension of solid argon. In contrast to the classical theory, quantum-mechanical calculations predict several characteristic properties for clusters, e.g. an anomalous size dependence of heat capacity, and a non-monotonic dependence of q on g. Abraham and Dave[67–69] showed that results identical with those of Burton and of McGinty can be obtained more simply by calculating the thermodynamic properties of crystalline clusters by means of the Einstein theory of the heat capacity of crystals extended to a system bounded by an interface.

Burton's most recent calculations[70] of rates of nucleation in argon vapour, based on quantum-mechanical calculations of ΔG, differ markedly from the predictions of the classic theory: over the range of supersaturations 12–72 and at reduced temperatures of $T/T_{cr} = 0.35–0.47$ the ratio of his values of I to the classical values increases from 10^{-2} to 10^7. Bonissent and Mataftschiev[71] made similar calculations for an arbitrary model substance whose molecules interacted in conformity with a Lennard-Jones potential. Having calculated the equilibrium concentrations of hexagonal clusters of 2–14 atoms, they also computed the surface tension for crystals of the same model molecules, and from this latter value found the classic equilibrium concentrations. Good agreement was found between such pseudoclassical calculations and rates of nucleation calculated in terms of the intermolecular interaction potential. These authors concluded that the possible existence of different configurations of the clusters does not affect significantly the values of c_g, but Burton[70] holds the opposite view.

It is interesting that the process of selecting configurations for clusters by successive approximation to the configuration corresponding to minimum free energy involves significant distortion of the lattice assigned *a priori* to the clusters. Use of the Lennard-Jones potential yields especially considerable distortions of crystal structure for $g = 13$ and 55.[72] Use of the Morse potential in the calculations encountered the same difficulty[73–75]. It was concluded that this problem is complicated by taking long-range forces into account, and this is what prevents the application of quantum-mechanical calculations to clusters containing $>$100 atoms.

The impossibility of achieving crystalline structures in clusters is probably the reason for the frequent observation of amorphous disperse condensates. This supports the concept[76] that subcrystallites consisting of a few atoms appear before particle formation. A cluster formed from such subcrystallites cannot have a crystalline structure.

Quantum-mechanical calculations for molecular aggregates in the vapours of several metals[77] do not give good agreement with experimental results even for a dimer: adjustment with the aim of improving agreement for the bonding energy increases the divergence of vibration frequencies, and conversely. Nevertheless, these results were used for calculations of bonding energy in Ag_g and Pd_g complexes, for which great stability of linear and cyclic aggregates was predicted in comparison with aggregates having a three-dimensional structure[78].

Relatively numerous attempts have been made to calculate aqueous clusters. Inspection of results obtained by various workers[79] indicates that the properties of the dimer can be calculated quite well. Large clusters, however, exhibit discrepancies both in quantitative estimates of bonding energy and in the determination of the relative stability of linear and cyclic structures. Del Bene and Pople[80] found that cyclic clusters are the more stable, supporting this conclusion by the presence at 3.5 Å in liquid water of a maximum in the radial density distribution function, a position which can be interpreted as the distance along the diagonal in the cyclic tetramer[81]. Recalculation of cyclic clusters[82] suggested absence of the non-additivity of bonding energy which might have been responsible for their great stability, so that linear aggregates should be the more stable, the correctness of the calculation being illustrated by prediction of the true bonding energy of ice. The linear structure of water complexes is suggested by experimental observations[83] on the magnetic focusing of beams of molecular aggregates.

Plumer and Hale[84] calculated clusters containing up to 57 H_2O molecules, and arbitrarily chose a cyclic pentamer as unit cell. They assumed that a cluster has an ordered structure, as indicated by the existence of hydrogen-bonded complexes in liquid water. Nevertheless, the Hagler–Scheraga–Nemethy theory of the structure of liquid water[85] in fact interprets water as a mixture of clusters of different sizes, but the maximum in the size distribution function occurs at $g = 4–5$, and clusters larger than 50 molecules are completely absent from the liquid phase. A nucleus in the vapour phase, consisting of tens of molecules, is therefore also more logically regarded as a complex of smaller clusters of hydrogen-bonded molecules bound together by van der Waals interactions. The values obtained[84] for ΔG are scattered on both sides of the classic ΔG–g curve. This scatter would obviously have been diminished by taking into account the existence of a large number of ruptured hydrogen bonds in the cluster.

The possible existence of different geometrical configurations for clusters of a given size makes it necessary to consider the statistical contribution made to q_g by each configuration. The growth of clusters under such conditions should be regarded, strictly speaking, not as unidimensional diffusion along an axis but as displacement in a multidimensional space. Ziabiki[86] deduced a multidimensional kinetic equation of nucleation, the dimensions of which were equal to the number of faces on the cluster–nucleus. Semenchenko and Petrovskii[87] were able to reduce this equation to a one-dimensional form by using Semenchenko's thermodynamic theory of small crystals[88], enabling ΔG to be expressed in terms of the Wulf constant. In the view of these workers anisotropy of the crystal nucleus should have little effect on the magnitude of ΔG.

Equilibrium concentrations of dimers have been calculated not only in Refs. 61 and 62 but also in Ref. 89, in which the Morse potential was used for argon and krypton. The dynamic equilibrium in a system containing monomeric and dimeric molecules has been examined[90]: the concentrations of three types of bound states—stably bound, metastably bound, and dissociating—were calculated for various gases over a wide temperature range by use of the rectangular-well and Sutherland potentials. The temperature dependence of c_2 obtained at low temperatures was closely similar to the results of calculations by Reed's method[61], but the discrepancy increased with rise in temperature. Divergence between results in Refs. 89 and 90 was slight. In a monomer–dimer system not in contact with a thermostat the temperature of the dimer is below, while that of the monomer is above, the average temperature of the mixture[91]. Even when this effect is taken into account, however, the concentration of dimers is similar to that calculated by Stogrin and Hirschfelder[90].

V. NUCLEATION UNDER NON-STATIONARY CONDITIONS

Two cases of non-stationary nucleation can be distinguished: either supersaturation is established instantaneously and then remains constant, or it varies continuously throughout the process. A steady state may be established in the former case, but some time is required for the concentrations to become steady, and during this period the rate of nucleation will increase from zero to the steady value I_0. Several workers investigated the time of attainment of a steady state[92-96] by solving the time-dependent equation for the diffusion of nuclei along the size axis with the initial conditions $c_1 = 1$ and $c_g = 0$ with $g \neq 1$. The rate of nucleation under non-stationary conditions was shown to be related to the steady value:

$$I(t) = I_0 \exp(-\tau/t), \tag{35}$$

where

$$\tau = A(\beta_1 c_1 S_g)^2 Z,$$

is the relaxation time of nucleation, in which A is a numerical coefficient estimated by various authors to lie within the range $\frac{1}{4}(1-\pi)$.

Abraham[97] used a computer to solve Eqns. (2) with the aim of studying non-stationary nucleation at a constant supersaturation S, and his results indicated the analytical solution in Refs. 95 and 93 to be the most accurate. Similar values of τ were obtained[98] in a numerical tabulation of the solution of the equation of non-stationary diffusion in quadratures. Computer calculations by Courtney[92] indicated rather slower establishment of a steady state, probably because of his use of a different expression for c_g.

Abraham also investigated the effect of the cluster-size dependence of the condensation coefficient on the time of establishment of the steady state. Although the erroneous Okuyama–Zung formula[48] for the γ–g dependence was used in these calculations, the results give an idea of the possible influence of this factor. According to Abraham's calculations[99] the concentration of clusters considerably smaller than the critical size approaches steady values, passing through a maximum; the concentrations of clusters of near critical sizes increase monotonically to steady values.

If the change of supersaturation during the process is sufficiently slow, the cluster concentrations may have time to assume the steady-state values for the instantaneous temperature and monomer concentration. Raizer[100] deduced a criterion of slowness in the variation of supersaturation for the adiabatic expansion of a cloud condensing in a vacuum.

It can readily be seen that a steady state is attainable only in cases of slow nucleation. Rapid and intermediate types of nucleation are usually accompanied by rapid change in the external conditions. In this case the description of condensation should be based on numerical integration of the set of equations for the concentration variation of critical and subcritical clusters together with the equations for the concentrations of monomer and supercritical species[43]. Methods have been published[16,19] for reducing the number of equations of type (2) to a reasonable level permitting numerical integration on modern computers.

VI. NUCLEATION UNDER NON-ISOTHERMAL CONDITIONS

The theory outlined in Section II describes an isothermal process: i.e. it is based on the hypothesis that the mixture of clusters and monomeric molecules is in contact with a thermostat that will instantly level out local variations in temperature. In real systems the role of such a thermostat can be played only by an uncondensable carrier gas, which dilutes the vapour of the condensable component. Energy is transferred by collisions between carrier-gas molecules and clusters, i.e. at a finite rate. Several non-isothermal effects during condensation arise from the finite rate of energy exchange and the finite number of molecules of the carrier gas[101]: firstly, the mean temperature of clusters of a given size is higher than that of the mixture, with a consequent increased probability of evaporation; secondly, the non-instantaneous removal of the excess of kinetic energy of the condensing molecules may diminish the efficiency of primary acts of addition of molecules to small clusters.

Application of the theory of rate processes to condensation[102] indicates that the transfer of molecules from the vapour to the condensed phase is preceded by formation of an activated complex on the surface. This complex may either dissociate with re-evaporation of the molecule or undergo deactivation, when the molecule will pass into the condensed phase. In the case of a flat surface and sufficiently large clusters deactivation of the complex takes place by the exchange of energy with the condensed phase, the consequent rise in whose temperature is too small to cause immediate vaporisation of another molecule. Deactivation of very tiny clusters can result only from collision with carrier-gas molecules or with molecules of the vapour at the cold end of the energy distribution. In the limiting case of formation of a dimer from two single molecules, a third body must be involved in the collision. Since three-body collisions take place far less often than two-body collisions, the rate of growth of small clusters should be considerably lower than is assumed in the isothermal theory. Furthermore, if nucleation occurs while the temperature of the vapour is falling or immediately after rapid cooling, the temperature relaxation of the clusters will be slower than for free molecules.

Salpeter has recently[103] distinguished three cases of non-isothermal growth of clusters determined by the conditions

(i) $c_p k \gg B/kT$ (large clusters)
(ii) $(B/kT)^2 \gg c_p/k \gg B/kT$ (intermediate clusters)
(iii) $c_p/k \ll B/kT$ (small clusters)

where B is the heat of condensation per molecule, and c_p is the heat capacity of a cluster. By supposing that the temperature of a cluster relaxes exponentially after addition or vaporisation of a molecule, he obtained an expression for the non-isothermal rate of growth of a cluster as a function of a parameter representing the thermal relaxation of clusters and supersaturation. For large clusters a formula for rate of growth was obtained that had been deduced earlier[104]; it predicted that the rate of addition of molecules to clusters during the condensation of water in a Wilson cloud chamber should be much smaller than in the isothermal approximation. The rate of growth found for intermediate clusters from the average temperature of the clusters is zero: i.e. their growth is possible only because of the presence of a temperature distribution both of clusters and of molecules. Salpeter considered that small clusters could grow during rapid cooling only by the addition not of single molecules but of dimers, from which one of the molecules subsequently vaporised.

As already mentioned in the account of the isothermal theory, its construction on the basis of equilibrium thermodynamics is an approximation, the crudeness of which increases with penetration into the region of metastable states. The use of the Szillard–Farkas model to describe non-isothermal nucleation was until recently not justified at all. However, Bashkirov and Novikov[105], using the non-equilibrium statistical operator method[106], have demonstrated that the notation based on the diffusion of clusters along the size axis can be used also to describe non-isothermal nucleation. In the Reviewers' opinion, nevertheless, this conclusion can relate only to "large" clusters in Salpeter's classification.

The presence of a large excess of a carrier gas relative to the vapour concentration is frequently accepted as the sole criterion of the isothermal character of nucleation. However, the relative departure from isothermal conditions at a constant concentration ratio of carrier gas to vapour n_0/c_1 may vary with I, because the rate of evolution of heat of condensation on nuclei of a given size is proportional not to $\beta_{1g}c_1$ but to the flux $I = f_g(\beta_{1g}c_1 - \alpha_g)$. Thus the isothermal criterion should be

$$\varepsilon = \frac{\beta_{ng}n_0}{\beta_{1g}c_1 - \alpha_g}, \tag{36}$$

where β_{ng} is the coefficient of collisions between molecules of the inert gas and clusters.

Unfortunately, it is not yet possible to predict by calculation the values of ϵ for which the isothermal approximation could be used, but certain rough estimates may serve as guide. Firstly, the thermal relaxation of polyatomic molecules requires 10^3–10^4 collisions with molecules having the equilibrium energy distribution. On the other hand, Katz[107] made an experimental study of the effect of the quantity of carrier gas on the rate of nucleation in a diffusion cell, and found that I was unaffected if the gas pressure was 50% greater than that of the condensing vapour. Adopting $c_1 \simeq 5 \times 10^{17}$ cm^{-3}, $\beta_{ng} \simeq 10^{-10}$ cm^3 s^{-1}, $I = 1$ cm^{-3} s^{-1}, and Abraham's calculation[97] of $f_g = 10^7$ cm^{-3}, we obtain $\epsilon \simeq 5$. From this last estimate it may be concluded that, with the carrier gas at atmospheric pressure, nucleation is isothermal in character only when $I < 10^2$. It should be noted that Katz was dealing with vapours comprising polyatomic molecules the heat capacity of each of which already exceeded the heat of condensation. In the condensation of monatomic or diatomic molecules the condition $\epsilon \simeq 1$ would be insufficient to ensure isothermal conditions.

Thus the isothermal approximation for nucleation has a very restricted range of application, although it is very often used for comparison with experiment and for engineering calculations under definitely non-isothermal conditions. However, a theory of non-isothermal nucleation has not yet been worked out. Construction of such a theory requires in general consideration of the diffusion of clusters in the size–energy phase plane (which is also approximate, since the possibility of different redistributions of energy between degrees of freedom of the cluster is ignored). Examination of the continuous spectrum of energy states of clusters has not yet been applied, but attempts have been made to replace averaging of the energy state by the division of clusters into two groups, at the equilibrium temperature and activated respectively. Hagena[108] tried to solve a set of differential equations in which the concentrations of activated and relaxed clusters were considered separately, and their interconversion was taken into account. Other workers[109] also discussed two types of states of clusters, but incorrectly neglected the possible evaporation of molecules from thermally relaxed clusters.

On the whole the theory of non-isothermal nucleation still remains in an unsatisfactory state.

VII. EXPERIMENTAL METHODS FOR THE STUDY OF SPONTANEOUS CONDENSATION AND INTERPRETATION OF THE RESULTS

The chief parameters used in the theory of nucleation—rate of nucleation, equilibrium concentrations of nuclei, size of critical nucleus, and free energy of their formation—cannot be measured experimentally. Experiments provide information only on the new phase: its formation when a certain supersaturation is reached is confirmed, the particle size and concentration of the condensed phase are indicated, and in the most favourable case data on the variation in particle size and concentration during condensation are obtained. Such information can be used for comparison, not with the actual theory of nucleation, but only with certain models calculated by use of the theory. Since such models themselves involve various postulates and errors, additional uncertainty is introduced into the problem of agreement between theory and experiment.

The Wilson chamber has been used longest for the study of spontaneous condensation. For decades it has been employed simply to confirm the formation of a disperse phase on attainment of a certain supersaturation, regarded as critical and compared with that predicted by theory. Measurement of the concentration of droplets formed was usually omitted, and the time during which supersaturation was maintained at the critical level was merely estimated. During recent years cloud chambers have been produced enabling a constant temperature to be maintained by means of a programmed expansion cycle lasting tens of times longer than in simple cloud chambers[110,111]. It was found that expansion was adiabatic only in sufficiently large chambers[112]. In view of statements on the possible evolution of foreign condensation nuclei from the walls of the chamber following reaction with atmospheric oxygen[59], experiments began to be made in pure inert gases, and materials for the manufacture of the chambers were chosen more carefully. Reasons were established why the critical supersaturation was lower for repeat expansions: droplets formed in the first cycle had insufficient time to evaporate during the compression period[113].

The most recent work with a Wilson chamber has followed the time variation of the degrees of dispersion and the particle concentration, either by measuring the intensity of scattering of a monochromatic beam of light or by high-speed microcinematography with dark-field illumination. In the former case the mean size is obtained by comparing the measured absolute intensity scattered at a given angle with calculations based on the Mie theory; measurement of the angular dependence of the polarisation ratio of light scattered by the particles will give the width of their size distribution[114-116].

Comparison of theory with experiment at only the one, critical supersaturation, although giving less information, is logically more soundly based, since it describes more correctly the metastable state of the vapour, not the breakdown of this state. However, the need to establish methods of calculation for engineering bulk condensation compels the use of nucleation theory even to describe processes in which nucleation takes place on a background of exhaustion of the vapour. Allowance for the decrease in supersaturation due to consumption of the vapour was first proposed by Tunitskii[117]. A more accurate method, requiring simultaneous numerical integration of the equations of adiabatic expansion, nucleation, and condensation growth of particles, was suggested by Courtney[118] and then used in many papers for the interpretation of experimental results,

A method for the study of bulk condensation—the diffusion cell—has recently been used very successfully by Katz[120,121] following its early first application[119]. Gradients of temperature and vapour concentration are established between two plates (by evaporating the vapour from the hot plate and condensing it on the cold plate). Because of the non-linear temperature dependence of the vapour pressure the vapour becomes supersaturated at some distance from the hot plate, and the supersaturation may exceed the critical value. Formation of the condensed phase can then be detected by the usual methods. In contrast to the Wilson chamber, condensation here is a steady-state process, which is a great advantage. Furthermore, the diffusion cell is self-purifying: i.e. various impurity centres of condensation are immediately removed by the condensing vapour. In this case comparison of theory with experiment reduces to calculating the height distribution of supersaturation, determining the level at which mist is formed, and thus finding the critical supersaturation.

Just as in the Wilson chamber, supersaturation by adiabatic cooling is produced during supersonic flows of vapour and vapour–gas mixtures through a nozzle. Investigations of condensation under such conditions have become widespread because of the great interest for energetics presented by the possibility of controlling formation of the disperse phase. Condensation is studied by measuring the static pressure distribution along the axis of the nozzle (formation of a condensed phase is accompanied by a change in pressure), by observing the flow with shadow optical instruments (schlieren) and by measuring the scattering of a laser beam in different cross-sections of the nozzle. The last method will now detect the formation of particles of mean size 20 Å.[115] Many studies have now established agreement between the mass of the condensed phase calculated from changes in the static pressure and from light scattering[114,122]. Results of the determination of the mass of the condensed phase or of the mean size of the particles and their concentration are compared with those of the simultaneous numerical solution of the equations of the conservation of mass, energy, and momentum, the equation of state, and the equations for the number of particles

$$\mathrm{d}n_g/\mathrm{d}t = I(t) \tag{37}$$

and for particle growth by condensation. Such a set of equations was first used and solved analytically with several simplifications by Oswatitsch[123]. More accurate methods requiring numerical integration have been described by several authors[124-126]. Especially noteworthy is the work of Campbell and Baktar[124], whose methods of calculation yield not only the mean particle radius but also the size distribution, since separate kinetic equations are written for the growth of particles formed in different portions of the flow. In the Reviewer's opinion, however, these authors made several unnecessary postulates (e.g. neglect of the growth of nuclei beyond the critical size in the zone where they had been formed). In calculations on condensation most authors use free molecular rotations in the kinetics of the growth of particles and the transfer of heat to them, which is incorrect, since with particle growth the Knudsen numbers characterising the régime of heat and mass transfer to the particle become too small for free molecular rotations to remain applicable. However, the main complexity in the use of nucleation theory for such calculations is the great non-uniformity and non-isothermality of the process when the vapour escapes in the absence of a carrier gas.

Adiabatic cooling of a gas takes place also in so called high-intensity molecular beams, which are fine, supersonic jets emerging into a high vacuum, from which the central portion of the flow is isolated by means of a set of conical diaphragms[127]. Very rapid and strong cooling is achieved in such flows. Formation of molecular aggregates comprising tens, and sometimes even thousands, of molecules can be detected by means of ionisation detectors, as well as by time-of-flight and quadrupole mass spectrometers. Information on the size of clusters formed in molecular beams can be obtained from measurements on its weakening by a cross beam. Measurement of the weakening of the latter beam will also give the fraction of monomer uncondensed. Such a method was used to study the agglomeration of clusters after complete exhaustion of the monomer[128], i.e. essentially coagulation in the beam.

The state of the internal degrees of freedom of molecules in such beams is very far from equilibrium: their vibrational, rotational, and translation temperatures may differ several-fold. Thus the formation of clusters of polyatomic molecules in such beams has little in common with the concepts of nucleation theory. The main use of such experiments is to provide information on the primary acts in the aggregation of monatomic molecules and on the possibility of the formation of mixed molecules aggregates by the condensation of multicomponent systems. The interpretation of data obtained by means of powerful molecular beams is complicated by the inability of existing escape theories to explain certain qualitative features—e.g. the presence of maximum intensity at a certain distance along the beam between the nozzle and the first conical shield (skimmer)[129,130] and the angular separation of components differing in mass.

Cooling during the molecular diffusion of a vapour through a cold gas takes place in certain forms of equipment for the production of metal powders. Such experiments give some useful information on the condensation of metal vapours. Similar results are obtained in experiments on exploding wires, in which cooling is due both to the diffusion mixing of the vapour with the surrounding gas[76,131].

Several studies have been made on condensation during the turbulent mixing of a hot vapour–gas mixture and a cold gas. The Reviewers have shown[132] that calculation of condensation in turbulent flows must take into account the three-dimensional transport of clusters by the turbulent vortices, so that Eqns. (2) for the description of nucleation must be replaced by the set of partial differential equations

$$v\,\mathrm{grad}\,f_g = \mathrm{div}\,(D_t \mathrm{grad}\,f_g) + I_g, \tag{38}$$

where v is the time-average rate of flow, I_g the operator of the right-hand side of Eqn. (2), and D_t the coefficient of turbulent diffusion.

Another peculiarity of the condensation consists in the effect of turbulent pulsations of temperature and concentration. Pulsations lasting longer than the relaxation time of deviation may obviously distort significantly the course of condensation, but this aspect has not yet been investigated. In spite of these complicating factors, it is necessary to investigate condensation in turbulent flows, because such processes are often met in technology. Furthermore, turbulent mixing is convenient for the study of condensation at high temperatures. The above complications disappear when mixing precedes condensation, i.e. with rapid mixing and slow condensation—and hence at low vapour concentrations—even if condensation may be of the "rapid" type.

A one-dimensional approximation was suggested[13,14,16] for calculating condensation in a submerged turbulent jet. This involves numerical integration of an equation, averaged over time and angle, for rate of mixing and a set of equations (2) for the concentrations of small clusters, as well as equations for the growth of superciritcal particles of average mass. In another modification of this method, applicable to processes in which coagulation predominates, Eqns. (2) are combined with the coagulation equations of the Rosinski–Snow model[133]. Amelin et al.[134] suggested a method for studying condensation during turbulent mixing, in which nucleation and enlargement of the particles took place in different apparatus, so that there was no need to consider exhaustion of the vapour during nucleation. Equipment in which a vapour-gas mixture is diluted by a coaxial flow of a cold gas in a diffuser with cooled walls has been used[135] to study condensation in a turbulent flow; these experiments were interpreted on the assumption that condensation is preceded by mixing.

Shock tubes have also been used for the study of nucleation. They may serve two purposes: in some cases[136] vapour condensers in the rarefaction formed behind the detonation front; in other cases the heating effect of the detonation wave causes decomposition of a chemical compound with formation of a non-volatile component, whose condensation is studied[137].

VIII. EXPERIMENTAL RESULTS ON SPONTANEOUS CONDENSATION

The large majority of experimental results, including those on the condensation of one-component systems, compare with the predictions of the isothermal theory, although isothermal conditions are not always observed even when condensation is studied in the presence of a carrier gas. In Wilson chambers possible non-isothermal effects become more intense with rise in the initial temperature.

Calculations based on the classic theory[118,141] agree with results on the condensation of water[110-112,138-140] only within a narrow range of supersaturations. On the whole the experimental dependence of rate of nucleation on supersaturation has a smaller slope than the theoretical curve, and intersects the latter at $S = 5$. Observations on the establishment of a steady state in Wilson chambers indicate a slower increase in I than is predicted by Courtney's calculations[118] or else agree with them only at low temperatures[138]. We recall that these calculations[118] use a formula for I which is smaller by the factor $1/S$ than that obtained by Frenkel'. The slower experimental attainment of a steady state may indicate either that the condensation coefficient is lower with small nuclei or that the process is non-isothermal.

Special attention should be given to the extremely thorough and carefully conducted work by Kassner and his coworkers[110,111,140], in which the rate of nucleation was measured as a function of supersaturation for several temperatures by the use of various inert carrier gases. These results are fully consistent with those obtained earlier, and support all the earlier conclusions, but cover far wider ranges of temperature and supersaturation. Among the important conclusions reached by these workers was that, when the supersaturation is maintained constant after expansion, the rate of formation of new particles does not remain constant, but diminishes, the effect becoming more marked with increase in supersaturation. This phenomenon was explained by the presence in water vapour of molecular nuclei, whose concentration is proportional to that of the vapour. The I–S curve has a point of inflexion in the range $I = 10$–100 cm^3, which is most clearly defined at low temperatures. The experimental curve generally intersects the curve calculated on the classic theory, so that the rate of nucleation is underestimated at low supersaturations, and overestimated at high supersaturations. On the other hand too high rates at low supersaturations are explained by the substantial contribution of heterogeneous condensation on molecular condensation nuclei. Rates are distinctly greater in heavy than in light inert carrier gases.

Allard and Kassner[110] attributed the formation of foreign nuclei to the radiolysis of water vapour by the background cosmic radiation. The heterogeneous character of condensation at low supersaturations most probably applies to all other experiments on the condensation of water in Wilson chambers. The difference between results obtained in argon and in helium was explained on the hypothesis that these gases form clathrate compounds with water, of which the argon clathrates are the more stable. The untenability of this hypothesis was shown by Burke[142], who also suggested possible mechanisms of the radiation formation of foreign nuclei and pointed out that argon, which should act as a third body in several of the reactions involved, will ensure a greater cross-section of three-body reactions than will helium, which explains the difference in the kinetics of condensation in these gases. Moreover, argon promotes more rapid removal of heat from nuclei than occurs with helium, as follows from Luke's calculations[143]. Clark and Noxon[144] reported the formation, under the influence of ionising radiation in helium containing unsaturated water vapour, of particles reaching 10^{-4} cm. This also supports the heterogeneous character of condensation at low supersaturations. The formation of aggregates $Ar_x(H_2O)_y$ was reported[145], but at far lower temperatures than in the experiments of Allard and Kassner.

The point of inflexion on the I–S curve was explained by White and Kassner[146] on the hypothesis that an electrical double layer is formed on the surface of aqueous clusters by the orientation of water-molecule dipoles. Such a point was indeed present on the dependence of rate of nucleation on supersaturation which they obtained by using a formula for ΔG allowing for the contribution by a double layer, but this contribution was only estimated.

The temperature dependence of the critical supersaturation was studied on methanol, ethanol, water, hexane, octane, nonane, and heptane by Katz and Ostermeyer[120] and by Katz[121]. The hot plate, from which vaporisation occurred, was located at the bottom of the diffusion cell used, so that, to avoid mixing by convection currents, the temperature gradient had to be balanced by a composition gradient in the vapour–gas mixture, with a light gas (hydrogen, helium, or neon) at reduced pressure employed as carrier. As a consequence, the concentration ratio of vapour and carrier gas was still lower than is usual in Wilson chambers, which is dangerous to isothermal conditions. However, this aspect might be unimportant, since most experiments were made with polyatomic substances, for which the difference in heat capacity between condensed and vapour phases is relatively small. For organic compounds these workers obtained very good agreement with the classic theory in the Becker–Döring form; for water, however, as in Wilson chambers, agreement was observed only over a narrow temperature range and with considerable scatter.

Reiss and Heist made accurate measurements of the critical supersaturation of water vapour in a diffusion cell over a wide temperature range[147]. Their results show little experimental scatter and give S_{cr} values 8% above those predicted by the Frenkel' formula. In contrast to measurements in a Wilson chamber, the nature of the carrier gas is of no significance in a diffusion cell. This indicates truly isothermal conditions and the absence of foreign nuclei, whose formation involves molecules of the inert gas.

Formation of a condensed phase during supersonic flows of a one-component vapour, of course, cannot be described on the basis of the isothermal theory. It is not surprising, therefore, that the large majority of results for the condensation of water vapour in nozzles can be reconciled with calculations based on the classic theory only after the introduction of empirical parameters. A single parameter, e.g. a condensation coefficient less than unity, is insufficient to obtain the correct form of static pressure curve. Therefore two or three parameters are generally employed[124,148–151].

Non-isothermal conditions are not in general the sole factor casting doubt on the use of steady-state solutions of the classic theory to describe condensation in nozzles. The large supersaturations and the small critical nuclei indicate that the processes occurring in nozzles belong to the rapid type of nucleation. Introduction of a correction for the non-stationary character of the process in these cases is equivalent to adjusting the condensation coefficient, and by itself, therefore, cannot improve the agreement with calculations.

In contrast to the above results the later papers by Wegener and his coworkers[114,152] on the condensation of water vapour gave good agreement with the classic theory for liquid nuclei with $\gamma = 0.01$. In his earlier papers Wegener[153,154] had obtained agreement only by adopting lower values for γ and postulating that the nuclei had a crystalline structure.

A group of investigators[155,156] studied the condensation of the vapours of water, benzene, chloroform, and trichlorofluoromethane at partial pressures of 0.01–0.1 mm in air emerging through a Laval nozzle. At low supersaturations the rate of condensation of water was predicted satisfactorily on the basis of the classic theory with $\gamma = 0.01$, but the organic liquids condensed significantly more rapidly than might have been expected from calculations with $\gamma = 1$. These results may be affected by the presence of impurities, most likely water. The same workers found[156] that 0.001% of water greatly accelerates the condensation of ammonia, which is explained by the greater rapidity of binary nucleation.

Great interest attaches to the non-stationary jumps in condensation occurring in Laval nozzles, a phenomenon studied in detail by Deich et al.[157] and given a theoretical explanation[158,159]. The jump in density preceding the jump in condensation moves upstream into the subsonic zone, as a consequence of which the jump in condensation moves downstream, until the effect of the former jump on the flow parameters becomes negligible and jumps reappear at the previous sites. The frequency of the oscillations in the position of the condensation jump reaches 1 kHz. This phenomenon illustrates clearly the non-isothermal character of condensation in nozzles. A peculiar type of condensation with adiabatic cooling was predicted by Deich and Filippov[159] and investigated experimentally by Deich et al.[160]; it involved condensation by turbulent perturbation of a subsonic unary flow, in which the supersaturation was considerably less than the critical value.

A considerable number of studies with Laval nozzles were made on condensation in the presence of two condensable components. However, the thermodynamic properties of the components frequently differed so greatly that the start of condensation of the more volatile component was preceded by formation of large drops of the less volatile component. Hence the results relate to heterogeneous condensation rather than to homogeneous binary nucleation. The condensation of mercury is accelerated by the introduction of rubidium vapour and of nitrogen, as well as on the addition of argon[161]. The need to use higher values of σ to bring calculation into agreement with experiment gave rise to hypotheses[42–66] as to the structure of aqueous clusters, which should actually have possessed a surface tension greater than σ_0. In the Reviewers' opinion the divergence of theory from experiment has other explanations—non-isothermal and non-equilibrium conditions, decrease in γ with small nuclei, non-monotonic dependence of the free energy of formation of nuclei on their size.

Experiments[134] on the condensation of water vapour with turbulent mixing of flows at the same temperature gave a result analogous to those obtained by other methods: the rate of nucleation exceeds the theoretical value at low supersaturations, but is smaller at high separations. The same situation has been observed for the vapour of dibutyl phthalate.

Study of the rapid type of nucleation is still more complicated than that of the slow type, since in this case a relatively short period of nucleation is followed by coagulation, which begins when even the coarsest particles of the condensed phase do not exceed 100 molecules[13]. Because coagulating systems tend to "forget" their initial state, it is difficult to reach any quantitative conclusions on the process of nucleation. In such a case the only requirement of theory is a reasonable estimate of the lag in the early stages of the agglomeration of vapour molecules relative to systems in which avalanche condensation takes place with 100% collision efficiency.

Some idea of the character of rapid nucleation could be obtained from studies on the condensation of very dilute inorganic vapours and the mechanism of the formation of highly disperse uncoagulated aerosols[162–164]. It is well known that such aerosols of low number concentrations can be obtained when a gas flow passes over the heated surfaces of metals, their oxides, and their salts. Calculation shows that the critical nucleus is very small in such cases, most probably a dimer, whose condensation provides a typical example of the second type of nucleation. The aerosol obtained would be of coagulation origin: i.e. with short lifetimes of the condensing system the number concentration is high and the scatter of sizes large. The experimental observation of relatively monodisperse aerosols of low number concentration can be explained only by the heterogeneous origin of the particles. The problem remains as to why homogeneously formed particles are not observed in these experiments. The only possible explanation is the dependence of the efficiency of collisions of vapour molecules with clusters on the size of the latter, which has been discussed in Section IV. Computer experiments simulating agglomeration of a vapour involving such a dependence showed that the induction period in the formation of homogeneous particles may be sufficiently long for the vapour to condense on the walls before the appearance of particles formed by homogeneous condensation. Since the length of the induction period decreases with increase in the initial vapour concentration, it may be expected in some cases that particles may, nevertheless, be formed by condensation, but they will be significantly smaller than those resulting from heterogeneous condensation on impurity nuclei.

This prediction has been confirmed experimentally[16,163] for the vapours of silver, sodium chloride, and silver iodide. It is interesting that the difference in size between particles formed homogeneously and heterogeneously was quite large in the agglomeration both of monatomic and of diatomic molecules: i.e. formation of a dimer of a diatomic molecule also requires the participation of a third body. The possible dissipation of excess kinetic energy in an internal degree of freedom of the diatomic molecule is evidently insignificant.

The fact that formation and growth of the smallest clusters are possible only as a consequence of three-body collisions will explain the dependence of particle dispersion on experimental conditions. The decrease in particle size as the gas pressure falls in the diffusion of metal vapours through rarefied inert gases[16,131,165] can be attributed to the increasing rarity of three-body collisions and the attainment of the earlier stages of agglomeration. The increase in dispersity when argon is replaced by helium is explained similarly: the latter is less efficient as a third body, which also slows down agglomeration. The fact that from a certain point further decrease in gas pressure has no effect can be attributed to the coalescence of fine particles after their deposition on the walls.

Considerable understanding of the course of the early stages in the aggregation of molecules has been provided by experiments on high-intensity molecular beams. Miln et al.[166] compared the results of computer experiments simulating the kinetics of dimerisation in a fine supersonic jet of argon with the measured concentrations of dimers, and found that at sufficiently low temperatures the termolecular rate constant is similar in order of magnitude to that calculated for the three-body collision cross-section of solid spheres. However, the strong temperature dependence of the constant suggests that not all three-body collisions result in formation of the dimer. The dissociation constant of the dimers was estimated in this work by the method of Stogrin and Hirschfelder[90]. Golomb et al.[167] found $k_3 = 3\times10^{-33}T^{1/2}$ for the termolecular dimerisation constant of argon; the concentrations of dimers were 25–50% of the equilibrium values calculated according to Stogrin and Hirschfelder.

Concentrations of dimeric argon closely similar to those calculated by this method were observed by Milne[168]. The addition of nitrogen and argon to a jet of carbon dioxide has the opposite effect on the kinetics of the formation of clusters. His explanation was that the drop in temperature of the escape of nitrogen into a vacuum is slower than with argon, so that dimers of the latter are more effective as third bodies in the collisions of carbon dioxide molecules. The rate of formation of dimers in an argon beam was greatly diminished by additions of polyatomic molecules. Mixed clusters Ar_xH_2O and $Ar(H_2O)_x$ were detected. Henkes[169] established by mass-spectrometric analysis of products from the condensation of carbon vapour that the concentrations of clusters decrease non-monotonically with increase in their size. This can probably be attributed to a non-monotonic variation in the free energy of formation of clusters with their size.

Hagena and Obert[170] found that similarity was observed in the condensation of neon, argon, xenon, krypton, nitrogen, and carbon dioxide in a supersonic jet. In particular, mean cluster size remains constant with variation in the pressure preceding the nozzle, provided that the temperature in the nozzle varies simultaneously to maintain $p_0T_0^{\gamma(\gamma-1)}$ constant (where γ is the exponent of the adiabatic curve). Similarly, the particle size of the condensed phase remains constant with variation in nozzle diameter if p_0d^q remains constant, where q has the values 0.8 and 0.6 for argon and carbon dioxide respectively. Dimerisation in molecular beams of carbon dioxide takes place[171] only as a result of three-body collisions. The dependence of the concentrations of large clusters (beginning with the trimer) on the pressure in the source and the diameter of the nozzle shows that they may be formed by the combination of single molecules with smaller clusters without the involvement of third bodies. The efficiency of collisions of the monomer with $(CO_2)_x$, where $x = 2–4$, is ~0.03.[172]

It is interesting that Hill and Whitfield[173] observed chemiluminescence in the condensation of nitric oxide, which they attributed to oxidation of a molecule in a cluster to nitrogen dioxide and its detachment in an excited state followed by emission of a photon. The yield of photons is 20% of the number of $(NO)_x + O_2$ collisions. In the Reviewers' opinion this phenomenon indicates that the excitation of an individual molecule in a cluster does not lead to breakdown of the latter; it is of interest in connection with the possible disintegration of clusters on ionisation in the sources of the mass spectrometers normally used for the emission of molecular beams. Becker et al.[174] studied the reflection of nitrogen clusters from a stainless-steel surface. Dissociation of the clusters was not observed on reflection, and the intensity of the beam was almost independent of the temperature of the surface: i.e. the clusters did not absorb energy during the collisions. The beam had greatly narrowed on reflection, since the velocity of the clusters remained constant only parallel to the steel surface. The angles of incidence of the clusters lay in the range 50–75°, and the angles of reflection between 85° and 90° to the normal to the surface. These observations throw a somewhat unexpected light on the character of energy transfer in clusters.

From a study of the formation of a lead aerosol by the decomposition of tetramethyl-lead vapour in a shock tube at 920–960 K Graham and Homer[137] concluded that coagulation is the main factor determining the course of the particle-size distribution in this case. They were able to measure the aerosol coagulation constants, and showed that the decrease in particle concentration with time obeys a $t^{-6/5}$ law, which indicates establishment of a self-sustaining régime of coagulation.

Barschdorf[175] studied the condensation of water vapour in a shock tube in the presence of various carrier gases. He found that, with a mass fraction of the vapour of 0.1, the classic theory underestimates the rate of nucleation, depending on the nature of the carrier gas, by factors of 30–1000. At higher moisture contents the rate of smaller than the calculated value, and for the pure vapour theory overestimates *I* by factors of 10–100. The condensation of the vapours of chloroform and Freons in a shock tube was far more rapid than according to the classic theory.

Isothermal condensation of the vapours of several compounds—alcohols, n-alkanes, esters, and a number of acids—is well described by the classic theory based on the usual surface tension. The rate of nucleation is underestimated, but the discrepancy between theory and experiment can be eliminated by using values of the surface tension found by Band's method[36] from the equation of state of the vapour. For water, sulphuric acid, and certain other compounds theory predicts too low a rate of nucleation at low supersaturations, and too high a value at high supersaturations; no satisfactory explanation has yet been given for this divergence. Nevertheless, the condensation of water has been studied over a wide range of conditions, including non-isothermal conditions with water vapour escaping through a nozzle under various régimes. This permits the use for engineering calculations of formal expressions for the rate of nucleation with empirical corrections.

In the case of the rapid type of nucleation, with a sufficiently long lifetime of the condensing system $t > \theta^* \gg \theta$, the degree of dispersion and the concentration of the condensed phase can readily be calculated by means of known solutions of the coagulation equations, without the need to determine the bonding energy of small clusters or to obtain detailed information on the primary acts of condensation. Results obtained by several workers on these lines permit θ^* and θ to be estimated, and also indicate that θ^* never exceeds $\sim 10^4$. When $t < \theta^*$, the description of rapid condensation requires the above information, which has been successfully accumulated in work using molecular beams.

The theory of non-isothermal nucleation remains in an unsatisfactory position. Most real cases of condensation take place in multicomponent systems. Metastable states of such systems have been subjected to only most general examination[32]. No practical advances in the description of nucleation in multicomponent systems have been made since the early work of Reiss[176,177]. Some little experimental investigation has been made on nucleation in binary mixtures, but not at all in multicomponent systems. It is extremely desirable to develop experimental methods for direct examination of the properties of small clusters and of primary acts in condensation. The only technique used for the latter purpose—molecular beams of high intensity—deals with molecules whose state is far from equilibrium.

Great difficulties are presented by the study of chemical condensation, in which disperse particles arise from chemical reaction in the gas phase. For the present, qualitative and semi-quantitative data are being accumulated on the role of various factors in these complicated processes. The greatest progress has been made in connection with the formation of carbon black[178] and also of photochemical smog[179]. Sufficient attention has not yet been paid to the theoretical study of chemical condensation in other systems, especially in simplified model cases.

Progress in and Prospects for the Use of Heterocyclic Azo-compounds in Analytical Chemistry

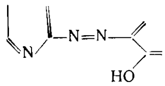
V.M.Ivanov

The effects of substituents in bases and coupling components on the properties of heterocyclic azo-compounds are examined in the pyridine, anabasine, thiazole, quinoline, and antipyrine series and their compounds with metal ions. Methods are indicated for varying the sensitivity of the reagents, the stability of the resulting complexes, and the selectivity of reactions with inorganic ions. Prospects for the use of heterocyclic azo-compounds in analytical chemistry are noted. A list of 199 references is included.

CONTENTS

I. INTRODUCTION

Heterocyclic azo-compounds include reagents containing the atomic grouping



The bases used are amines of nitrogenous heterocycles (pyridine, thiazole, benzothiazole, quinoline, pyrimidine, anabasine, antipyrine, and other derivatives), and the coupling components are aromatic hydroxy-compounds (phenol, resorcinol, naphthol, quinolinol, etc.). The number of papers on heterocyclic azo-compounds and their analytical applications increases annually, having reached around 150, 400, 700, and above 1100 by 1964, 1968, 1972, and the end of 1975 respectively. Such compounds are widely used as reagents for photometric and extraction–photometric determinations, as complexometric indicators, and as indicators in the determination of various anions by precipitation[1–4]. They form with many metal ions intensely coloured compounds, the complexing reactions exhibiting high contrast, which underlies many methods for determining inorganic ions by their use.

Most of the publications have been devoted to the practical application of heterocyclic azo-compounds in the analysis of naturally and industrially occurring substances, and very few studies have been concerned with elucidating the reasons for the great reactivity of these reagents, examining the effect of substituents on the properties of reagents and complexes, and other theoretical aspects.

The present Review deals only with the optical characteristics of the complexes, since, as noted above, the ability to form coloured complexes with metal ions underlies methods for determining the latter. Table 1 lists structural formulae and the abbreviations for the reagents adopted in the literature.

The following symbols are used in the Review: ϵ is the molar extinction coefficient, β the overall stability constant of the complex, K_{eq} the equilibrium constant of complex formation, K_{OH} the dissociation constant of the hydroxy-group *ortho* to the azo-group, K_{NH} the dissociation constant of the protonated heterocyclic nitrogen atom *ortho* to the azo-group, E the dielectric constant of the solution, and μ the ionic strength of the solution.

Table 1. Structural formulae and abbreviations for heterocyclic azo-compounds.

Coupling component	Base				
	 pyridine	 thiazole	 quinoline	 methylanabasine	 antipyrine
	1-PAN	1-TAN	1-(2-QAN)	1-MAN	1-ANAN
	2-PAN	2-TAN	2-(2-QAN)	2-MAN	2-ANAN
	*o*-PAC	*o*-TAC	–	–	–
	PAR	TAR	2-QAR	MAAR	ANAR
	PAAC	TAAC	2-QAAC	MAAC	ANAC
	–	–	–	MAAP I	–
	PAAP	TAAP	2-QAAP	MAAP II	ANAP

The value of photometric organic reagents is determined by the totality of properties of reagents and complexes—the sensitivity and selectivity of the reagent, the degree of contrast in the colour change of the solution on complex formation, the stability of the complexes formed—properties which will be surveyed below.

II. SENSITIVITY OF HETEROCYCLIC AZO-COMPOUNDS

The sensitivity of reagents in photometric analysis is expressed by the limiting dilution or the detectable minimum. Increasing use has been made during recent years of the molar extinction coefficient as the most objective characteristic of the sensitivity: from its value together with the sensitivity of the instrument, the minimum determinable optical density, the volume of the solution, and the thickness of the absorbing layer we can calculate the limiting dilution or the detectable minimum. The extinction coefficient ϵ is used in the present Review as a measure of the sensitivity of a reagent.

Role of Base

Azo-compounds derived from pyridine are usually the most sensitive. They are followed by anabasine, quinolin-2-amine, thiazole, and finally antipyrine derivatives. This rule is confirmed with reagents formed with resorcinol (Table 2), ethylamino-*p*-cresol, and *m*-diethylaminophenol, and is valid for the majority of ions. However, not only the nature of the heterocycle but also the position of the amino-group relative to the heterocyclic atom is significant. Reagents based on quinolin-2-amine are more sensitive than those based on quinoline-8-amine. Thus $10^{-4}\epsilon$ has the values 7.1 and 6.0 for the compounds of cobalt(II) with 2-QAAC and 8-QAAC respectively; the corresponding values for the gallium compounds are 9.8 and 7.4, and with 2- and 8-QAAT 10.5 and 7.7.[17,18] Derivatives of quinolin-2-amine are preferable to those of the 8-isomer also for copper and indium.

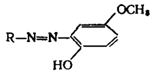
Table 2. Effect of base on sensitivity of determination of ions (resorcinol derivatives)*.

Reagent	$10^{-4}\epsilon$				
	Cu^{II}	Ga^{III}	In^{III}	Ni^{II}	Co^{II}
PAR	5.9[5]	9.9[6]	3.3[7]	7.3[8]	6.0[9]
TAR	3.1[10]	6.3[11]	2.3[12]	6.6[13]	5.6[9]
2-QAR	4.9[14]	4.7[14]	6.0[14]	5.5[14]	6.6[14]
MAAR	5.4[15]	—	3.8[16]	—	—

* Complexes having a dissociated *p*-hydroxy-group are compared.

The sensitivity of a reagent is little affected by increase in the number of heteroatoms in the base, provided that the latter does not contain fused rings. Indeed, reagents derived from pyridine and from thiazole are closely similar in sensitivity, although introduction of the new heteroatom (sulphur) may change the reactivity of the reagents and the mechanism of complex formation. The optical characteristics of the reagents change significantly. The introduction of fresh heteroatoms, e.g. nitrogen, has a substantial effect on the properties and the ionic form of the reagent, the absorption maxima and intensity, and the dissociation constants (Table 3). The properties of the complexes are also changed: for the copper compounds of TAMP, TRAMP, and TEAMP, for example, the light-absorption maxima occur respectively at 631, 578, and 578 nm, the logarithms of the stability constants are 9.8, 16.28, and 10.56, and the sensitivity ($10^{-4}\epsilon$) is practically the same (0.71 and 0.84 for the TRAMP and TEAMP compounds)[19].

Table 3. Effect of number of heterocylic nitrogen atoms on properties of reagents[19] (2 vol.% ethanol).



Reagent (R)	Form	λ_{max}, nm	$10^{-4}\epsilon$	pK_n
TAMP 	H_2R^+ HR R^-	523 468 561	1.4 1.2 1.4	—0.03±0.03 8.13±0.02
TRAMP 	H_3R^{2+} H_2R^+ HR R^-	470 432 520—550 494	0.6 0.5 0.5 1.1	—0.10±0.02 7.79±0.05 9.69±0.04
TEAMP 	H_3R^{2+} H_2R^+ HR R^-	468—480 460 422 503	1.4 5.3 5.4 9.2	—2.81±0.05 3.37±0.06 8.69±0.06

A similar rule is observed with the six-membered pyridine and pyrimidine heterocycles: thus the zinc(II), copper(II), and nickel(II) compounds of 2-pyrid-2′-ylazo-1-naphthol (1-PAN) have sensitivities ($10^{-4}\epsilon$) of respectively 2.5, 2.1, and 2.2,[20] while the corresponding 2-pyrimidin-2′-ylazo-1-naphthol (1-PAN) compounds have 2.5, 2.0, and 2.1.[21] The absorption maxima of the two series of complexes are slightly displaced (by 2–4 nm).

Hence the sensitivity of heterocyclic azo-compounds towards metal ions should be enhanced primarily not by changing the nature of the base but by a different procedure, e.g. by introducing substituents at certain positions. Monatomic substituents having a high Coulombic integral, e.g. chlorine or bromine, may have a significant influence on the sensitivity of reagents when located at position 5 in the pyridine ring[22–25]. Reagents containing bromine are usually more sensitive than those with chlorine at this position (Tables 4 and 5).

Table 4. Comparative sensitivity of 2-Pan and its halogenated derivatives.

Ион	2-PAN (Ref.26)		5′-Cl-PAN (Ref.26)		5′-Br-PAN (Ref.27)	
	λ_{max}, nm	$10^{-4}\epsilon$	λ_{max}, nm	$10^{-4}\epsilon$	λ_{max}, nm	$10^{-4}\epsilon$
Mn^{II}	562	4.8	566	7.2	574	7.2
Ni^{II}	570	5.0	580	7—8	582	8—9
Cu^{II}	564	4.4	567	5.8	572	5.2
Zn^{II}	550	5.6	569	7.1	570	6.7
Pd^{II}	678	1.9	670	0.8	695	1.8
Cd^{II}	555	4.9	560	7.0	568	7.3

The effect of a methyl group can be traced only on a few complexes. For example, the sensitivity of resorcinol reagents towards indium is enhanced by the introduction of methyl: values of $10^{-4}\epsilon$ for the compounds with PAR and 4′-6′-CH_3-PAR are respectively 3.3, 4.5, 3.9, and 4.3; the bromo-derivative is more sensitive (5.6 for 5′-Br-PAR)[7,14]. Towards copper(II), cobalt(II), nickel(II), zinc(II), and uranium(VI) PAR is more sensitive than its analogues containing methyl in the pyridine ring[43]: the sensitivity towards these ions diminishes in the sequence PAR > 4′-CH_3-PAR > 5′-CH_3-PAR > 6′-CH_3-PAR. Methylation of the pyridine or thiazole ring is evidently undesirable, since in most cases it lowers the sensitivity of the reagents (Table 6). The enhancement of sensitivity towards indium can be explained by the formation of compounds having the proportions M : R = 1 : 3 in the case of the methylated derivatives, but 1 : 1 compounds when indium reacts with PAR. The diminished sensitivity in the case of 3′-CH_3-PAR was attributed[43] to steric hindrance due to rotation of the hydroxy-group in the coupling component to the *trans*-position relative to the 3-substituent in the base. If this is true, any 3-substituent in the base, especially a bulky substituent, should diminish the sensitivity of the reagent. This rule applies to most ions (Table 7). Dibromo-derivatives are almost always less sensitive than the monobromo-derivatives, although in several cases more sensitive than the unbrominated reagents.

Table 5. Effect of halogenation of base on sensitivity of reagents.

Reagent	$10^{-4}\epsilon$					
	Co^{II}	Cu^{II}	Pd^{II}	Ga^{III}	In^{III}	Tl^{III}

A sulpho-group is usually introduced to increase the solubility of the reagent and of the complex. It has little effect on the sensitivity of the reagent or the degree of contrast of the reaction. For example, values of $10^{-4}\epsilon$ for compounds of palladium with TAR, TAR-5′-sulphonic acid, 2,4-dihydroxy-5-thiazol-2′-ylazobenzoic acid, and its 5′-sulpho-derivative are respectively 0.93, 0.93, 0.82, and 0.69.[59,60]

From the above effects of substituents it may be concluded that reagents based on 5-bromopyridin-2-amine should be the most sensitive.

Role of Coupling Component

It was shown[22,23] by a quantum-chemical method that substituents introduced *para* to the azo-group into the coupling component may change significantly the sensitivity of the reagents: the more polarisable the substituent, the more sensitive the reagent. The sensitivity should thus increase in the sequence of reagents containing the substituent

phenol < naphthol < resorcinol < ethylamino-*p*-cresol < diethylaminophenol

Naphthol derivatives are used most often, but the general rule is not observed with azonaphthols based on pyridine and anabasine. Among pyridylazonaphthols, for example, 1-PAN is more sensitive than is 2-PAN: the corresponding values of $10^{-4}\epsilon$ for the nickel(II) compounds are 2.2 and 1.9,[20] for cobalt(III) compounds 3.3 and 2.5,[27,31] cobalt(II) 3.9 and 3.0,[28,31] copper(II) 4.8 and 4.4,[27,61] zinc(II) 6.6 and 5.8,[62,63] and thallium(III) compounds 3.9 and 2.2.[30,63] With anabasine, 2-naphthol derivatives are the more sensitive: values of $10^{-4}\epsilon$ for the copper(II) compounds of 1-MAN and 2-MAN and respectively 2.2 and 3.0;[15] the corresponding values for the cobalt(II) compounds are 1.0 and 1.9.[65,66] The influence of the substitution in the coupling component on the sensitivity of the reagents is shown in Tables 8 and 9.

Resorcinol derivatives, able to form two types of complexes, occupy a special position. In acid medium the *para*-hydroxyl does not dissociate, and *protonated* complexes (MRH) are formed. The degree of contrast in the change in colour on complex formation is very great, especially with complexes of cobalt(II) and the platinum metals; the sensitivity of the reagents is close to that of azo-derivatives of phenol. In neutral medium the *para*-hydroxyl begins to dissociate, which is equivalent to introduction of an auxochrome into the reagent molecule. The complexes formed have been termed *normal* (MR), and are intensely coloured (Table 10); they are extracted only by polar solvents such as alcohols. The conversion of protonated into normal complexes is reversible and very rapid. The former may find application in analytical chemistry, despite the weakness of their colour. They are formed only by certain metal ions, and in acid medium, where interaction of these ions with heterocyclic azo-compounds is highly selective, the complexes are readily extracted by non-polar solvents. After selective extraction they can be re-extracted by a buffer solution as normal complexes having high molar extinction coefficients.

Table 10. Molar extinction coefficients of protonated and normal complexes (MRH and MR).

Reagent	Ion	$10^{-4}\epsilon$		Reagent	Ion	$10^{-4}\epsilon$	
		MRH	MR			MRH	MR

	Er^{III}(Ref.80)	1.6	4.1		Zn^{II}(Ref.10)	3.1	3.5

The effect of dissociation of the *para*-hydroxyl on the sensitivity of reagents has been demonstrated convincingly. If this group is methylated, the sensitivity of the reagents is greatly decreased, although the degree of contrast of the reaction is not appreciably affected (Table 11).

Table 11. Molar extinction coefficients of compounds with thiazolylazoresorcinol and its methyl ethers.

* Absorption maxima (nm) indicated in parentheses.

Both the coupling component and the base contain positions (e.g. 6) at which the sensitivity of the reagents is greatly diminished by substituents. Indeed, the reagent becomes much less sensitive, although the degree of constrast of the reactions changes just as greatly (Table 11). The marked decrease in sensitivity can be attributed to steric hindrance due to possible rotation of the *ortho*-hydroxyl to the *trans*-position with respect to the heterocyclic nitrogen atom. This also explains why *p*-cresol derivatives are the least sensitive reagents of all those listed in Table 8. The size of the substituent has different effects in azo-derivatives of pyridine and of thiazole, as is shown by Table 12 for compounds of uranium(VI) with PAR, TAR, and their derivatives[84].

Table 12.

Reagent	PAR	6′-CH_3-PAR	6′-C_2H_5-PAR	6′-C_3H_7-PAR	TAR	6′-CH_3-TAP	6′-C_2H_5-TAR
$10^{-4}\epsilon$	3.8	3.6	1.3	1.7	3.2	3.0	2.9

The introduction of substituents into bases and coupling components at positions giving rise to steric hindrance on complex formation produces a sharp decrease in the molar extinction coefficient. For compounds of cobalt(II) with PAR, 5′-Br-PAR, 4-(3,5-dibromopyrid-2-ylazo)resorcinol, 2,6-dibromo-4-pyrid-2′-ylazoresorcinol, and 2,6-dibromo-4-(3,5-dibromopyrid-2-ylazo)resorcinol, for example, values of $10^{-4}\epsilon$ are respectively 6.0, 5.6, 2.4, 5.2, and 3.0.[9]

*μ = 0.1; 50 vol.% CH_3OH.

Sulphonation of the coupling component has hardly any effect on the sensitivity of the reagents, but influences the acid–base properties of the ligands (Table 13). Reactions showing the greatest and smallest contrast are obtained with a sulpho-group at positions 8 and 4 respectively. The sharp increase in sensitivity of the sulphonic acids towards nickel was attributed[20, 21] to the formation of compounds having Ni : R = 1 : 2, whereas 1-PAN and 1-PIAN yield 1 : 1 compounds. The interesting rule was established[20] that the bathochromic shift on passing from the protonated form H_2R^+ to the completely dissociated R^- is proportional to the overall

$$H_2R^+ \rightleftarrows 2H^+ + R^-$$

dissociation constant for 1-PAN, 2-PAN, and the sulphonated derivatives. This rule probably applies to other reagents, as the Reviewer has established for 1-PIAN and its sulphonic acids—data taken from Ref. 21 (Fig. 1 and Table 14).

Extraction enables the sensitivity of the reagent to be improved by concentrating the element. Little attention has hitherto been paid to the influence of the dielectric constant of the solution, which can be varied by suitable choice of solvent and the use of solvent mixtures. With aqueous-organic and organic-solvent solutions the molar extinction coefficients can also be changed. For example, among the solvents studied—tetrachloromethane, chloroform, benzene, diethyl and di-isopropyl ethers, and 4-methylpentan-2-one—the sensitivity for the determination of zinc[85] and cadmium[86] by means of 5′-Cl-2-PAN is greatest in diethyl-ether solution ($10^{-4}\epsilon$ = 8.5 and 6.6 for the respective metals) and least in di-isopropyl ether (5.1 and 5.4). The degree of contrast of the reactions remains almost unchanged (Table 15).

An advantage of heterocyclic azo-compounds is the great contrast of the change in colour of the solution on complex formation. This is responsible for their widespread use as complexometric indicators. Reactions with such compounds based on cresol derivatives and the reactions of almost all the reagents with cobalt(III) and the platinum metals exhibit especially high degrees of contrast: the absorption of light by the reagents at the absorption maximum of the complex is almost zero, while this maximum for the complex is displaced 200 nm or more relative to the absorption maximum of the reagents under the same conditions.

Table 15. Molar extinction coefficients of cobalt(II) compounds of heterocyclic azo-compounds in various solvents[31].

Solvent	Absorption max. (nm) (and molar extinction coefficients, $10^{-4}\epsilon$) of Co^{II} complexes of the reagents				
	2-PAN	Cl-PAN	Br-PAN	TAN	Br-TAN
CCl_4	2.7 (500)	2.4 (535)	3.1 (540)	3.2 (550)	4.8 (570)
$CHCl_3$	3.0 (525)	3.1 (535)	4.1 (540)	3.3 (555)	4.7 (570)
C_6H_6	3.5 (530)	2.7 (535)	4.0 (540)	3.4 (550)	5.3 (570)
$(C_2H_5)_2O$	3.2 (520)	— —	4.4 (540)	3.3 (550)	4.2 (560)
n-$C_5H_{11}OH$	2 7 (520)	2.9 (535)	4.6 (540)	3.3 (550)	— —

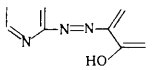
Table 16. Degrees of contrast of reactions of PAAC, PAAP, and their derivatives with metal ions.

Reagent	Ga^{III} (Reg.17)		Cu^{II} (Ref.24)		Nb^{V} (Ref.52)	
	Δλ, nm	ϵ_c/ϵ_r	Δλ, nm	ϵ_c/ϵ_r	Δλ, nm	ϵ_c/ϵ_r
PAAC	100	91.0	105	2.7	145	41
5-Br-PAAC	110	100.0	105	14.9	145	31
3,5-Di-Br-PAAC	115	94.5	105	4.9	140	20
PAAP	110	46.0	100	5.9	145	38
5-Br-PAAP	125	137.0	115	6.4	140	27
3,5-Di-Br-PAAP	120	52.0	110	7.3	145	17

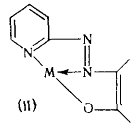
Improvement by monohalogenation of the analytical properties of the most promising reagents—PAAC and PAAP—increases the degree of contrast of complex formation as a consequence of a bathochromic shift; often the ratio of the molar extinction coefficients of complex and reagent ϵ_c/ϵ_r at the absorption maximum of the former becomes larger, the molar extinction coefficient of the compound with the monohalogenated reagent increasing considerably in comparison with the corresponding value of the unhalogenated reagent. Use of these reagents in photometric analysis is restricted by the poor sensitivity of azo-derivatives of *p*-cresol, despite the high degree of contrast of the reaction (Table 16).

III. STABILITY OF COMPLEX COMPOUNDS

Stability is an important characteristic of a complex compound, since the stability constants of the complexes and the acid dissociation constants of the ligands enable optimum conditions to be calculated for determining an inorganic ion and making its reaction with the chosen ligand as selective as possible. The stability of a complex compound depends on the denticity of the ligand, the basicity of the donor atoms in it, the acid-base properties of the functional group involved in complex formation, the coordination number and the ionic radius of the central ion, the number and size of the rings formed, the molar proportions in which the components interact, and other factors.



(I)



(II)

Most investigators regard heterocyclic azo-compounds as terdentate ligands. The atomic grouping (I) is involved in complex formation, and yields two rings (II) on interaction with one ligand. Of the two nitrogen atoms forming the azo-group that which is farther from the heteroatom of the base is the more reactive.

The multidenticity of heterocyclic azo-compounds as ligands explains that great stability of the complexes formed. Elimination of one of the atoms from the grouping (I) and its replacement by a carbon atom have marked effects on the stability of the complexes. For example, values of lg β_1 for the compounds of copper with PAR, 2-PAN, 4-phenylazoresorcinol (replacement of heterocyclic nitrogen atom by a carbon atom), *o*-pyrid-2ʹ-ylmethylenaminophenol (azo-group replaced by CH : N), *o*-pyrid-2ʹ-yliminomethylphenol (azo-group replaced by N : CH), and *NN*-dimethyl-4-pyrid-2ʹ-ylazoaniline (hydroxy-group eliminated from coupling component) are respectively 16.4, 16.0, 13.9, 13.8, 7.3, and 5.2.[2]

Basicity of Ligand

The basicity of the heterocycle decreases in the sequence of heterocyclic amines (values of pK_a given in parentheses) 2-aminoquinoline (7.34) > 2-aminopyridine (6.86) > 2-aminothiazole (5.39) > 2-aminobenzothiazole (4.51) > 8-aminoquinoline (3.99) > 2-aminopyrimidine (3.54).[87]

Table 17. Dissociation constants (pK_{OH}) of heterocyclic azo-compounds.

Reagent	Conditions	pK_{OH}	Ref.
4-Thiazol-2ʹ-ylazoresorcinol	2 vol.% C_2H_5OH, $\mu = 0.1$	9.44	10
3-Thiazol-2ʹ-ylazopyridine-2,6-diol	8 vol.% C_2H_5OH, $\mu = 0.1$	5.83	88
2-Quinol-2ʹ-ylazo-1-naphthol	50 vol.% dioxan	10.65	89
7-Quinol-2ʹ-ylazoquinolin-8-ol	$\mu = 0.1$	8.30	90
2-Benzothiazol-2ʹ-ylazo-1-naphthol	isopentanol	7.90	91
7-Benzothiazol-2ʹ-ylazoquinolin-8-ol	10 vol.% C_2H_5OH, $\mu = 0.01$	7.22	9[?92]
2-Pyrid-2ʹ-ylazo-1-naphthol	20 vol.% C_2H_5OH, $\mu = 0.5$	11.11	61
7-Pyrid-2ʹ-ylazoquinolin-8-ol	4 vol.% C_2H_5OH, $\mu = 0.4$	7.90	93

The introduction of a heterocyclic nitrogen or sulphur atom, having a lone pair of electrons not involved in the general chain of conjugation, is equivalent to introducing a strongly negative substituent such as a nitro-group. The acidic properties of such ligands should be intensified, and the stability of the resulting complexes diminished. If a heteroatom is introduced also into the coupling component, the acidity of the hydroxyl *ortho* to the azo-group is strengthened, and to a greater extent the closer is the heteroatom (resorcinol and pyridinediol, naphthalene and quinolinol azo-derivatives—Table 17).

Influence of Solvent

The widespread use of organic reagents in analytical chemistry poses the problem of studying the effect of solvents on the acid–base properties of ligands and the stability of complexes. If the reagent is present in protonated form (with the heteroatom protonated) in solution, its dissociation constant will increase with decrease in the dielectric constant of the solution; but if it is present in molecular or anionic form, it will become less acidic with decrease in the dielectric constant. This rule holds for 1-(2-QAN),[89] PAN and TAN,[94] PAR and TAR,[95] TAMR,[96] methyl 2-3ʹ,4ʹ-dihydroxyphenylazo-4-hydroxymethylthiazole-5-carboxylate[97], and 4-thiazole-2ʹ-ylazocatechol[98]. For PAN and TAN, independently of the nature of the solvent (dioxan, ethanol, acetone, dimethylformamide) at concentrations of 20–50 vol.%, a single equation can be deduced[94] relating the conventional dissociation constant of the reagent with the dielectric constant of the solution (Table 18).

Table 18.

for PAN $\mathrm{p}K_{NH} = 1.12 + 0.0175E - A\ (E = 35 - 75)$,
$\mathrm{p}K_{OH} = 14.07 - 0.0260E - A\ (E = 50 - 75)$;
for TAN $\mathrm{p}K_{NH} = 0.47 + 0.0235E - A\ (E = 45 - 70)$,
$\mathrm{p}K_{OH} = 10.43 - 0.0215E - A\ (E = 50 - 70)$,

where $A = \dfrac{\sqrt{\mu}}{1 + \sqrt{\mu}}\ (\mu = 0.1 - 0.5)$.

Table 19. Effect of dioxan on ionisation constants of 1(2-1-(2-QAN) and its copper and zinc complexes (μ = 0.1).[89]

Dioxan, vol.%	Reagent		Copper complex	Zinc complex	
	pK_{NH}	pK_{OH}	lg β_2	lg β_1	lg β_2
30	2.65	10.03	12.74	—	—
34	2.59	10.16	12.85	—	—
40	2.33	10.35	13.04	—	—
44	—	—	13.20	9.73	—
50	2.03	10.65	13.35	9.88	20.25
54	—	—	—	9.97	20.34
60	—	—	—	10.13	20.29

This rule must be taken into account when the selectivity of determination is to be enhanced. With decrease in dielectric constant of the solution the ligand should interact with the test ion in a more acid medium because of the more acidic properties of the protonated heteroatom, while the complex should become more stable as a result of the increased basicity of the hydroxy-group (Table 19).

Molar Ratio of Components and Scheme of Complex Formation

The example of a single ligand, 2-PAN, can be used to show the variety of types of complexes formed with ions of different metals[99]: MR_2^0 with manganese, cadmium, nickel, and uranium(VI); MR_2^+ with iron(III), yttrium, indium, and cobalt(III); MR^{2+} with gallium and thallium(III); MR^0 with vanadium(V); and MR^+ with palladium(II) and copper(II). Complexes having M : R = 1 : 2 are in all cases more stable than the 1 : 1 complexes: for zinc(II) lg β_1 = 12.3 and lg β_2 = 21.7, nickel(II) 14.0 and 27.5, manganese(II) 8.5 and 16.4,[100] and copper(II) 16.2 and 30.5.[101] Highly coordinated complexes are especially stable: for example, lg β_{1-4} for the europium(III) complexes with 2-PAN have the values 12.4, 23.8, 34.5, and 43.7; the corresponding values for the holmium(III) complexes are 12.7, 24.4, 34.8, and 44.1; and for the complexes of ytterbium(III) with 2-TAN 9.8, 19.3, 28.5, and 37.4.[101,102]

Table 20.

$H_3R^+ + Pt(II) \rightleftarrows PtRH + 2H^+$	PAR	pH 1.6—2.1
$PtRH \rightleftarrows PtR + H^+$	PAR	pH 3.9—4.5
$\begin{cases} HR + Pt(II) \rightleftarrows PtR + H^+ \\ H_2R^+ \rightleftarrows HR + H^+ \end{cases}$	PAN	pH 0.5—3.1
	5-Br-PAAP	pH 2.0—3.2
$H_2R^+ + Pt(II) \rightleftarrows PtR + 2H^+$	PAAC	pH 0.5—2.0
	PAAP	pH 0.2—1.6
	5-Br-PAAP	pH — 0.1—1.2

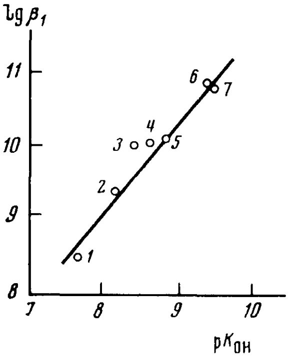


Figure 2. Effect of basicity of ligand[104] on stability of copper compounds[105] (1 : 1 complexes; spectrophotometric determination in presence of 20 vol.% of dioxan) of: 1) 4-chloro-2-thiazol-2′-ylazophenol; *2*) 4-methyl-2-4′-methylthiazol-2′-ylazophenol; *3*) 4-methoxy-2-thiazol-2′-ylazophenol; *4*) 4-methoxy-2-4′-methylthiazol-2′-ylazophenol; *5*) 4-methyl-2-thiazol-2′-ylazophenol; *6*) 2,4-dimethyl-6-4′-methylthiazol-2′-ylazophenol; *7*) 2,4-dimethyl-6-thiazol-2′-ylazophenol.

The diversity of the schemes of complex formation with azo-compounds of the pyridine series can be shown with platinum(II) as example (Table 20—charges on complexes omitted)[103]. These differences even in schemes involving related ligands must be considered in establishing the dependence of the stability of the complexes on the basicity of the ligand. Here we can examine a few cases of interaction and the corresponding types of correlation.

1. One complexing metal ion reacts with different related ligands by a single scheme of complex formation. In this case lg β can be plotted against lg K_{eq} and against pK_{OH} (Figs. 2 and 3). Departures from these relations often indicate incorrect determination of K_{eq} or pK_{OH}.

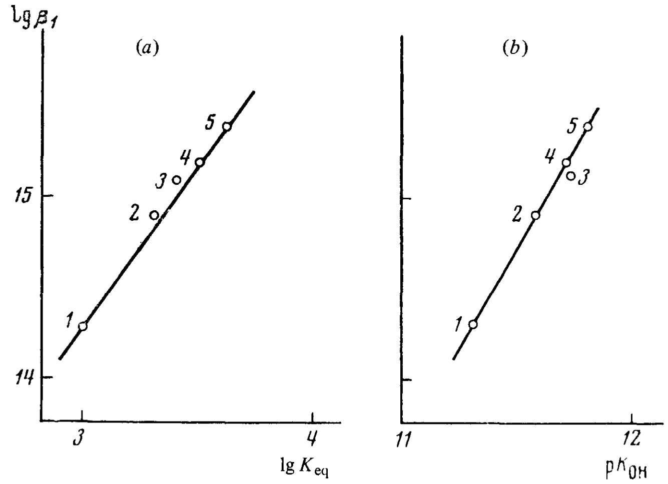

Figure 3. Effects of (*a*) complex-formation equilibrium constant and (*b*) basicity of ligand on stability of copper compounds of: *1*) 5-Cl-PAAC; *2*) 5-Br-PAAC; *3*) 5-Cl-PAAP; *4*) 1-PAN; *5*) 5-Cl-PAAP.[24]

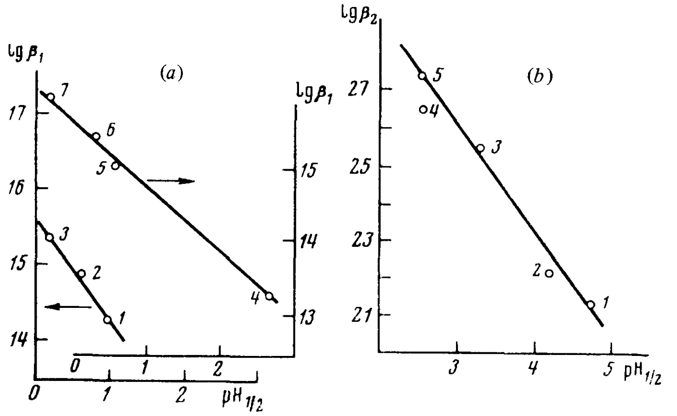

Figure 4. Effects of half-reaction pH on stability of: (*a*) copper compounds (1 : 1 complexes)[24] of: *1*) 5-Cl-PAAC; *2*) 5-Br-PAAC; *3*) 3,5-di-Br-PAAC; *4*) PAAP; *5*) 5-Cl-PAAP; *6*) 5-Br-PAAP; *7*) 3,5-di-Br-PAAP; (*b*) cobalt compounds (1 : 2 complexes)[9] of: *1*) PAR; *2*) 5-Br-PAR; *3*) 3,5-di-Br-PAR; *4*) tetrabromo-PAR; *5*) 2,6-dibromo-4-pyridylazoresorcinol.

A more universal relation is the dependence of lg β on pH$\frac{1}{2}$:

$$-n\,\mathrm{pH}_{1/2} = \lg K_p + n \lg C_R;$$

$$-n\,\mathrm{pH}_{1/2} = \lg \beta - n\,\mathrm{p}K_{OH} + n \lg C_R\ .$$

These results are plotted in Fig. 4 (for Cu : R = 1 : 1 and Co : R = 1 : 2) and were obtained on the assumption that the reagent concentration was 10^{-4}M. We can use these relations to estimate β from the experimental value of pH$\frac{1}{2}$ (by plotting the pH dependence of the optical density).

2. Several complexing metal ions react with a single ligand according to the same scheme. Here it is advisable to plot lg β against pH$\frac{1}{2}$ as in Figs. 4 and 5. For example, PAR is able to interact with metal ions according to several schemes, to form protonated and normal complexes (MRH and MR). For each scheme pH$\frac{1}{2}$ is calculated by means of the appropriate equation:

$$M + H_2R \rightleftarrows MRH + H^+,$$

$$-\mathrm{pH}_{1/2} = \lg \beta - \mathrm{p}K_{OH} + n \lg C_R;$$

$$M + H_2R \rightleftarrows MR + 2H^+ \text{ or } MRH \rightleftarrows MR + H^+,$$

$$-\mathrm{pH}_{1/2} = \lg \beta - \mathrm{p}K_{OH} - \mathrm{p}K_{p\text{-}OH} + n \lg C_R$$

where $\mathrm{p}K_{p\text{-}OH}$ is the logarithm of the reciprocal of the dissociation constant of the hydroxy-group *para* to the azo-group.

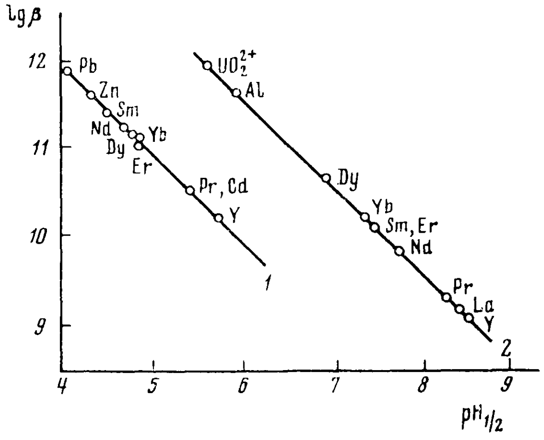

Figure 5. Stability sequences of PAR complexes: *1*) protonated (MRH); *2*) normal (MR). Constants for the rare-earth metal complexes taken from Ref. 80; that for uranium from Ref. 76; and those for lead, zinc, and cadmium from Ref. 17.

These relations enable us (*a*) to compare the stability of protonated and normal complexes of the same complexing agent, (*b*) to find lg β from the experimental value of pH$\frac{1}{2}$, (*c*) to construct a stability sequence of complexes of different complexing metals with the same ligand, and (*d*) to confirm a suggested scheme of complex formation by means of the values found for pH$\frac{1}{2}$ and lg β.

3. One complexing metal ion reacts with related ligands according to different schemes. No correlation of the above types is possible here: only the dependence of lg β on lg K_{eq} is applicable (Fig. 6). Exceptions are the normal complex with PAR of type MR formed at pH 3.9–4.5 and the complex with 5-Br-PAAP formed at pH 0.1–1.2 (protonated complex of type MRH). It is easy to explain these exceptions: investigation of complex formation between platinum(II) and PAR established[79] the effect of the acetate ion on the conditions of complex formation and on the properties of the complex, in particular the molar extinction coefficient ($10^{-4}\epsilon$ = 6.0). This suggests the formation of the mixed-ligand three-component compound platinum–acetate–PAR. All azo-derivatives of pyridine other than 5-Br-PAAP (at pH 0.1–1.2) react with platinum in weakly acid medium; the acidity ranges roughly coincide, which may indicate indirectly that the ionic state of the platinum is the same. The complex formed with 5-Br-PAAP in strongly acid medium probably contains platinum in a different ionic state from that occurring on interaction with other azo-derivatives of pyridine. Therefore the properties of the resulting complex differ markedly from those of complexes formed in weakly acid medium.

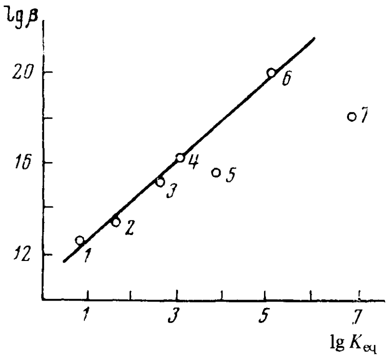

Figure 6. Effect of complex-formation equilibrium constants on stability of compounds of platinum(II) with pyridylazo-compounds[103]: *1*) 2-PAN; *2*) 5-Br-PAAP (ph < 2.0); *3*) PAAP; *4*) PAAC; *5*) PAR (ph < 4.5); *6*) PAR-(pH < 1.6); *7*) 5-Br-PAAP (pH ≃ 0).

Hence the scheme of complex formation can be confirmed by plotting lg β against lg K_{eq}.

4. Complexing metal ions adjacent in the Periodic System react with related ligands. If complex formation is described by a single scheme, correlations are present between the stability of complexes of two complexing metal ions as well as between the stabilities of complexes of two neighbouring metals in a series, and the basicity of the ligand (Figs. 7 and 8). Departure from the correlation usually indicates an incorrect value of the dissociation constant of the reagent for the actual conditions: it is necessary to compare constants determined by the same method.

Very large differences exist between the values given by different authors for the stability constants of the same complex, e.g. lg β = 9.8,[107] 17.93,[12] and 24.17[108] for compounds of PAR with thallium(III), and 10.0[107] and 14.5[6] for the gallium compounds. These differences are partly due to incorrect determination of the ratio of the components in the complex, the choice of scheme for complex formation, and the use of thermodynamic instead of conventional dissociation constants of the reagents, without taking into account the nature of the solvent and the dielectric constant of the medium.

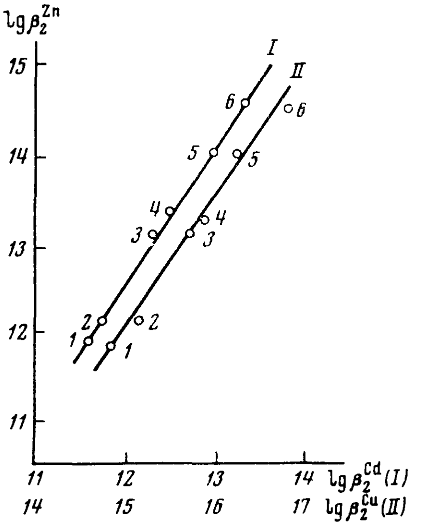

Figure 7. Relative stability constants (determined potentiometrically in 50% dioxan) of zinc, copper, and cadmium complexes[106] of compounds having the same type of ligands: *1*) 4-methyl-2-thiazol-2′-ylazophenol; *2*) 4-methoxy-2-thiazol-2′-ylazophenol; *3*) 2,4-dimethyl-6-thiazol-2′-ylazophenol; *4*) 4-methyl-2-(4,5,6,7-tetrahydrobenzothiazol-2-ylazo)phenol; *5*) 4-methoxy-2-4′-methylthiazol-2′-ylazophenol; *6*) 4-methoxy-2-(4,5,6,7-tetrahydrobenzothiazol-2-ylazo)phenol.

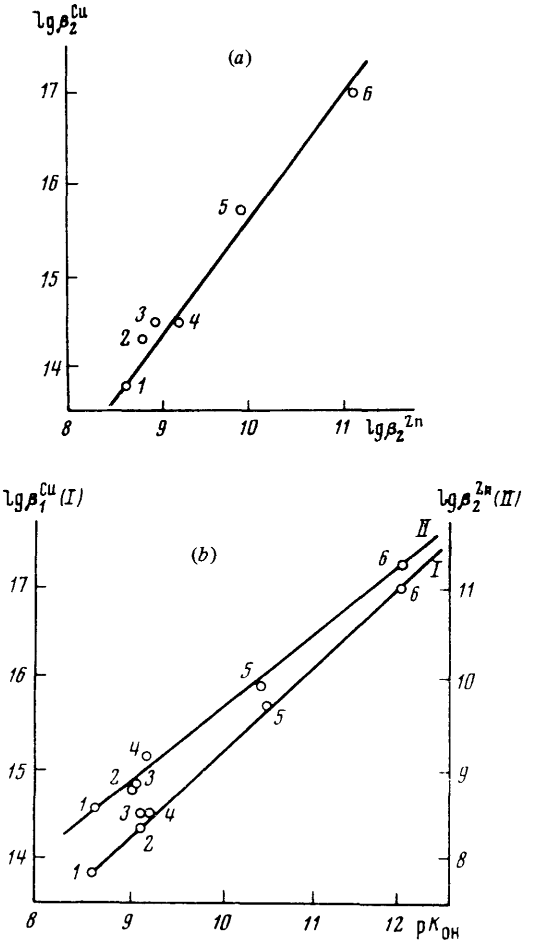

Figure 8. (*a*) Correlation of stability constants and (*b*) effect of basicity of ligands on stability of copper and zinc compounds[20] of: *1*) 1-PAN; *2*) 1-PAN-5-SO_3H; *3*) 1-PAN-7-SO_3H; *4*) 1-PAN-6-SO_3H; *5*) 1-PAN-8-SO_3H; *6*) 2-PAN.

Table 21. Methods of enhancing selectivity of reactions of heterocyclic azo-compounds with metal ions.

Method	Metals
Determination in acid medium	Cu[109], In[110], V[111], Sb[112,113], Pd[114]
Difference in rates of formation	Co, Cr[44,115,116], Pd, Rh[117], Pt[118]
Use of masking	Cu[64], Zn, Cd[119], Ga[120], In[110], Gd[121] lanthanide [122] U[123,124]
Coprecipitation of test elements	Co[9,125]
Electrodeposition of interfering elements	Sm[126], Ti, Nb[127], V[128]
Extraction of test ion	Cu[129], Zn[62], Ga[130], In[110], Nb[131]
Extraction of interfering elements	Zn[132], Nb[133], U[124], Mn[134, 135], Ni[136]
Re-extraction of test or interfering elements	Zr[137], Sn[138], V[139], Nb[140], Co, Ni[141]
Chromatographic separation	Mn[142], Co[143, 144], Ni[145]
Difference in absorption spectra	Fe[146], Ru, Os[147], Rh, Ir[148]

IV. SELECTIVITY OF HETEROCYCLIC AZO-COMPOUNDS

Heterocyclic azo-compounds are very widely used for the photometric and the extraction–photometric determination of ions of almost all metals, other than alkali and alkaline-earth metals, in naturally occurring and artificially produced materials. This is promoted by the high sensitivity of the reagents and the selectivity of their reaction with a series of ions. Several methods are available for enhancing the selectivity of reactions with organic ligands, some of which have been achieved with heterocyclic azo-compounds (Table 21).

The wide range of ions with which heterocyclic azo-compounds react and the possibility of the extraction of complexes combined with spectral analysis have permitted the determinations e.g. of copper, cobalt, cadmium, gallium, iron, indium, manganese, nickel, thallium, and vanadium in alkali-metal bromates and iodates (at concentrations of $7 \times (10^{-7}-10^{-5})$ mass %).[149] After being concentrated by extraction, many elements can probably be determined in a single aliquot by atomic absorption or polarographic methods. The specificity of heterocyclic azo-compounds can usefully be exploited in activation analysis.

V. PROSPECTS FOR STUDY AND USE IN ANALYTICAL CHEMISTRY

Extraction

This procedure may prove very useful for enhancing sensitivity, improving the selectivity of determination, and the study of complex formation. Although reagents are often employed for extraction-photometric determination, the extraction of complexes of heterocyclic azo-compounds has not been adequately characterised. Several studies have recently been published on rates of extraction[150–152] and on the effect of various solvents on the distribution of reagents between organic and aqueous phases[101,151,152]. The rules thus found can be used to raise the selectivity of reagents.

Mixed-ligand Compounds

The introduction of two ligands into the coordination sphere of a complex will often improve the sensitivity and the selectivity of reagents. Mixed-ligand (mixed) complexes of heterocyclic azo-compounds are beginning to be investigated intensively. Some examples of mixed complexes are listed in Table 22.

Table 22. Mixed-ligand complexes of heterocyclic azo-compounds.

Complexing metal	Heterocyclic azo-cpd..	Second ligand
Al^{III}	PAR	antipyrine[154]
Ga^{III}	PAR	antipyrine[155]
In^{III}	PAR	antipyrine[154]
	PAN	acetate, chloride[152]
Ti^{IV}	PAR	H_2O_2[156], SCN[157], acetate[158], catechol[159], salicylic and 5-sulphosalicylic acids[160]
	PAN	H_2O_2[161]
V^V	PAR	H_2O_2[111, 162], tetraphenylarsonium, tetraphenylphosphonium[163], diantipyrylmethane[164], quinine[165]
Nb^V	PAR	H_2O_2[166], oxalate, tartrate[50, 52]
	PAN	H_2O_2[161]
Ta^V	PAR, PAN	H_2O_2[161, 166]
Mo^{VI}	PAR,TAR	hydroxylamine[167, 168]
Fe^{II}	PAR	hydroxylamine[169]
Co^{III}	PAR	quaternary ammonium bases[169]

Preparation of New Reagents

Besides the above heterocylic amines, derivatives of pyrrole[170], imidazole[171], antipyrine[172], triazole[19], tetrazole[173,174], and thiadiazole[175] have been used as bases, and bisazo-compounds have been prepared[173,174,176–178]. However, azo-derivatives of pyridine have hitherto been the most promising. The synthesis has begun of compounds containing as coupling components reagents that are themselves widely used in analytical chemistry, e.g. azo-derivatives of rhodanine[179–184], catechol[92,97,185–187], and chromotropic acid. The reagents possess several advantages in comparison with these compounds: stepwise complex formation is absent, the stability of the complexes is increased, and maximum absorption by the complexes takes place at longer wavelengths. This method is evidently most useful in the synthesis of new reagents.

Research Methods

Extraction has begun to be used as well as the widely employed photometric and potentiometric methods. The characteristics of the complex compounds are obtained by computer methods according to suggested programmes[96,171,188–190]; the advantages of such methods have been demonstrated many times. The structures of complex compounds and reactive forms of reagents are established by quantum-chemical calculations[22,23,191,192], nuclear magnetic resonance[193], determination of magnetic and dipole moments of the complexes[194,195], and by study of the infrared spectra[50,52,193,196–199].

* * *

Heterocyclic azo-compounds are widely used as reagents for the photometric determination of elements and as complexometric indicators. The most sensitive are azo-derivatives of pyridine and 2-aminoquinoline, which form stable compounds with metal ions. A hydroxy-, amino-, or dialkylamino-group can usefully be introduced into the coupling component *para* to the azo-group to improve the properties of the reagents. A halogen—chloro or bromo—must be substituted *para* to the azo-group in the pyridine base. Promising complexometric indicators are thiazolylazo-compounds, which form intensely coloured and moderately stable compounds with metal ions. The solubility of these reagents can be increased by sulphonating the coupling component and the base. Reagents containing heterocyclic nitrogen in the coupling component—quinolinol, 2,6-dihydroxypyridine, etc. — should be valuable for the determination of readily hydrolysed ions of multivalent metals. Promising uses of extraction are the investigation of complex formation and the concentration of groups with the aim of subsequent polarographic, spectral, or atomic-absorption determination.

Silicon-containing Derivatives of Carbamic Acid—Silylurethanes

V.D.Sheludyakov, V.P.Kozyukov, and V.F.Mironov

Methods of synthesis, properties, and likely applications of silicon-containing derivatives of carbamic acid—silylurethanes—are discussed for the first time. Together with monomeric compounds, oligomeric and polymeric products as well as various compositions based on them, containing silicon and urethane groups, are considered. The review includes studies which have been published up to the middle of 1975.

The bibliography consists of 527 references.

CONTENTS

I. INTRODUCTION

The chemistry of silyl derivatives of carbonic acid, i.e. of organosilicon carbonates, chloroformates, isocyanates, ureas, urethanes, carbodiimides, etc. began to develop only in the last decade in connection with the suggested applications of such compounds.

The present review completes a series of surveys of new organosilicon materials[1-10] and is closely related to the previous surveys devoted to silyl derivatives of carbonic acid-organosilicon isocyanates[11] and ureas[12].

In terms of structural features, silyl derivatives of carbamic acid can be divided into three main types. In the first type of silylurethanes, the so called *O*-silylurethanes, we include compounds with the structural element $\equiv Si-O-C(O)-N=$. The second type incorporates *N*-silylurethanes, characterised by the fragment $\equiv Si-\overset{|}{N}-C(O)-O-$. Finally, we have silicon-containing urethanes with a carbon-based functional group in which the carbamic acid group is linked to the silicon atom via a hydrocarbon bridge. In the last case it is useful to introduce a subdivision of the silylurethanes into independent groups containing the bond sequences $\equiv Si-R-O-C(O)-N=$ and $\equiv Si-R-\overset{|}{N}-C(O)-$. Very many examples of each of these groups are now known.

II. COMPOUNDS WITH THE URETHANE GROUP AT THE SILICON ATOM

There are 12 theoretically possible structures of this type:

$R_3SiOC(O)NH_2$ (I); $R_3SiOC(O)NHSiR_3$ (II); $R_3SiOC(O)N(SiR_3)_2$ (III);
$R_3SiOC(O)NHR$ (IV); $R_3SiOC(O)N(R)SiR_3$ (V); $R_3SiOC(O)NR_2$ (VI)
$R_3SiNHC(O)OH$ (VII) $R_3SiN(R)C(O)OH$ (VIII) $(R_3Si)_2NC(O)OH$ (IX)
$R_3SiNHC(O)OR$ (X) $R_3SiN(R)C(O)OR$ (XI) $(R_2Si)_2NC(O)OR$ (XII)

but only nine are actually known: (I)-(VI) and (X)-(XII). Incidentally, the carbamic acids (VII)-(IX) can hardly exist in a free state, since, owing to the ease of the silyl-proton exchange, they must be immediately converted into the *O*-silyl derivatives (I)-(VII).

1. METHOD OF SYNTHESIS

N-Silylurethanes

N-Monosilyl-substituted carbamic acid esters were obtained for the first time in 1959[13,14] by the silylation reaction

$$Q{-}NHSiMe_3 + ROC(O)NH_2 \rightarrow ROC(O)NHSiMe_3 + Q{-}NH_2;$$
$$Q{=}Alk,\ Ar,\ AlkC(O),\ ArC(O).$$

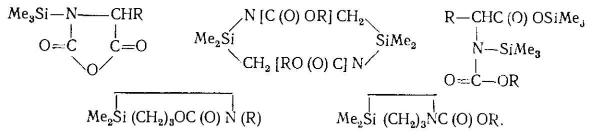
The silylation of the urethane $EtOC(O)NH_2$ by chlorotriorganylsilanes in the absence of acceptors for the HCl released apparently does not occur and the authors claim concerning the possibility of the conversion of the resulting *N*-silylurethanes with boiling water or alkali into the water-soluble acids $R_3SiNHC(O)OH$ is clearly erroneous, since no account is taken of the susceptibility of the N–Si bond to hydrolysis and the instability of free carbamic acid[15].

The interaction of urethane with $SiCl_4$ leads to the formation of the complex $SiCl_4.6CO(NH_2)_2$ (Wannagat et al.[16]), tentatively via the following mechanism:

$$2\,EtOC(O)NH_2 \rightarrow NH_2C(O)NH_2 + CO(OEt)_2;$$
$$SiCl_4 + 6CO(NH_2)_2 \rightarrow SiCl_4 \cdot 6\,CO(NH_2)_2;$$
$$SiCl_4 + 4CO(OEt)_2 \rightarrow Si(OEt)_4 + 4\,EtCl + CO_2.$$

Subsequently, when Me_3SiCl or $Me_3SiCl/HN(SiMe_3)_2$ were used as the silylating systems in the presence of organic bases and the reaction was carried out in aprotic organic solvents, *N*-silylurethanes became readily available. Numerous *N*-silyl derivatives of both linear and cyclic urethanes were obtained by this procedure[17-34]:

$R_3Si(CH_2)_nN(SiMe_3)C(O)OR$ $(R_3Si)_2NC(O)OR;$



The expected urethane could not be isolated after the reaction between Ph_3SiCl and $NaNHC(O)OEt$, since its β-decomposition resulted in the formation of Ph_3SiNCO in 48% yield[35]:

$$Ph_3SiNHC(O)OEt \rightarrow Ph_3SiNCO + EtOH.$$

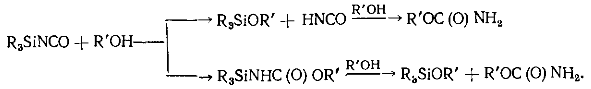
N-Silylurethanes have been synthesised in high yields by the reactions of alkylbis(trimethylsilyl)amines and alkyl chloroformates[27]:

$$RN(SiMe_3)_2 + ROC(O)Cl \rightarrow RN(SiMe_3)C(O)OR.$$

The reaction of chloroformates with hexamethyldisilazane (HMDS) and $R'NHSiR_3$, which proceeds preferentially via the Si–N bond rather than N–H, is of limited importance[36,37]:

$$(Me_3Si)_2NH + ROC(O)Cl \rightarrow Me_3SiNHC(O)OR + Me_3SiCl$$
$$R'NHSiMe_3 + ROC(O)Cl \rightarrow R'NHC(O)OR + Me_3SiCl.$$

The attempt to synthesise *N*-silylurethanes via the reactions of isocyanatosilanes with alcohols[11,26,35–44] and silanols[45–51] was unsuccessful owing to the ease of the alcoholysis of the N–Si bond and the inertness of silanols. The reaction with alcohols can be represented by the following mechanisms of which the second is to be preferred:



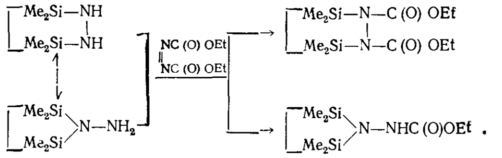
$$R_3SiNCO + R'OH \rightarrow R_3SiOR' + HNCO \xrightarrow{R'OH} R'OC(O)NH_2$$
$$R_3SiNCO + R'OH \rightarrow R_3SiNHC(O)OR' \xrightarrow{R'OH} R_3SiOR' + R'OC(O)NH_2.$$

An increase in the size and branching of the groups in both the silane and the alcohol leads to a fall of the rate of alcoholysis[35,39] and Ph_3SiNCO does not change at all in boiling benzene in the presence of alcohol[35].

N-silyl-substituted esters of carbazic acids, which have been obtained from mercury-containing reagents[52–54], constitute a group of *N*-silylurethanes having the same structure:

$$EtOC(O){-}N{=}N{-}C(O)OEt + (Me_3Si)(Me_3M)Hg \xrightarrow[M=Si,\,Ge]{-10^\circ} EtO{-}C(O){-}N(SiMe_3){-}N(MMe_3){-}C(O){-}OEt \quad (95\%).$$

They have also been obtained on the basis of equilibrium mixtures of tautomeric froms of disilyl-substituted hydrazines[55], for example:



Silylurethanes of the type $ROC(O)N(SiR'_3)_2$ are not formed by the above reactions. They have been synthesised by the reaction of $NaN(SiMe_3)_2$ with alkyl chloroformates[56] and, by analogy with bis(trimethylsilyl)amides of carboxylic acid, the imide structure (XIII) has been attributed to them:

$$ROC(O)Cl \xrightarrow[-NaCl]{NaN(SiMe_3)_2} ROC(O)N(SiMe_3)_2 \longleftrightarrow \underset{(XIII)}{ROC(=NSiMe_3)OSiMe_3}.$$

When these compounds were hydrolysed with an equimolar amount of water, *N*-monosilylurethanes were obtained:

$$2ROC(=NSiMe_3)OSiMe_3 \xrightarrow{H_2O} 2ROC(O)NHSiMe_3 + Me_3SiOSiMe_3.$$

O-Silylurethanes

The principal method for the synthesis of these compounds is carboxylation of aminosilanes[57–75]:

$$(R'R''N)_nSiR'''_{4-n} \xrightarrow[n=1\div4]{n\,CO_2} [R'R''NC(O)O{-}]_nSiR'''_{4-n};$$
$$R', R''=H, Alk, AlkO, Ar;\ R'''=Alk, Ar,$$

which proceeds via an ionic-chain mechanism[62,63,70–73] and as a rule leads to the formation of the desired product in quantitative yield.

Compounds with a reduced basicity constitute exceptions to the general series of aminosilanes[60,61,69,73,76,77]: $MeN(SiH_3)_2$, $HN(SiMe_3)_2$†, $AlkN(SiMe_3)_2$, $AlkN(SiMe_2H)_2$, $PhNHSiMe_3$, $MeC(O)NHSiMe_3$, and $MeC(O)N(SiMe_3)_2$. Incidentally under severe conditions the following reaction takes place[69]:

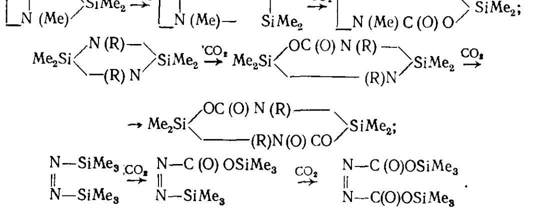
$$RN(SiMe_3)_2 \xrightarrow[500^\circ]{CO_2} [R{-}N(SiMe_3)C(O)OSiMe_3] \rightarrow RNCO + (Me_3Si)_2O.$$

However, when a mixture of a weakly basic amine and the silylating agent is carboxylated, it is nevertheless possible to obtain the corresponding *O*-silylurethanes, since in this case the species silylated is the intermediate carbamic acid in which the hydrogen atom is dissociated to an incomparably greater extent[73]. For example:

$$PhNH_2 + CO_2 \rightarrow PhNHC(O)OH \xrightarrow{H-N(SiMe_3)_2} PhNHC(O)OSiMe_3.$$

Urethanes are then formed rapidly and in high yields.

In many instances carboxylation of compounds with several Si–N bonds proceeds in steps and leads to adducts with both one and two CO_2 molecules[66,74,78–80]:



Aminoacids containing silicon-substituted carbamic acid groups are obtained with the aid of a wide variety of silylating agents[20,81–87]: Me_3SiCl/NEt_3, $HN(SiMe_3)_2$, organosilylcarbonates, etc. For example:

$$\text{L-tyrosine} + Me_3SiOC(O)OSiEt_3 \xrightarrow{\sim100^\circ} 4\text{-}Me_3SiOC_6H_4CH_2CH(COOSiMe_3)N(SiMe_3)C(O)OSiMe_3.$$

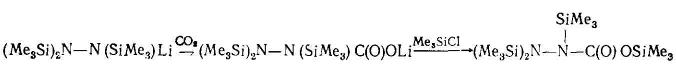
O-Silylurethanes can also be obtained by the silylation of carbamic acids or their salts by the usual procedures[34,64,66,85,87]:

$$R_2NC(O)OH + Me_3SiCl + R_3N \rightarrow R_2NC(O)OSiMe_3 + R_3N \cdot HCl;$$
$$H_2NC(O)ONH_4 + Me_3SiCl \rightarrow H_2NC(O)OSiMe_3 + Me_3SiNHC(O)OSiMe_3.$$

We believe that the reaction of silylated alkali metal amides with CO_2 followed by the reaction of the intermediate sodium salts, for example of *NO*-disilylated carbamic acids, with chlorosilanes[88–93] may become a convenient method for the synthesis of such compounds:

$$(Me_3Si)_2NNa \xrightarrow{CO_2} (Me_3Si)_2NC(O)ONa \xrightarrow{Me_3SiCl} (Me_3Si)_2NC(O)OSiMe_3.$$

This view is supported by the successful reaction with the lithium salt of carbazic acid[66]:



$$(Me_3Si)_2N{-}N(SiMe_3)Li \xrightarrow{CO_2} (Me_3Si)_2N{-}N(SiMe_3)C(O)OLi \xrightarrow{Me_3SiCl} (Me_3Si)_2N{-}N(SiMe_3){-}C(O)OSiMe_3$$

In order to obtain *O*silylurethanes, the interaction of silanols with organic and organosilicon isocyanates has been investigated and it has been shown that Ph_3SiOH and $Ph_2Si(OH)_2$ do not interact with Me_3SiNCO owing to steric hindrance and the reduced nucleophilic properties of the nitrogen atom in isocyanatosilane[49,94]. On the other hand, it has been established that $Me_3Si(NCO)_2$ acts on $Ph_2Si(OH)_2$ as a dehydrating agent. The reaction of monofunctional

---

† It has been stated[64] that $Me_3SiNHC(O)OSiMe_3$ is formed in a negligible yield on carboxylation of HMDS in tetrahydrofuran.

organic isocyanates with silanediols and oligosiloxanes containing terminal hydroxyls proceeds similarly[49,94-98].

Even if organosilicon polyurethanes $[-OSiR_2OC(O)NHR'NHC(O)-]_n$ (OSPU) are formed in the polycondensation of dialkylsilanediols and polyalkylsiloxanediols with hexamethylene and tolylene diisocyanates, oligourethanes with terminal isocyanato-groups, and other similar prepolymers, their yields are insignificant[51,99-106] and the reaction results mainly in the evolution of CO_2 and water and the formation of organic polyureas and polysiloxanes‡ :

$$HOSiR_2OH + OCN-R'-NCO \rightarrow [-NHC(O)NHR'-]_n + -[-SiR_2O]_n + CO_2.$$

It has been suggested that the reaction of $\equiv SiOH$ groups with PhNCO be used for the quantitative determination of OH groups in polyorganylsiloxanes[105]. Subsequently it proved possible to find conditions in which *O*-silylurethanes can be obtained from aromatic diisocyanates and trialkylsilanols[107-109]:

$$R_3SiOH + Q(NCO)_2 \rightarrow Q[NHC(O)OSiR_3]_2.$$

In this connection one should note that, since the reaction of silanols with isocyanates was carried out in most cases at high temperatures or in the presence of aluminium chloride[46,47,51,97,98,104-106,111-128], this may have been the reason why the reactions did not yield the corresponding polyurethanes, their decomposition products being formed instead: CO_2, H_2O, and mixtures of organic and organosilicon high-molecular-weight compounds. However, since such materials possess properties of practical value, some of them will be considered in Section V.

In conclusion we may note that the study of the sorption of BuNCO[129,130] and PhNCO[131] vapours by aerosil showed that two processes occur: physical sorption and chemisorption. The former is due to the hydrogen bonds formed between the isocyanate and the free silanol groups of the adsorbent, which probably creates conditions for the occurrence of a chemical reaction between the isocyanates and the hydroxy-groups with formation of urethane groups.

2. PHYSICAL PROPERTIES OF *N*- AND *O*-SILYL URETHANES

O-Silylurethanes

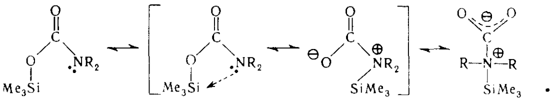
Urethanes of this type are high-boiling liquids or white crystalline, sometimes wax-like, substances which are more readily soluble in aprotic organic solvents[26,32,52,63-66,69,76,77,107-109,114]. Thixotropic properties are characteristic of organosilyltriscarbamates[58].

The combination of infrared, ultraviolet, and ^1H, ^{15}N, and ^{29}Si NMR data has shown that the N–Me groups in $Me_2NC(O)OSiH_3$ are equivalent, which is caused either by the rapid migration of the silyl group between the neighbouring oxygen atoms or by the ease of rotation about the C–N bond in consequence of its weak double bond character[60-62,76].

However, it was subsequently shown that trimethylsilyl esters of carbamic, thiocarbamic, and dithiocarbamic acids are characterised by different amounts of double bond character of the C–N linkage. For example, the study of the effect of the hindered internal rotation about the C–N bond in compounds described by the general formula $Me_3Si-Y-C(=X)-NR_2$, where X, Y = O, O, or S, S and R = Me or Et showed that it depends on temperature[132,133]. The experimental effective lifetimes of the rotational isomers made it possible to determine the activation energy and the free energy for the intramolecular rotation process and to compare them with the types of substituents surrounding the carbamic acid groups.

The infrared spectra of *O*-silylurethanes with an exocyclic carbamic acid group are characterised by absorption bands at 1020–1080, 1665–1690, and 3340–3350 cm^{-1}, which are due to the stretching vibrations of the Si–O–C, C=O, and N–H linkages[26,56,60-62,64,73,76,77]. One must note that the intensity of the Si–OC absorption band is very low.

We believe that the moderate solubility of *O*-silylurethanes, their high boiling and melting points despite their comparatively low molecular weights, the degenerate nature of the Si–O–C absorption band, and the specific features of the ^1H NMR spectra discussed above can be accounted for by their existence in equilibrium with the ylid form (XIVd):



(XIVa) (XIVb) (XIVc) (XIVd)

Under electron impact conditions, the molecules of the *O*-silylurethanes $Me_3SiOC(O)NH_2$ and $Me_3SiOC(O)NHSiMe_3$ each lose an electron and their mass spectra are characterised by molecular ion peaks[64].

N-Silylurethanes

Compounds of the type $R'N(SiR''_3)C(O)OR'''$, where R′ = Me, Bz§, α-naphthyl, or $N(SiMe_3)_2$, R″ = Me or Et, and R‴ = Me, Et, or Ph are mobile liquids or low-melting crystalline solids, readily soluble in the majority of the usual aprotic organic solvents[23,26,36,66], with the exception of n-hexane, petroleum ether, and carbon tetrachloride[26,36]. Their infrared spectra agree well with the amide structure[26,36]. The molar refractions of *N*-silylurethanes correspond rigorously to the theoretical values[26].

NO-Disilylurethanes

Disilyl-substituted urethanes and carboxylic acid amides are very close analogues. The non-equivalence of the Me_3Si protons in the ^1H NMR spectra at low temperatures is characteristic of the latter compounds, disappearing when the temperature is raised to a particular value in each specific case. On this basis and also on the basis of infrared spectroscopic data and certain chemical reactions, the structure of *N*-trimethylsilyl-*O*-trimethylsilyliminoesters (XVb) with rapid intramolecular two-centre exchange of the partially ionically bound Me_3Si groups between the N and O atoms in (XVb) at elevated temperatures, rather than the structure of *NN*-bis(trimethylsilyl)acylamides (XVa), was attributed to these compounds[56,134-138].

$$\underset{(XVa)}{R-C(O)N(SiMe_3)_2} \rightleftarrows \underset{(XVb)}{R-C(=NSiMe_3)OSiMe_3}\ .$$

Depending on the nature of the substituents linked to the silylamide group, the rate of migration of the Me_3Si group varies, which many investigators[134,138] believe to be a manifestation of the different degrees of hindrance of the

---

§ Bz = benzyl.

intramolecular rotation about the C–N bond. On passing from the disilyl amides $RC(=NSiMe_3)OSiMe_3$ to the disilylurethanes $ROC(=NSiMe_3)OSiMe_3$, the rate of exchange of the silyl groups increases and remains high even at low temperatures[56], while the $SiMe_3$ group is revealed by a singlet in the ^1H NMR spectrum.

3. CHEMICAL PROPERTIES OF *N*- AND *O*-SILYLURETHANES

O-Silylurethanes

O-Silylurethanes monoalkyl(aryl)-substituted at the nitrogen atom are extremely sensitive to hydrolysis, which proceeds via the formation of unstable carbamic acids, decomposing into CO_2 and amines[57–59,65,70,72,106–109].

The reactions with alcohols lead to the formation of CO_2, amines, and orthosilicate esters[108]. The authors suggest that hydrolysis (initially by traces of water in the alcohol), leading to the formation of trialkylsilanols, amines, and CO_2, takes place in the first stage. The trialkylsilanols then react with alcohols to form the corresponding orthosilicate esters and water[108]. However, we believe that a more convincing hypothesis is, for example, that the first stage involves the familiar decarboxylation reaction of urethanes[63,65,69,77] with subsequent alcoholysis of the resulting aminosilane:

$$R'(NH\overset{\overset{O}{\|}}{C}OSiMe_3)_2 \xrightarrow[-CO_2]{t^\circ} R'(NHSiMe_3)_2 \xrightarrow{R''OH} R'(NH_2)_2 + Me_3SiOR''.$$

This conclusion is also confirmed by the finding that urethanes of the type $R_2NC(O)OSiR'_3$, which are no less susceptible to hydrolysis than those discussed above but which do not undergo decarboxylation, fail altogether to react with alcohols.

When the urethanes $RNHC(O)OSiMe_3$ are heated to 100–130°C, they undergo complete and irreversible decomposition to the corresponding disiloxanes and symmetrical ureas[69,77]. Pyrolysis in the presence of reactive chlorosilanes, for example $SiCl_4$ or $RSiCl_3$, alters the nature of the side reactions and the final products are an organic isocyanate, HCl, Me_3SiCl, and chlorosiloxanes[69,77]:

$$RNHC(O)OSiMe_3 + SiCl_4 \rightarrow RNHC(O)OSiCl_3 + Me_3SiCl;$$

$$RNHC(O)OSiCl_3 \rightarrow RNCO + [HOSiCl_3] \text{ etc.}$$

It has been noted that the use of other chlorosilanes (Me_2SiCl_2, Ph_2SiCl_2) is less effective, since decarboxylation of *O*-silylurethanes is observed in this case.

The formation of isocyanates proceeds satisfactorily in the presence of $SOCl_2$ and PCl_5.

When urethanes of the type $RR'NC(O)OSiMe_3$ were treated with $COCl_2$, $SOCl_2$, PBr_3,[66,139] and PCl_5,[140] the corresponding carbamoyl chlorides were obtained. It is noteworthy that, when the molecule contains both *N*- and *C*-siloxycarbonyl groups, the carbamic acid group reacts first[66,83,139], for example:

$$Me_3SiOC(O)N(R)(CHR')_nC(O)OSiMe_3 \xrightarrow[-Me_3SiX]{+YX_2}$$

$$\rightarrow XC(O)N(R)(CHR')_nC(O)OSiMe_3;$$

$$R{=}H,\ Alk,\ SiMe_3;\ R'{=}H,\ Alk;\ X{=}Cl,\ Br;$$

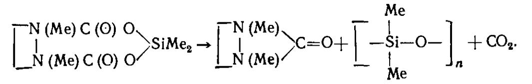
$$Y{=}{>}SO,\ {>}CO,\ {>}PBr,\ {>}PCl_3;\ n{=}1,2.$$

Apart from the thermally initiated decarboxylation noted above[63,65,69], the possibility of the disproportionation reaction has been demonstrated[64] for $Me_3SiOC(O)NH_2$:

$$2\,Me_3SiOC(O)NH_2 \rightarrow Me_3SiOC(O)NHSiMe_3 + [H_2NC(O)OH];$$

$$[H_2NC(O)OH] \rightarrow NH_3 + CO_2.$$

The cyclic *O*-silylurethane (XVI) is formed most readily when 1,1,2,5-tetramethyl-1-silaimidazolidine is treated with CO_2, being subsequently converted into polydimethylsiloxane, CO_2, and the corresponding imidazolidinone, probably via the following mechanism:



(XVI)

N-Silylurethanes

Urethanes of the type $MeN(SiMe_3)C(O)OR$, where R = Me or Et, are known not to interact with keten, but they do react with triethylsilylacetyl chloride to form $Et_3SiCH_2C(O)\cdot N(Me)C(O)OR$ in moderate yields[141].

N-Monosilyl-substituted amidals, which are at the same *N*-silylurethanes, undergo a symmetrisation reaction on heating and are then converted via β-decomposition into methylene diisocyanate[27,142]:

$$2\,CH_2[NHC(O)OR]N(SiMe_3)C(O)OR \rightarrow CH_2[N(SiMe_3)C(O)OR]_2 \rightarrow OCN{-}CH_2{-}NCO.$$

Other reactions of *N*-silylurethanes, for example *trans*-silylation and β-decomposition, are discussed in Section III (Subsections 3 and 4 respectively).

III. ORGANOSILICON URETHANES CONTAINING CARBON-BASED FUNCTIONAL GROUPS

1. METHODS OF SYNTHESIS

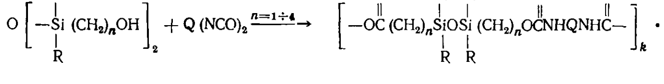
O-Silylorganyl Derivatives of Carbamic Acid

The reactions of organosilicon alcohols, glycols, and phenols (in which the functional groups are linked to carbon atoms) with isocyanates constitute a general method for the synthesis of *O*-silylorganylurethanes. For example, monohydric organosilicon alcohols[143–152] and phenols[153] readily give rise to the corresponding urethanes on reaction with both aliphatic and aromatic isocyanates:

$$R_3Si{-}Q{-}OH + R'NCO \rightarrow R_3Si{-}Q{-}OC(O)NHR' \quad (Q = \text{alkylene or arylene}).$$

It has been established that the reactivity of the hydroxy-group in homologous series of the alcohols $R_3Si(CH_2)_nOH$ and glycols $O[SiR_2(CH_2)_nOH]_2$ with $n = 1–3$ decreases as it becomes more remote from the silicon atom in the reactions with phenyl, octadecyl, and α-naphthyl isocyanates[148,149,151,152,154]. This is probably due to the rapid decay of the $+I$ effect of the electron-donating silyl group and the effect of the $(\sigma{-}p)$ conjugation of the Si–C bonds with the lone electron pair of the oxygen atom.

Polymeric urethanes have been obtained from the above glycols and organic diisocyanates, for example, hexamethylene (HMDI), *p*-phenylene (*p*-PDI), 1,5-naphthylene (1.5-NDI), tolylene (TDI), *pp*′-diphenylcyclohexyl, and *pp*′-diphenylmethylene diisocyanates[154–176]:



$$O\left[-\underset{R}{\overset{R}{Si}}(CH_2)_nOH\right]_2 + Q(NCO)_2 \xrightarrow{n=1\div 4} \left[-O\overset{O}{\overset{\|}{C}}(CH_2)_n\underset{R}{\overset{R}{Si}}O\underset{R}{\overset{R}{Si}}(CH_2)_nO\overset{O}{\overset{\|}{C}}NHQNH\overset{O}{\overset{\|}{C}}-\right]_k \cdot$$

Polyurethanes with a high silicon content (compounds (XVII) and XVIII)] are formed from oligosiloxanes containing hydroxyalkyl groups at the ends of the siloxane chain[158, 160,165,167,169,171,173,177-181] or in the side groups surrounding the chain[159,161-165,182]:

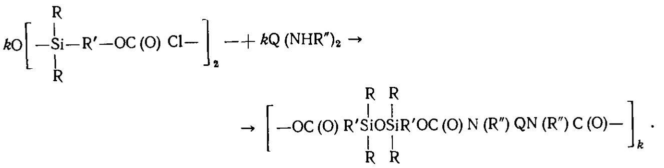
$$\underset{\text{(XVII)}}{HO(CH_2)_nSi(R_2)[OSiR_2-]_m-(CH_2)_nOH} \quad \underset{\text{(XVIII)}}{-[-OSi(R_2)(CH_2)_nOH-]_k-}.$$

Treatment of the products (XVII) and (XVIII) with monoisocyanates leads to oligosiloxanes modified by urethane groups[182]. Oligourethanes with terminal OH or OCN groups have been obtained by combining the glycols (XVII) with silicon-containing diisocyanates having carbon-based functional groups[175,183].

Apart from polyurethanes with an oxygen atom between silicon atoms, products with methylene, polysilamethylene, and ferrocenyl bridges or altogether without any bridges are also known[160,169,171,179].

More complex compositions are produced when the above glycols are initially converted by standard procedures into oligoesters and are then cross-linked by diisocyanates or the structures are modified by a polyisocyanate adduct containing biuret groups[157,168,174].

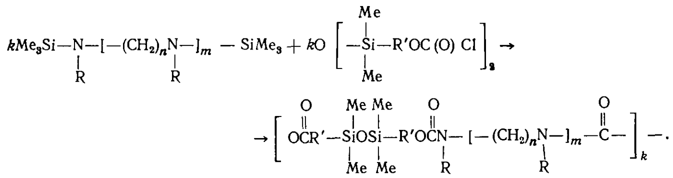
The synthesis of O-silylorganylurethanes by the aminolysis of organosilicon chloroformates[2,26,31,184-187] is also a general procedure. Condensation of bischloroformates of the disiloxane series with organic di- and poly-amines leads to the corresponding polyurethanes[2,151,188-191]:



$$kO\left[-\overset{\displaystyle R}{\underset{\displaystyle R}{Si}}-R'-OC(O)Cl-\right]_2-+kQ(NHR'')_2 \rightarrow \rightarrow \left[-OC(O)R'\overset{\displaystyle R}{\underset{\displaystyle R}{Si}}O\overset{\displaystyle R}{\underset{\displaystyle R}{Si}}R'OC(O)N(R'')QN(R'')C(O)-\right]_k.$$

Instead if diamines, hydrazines, dihydrazines, piperazine, and polyamines of the general type $H(R)N[-(CH_2)_n.N(R)-]_mH$, where R = M, n = 2 or 3, and m = 1 or 2, have also been used.

When the above starting compounds are replaced by their $\alpha\omega$-bis(trimethylsilyl) derivatives, the polycondensation is significantly simplified, since Me_3SiCl formed in the reaction is inert and can be readily removed[2,190,192]:



$$kMe_3Si-\underset{\displaystyle R}{N}-[-(CH_2)_n\underset{\displaystyle R}{N}-]_m-SiMe_3+kO\left[-\overset{\displaystyle Me}{\underset{\displaystyle Me}{Si}}-R'OC(O)Cl\right]_2 \rightarrow \rightarrow\left[O\overset{\displaystyle O}{\overset{\|}{C}}R'-\overset{\displaystyle Me}{\underset{\displaystyle Me}{Si}}O\overset{\displaystyle Me}{\underset{\displaystyle Me}{Si}}-R'O\overset{\displaystyle O}{\overset{\|}{C}}\underset{\displaystyle R}{N}-[-(CH_2)_n\underset{\displaystyle R}{N}-]_m-\overset{\displaystyle O}{\overset{\|}{C}}-\right]_k-.$$

The reactions involving the aminolysis of organosilicon carbonates with carbon-based functional groups are of preparative value for the synthesis of O-silylorganylurethanes[193-198]:

$$RMe_nSi-[-(CH_2)_mOC(O)OPh]_{3-n} \xrightarrow{NH_3} RMe_nSi-[-(CH_2)_mOC(O)NH_2]_{3-n},$$

as well as the reactions of silicon-containing alcohols with alkali metal cyanates in CF_3COOH[26,198,199]:

$$\equiv Si(CH_2)_nOH+KOCN \xrightarrow[n=1\div3]{CF_3COOH} \equiv Si(CH_2)_nOC(O)NH_2.$$

The hydrosilylation of O-alkenylurethanes, whereby it is possible to obtain urethanes with different numbers of functional substituents at the silicon atom[26,31,200-202], constitutes an interesting addition to the above procedures, for example:

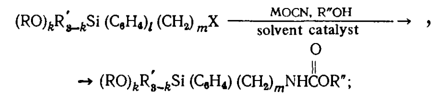
$$RR'NC(O)OCH_2CH{=}CH_2+HSiR''_nX_{3-n} \xrightarrow[n=1\div3]{X=Cl,\,OR} RR'NC(O)O(CH_2)_3SiR'_nX_{3-n}.$$

N-Silylorganylcarbamic Acid Derivatives

The reaction of organosilicon isocyanates containing carbon-based functional groups with alcohols¶ leads to urethanes with the silicon atom in the imide component of the molecule[26,178,183,203-211]:

$$R_3Si(CH_2)_nNCO+R'OH \xrightarrow{n\geqslant1} R_3Si(CH_2)_nNHC(O)OR'.$$

A modification of this method involves the interaction of halogenoalkylsilanes with alkali metal cyanates and the alcohol in molar aprotic solvents in the presence of $[(Alk)_4N]I$ as the catalyst[26,184,198,202,212,214], since organosilicon isocyanates are intermediates in this reaction:



$$(RO)_kR'_{3-k}Si(C_6H_4)_l(CH_2)_mX \xrightarrow[\text{solvent catalyst}]{MOCN,\ R''OH}, \rightarrow (RO)_kR'_{3-k}Si(C_6H_4)(CH_2)_mNH\overset{\displaystyle O}{\overset{\|}{C}}OR'';$$

R, R′=Alk, Ar; M=K, Na; X=Cl, Br; $k=1\div3$; $l=0, 1$; $m=1\div3$.

The reactivity of bromoalkylsilanes is higher than that of the chloro-derivatives and among the latter α-chloroalkylsilanes are the most reactive. On the other hand, the reactivity of the corresponding silyl isocyanates falls as the silyl and isocyanato-groups approach one another. Indeed, it has been shown in a number of investigations[26,178,183,203,205,207-210,213,215-217] that the reactivities of $(EtO)_3Si(CH_2)_3NCO$, $Et_3Si(CH_2)_3NCO$, and organic aliphatic isocyanates are comparable and approximately 20 times higher than that of Et_3SiCH_2NCO. The side products in the above reaction are organosilicon ureas and dimers (uretidinediones) and trimers (isocyanourates) of organosilicon isocyanates[26,212,213].

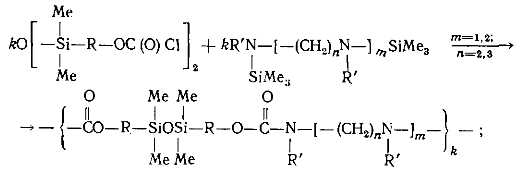
Polyurethanes with a silicon atom in the ester and amide components of the macromolecule simultaneously have been obtained by the condensation of silicon-containing diisocyanates and organosilicon glycols[178,183,208].

The interaction of alkyl(aryl)aminoalkylsilanes with organic chloroformates also leads to N-silylorganourethanes[201,218-220]:

$$\equiv Si(RNHR')_m \xrightarrow[m\geqslant1]{R''OC(O)Cl} \equiv Si[RN(R')C(O)OR'']_m,$$

but this method of synthesis holds out little promise, since half of the aminosilanes is consumed in binding HCl.

A modification of this reaction involving the treatment of N-silyl-substituted alkyl(aryl)aminoalkylsilanes with chloroformates is more important[2,27,67]:



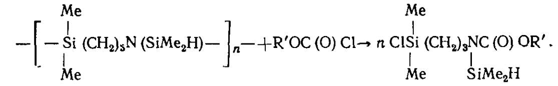
$$R_3SiCH_2N(SiMe_3)_2+R'OC(O)Cl \rightarrow R_3SiCH_2\overset{\displaystyle SiMe_3}{\overset{|}{N}}C(O)OR'+Me_3SiCl;$$

$$kO\left[-\overset{\displaystyle Me}{\underset{\displaystyle Me}{Si}}-R-OC(O)Cl\right]_2+kR'\underset{\displaystyle SiMe_3}{N}-[-(CH_2)_n\underset{\displaystyle R'}{N}-]_mSiMe_3 \xrightarrow[n=2,3]{m=1,2;} \rightarrow-\left\{-\overset{\displaystyle O}{\overset{\|}{C}}O-R-\overset{\displaystyle Me}{\underset{\displaystyle Me}{Si}}O\overset{\displaystyle Me}{\underset{\displaystyle Me}{Si}}-R-O-\overset{\displaystyle O}{\overset{\|}{C}}-\underset{\displaystyle R'}{N}-[-(CH_2)_n\underset{\displaystyle R'}{N}-]_m-\right\}_k-;$$

¶ Organic peroxides react with isocyanatoalkylsilanes similarly to alcohols[217]

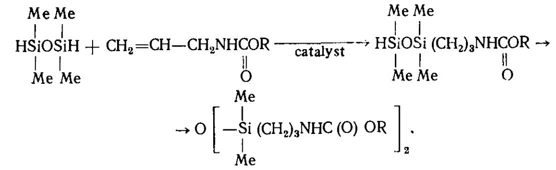
$$(MeO)_3Si(CH_2)_3NCO+HOOCMe_2Ph \xrightarrow[\text{catalyst}]{80^\circ} (MeO)_3Si(CH_2)_3NH\overset{\displaystyle O}{\overset{\|}{C}}OOCMe_2Ph.$$

$$R = -CH_2-,\ -(CH_2)_3-,\ -CH_2O(CH_2)_2-;$$



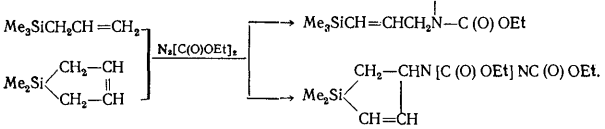
$$-\left[-Si(Me)_2(CH_2)_3N(SiMe_2H)-\right]_n- + R'OC(O)Cl \rightarrow n\,ClSi(Me)_2(CH_2)_3N(SiMe_2H)C(O)OR'.$$

The hydrosilylation reaction, the use of which in the synthesis of *N*-silylorganylurethanes makes it possible to obtain monomeric, oligomeric, and polymeric products with partial or complete blocking of the Si–H bonds by *N*-alkenylurethanes[26,202,221], is of independent importance, for example:



$$HSiMe_2OSiMe_2H + CH_2{=}CH{-}CH_2NHC(=O)R \xrightarrow[\text{catalyst}]{} HSiMe_2OSiMe_2(CH_2)_3NHC(=O)R \rightarrow O\left[-SiMe_2(CH_2)_3NHC(O)OR\right]_2.$$

The interaction of alkenylsilanes with azodiformic acid ester is accompanied by the migration of the double bond of the silane and leads to the formation of a mixture of addition products[222]:



$$Me_3SiCH_2CH{=}CH_2 \xrightarrow{N_2[C(O)OEt]_2} Me_3SiCH{=}CHCH_2N(C(O)OEt){-}C(O)OEt$$

Silicon-containing glycol carbamates are obtained by the aminolysis of alkylene carbonates by alkyl(aryl)aminoalkylsilanes[223,224]:

$$R_3Si(CH_2)_nNHR' + \overline{OCH_2CH_2OC}(O) \rightarrow R_3Si(CH_2)_nN(R')C(O)O(CH_2)_2OH;$$

$$R{=}OAlk,\ Alk;\ n{=}1,3;\ R'{=}H,\ Alk,\ -CH_2CH_2OCH{=}CH_2.$$

The reactivity of γ-amines ($n = 3$) is higher in this reaction than that of α-amines ($n = 1$) and $(Me_3Si)_2NH$ does not undergo this reaction at all.

It has been found that the amides of *C*-silyl-substituted carboxylic acids can be converted into *N*-silylorganylurethanes with retention of the Si–C bonds[225–227]:

$$Me_3Si(CH_2)_nC(O)NH_2 \xrightarrow[n>1]{MeONa/Br_2} Me_3Si(CH_2)_nNHC(O)OMe.$$

2. PHYSICAL PROPERTIES OF SYLYLORGANYLURETHANES

Organosilicon urethanes with carbon-based functional groups are colourless, transparent, mobile, and readily distilled liquids, which have been as a rule characterised by distinct melting points, refractive indices n_D^{20}, densities d_4^{20}, molar refractions MR_D, and infrared and ^1H NMR spectra[2,26,27].

The first amide band in the infrared spectra is in the range 1695–1733 cm^{-1}, as for other organic urethanes[25,26,228], while the second amide band is located in the wider range 1500–1625 cm^{-1}. The stretching vibrations of the free N–H group are manifested by shoulders of low and moderate intensity (3410–3450 cm^{-1}) on the more intense absorption band at 3328–3350 cm^{-1} corresponding to associated groups[25,26]. It is noteworthy that vibrations of the first type due to this group are characteristic of α-substituted urethanes alone. On passing from urethanes with an N–H group to $N{-}SiMe_3$ derivatives, the second amide band vanishes, but an intense absorption appears in the form of two bands at 1348 and 1321 cm^{-1} and there is a simultaneous increase in absorption intensity at 1400–1410 and 1440–1450 cm^{-1}. [25,26]

The ^1H NMR spectra of the urethanes $Me_n(RO)_{3-n}\cdot Si(CH_2)_mNHC(O)OR$, where R = Alk, n = 0 or 3, show the signal of the $N{-}CH_2$ groups split into two independent doublets, which can be explained (by analogy with dimethylformamide) by the double bond character of the linkage between the N and –C(=O)– atoms and the existence of these compounds in the *cis*- and *trans*-forms[26].

3. CHEMICAL PROPERTIES OF SILYLORGANYLURETHANES

Both *N*- and *O*-silylorganylurethanes with halogeno- or alkoxy-groups at the silicon atom are readily hydrolysed to the corresponding siloxanes[26,31,202]:

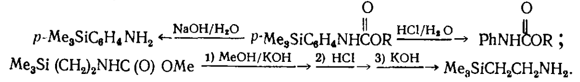
$$O[SiMe_2(CH_2)_3NHC(O)OR]_2;$$

$$O[SiMe_2(CH_2)_3OC(O)NR_2]_2.$$

When acted upon by high-boiling alcohols, they undergo the transesterification reaction[223,224]:

$$(RO)_3Si(CH_2)_3NHC(O)O(CH_2)_2OH \xrightarrow{-ROH} [-(RO)_2Si(CH_2)_3NHC(=O)O(CH_2)_2O-]_k-.$$

Depending on the conditions and the structure of the initial silylorganylurethane, the hydrolysis may involve either the carbamic acid group or the Si–C bond with formation of aminoalkyl(aryl)silanes or desilylation products[209,225,227]:



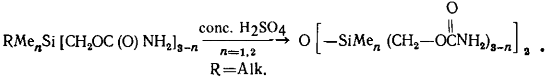
$$p\text{-}Me_3SiC_6H_4NH_2 \xleftarrow{NaOH/H_2O} p\text{-}Me_3SiC_6H_4NHC(=O)R \xrightarrow{HCl/H_2O} PhNHC(=O)R;$$

$$Me_3Si(CH_2)_2NHC(O)OMe \xrightarrow{1)\ MeOH/KOH} \xrightarrow{2)\ HCl} \xrightarrow{3)\ KOH} Me_3SiCH_2CH_2NH_2.$$

The reactions of α- or γ-silylurethanes containing N–H and Si–OAlk groups with $SOCl_2$ proceed only via the Si–O bond[26–28,31,184,228]:

$$ROMe_2Si(CH_2)_nNHC(O)R \xrightarrow[n=1,3]{SOCl_2} ClMe_2Si(CH_2)_nNHC(O)OR.$$

Disiloxanes with two and four urethane groups have been obtained by the Sommer reaction[196]:



$$RMe_nSi[CH_2OC(O)NH_2]_{3-n} \xrightarrow[n=1,2]{\text{conc. } H_2SO_4} O\left[-SiMe_n(CH_2{-}OC(=O)NH_2)_{3-n}\right]_2.$$

$$R{=}Alk.$$

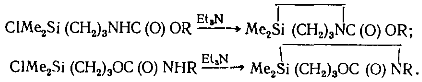
N-Silylorganylurethanes are nitrosated in accordance with the classical mechanism[220,229]:

$$R_3SiCH_2NHC(O)OR' \xrightarrow{NaNO_2/HNO_3} R_3SiCH_2N(NO){-}C(O)OR'.$$

On silylation with the Me_3SiCl/NEt_3 mixture, they are converted into disilylurethanes[26,27]:

$$R_3Si(CH_2)_nNHC(=O)OR' \xrightarrow[n=1,3]{Me_3SiCl/NEt_3} R_3Si(CH_2)_nN(SiMe_3){-}C(O)OR'.$$

In many instances the silylation is intramolecular[11,26–28,31,67,184,230,231]:



$$ClMe_2Si(CH_2)_3NHC(O)OR \xrightarrow{Et_3N} \overline{Me_2Si(CH_2)_3N}C(O)OR;$$

$$ClMe_2Si(CH_2)_3OC(O)NHR \xrightarrow{Et_3N} \overline{Me_2Si(CH_2)_3OC(O)N}R.$$

The formation of 2,5-disilylpiperazine derivatives is an exception[27]:

$$ClMe_2SiCH_2NHC(O)OR \xrightarrow{Et_3N} \{-SiMe_2CH_2N[C(O)OR]-\}_2.$$

N-Silylated organosilicon urethanes with carbon-based functional groups can undergo *trans*-silylation reactions[22,26–28,67,232,233]:

$$XMe_2Si(CH_2)_3N(SiR_3)C(O)OR' \xrightarrow[X=Cl,\,OR]{t^\circ} \overline{Me_2Si(CH_2)_3N}C(O)OR',$$

$$ROMe_2SiCH_2N(SiMe_3)C(O)OR' \xrightarrow{t^\circ} \{-Me_2SiCH_2N[C(O)OR']-\}_2,$$

$$ROMe_2SiCH_2N(R)C(O)OSiMe_3 \xrightarrow{t^\circ} [-Me_2SiCH_2N(R)C(O)O-]_2.$$

Since the thermolysis of *N*-silylurethanes, like that of other organosilicon urethanes, constitutes a new method for the synthesis of a wide variety of isocyanates and illustrates the theoretically important mechanism of β-decomposition in the ≡Si–N–C–X system of conjugated double bonds, data on this problem are reviewed in the next section.

4. THERMAL DECOMPOSITION OF ORGANOSILICON URETHANES

Sufficient data have now accumulated to reach definite conclusions concerning the factors controlling the β-decomposition in the ≡Si–N–C–X (X is an electronegative group) system of σ,σ conjugated bonds[11,12,26,28,31,151,184,230,234,235].

Like their purely organic analogues RNHC(O)OR, *N*-silylorganylurethanes decompose into isocyanates and alcohols on heating to 150–300°C, the decomposition taking place more readily the higher the acidity of the alcohol produced[26,145,186,194,201,218,219,234-238]:

$$R_3Si{-}Q{-}NHC(O)OR' \rightleftharpoons R_3Si{-}Q{-}NCO + R'OH.$$

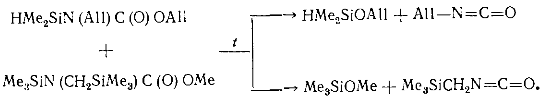
The reaction is reversible and alcohol is removed from the reaction zone in order to drive it to the right. The reaction then obeys first-order kinetics[194,237].

N-Silylurethanes containing the Si–N–C(O)–OR system of conjugated bonds decompose irreversibly on heating into an isocyanate and an alkoxysilane[11,12,20-22,24-28,31,32,36,56,68,142,145,151,184,228,230,232,234-249]:

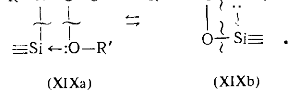
$$\equiv Si{-}\underset{}{\overset{R}{\overset{|}{N}}}{-}C(O){-}OR' \rightarrow \equiv Si{-}OR' + R{-}N{=}C{=}O.$$

With the exception of the special instances discussed below[22,28,31,32,239,241-246], the reaction is irreversible, obeys first-order kinetics, and has $E_{act} = 22$–30 kcal mole^{-1}.

The pyrolysis is intramolecular, which follows from the analysis of the product obtained as a result of the pyrolysis of a mixture of different urethanes[25,27,28,31,240]:



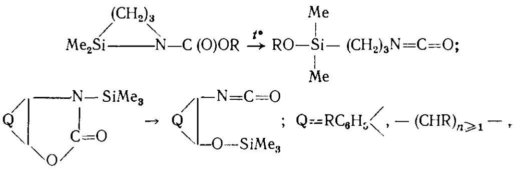
This finding suggests the intermediate formation of the following four-membered transition states involving the amide (XIXa) or imide (XIXb) forms of the *N*-silylurethane[25,26,28,31,230]:



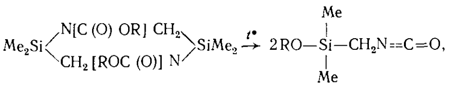
(XIXa) (XIXb)

However, according to the infrared spectra of *N*-silacyclourethanes[22] (the absence of the absorption due to the >C=N bonds at 1540–1640 cm^{-1}) and ^{1}H NMR (the singlet due to the Si–CH$_3$ protons), preference must be given to the amide form (XIXa). The strain in the four-membered transition complex does not rule out this mechanism, bearing in mind the possibility of the intense polarisation of the bonds involved in the electron redistribution[22,28,31,240]. This assumption is confirmed, for example, by the higher reactivity of the Si–N bond in the thermally less stable *N*-silylurethanes in relation to electrophilic agents of the type RC(O)Cl, RC(O)OC(O)R, PhNCO,[22,144], etc.

Depending on the *exo*- or *endo*-location of the ≡Si–N–C(O)–OR atomic group, silacyclourethanes form various β-decomposition products. For example, ring opening takes place in one instance[22,28,29,31,32,184,230,234,239]:



in an other the urethane decomposes into two isocyanate molecules[25,27,28,31,68,142,234]:



$$Me_2Si\genfrac{}{}{0pt}{}{\diagup N[C(O)OR]CH_2 \diagdown}{\diagdown CH_2[ROC(O)]N \diagup}SiMe_2 \xrightarrow{t^\circ} 2RO{-}\overset{Me}{\underset{Me}{Si}}{-}CH_2N{=}C{=}O,$$

and in the third case, the ring contraction reaction takes place[26,28,31,184,230,234]:

$$Me_2Si(CH_2)_3N(R)C{=}O \xrightarrow{t^\circ} Me_2Si(CH_2)_3O + R{-}N{=}C{=}O.$$

The β-decomposition (D) of the urethanes (XX) is accompanied by the simultaneous *trans*-silylation reaction (T):

	m	n	X	Reaction, %	
				D	T
a	2	1	Cl	0	100
b	2	1	EtO	13	87
c	1	3	EtO	70	30

Evidently the D/T ratio is influenced not only the nature of the substituents at the silicon atom but also by the relative positions of the silyl groups in the urethane molecule[27,28,31,184,232,247]. This is why the study of the kinetics of the β-decomposition of the urethanes $Me_n(MeO)_{3-n}Si(CH_2)_mN.(SiMe_3)C(O)OR$ does not yield a direct answer to the question of the *C*-silyl group on the β-decomposition proper when n varies from 0 to 3.[24-26,184]

The influence of the substituents in the urethanes having the general formula RN(SiMe$_3$)C(O)OR′ on the temperature of the onset of appreciable decomposition is clearly illustrated by the Table below[21,22,25,26,28,29,31,56,68,184,230,250-254].

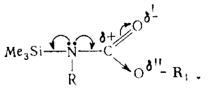
The influence of the substituents R and R′ in the urethanes RN(SiMe$_3$)C(O)OR′ on the temperature of the onset of appreciable decomposition (T_{decomp}).

R	R′	T_{decomp}, °C	R	R′	T_{decomp}, °C
Alk	C_2H_5	170	Ph	C_2H_5	100
Alk	C_6H_5	110	Ph	$N{=}C(CH_3)_2$	60
Alk	C_6H_4Cl-*p*	60	Ph	C_6H_5	20
Alk	$C_6H_4NO_2$-*p*	0	Ph	$C(O)C_6H_5$	0
Alk	Cl	$\leqslant 0$	$SiMe_3$	$SiMe_3$	< 20

The aliphatic oxa(thia)zolidinones $Me_3SiNC(X)OCH(R')C.(R'')H$ (XXI) [a) R′ = R″ = H, X = O; b) R′ = R″ = H, X = S] are converted into isocyanates under more severe conditions (>180°C) than the analogous oxa(thia)azolidine-2,5-diones $Me_3SiN-C(=X)O-C(=O)CHR$ (XXII) and the benzo-derivatives (XXIII) [c) $R' + R'' = C_6H_4$; d) $R' + R'' = 5-MeC_6H_3$; e) $R' + R'' = 5-ClC_6H_3$; X = O throughout], corresponding to the oxa(thia)azolidinones (XXI). The latter compounds form isocyanates at 125–130°C, and the content of the β-decomposition product in the equilibrium mixture decreases in the sequence (XXIIIe) > (XXIIIc) > (XXIIId) and increases with rising temperature and also when it is removed from the reaction sphere[22]. On the other hand, compounds (XXIII) with X = O and $R' + R'' = 4-NO_2C_6H_3$ (f) or $5-NO_2C_6H_3$ (g) do not form isocyanates even at 165°C. [22,28,31,32] For comparison, we may note that *N*-(trimethylsilyl)benzothiazolidin-2-one is stable on heating to 260°C, while its very close analogues *N*-(trimethylsilyl)benzoxalidine-2-thione and 5-nitro-*N*-(trimethylsilyl)-benzoxazolidine-2-thione undergo β-decomposition even in the course of the introduction of silyl protecting groups into the heterocycles[22,239,242,244–246,255]. Furthermore, it is striking that in all cases thiazolidine derivatives show a small tendency towards isomerisation, while silylated oxazolidine-2-thiones rearrange irreversibly and quantitatively and *N*-(trimethylsilyl)oxazolidinones rearrange reversibly[22,239,242,244–246,255].

One may therefore conclude that the thermal stability of *N*-silylurethanes decreases when (a) the electronegativity of the RO group increases, (b) the *N*-alkyl group is replaced by an aromatic group, in particular by a group containing electronegative substituents, (c) on passing from aliphatic *N*-silacyclourethanes to benzo-derivatives, and finally (d) following the introduction of the thiocarbonyl group in place of the carbonyl group[21,22,24–29,31,32,56,68,77,91,142,184,230–234,239,242–256].

Indeed the introduction of an electronegative substituent lowers the basicity of the nitrogen atom as a result of which the amount of double bond character of its linkage with neighbouring Si and C atoms falls:

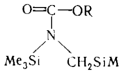


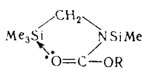
Therefore the β-decomposition reaction involves preferentially compounds containing σ,σ conjugated bond systems $\equiv Si-N-C(O)-OR'$, i.e. in the amide form of the transition complex (XIXa) mentioned above and not in the corresponding imide form $\equiv Si-N=C-OR'$ (XIXb). [26] Experiment confirmed this conclusion: the model compound $MeC(=N-SiMe_3)OEt$ decomposes into MeCN and ethoxytrimethylsilane only above 250°C. [26]

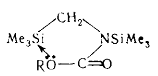
In the light of the foregoing, the instability of $(Me_3Si)_2NC(O)OR$ (decomposition temperature of about 20°C) becomes understandable, since the degree of degeneracy of the basic properties of the nitrogen atom owing to the $(p-d)\pi$ interaction via two Si–N bonds is in this case still greater[56].

The analogous effect of two silyl groups in combination with the high electro-negativity of the NaO^- substituent is the cause of the easy β-decomposition of compounds of the type $(Me_3Si)_2NC(O)ONa$ even in the synthesis of bistrimethylsilylcarbodiimide [88–92].

Furthermore, since the Me_3Si group enhances the nucleophilic properties of the nitrogen atom in the α-position[87], it was to be expected that the thermal stability of the compounds $Me_3SiN(CH_2SiMe_3)C(O)OR$ will be higher than that of $Me_3SiN(Me)C(O)OR$, which, however, conflicts with experiment. The apparent inconsistency is probably a consequence of the superposition of the σ,σ conjugation effects in the $\equiv Si-C-N-C\equiv$, $\equiv Si-C-N-Si\equiv$, and $\equiv Si-N-C-OR$ bond systems or is a result of the transannular interaction of the $C-SiMe_3$ group with one of the oxygen atoms:







.

An appreciable decrease of the thermal stability of *N*-silylurethanes is observed not only after the interaction of aryl or silyl substituents at the nitrogen atom but also after the introduction of acyl groups. For example, the acylurethanes $MeC(O)N(SiMe_3)C(O)OMe$ and $PhC(O)N.(SiMe_3)C(O)OMe$ decompose readily at 85–100°C. [257]

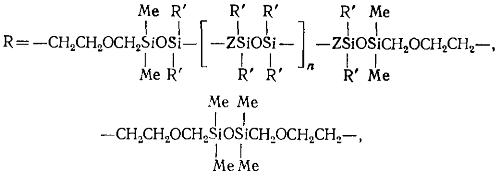
IV. OTHER TYPES OF SILYLURETHANES

This section surveys mainly the available information about systems in which the silicon atom and the carbamic acid fragment are separated by a bridge which does not consist of carbon atoms alone. We have divided the methods for the introduction of silicon into the polyurethane macromolecule into six independent groups†.

1. The polycondensation reactions of a wide variety of monoisocyanates with silicon-containing glycols lead to the synthesis of adducts with terminal urethane groups, for example[260–266]:

$$HO-R-OH + 2R'''NCO \rightarrow R'''NHC(O)O-R-OC(O)NHR''',$$

where



$$R = -CH_2CH_2OCH_2\underset{Me}{\overset{Me}{Si}}O\underset{R'}{\overset{R'}{Si}}-\left[-Z\underset{R'}{\overset{R'}{Si}}O\underset{R'}{\overset{R'}{Si}}-\right]_n-Z\underset{R'}{\overset{R'}{Si}}O\underset{Me}{\overset{Me}{Si}}CH_2OCH_2CH_2-,$$

$$-CH_2CH_2OCH_2\underset{Me}{\overset{Me}{Si}}O\underset{Me}{\overset{Me}{Si}}CH_2OCH_2CH_2-,$$

$R', R'', R''' = $ Alk, Ar; Z = arylene or hydroxyarylene; $n = 0$ or 1.

The replacement of monoisocyanates by di- and polyisocyanates leads to polyurethanes with terminal isocyanato-groups capable of further structure formation[263,267–281]. Polyurethanes with a cross-linked structure are obtained when the structure-forming agent is a polyisocyanate having the biuret structure[275,282–286], as already noted above for organosilicon diols with purely carbon-based functional groups. In practice adducts of 2,4-TDI or 2,6-hexamethylene diisocyanate (2,6-HMDI) with tri(hydroxymethyl)propane are most frequently used as the polyisocyanates and the glycol components consist of ester-alcohols of the series[263,274,275,287–289,302].

Similar products have been obtained from glycols with Si–OC bonds of the general type $R_nSi(OZOH)_{4-n}$ (XXIV) and $Q(SiMe_2OZOH)_2$ (XXV), where R = alkyl or aryl, Z = alkylene, arylene, hydroxyalkylene, or oligohydroxyalkylene, Q = arylene, hydroxyarylene, or oligosiloxane,

---

† Since studies on the utilisation of organosilicon compounds in industry and in the processing of polyurethanes (for example as surfactants, stabilisers, pore regulators, etc., i.e. in processes without the obligatory formation of chemical bonds with the polyurethane) are of great practical importance, they merit independent consideration. Certain data on this problem have been reviewed by Adamowski et al. [258] and Zwolinski et al. [259]

and $n = 1-4$.[66,67,113,261-265,274,282,286,290-307] By varying the reactant ratio, the polycondensation process can be arrested in many cases, at the stage involving the formation of the oligomer with terminal hydroxy- or isocyanato-groups, which are responsible for the hardening of prepolymers when suitable reagents are chosen.

2. The condensation reactions of polyethers, which do or do not contain urethane fragments but always have hydroxy-groups in side substituents or at the ends of the chain, with silanes or polysiloxanes containing hydroxy-, alkoxy-, acyloxy-, or amino-groups at the silicon atoms and subsequent condensation of the products with polyisocyanates make it possible to synthesise copolymers with a wide variety of compositions and structures[115,166,180,267,275,290,308-350].

The silicon content in polyurethanes is then regulated by the type and size of the siloxane blocks and their amount in the reaction mixture. In a typical instance of this method, the polysiloxane containing ≡SiOEt groups undergoes transesterification with poly(ethyleneglycol adipate) having terminal hydroxy-groups and is treated with TDI in the presence of a special plastisol composition. Structure formation in the copolymer is completed by heating the mixture at 150°C for 5 min.[322]

Sulphur-containing organosilicon glycols, for example $\alpha\omega$-bis-(β-hydroxyethylthiomethyl)polydimethylsiloxanes, behave in the polycondensation reactions like their oxygen analogues[272,351-353] and in the case of glycols based on diethanolamine, particularly bis-(β-hydroxyethylaminoethyl)dimethylsilane, both N–H and H–O bonds are involved in the reaction[354,355].

3. The hydrosilylation or catalytic dehydrocondensation reactions[222,223,348,356-373] involving polysiloxanes with ≡Si–H bonds and oligourethanes containing C=C and OH groups make it possible to obtain various block-copolymers. For this purpose, oligomers containing free OH or OCN groups are usually treated with the corresponding alkenyl isocyanate or an unsaturated alcohol with subsequent addition of the prepolymer to polysiloxanes with ≡Si–H bonds. Copolymers obtained from silicon-containing glycols or diisocyanates with carbon-based functional groups have similar structures. However, the first version of the synthesis is based on a more readily available starting material[2,26,99-103,368-370,374,375].

The method of synthesising oligourethanes by the reaction of alkyl(aryl)aminoalkylsilanes with chlorocarbonate esters is still less suitable owing to the difficulty of removing the HCl evolved, which causes side reactions[376,377].

Another variety of block-copolymers is obtained by the reaction of $\alpha\omega$-dihydroxy-derivatives of polyesters, polyester-amides, and poly(alkylene glycols) with di- and poly-isocyanates having different ratios of the functional groups ≡Si–H, OH, and OCN to form adducts. The synthesis can involve any of the above groups, for example the isocyanato- or silamethylidyne groups in the polysiloxane[352,355,378,379]:

$$\mathrm{Me_3SiO{-}[{-}SiHMeO{-}]_{\mathit{m}}{-}[{-}\underset{\textstyle |\atop (CH_2)_3OC(O)NHC_6H_3(3\text{-}Me)NCO}{SiMe}O{-}]_{\mathit{p}}{-}[{-}SiMe_2O{-}]_{\mathit{q}}{-}OSiMe_3}\ ;$$

$$m = 2-4.5;\ p = 1-6.5;\ q = 5-22\ ,$$

and the hydroxy-groups in the polyester.

In view of their ready availability and high chemical reactivity, the isocyanates $R_nSi[O(CH_2)_mNCO]_{4-n}$ with R = NCO and particularly with R = H or $CH_2{=}CH$ ($n = 0-2$ and $m \geqslant 1$) may become suitable for the same purposes and may replace glycoxysilanes of type (XXIV)[46,47,380].

Silyl esters of isocyanatocarboxylic acids can also be used to synthesise silicon-containing urethane intermediates[381].

4. Hydrolysis of organosilicon urethanes with SiOR (R = alkyl) and carbon-based functional groups leads to di- and poly-siloxanes containing carbamic acid groups. This property of urethanes is used in the manufacture of polyurethane compositions for cold vulcanisation[2,26,27,382,383].

The low-temperature adducts (XXVI) can harden as a result of hydrolysis involving the SiOMe and OCN groups simultaneously or separately[260,271,273]:

$$\mathrm{REtC(CH_2OH)_2 + TDI \rightarrow REtC{-}[{-}CH_2OC(O)NHC_6H_3(4\text{-}Me)NCO]_2},$$

(XXVI)

where

$$\mathrm{R = (MeO)_3Si(CH_2)_3S(CH_2)_3OCH_2{-},\ (MeO)_3Si(CH_2)_3OCH_2{-}}\ \text{etc.}$$

5. Radical polymerisation reactions are used to a limited extent for the synthesis of polyurethanes[330,339,384-388]. For example, copolymers of $\alpha\beta$-unsaturated urethanes and products of the transesterification of oligosiloxanes with the HO and AlkO terminal groups of acryloyloxy- and methacryloyloxy-derivatives of ester-alcohols, which are hardened by ionising radiation, have been obtained by this method. Styrene is used as a reactive diluent[387,388]. It appears useful to employ in this reaction vinyloxyalkyl and vinylthioalkoxyalkyl carbamates[389].

In the presence of $\alpha\alpha'$-azobisisobutyronitrile, it proved possible to copolymerise vinyltriethoxysilane and 5-methyl-*N*-vinyl-2-oxazolidinone[385].

6. Graft copolymers have been obtained with the aid of the polycondensation reactions already considered from block- or homo-polymers. For example, dyed wear-resistant articles have been obtained by grafting polysiloxane to an organic polyurethane[390-392]. Graft copolymers have been synthesised in which low-molecular weight hydroxylated oligoisoprene and oligobutadiene are linked to a polysiloxane block directly or via a bond system incorporating carbamic acid groups[114,316,393,394].

In another instance hydrated silica (or corundum[388]) is incorporated in polyurethane compositions via a transesterification reaction involving the terminal hydroxy-groups of polyesters [for example, the copolymer of poly(ethylene glycol) and pentaerythrityl adipate] with the corresponding structured tolylene diisocyanate[324,395,396]. It has been shown that polysiloxanes may be grafted to carboranephthalocyanine derivatives[397], thiocol, and $\alpha\omega$-dihydroxypolyfurite [poly(tetrahydrofuran)diol-$\alpha\omega$-bis-(3-hydroxypropane)][180,398], polyamides[59], polyamidourethanes[399], polyamide–polyimides[312], glass[302,317,400], fibreglass[401], leather and poly(vinyl chloride)[269,270,311], derivatives of castor oil and metallocene compounds[402-404], polyester fibres[405-407], and other materials containing different forms of urethane groups.

V. APPLICATIONS

1. *N*- and *O*-Silylurethanes

Like silylated ureas[12], *N*-silylurethanes are used for the treatment of fabrics, paper, leather, cellophane, and other materials in order to make them hydrophobic, reduce their brittleness, impart to them crease resistance, make them electrically insulating, and improve other technical characteristics [13-15]. Organylsilyl tricarbamates $RSi[OC(O)NR'_2]_3$ have been suggested for the low-temperature hardening of organosilicon oligomers with terminal silanol groups [57-59,72].

Although the mode of the reactions of organic diisocyanates with silanediols and oligosiloxanes having terminal OH groups is not always clear, the polymeric products formed are capable of hardening on heating and of giving rise to a film which hardens spontaneously in air [120]; such compounds have a fairly high thermal stability and elasticity [121]. They have therefore been recommended for the preparation of fibres, plastics [104], and for other purposes [97,111,115,128]. In those cases where the principal mode of reaction involves the dehydrocondensation of silanediols [118,122,408], the polysiloxanes formed act as plasticisers on the polymeric ureas produced.

The products of the condensation of $\alpha\omega$-diisocyanatopolyurethanes and polysiloxanes with terminal hydroxy-groups impart to textiles antipilling properties and resistance to shrinking, improve physicomechanical properties, give rise to a pleasant feel, etc., and withstand frequent washing and dry-cleaning as well as prolonged action of light; they also make textiles elastic [117].

Powdered polyurethanes can be pressed into articles with satisfactory electrical insulating properties and high mechanical strength [51,106]. Silyl esters of *N*-alkyl(aryl)-carbamic acids are important intermediates in the synthesis of isocyanates by phosgene-free methods [69,73,77]. The products of the condensation of alcohols with $R_2Si(NCO)_2$ are used to stabilise poly(vinyl chloride). [41] Certain *N*-silylcarbamates exhibit anticholinesterase and insecticidal activities [86,409]. They are isolated in a pure form by a chromatographic procedure [18,19,30].

2. Compounds with Silyl and Urethane Groups Separated by a Bivalent Group

These are extremely numerous and have a wide variety of practical applications. We shall mention some of the most important of these.

Polyurethane film-forming compositions obtained by both cold and hot drying adhere to glass, wood, metals, plastics, and other constructional materials [158,159,162,163,166,183,217,273,287,288,290,292,294,306,307,311,313,316,334,344,352,356,363,373,390,405]. They have a very attractive outward appearance (smooth, transparent, and elastic or solid and lustrous films), are resistant to water, oil, petrol, corrosion, wear, and the atmosphere, their colours are fast, and their useful characteristics are retained under the conditions of high temperatures and humidities. These remarkable qualities have been used in the manufacture of decorative finishing materials [113,168,174,264,265,275,277-282,287-289,298-307,347,409-413].

Various polyurethane compositions are used to treat textile and leather articles in order to make them wear resistant and impart to them dirt-, water-, and oil-repellent properties [161,177,182,212,268,309,310,363,405]. It is important to note that, after treatment, fabrics, paper, and leather articles remain permeable to vapours and gases, are elastic, and are not sticky.

One-component oligopolyurethanes which undergo self-vulcanisation in air are used as cements, fillers, hermetically sealing compounds, gaskets, and shock absorbers in building, automobile, and avaiation industries, and as potting compounds which adhere to glass, wood, porcelain, metals, and plastics. The advantage of coatings based on them (apart from the unique combinations of different types of stability to external influences already mentioned in connection with fancy leather goods and decorative articles) consists also in their capacity to form remarkable gas-filtering and vapour permeable films which are used for encapsulation for the purpose of conservation and storage of specific materials [292,334,352,361,363,367,382-284,405].

In certain cases urethane–siloxane adducts are used as primers which improve the adhesion of polyurethanes to the support [260,271,362,376,377,414], as binders for glass and textile fibres [362], as surface-plasticising coatings [269,270], as electrically insulating articles [222,272,292,315,320-322,325-327,333,334,337,351,358,368,371,372], as sensitisers for heat-sensitive latexes [222,272,315,321,322,327-329,332,333,343,351,358,371,372,403,404,407], as antioxidant additives to anti-detonators [403,404], and as catalysts of the combustion of rocket fuels [348]. Silicon-containing stabilised liquid, semi-liquid, and elastic resins, rubbers, plastics, and other materials with prolonged resistance to water, heat, and fire with retention of geometrical dimensions are manufactured on their basis [59,115,165,183,323,330,331,335,336,342,344,354,355,360,362,378,379,396,415].

The wide variety of the physicochemical characteristics of polysiloxane–polyurethane materials gives rise to the possibility of using them as liquids with very low glass temperatures (down to −125°C) [180,183,190,287,294,296,306,356] and in the form of corundum-filled and mould-hardened grinding discs or other types of abrasive devices [388,416].

Polyurethanes with a siloxane–hydroxyalkylene base can be used as liquid heat exchangers, emulsifiers, wetting agents, lubricants facilitating the removal of articles from moulds, for the formation of completely smooth surfaces of polymers, as well as other purposes [267,269,270,292,334,352,362]. Laminated products used as splinter-proof glass [317], in which the linking element is polyurethane based on an organic oligoisocyanate and an organosilicon polyfunctional alcohol, have been reported.

Compositions comprising silicon-containing products with organic polyurethane materials in which the individual components are not necessarily chemically combined but the formation of chemical linkages via residual functional groups is quite likely and even inevitable under certain conditions, have assumed considerable practical importance [150,161-134,237,259,269,290,308,311,323-327,329-333,338-340,342,345,346,358,364,365,371,372,396,401,406,407,412,416-517].

The siloxane component has become particularly important in the manufacture of polyurethane foam plastics [237,308,326,327,329,331,332,338,340,342,346,358,365,366,371,372,407,419,440-479]. It plays a versatile role which involves a decrease of the surface tension of the system, the emulsification of the reaction mixture (isocyanate–polyester–catalyst), the stabilisation of the foam before its hardening, and the regulation of the structure and size of the cells; at the same time it abolishes the inevitable imbalance between the functional groups of the starting materials without impairing the quality of the polyurethane foam plastic.

However, mechanical mixtures exhibit only a weak stabilising effect, probably owing to the insufficiency and random nature of the chemical linkages between the components of the reaction mixture, which in certain cases complicates the technology owing to the poor compatibility of the individual components and leads to polyurethane foam plastics having inhomogeneous compositions and variable quality [237,338,486,488,489].

Polyester–polysiloxane block-copolymers [237,308,326,327,329,331,332,338,340,342,346,358,365,366,371,372,407], which exhibit a more pronounced stabilising effect, are more compatible. The overall favourable effect is greater the greater the uniformity of the alternation of polyester and polysiloxane blocks in the copolymer[340,485,489]. Under these conditions, the presence of ≡Si–OC groups in the macromolecule is less preferable compared to Si–C bonds[329,331,340,407,464,468,485]. Because of this and the difficulty of synthesising such copolymers, they have been replaced by polysiloxane compounds with free hydroxy-groups attached to carbon atoms[355,485–489], particularly those in which the hydroxyl-containing group is joined to silicon via the ≡Si–C linkage[355,487].

Nevertheless the degree of order among the component macromolecular units and the concentration of OH groups relative to the total number of functional groups of the polyester proved to be insufficient. The preparation of polysiloxane–polyurethane copolymers with rigorously alternating functional groups by the successive introduction into the reaction zone of the diisocyanate, the organic polyester, and the polysiloxane with OH (SH) groups attached to carbon atoms did not solve the problem completely either, since the resulting surface-active substances contained only random chemical linkages with the main polymeric mass.

The optimal version of this synthesis now provides for the use of organosilicon oligoisocyanates with carbon-based functional groups in a pure form or in combination with organic di- or poly-isocyanates. After such a substance is brought into contact with an organic polyester, a homogeneous, high-quality, self-stabilising system is produced. The use in the synthesis of organosilicon alcohols, glycols, isocyanates, etc. with carbon-based functional groups as part of the glycol or isocyanate components of the reaction mixture made it possible to obtain, as already described above to some extent, polyurethanes with an exceptionally favourable combination of technically useful characteristics[159,162,309,355,409,412,518–523].

Monomeric derivatives of carbamic acid are used as additives which improve the properties of polysiloxane lubricants for high-temperature high-speed bearings[492], as dispersing additives improving the thickening capacity of silica gel in the manufacture of greases[493], for the vulcanisation of silicone rubbers[27,494–496], and for other purposes[26,497–499].

The widely variable physiological activity of organosilicon urethanes is striking[81,86,153,166,178,193,195–198,204,362,386,399,402,409,524–527].

Chemical Degradation of Polymers in Corrosive Liquid Media

Yu.V.Moiseev, V.S.Markin, and G.E.Zaikov

The physicochemical foundations of the degradation of polymeric materials in corrosive liquid media are examined and the characteristics of the polymer degradation processes, the mechanisms of reactions of chemically unstable bonds, and the principal types of decomposition of polymeric molecules as well as the characteristics of the diffusion of corrosive media into polymeric materials are discussed. Kinetic equations have been obtained for the principal types of chemical degradation of polymeric materials under heterogeneous conditions.
The bibliography includes 86 references.

CONTENTS

I. INTRODUCTION

As a result of the wide-scale application of polymers in the chemical and petrochemical industries, in medicine, in the building industry, and in various branches of modern engineering, much attention has been devoted to their degradation processes in corrosive media. In many instances these processes are undesirable, because they lead to loss of valuable practical properties of polymeric articles. In other cases they are used for numerous chemical transformations, the etching of polymers, the dissipation of polymers in living organisms, etc.

The problems of the chemical stability of polymers have been the subject of numerous investigations, but the latter have not as a rule involved a theoretical analysis of the experimental data and are in many instances empirical in nature. The inadequacy of the theoretical studies in the field of chemical degradation of polymers and the availability of a large amount of experimental data make it necessary to discover quantitative relations in the first place.

Corrosive media can be divided into two groups in terms of the type of their action[1,2]:

1. Physically corrosive media giving rise to reversible changes in the polymer.
2. Chemically corrosive media (acid–base and oxidative) under the influence of which the polymer undergoes irreversible changes†.

Naturally, certain media (for example many organic acids) can behave simultaneously as both physically and chemically corrosive media.

Concepts such as chemical ageing, corrosion, chemical degradation, and longevity of the material are nowadays used in the literature and in standards[2] to characterise the decomposition of polymeric materials under the influence of corrosive media.

The term "ageing" was taken from biology and is widely applied in science and engineering. The ageing of polymers is understood as the set of physical and chemical processes occurring in the polymer in corrosive media and giving rise to changes in the properties of polymeric materials. These changes usually lead to the impairment of the practical properties of the polymer.

The term "corrosion" was borrowed from metals science; chemical corrosion of metals is understood as the interaction of the metallic surface with the surrounding corrosive medium. The decomposition of polymeric materials in corrosive media usually occurs in a reaction zone the size of which may vary from several monolayers to the entire bulk of the polymeric article. Therefore the term "corrosion" as applied to polymers is too narrow and cannot be recommended.

Chemical degradation is usually understood as all the processes leading to a change in the chemical structure of polymeric materials. Thus chemical degradation constitutes the set of the following chemical processes occurring in the polymer in corrosive media and altering its molecular weight:

(a) depolymerisation—the abstraction of the monomer from the end of the macromolecule;

(b) polymer-analogue decomposition of the monomer—the abstraction of a group of atoms from the macromolecule with retention of the initial degree of polymerisation;

(c) decomposition of the main chain leading to a decrease of the degree of polymerisation;

(d) cross-linking—reactions involving the formation of chemical bonds between the macromolecules and leading to the appearance of branched and network structures.

The chemical degradation of polymers under the influence of oxidants is a complex process including, as a rule, radical, molecular, and ionic chemical reactions; degradation under the influence of acids and bases consists largely of hydrolytic, solvolytic, or abstraction reactions.

The criteria of the chemical resistance of polymeric materials to the action of corrosive media have been defined in a number of standards[2]. Longevity should be understood as the period during which the properties of the polymeric material change under particular conditions of its employment to the level specified in the technical documentation.

The study of the kinetics of chemical degradation is extremely difficult both as regards the determination of

---

† Biochemical media are also included here.

correct experimental data and the determination of the kinetic parameters of the individual fundamental steps. For a successful solution of this problem, it is necessary to discover in the first place whether the chemical degradation process can be resolved into a series of simpler processes (for example diffusion of the corrosive medium into the polymer and chemical reaction of the functional groups) in order to investigate them separately; secondly, one must find out to what extent these processes can be simulated using low-molecular-weight analogues. Such simulation is necessary, because one cannot always separate the chemical reaction step from diffusion phenomena and, furthermore, it is always interesting to compare the calculated kinetic and diffusion parameters of the chemical degradation process with the corresponding parameters of model processes.

The aim of the present review is to examine the physicochemical foundations of the degradation of polymeric materials in corrosive media, whereby one can characterise the chemical degradation process in terms of kinetic and diffusion parameters and to predict the chemical stability of polymeric materials under the conditions of their employment. We do not aim to quote all the known facts and data concerning the chemical degradation of polymers. An attempt has been made in the review to examine at a quantitative level the degradation processes of polymeric materials in corrosive media. The review deals mainly with the degradation of polymers under the influence of acids and bases, which is most frequently encountered in practice.

II. THE CHARACTERISTICS OF POLYMER DEGRADATION PROCESSES

Flory[3] formulated the main principles of the independence of the reactivities of the functional groups in oligomers and polymers of molecular weight for various types of reactions. The functional groups in the polymer must have the same reactivities as in a low-molecular-weight model compound when the following conditions are observed:

(a) the reaction proceeds in a homogeneous medium in which the initial reactants and products are soluble;

(b) one type of functional group of the polymer is involved in each fundamental step, and the molecules of all the remaining reactants are small and fairly mobile;

(c) the low-molecular-weight analogue is chosen taking into account the steric hindrance which may arise when the conformation of the macromolecule changes during the reaction.

Alfrey[4] noted that identical reactivities of the functional groups in the polymer and in the low-molecular-weight analogue may be observed even if one of the above conditions does not hold.

However, many instances are now known where the reactivities of various groups in the polymer are anomalous owing to the specific influence of the polymeric state[5-7]. We shall consider for simplicity the homogenous catalytic degradation of a polymer via the following mechanism:

$$\sim R + \mathrm{Cat} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \sim X; \qquad \text{(I)}$$

$$\sim X + R' \xrightarrow{k_3} P + \mathrm{Cat}, \qquad \text{(II)}$$

where R is a functional group in the polymer, Cat the catalyst, X an intermediate state, R′ a reactant (for example H_2O in hydrolysis), and P the reaction product.

The viscosity of polymer solutions may be several orders of magnitude greater than that of solutions of low-molecular-weight analogues; furthermore, the functional groups in polymers are as a rule distributed close to one another. Therefore, in comparing the reactivities of the group R in the polymer and in the low-molecular-weight analogue (chosen taking into account the steric hindrance arising during the change in the conformation of the macromolecule during the reaction), one must elucidate the influence of the macroviscosity of the solution and of the interaction of the functional groups on the degradation reactions (I) and (II).

1. A QUANTITATIVE ESTIMATE OF THE INFLUENCE OF THE MACROVISCOSITY OF THE SOLUTION ON THE DEGRADATION KINETICS

The influence of the macroviscosity of the solution on the kinetics of the degradation of small molecules has already been examined[8-10]. If, for example, the rate of the reaction of R with Cat is high compared with the rate diffusion of Cat to R, then the concentration of Cat in the immediate vicinity of R may be reduced, which creates a concentration gradient causing a diffusional flux of the species directed towards R. In the steady state the velocity of this flux becomes equal to the rate of the reaction of R with Cat. According to Plate[6], we obtain

$$k_{\mathrm{eff}} = \frac{4\pi\rho D k_{\mathrm{true}} \cdot \beta}{k_{\mathrm{true}} + 4\pi\rho D\beta}, \qquad (1)$$

where k_{eff} and k_{true} are respectively the effective and true rate constants, ρ is the distance between the centres of the reacting species, β a proportionality coefficient having the dimension molecule^{-1}, and D the diffusion coefficient of Cat or the reactant R′ in the medium. One should note that, even when the functional group in the polymer completely lacks mobility, the frequency of the collisions of R with Cat does not change significantly.

Conditions governing the reaction in kinetic or diffusion regions can be readily obtained from Eqn. (1):

when $k_{\mathrm{true}} \ll 4\pi\rho D\beta$, $k_{\mathrm{eff}} = k_{\mathrm{true}}$,

i.e. there is an equilibrium statistical distribution of the species in solution (the kinetic region of the reaction);

when $k_{\mathrm{true}} \gg 4\pi\rho D\beta$, $k_{\mathrm{eff}} = 4\pi\rho D\beta$,

i.e. there is a sharp breakdown of the equilibrium statistical distribution of the species in solution (diffusion region of the reaction).

At the usual temperatures in non-viscous media, we have $D_{\mathrm{cat}} \simeq 10^{-6}-10^{-5}$ cm^2 s^{-1} (Table 1) and the values of ρ for typical functional groups and catalysts amount to seversl angstroms. Consequently, $4\pi\rho D\beta \simeq 10^{-12}-10^{-11}$ cm^3 mol.$^{-1}$ s^{-1} or 10^9-10^{10} litre mole^{-1} s^{-1}. Thus reactions with $k_{\mathrm{true}} > 10^8$ litre mole^{-1} s^{-1} occur in the diffusion region. The reactions of the proton, the hydroxide, ion[9], and enzymes[10] with the functional groups of the reactants, i.e. stage (1) of the polymer degradation process, do in fact occur in this region.

The rate of reactions with $k_{\mathrm{true}} < 10^8$ litre mole^{-1} s^{-1} is not limited by diffusion and such reactions occur in the kinetic region. These include the decomposition of the ionised forms of the functional groups and of the majority of enzyme–substrate complexes involving the formation of the reaction products [stage (II) of the polymer degradation process]. In the majority of cases the rate of this stage limits rate of the entire degradation process. On passing to viscous systems, ρ hardly changes, while D decreases with increase of the viscosity of the system. For example, D changes with increase of the viscosity of electrolyte solutions in accordance with the equation[11]

$$D = D_0\left(\frac{\eta_0}{\eta}\right)\left(1-\frac{e^2q}{4\epsilon kT}\right), \tag{2}$$

where D_0 and η_0 are the diffusion coefficient and the viscosity at infinite dilution respectively, e is the electronic charge, ϵ the dielectric constant of the medium, q a variable quantity which depends on the electrolyte concentration, and k the Boltzmann constant.

Table 1. Diffusion coefficients of acids in water.

Catalyst	$10^6 D_{25°}$, $cm^2\ s^{-1}$	References
HCl	30.0	13
H_2SO_4	12.0	11
H_3PO_4	8.7	14

It is noteworthy that Eqn. (2) is inapplicable to very viscous media. In solid polymers, $D_{25°} \simeq 10^{-9}-10^{-8}$ $cm^2\ s^{-1}$ for water[12] and $4\pi\rho D\beta \simeq 10^5-10^6$ litre $mole^{-1}\ s^{-1}$. These data lead to the conclusion that, even in very viscous media (solid polymers), the rate of state (II) is not limited by diffusion, i.e. this stage occurs in the kinetic region (we have in view a microkinetic treatment in contrast to a macrokinetic treatment, to which the last part of the review is devoted).

Thus the macroviscosity of the reaction medium influences significantly the rate of reaction between catalysts and the functional groups of the reactants and has almost no effect of the decomposition of the complexes of the functional groups with catalysts, resulting in the formation of products. On the other hand, in most cases the latter reaction in fact constitutes the rate-limiting stage of the entire degradation process.

2. A QUANTITATIVE ESTIMATE OF THE INFLUENCE OF THE INTERACTION OF FUNCTIONAL GROUPS ON THEIR REACTIVITY IN THE POLYMER

If the functional groups in the polymeric molecules are distributed at distances which virtually rule out their mutual influence, then the kinetic parameters of the degradation reactions of polymers and their low-molecular-weight analogues are similar, i.e. the principle of independence of reactivity of molecular weight is valid. Table 2 lists the kinetic parameters for the degradation of polymers and their low-molecular-weight analogues; within the limits of experimental error, these parameters are similar. It is interesting to note that the reactivity (k_{eff}) of acrylic polymers in the H–D exchange reaction is approximately two orders of magnitude lower than that of the corresponding low-molecular-weight analogues (Table 3); according to Scarpa et al.[21], this is due to the decrease of the dissociation constant of water near amide groups relative to the solution.

However, functional groups are frequently distributed close to one another (at distances <10 Å) and this is in fact the cause of the anomalous reactivity of the functional groups in polymers. The following types of the anomalous reactivity of the functional groups in polymers have been distinguished: (a) the effect of an adjoining group which may be either of the long-range type (the "chain effect") or of the short-range type (i.e. the influence of groups located in the immediate vicinity of the given functional group); (b) conformational effects—effects due to the change in reactivity caused by the changes in the form of the macromolecule in the given reaction medium or in the course of the reaction.

Table 2. Kinetic parameters of the degradation reactions of polymers and their low-molecular-weight analogues.

Polymer and its low-molecular-weight analogue	Solvent-catalyst	$k_{true}(25°)$, s^{-1}	E, kcal $mole^{-1}$	lg A* (s^{-1})	References

*The rate constant at the minimum in the relation between lg k_{eff} and pD.

These effects can probably be accounted for by polar, resonance, and steric effects[24], which are well known in organic chemistry, just as the mechanism of the hydrolytic action of chymotrypsin has been explained with the aid of explicit chemical analogues[25].

a. The Long-range Effects of Neighbours of the Group

As a rule, this effect is illustrated by comparing the reactivities of monomers having a system of conjugated double bonds and of a model compound having a single double bond. We shall consider the manifestation of the chain effect in the dehydrochlorination of poly(vinyl chloride) (PVC) at high temperatures. The dehydrochlorination process is known to occur in steps, the double bonds formed activating the next dehydrochlorination step (allylic activation). An attempt has been made[26] to subdivide the complex dehydrochlorination process into two reactions: (1) the random formation of isolated double bonds and (2) the growth of the system of conjugated bonds as a result of allylic activation.

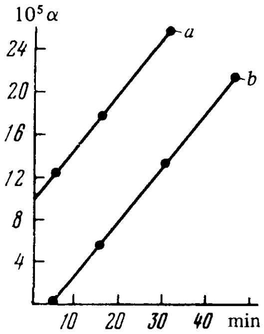

Figure 1. The rate of dehydrochlorination of PVC (*a*) and chlorinated PVC (*b*) at 175 °C; α is the number of breaks per mole of the polymer[26].

Fig. 1 presents the rates of dehydrochlorination of PVC (a) and chlorinated PVC (b) at 175 °C. Evidently the formation of isolated double bonds is independent of the nature of the PVC specimen and proceeds at the same rate ($k_1 = 8.6 \times 10^{-8}$ s^{-1}). In the general case the overall PVC dehydrochlorination process can be described by the following equation without taking into account the destruction of kinetic chains in the initial stages:

$$\frac{\mathrm{d}[\mathrm{HCl}]}{\mathrm{d}t} = k_1 + k_2 X_t,$$

where $k_2 = (W_{\mathrm{PVC}} - W_{\mathrm{CPVC}})/X_0 = 9.3 \times 10^{-4}$ s^{-1}, W_{PVC} and W_{CPVC} are the rates of dehydrochlorination of PVC and chlorinated PVC respectively, and X_0 and X_t are respectively the numbers of double bonds in PVC at the initial instant and at time t.

Table 4. Kinetic parameters of the dehydrochlorination reaction of model compounds for PVC in the gas phase[27].

Model compound	Temp. range, °C	$10^{11}k_{117°}$, s^{-1}	E, kcal mole^{-1}	lg$A$
2-Chlorobutane	347—394	3.6	49	13
2,4-Dichloropentane	347—397	3.3	49	13
2,4,6-Trichloroheptane	346—386	3.4	51	14
4-Chloropent-2-ene	296—345	859	41	12
6-Chlorohepta-2,4-diene	302—347	45 900	35	10
3-Chloropent-1-ene	319—380	8.9	51	15

It is interesting to compare the constants obtained with the results[27] for compounds simulating PVC (Table 4).

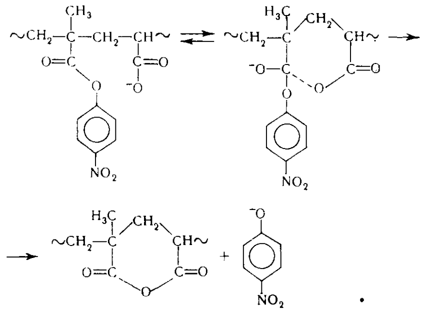
The presence of a double bond at the end of the macromolecule does not have an appreciable influence on the dehydrochlorination reaction (3-chloropent-1-ene); the double bond in the 2- or 4-position greatly accelerates the dehydrochlorination reaction and 4-chloropent-2-ene and particularly 6-chlorohepta-2,4-diene can simulate the allylic activation effect. It is noteworthy that the rate constant for the dehydrochlorination of the latter compound is 10^4 times higher than the rate constant for alkyl chlorides.

Thus the formation of isolated double bonds and the growth of the system of conjugated bonds as a result of allylic activation can be simulated by the dehydrochlorination reactions of alkyl chlorides and 6-chlorohepta-2,4-diene respectively.

b. The Short-range Effect of a Neighbouring Group

Effects of this type occur when the substituent adjoining the given functional group favours or hinders the formation of the activated complex.

For example, the hydrolysis of the copolymer of acrylic acid and *p*-nitrophenyl methacrylate proceeds more readily than that of *p*-nitrophenyl acetate, since in the former case a six-membered activated complex is formed easily following the attack by the carboxylate ion on the ester linkage[28]:



(III)

At 0 °C and pH 6 the rate constants for the intramolecular (copolymer of acrylic acid and *p*-nitrophenyl methacrylate) and intramolecular (*p*-nitrophenyl acetate or acetate ion) hydrolysis are respectively 2×10^{-3} s^{-1} and 6.5×10^{-7} litre mole^{-1} s^{-1}.

The question of the influence of neighbouring groups on the given functional group has been examined theoretically[29-35]. Functional groups of three types may be present in a polymeric molecule under the conditions of a low degree of conversion:

1) groups whose nearest neighbours have not reacted;
2) groups having one neighbour which has reacted;
3) groups having two neighbours which have reacted.

The rates of reaction of functional groups under the conditions of an excess concentration of the catalyst are defined by the equation

$$-\frac{\mathrm{d}x}{\mathrm{d}t} = k_0 N_0 + k_1 N_1 + k_2 N_2,$$

where k_0, k_1, and k_2 are respectively the rate constants for reactions of type 1, 2, and 3 functional groups and N_0, N_1, and N_2 are the mole fractions of the corresponding types of functional groups. The solution of the system of the corresponding differential equations relating the change in N_n of a sequence of n groups which have reacted to the corresponding concentrations of functional groups of different types, the rate constants, and time leads to the following expressions[29]:

$$N_0 = \exp\left\{-\left(2\frac{k_1}{k_0}+1\right)k_0t - 2\left(\frac{k_1}{k_0}-1\right)[(\exp - k_0t) - 1]\right\};$$

$$N_1 = [\exp k_0t - 1]\exp\left\{-\left(2\frac{k_1}{k_0}+1\right)k_0t - 2\left(\frac{k_1}{k_0}-1\right)[(\exp - k_0t) - 1]\right\}.$$

The solution for N_2 is complex: for example, when $k_1/k_0 = 1$, we have

$$N_2 = \frac{2}{\left(\frac{k_2}{k_0}-2\right)\left(\frac{k_2}{k_0}-3\right)}\left[\left(\frac{k_2}{k_0}-3\right)\exp(-2k_0t) - \left(\frac{k_2}{k_0}-2\right)\exp(-3k_0t) + \exp(-k_2t)\right].$$

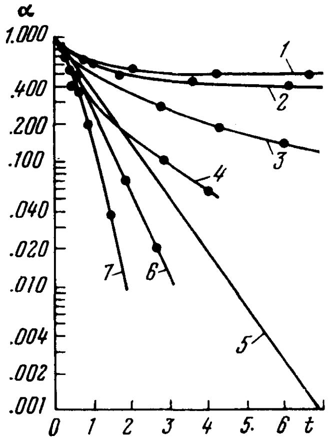


Figure 2. Variation of the degree of conversion of the functional groups in the polymer with time for different reaction rate constants[31]; respective values of the rate constants k_0, k_1, and k_2: 1) 1.0, 4×10^{-2}, 4×10^{-4}; 2) 1.0, 0.2, 1×10^{-2}; 3) 1.0, 0.5, 0.2; 4) 1.0, 1.8, 0.5; 5) 1.0, 1.0, 1.0; 6) 1.0, 1.8, 1.5; 7) 1.0, 2.0, 5.0.

Fig. 2 illustrates the variation of the degree of conversion of the functional groups in the polymer with time for different reaction rate constants obtained by Arends[31]:

$k_0 = k_1 = k_2$ (linear relation),
$k_0 = 1,\quad k_1 < 1,\quad k_2 < 1$ (self-inhibition),
$k_0 = 1,\quad k_1 > 1,\quad k_2 > 1$ (self-acceleration).

The second case, where the degradation process does not reach completion owing to self-inhibition, i.e. there is a certain limiting degree of conversion, is encountered most frequently. A statistical approach to the solution of this problem has been adopted[31-33].

The limiting degrees of conversion of functional groups in the polymer (α) for different ratios k_0/k_1 are listed below[35]:

α	0,667	0,632	0,606	0,600	0,586	0.577	0,50
$\frac{k_1}{k_0}$	1	0,5	0,25	0,20	0,10	0.05	0,01

The kinetics of the alkaline hydrolysis of polyacrylamide have been thoroughly investigated in the same study[35]. In order to describe the experimental data, the authors made the mechanism more involved by assuming that the carboxylate group formed can influence not only the neighbouring group but also the next amide group. They quote the following data for the influence of the carboxylate groups on the reactivity of the amide linkages in the alkaline hydrolysis of polyacrylamide at 60°C:[35]

	—A—A—A—	—A—A—C—A—A—	—C—A—A—C	—C—A—C—
10^4k, litre mole^{-1} s^{-1}	10.8	3	2	0.05
$\Delta G^{\neq}$, kcal mole^{-1}	0	0.7	1 0	3.0

A = amide group, C = carboxylate group

The increase of the free energy of activation owing to the influence of the neighbouring carboxylate groups was determined from the formula

$$\Delta G = \frac{e^2R}{\varepsilon\cdot\bar{r}\cdot k},$$

where R is the gas content and $\bar{r}$ the average distance between the amide linkage and the carboxylate group, assumed to be 3.5 Å.

When the effect of a neighbouring group is considered, it is important to discover (a) what changes in the reactivity of the given functional group may be expected as a result of its approach to the neighbouring functional group, and (b) the mechanism of the action of the neighbouring functional groups. We shall consider as an example the intramolecular alkaline hydrolysis of monophenyl esters of dicarboxylic acids[36,37].

Table 5. The influence of structure on the reactivity of monophenyl esters of dicarboxylic acids in the intramolecular hydrolytic reaction in an alkaline medium[36,37].

No.	Reactants	Relative rate constant
I		1.0
II		20
III	 $\begin{array}{l}CH_2{-}COOR\\ \vert\\ CH_2{-}COO^-\end{array}$	230
IV	 $\begin{array}{l}CH{-}COOR\\ \Vert\\ CH{-}COO^-\end{array}$	10 000
V	 R = C_6H_5 or p = BrC_6H_4	53 000

The data presented in Table 5 show that the bicyclic compound (V) reacts 53 times faster than monophenyl glutarate (I), i.e. in a series of low-molecular-weight compounds it is possible to attain greater differences between reactivities than in the example quoted above.

The intramolecular reactions cannot be accelerated by the following factors[38,39]:

(a) A local increase of the concentration of reactant near the bond being hydrolysed during the intramolecular reaction. For example, the effective concentration of carboxylate groups near the ester linkage in the hydrolysis of the copolymer of acrylic acid and p-nitrophenyl methacrylate may be estimated from the ratio $k_{\text{intramol.}}/k_{\text{intermol.}}$. It amounts to 3×10^3 mole litre^{-1}, which is much larger than the concentrations actually reached.

(b) A favourable mutual orientation of the reacting groups, since the kinetic differences between the intramolecular and intermolecular reactions cannot be reduced to the entropy effect alone.

Changes in solvation can make a considerable contribution to the acceleration of certain intramolecular reactions (including "polymerisation" reactions). For the formation of the activated complex via the intramolecular hydrolytic reaction of monophenyl esters of dicarboxylic acids, it is necessary that the water molecules hydrolysing the charged carboxylate group should be removed. Examination of molecular models shows that in the ester (V) this group cannot be hydrated by water on the side where the ester linkage is attacked. Therefore, during the above intramolecular reaction, energy is not required for the removal of water from the hydration shell.

It is also possible to draw the following analogy. The catalytic properties of the proton, expressed in terms of the acidity function, increase as water molecules are eliminated from its hydration shell. In non-aqueous solvents, for example acetic acid, nitromethane, and sulpholane, the acidity function is several orders of magnitude higher than in aqueous solution at the same sulphuric acid concentration[40]. These effects are probably the cause of the high rates of intramolecular reactions in both polymers and in their low-molecular-weight analogues.

c. Conformational Effects

Depending on the temperature and the composition of the solution, the macromolecules can exist in different conformations where the functional groups differ in reactivity. This is associated with the change in the relative disposition of the functional groups and in addition with their different accessibilities to the external reactant. This case obtains in the alkaline hydrolysis of polyacrylamide, where the formation of carboxylate groups leads to a transition of the macromolecule from the globular to the uncoiled form; unfortunately a kinetic assessment of this effect has not been made. Similar effects are characteristic of polymeric molecules with a pronounced secondary structure (polypeptides, polyorganosiloxanes, etc.).

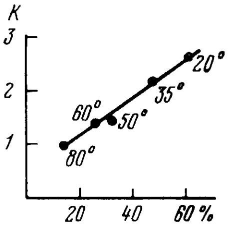

Figure 3. Variation of the ratio of the rate constants for the $^1H \rightarrow {}^3H$ exchange reaction involving AMP and poly-A with the fraction of bases in poly-A participating in the stacking interaction[41].

The $^1H \rightarrow {}^3H$ exchange reaction has been investigated in polyriboadenylic acid (poly-A) and its low-molecular-weight fragment—adenosine 5-monophosphate (AMP)—at pH 7.1.[41] In neutral solutions below 0°C, the poly-A molecules have the conformation of rigid rods consisting of helices of the same type. The stabilisation of these helices is determined primarily by the stacking interaction via the π electrons of the purine rings and hydrogen bonds. With increase of temperature, the interaction between the bases weakens and the polymer molecules become more labile. The AMP molecules retain their structure at all temperatures.

Fig. 3 illustrates the variation of the ratio K of the rate constants for the $^1H \rightarrow {}^3H$ exchange reaction involving AMP and poly-A with the fraction of the bases in poly-A participating in the stacking interaction. The latter quantity was determined by an independent procedure. The observed proportionality between K and the fraction can be regarded as evidence that the stacking interaction causes the retardation of the exchange of hydrogen atoms in the C–H bonds of the adenyl residues.

Thus the anomalous reactivity of "polymeric" functional groups, caused by the primary structure (the short- and long-range effects of the neighbouring group), can probably be determined and simulated with the aid of low-molecular-weight analogues. The anomalous reactivity caused by the secondary structure (conformational effects) is specific to the polymeric state.

III. THE MECHANISMS OF REACTIONS OF CHEMICALLY UNSTABLE BONDS OF VARIOUS POLYMERS IN CORROSIVE MEDIA

Solutions of acids and bases catalyse chemical degradation reactions of monomers. By the mechanism of the catalytic action of acids and bases, we mean the set of data concerning the equilibrium between the ionised and unionised forms of the substance in the reaction medium and the mechanism of the slow fundamental stages limiting the rate of the process.

1. THE MEASURE OF THE CATALYTIC EFFECT OF CORROSIVE MEDIA

The catalytic effect of acids and bases is usually estimated in terms of the capacity of the medium to behave as a donor of protons or hydroxyls. In dilute aqueous solutions of acids and bases, the pH may serve as a quantitative measure of the catalytic effect. However, at electrolyte concentrations in excess of 0.1 M the deviation from ideal solutions becomes appreciable, so that a rigorous quantitative determination of the activity of the proton or the hydroxyl becomes impossible. Hammett[42] proposed an empirical approach to the determination of the acidity of solutions of acids with the aid of indicators.

For the protolytic equilibrium

$$\mathrm{In} + \mathrm{H}^+ \rightleftarrows \mathrm{InH}^+ ,$$

the dissociation constant of the conjugate acid of the indicator InH^+ can be expressed as follows:

$$K_{\mathrm{InH}^+} = \frac{a_{\mathrm{H}^+} f_{\mathrm{In}}}{f_{\mathrm{InH}^+}} \cdot \frac{c_{\mathrm{In}}}{c_{\mathrm{InH}^+}} ,$$

where a is the activity, f the activity coefficient, and c the concentration. The concentrations of the ionised and unionised forms of the indicator are determined spectrophotometrically. Knowing K_{InH^+}, the quantity

$$h_x = a_{H^+}\frac{f_{In}}{f_{InH^+}}, \tag{3}$$

called the acidity of the medium, can be calculated. By analogy with pH, the acidity function is $H_X = ph_X$. More than ten acidity functions, defined with the aid of different classes of indicators, are now known and according to Hammett none of them have any advantages over the others[43].

Thus, since the acidity is determined not only by the capacity of the medium to give up protons but also by the capacity of the indicators to combine with protons, the absolute acidity of the medium cannot be determined by the indicator method, although definite progress has been made in this field during recent years.

Yates et al.[44] calculated a_{H^+} for aqueous solutions of sulphuric and perchloric acids by Eqn. (3) and the activity coefficients were determined by the solubility method. The values of a_{H^+} thus obtained agree with the results determined by electrochemical methods using the ferrocene–ferrocenium system as the reference electrode. Several alkalinity functions are also known for solutions of bases[45,46].

2. CLASSIFICATION OF THE MECHANISMS OF HYDROLYSIS

The mechanisms of the hydrolysis of various compounds have been classified by Ingold[47] on the basis of two main features:

1. Type of catalysis (A—acid, B—base).
2. The molecularity of the rate-limiting stage.

We shall consider the principal relations for uni- and bi-molecular processes.

A. The Unimolecular Mechanism

Consider a reaction via the mechanism

$$R + Cat \overset{K_X}{\rightleftarrows} X;$$

$$X \rightleftarrows M^{\neq} \xrightarrow{k_{true}} P + Cat,$$

where $M^{\neq}$ is the activated complex. The rate of reaction can be formulated as follows:

$$W = k_{eff}c_0 = k_{true}\cdot\frac{a_{\neq}}{f^{\neq}} = k_{true}\, c_X\,\frac{f_X}{f^{\neq}}.$$

Taking into account the equilibrium constant for the formation of X and assuming that X is the Arrhenius complex and that the rate of decomposition of the complex into the catalyst and the substrate is higher than the rate of formation of the reaction product, we obtain

$$c_R = \frac{K_X c_X}{a_{Cat}}\cdot\frac{f_X}{f_R}.$$

Taking into account the material balance equation

$$c_0 = c_R + c_X,$$

we find the general equation for the unimolecular process:

$$k_{eff} = \frac{k_{true}\cdot\dfrac{f_X}{f^{\neq}}}{1+\dfrac{K_X f_X}{a_{Cat}\, f_R}}. \tag{4}$$

If the mechanism of the ionisation of the substrate is known, then, using Hammett's postulate

$$\frac{f_X}{f_R} = \frac{f_{X'}}{f_{In}} = \text{const}$$

we introduce into Eqn. (4) the corresponding acidity or alkalinity. Furthermore, the complex X and the activated complex usually have the same composition, charge, and structure, i.e. $f_X/f^{\neq}$ = const., which greatly simplifies Eqn. (4):

$$k_{eff} = \frac{k_{true}}{1+\dfrac{K_X}{h_X}}. \tag{5}$$

The values of c_X have now been determined by independent methods in a number of studies[48] and the validity of Eqn. (5) has been demonstrated.

B. The Bimolecular Mechanism

In reactions involving a bimolecular mechanism, the activated complex includes the reactant, the catalyst, and, in hydrolytic reactions, a water molecule. In some cases the activated complex is formed when X interacts with a water molecule and in others when the reactant interacts with the complex of the catalyst and a water molecule, for example the hydronium ion.

The rate of reaction can be defined by two identical equations:

$$W = k_{eff}\, c_0 = k_{true}\frac{a_{\neq}}{f^{\neq}} = \begin{cases} k_{true}\,\dfrac{a_R\cdot a_{Cat.H_2O}}{f^{\neq}} \\ k_{true}\,\dfrac{a_{R.Cat.}\cdot a_{H_2O}}{f^{\neq}} \end{cases}.$$

These equations cannot be solved in a general form, since there are as yet no reasonable quantitative methods for estimate $f^{\neq}$. However, there are many empirical approaches. We shall consider briefly some of them, assuming for simplicity that the concentration of R is much higher than of the complex X.

In Bunnett's approach[49], specific hydration numbers are assigned to all the species in the reaction medium. After formulating the equation

$$R\cdot(H_2O)_s + Cat\,(H_2O)_n \overset{K_X}{\rightleftarrows} X\,(H_2O)_p + (s+n-p)\cdot H_2O,$$

$$X\cdot(H_2O)_p + (H_2O)_r \rightleftarrows M^{\neq}\,(H_2O)_t \xrightarrow{k_{true}} \text{products},$$

and taking into account the indicator equilibrium

$$In\,(H_2O)_b + Cat\,(H_2O)_n \rightleftarrows In\cdot Cat\,(H_2O)_c + (b+n-c)\cdot H_2O,$$

we obtain

$$k_{eff} = \frac{k_{true}}{K_X}\cdot h_X\,\frac{f_{R(H_2O)_s}\cdot f_{In\,Cat(H_2O)_c}}{f^{\neq}_{M(H_2O)_t}\cdot f_{In(H_2O)_b}}\cdot a_{H_2O}^{(b-c)-(s-p)+r}. \tag{6}$$

Using Hammett's postulate and assuming that $f_{In\,Cat(H_2O)_c}/f^{\neq}_{M(H_2O)_t}$ is independent of the composition of the medium because the complex of the reactant and the catalyst (or of the indicator and the catalyst) and the activated complex have the same charge and similar structures, we obtain

$$k_{eff} = \frac{k_{true}}{K_X}\cdot h_x\cdot a_{H_2O}^r. \tag{7}$$

Bunnett treated in terms of this equation numerous data for the hydrolysis of various compounds[49]. However, Eqn. (7) is frequently inapplicable when the catalyst concentration range is fairly wide. Strictly speaking, one cannot assume that the ratio $f_{\mathrm{In\,Cat(H_2O)_c}}/f^{\neq}_{\mathrm{M(H_2O)_t}}$ is constant in Eqn. (6), because the two complexes should have different compositions (differ hydration numbers); however, the lack of knowledge of this ratio is compensated by an empirical parameter r, formally expressing the number of water molecules involved in the activated complex.

Vinnik's approach[50] consists in the hypothesis that an intermediate complex M (of R and H_3O^+) is formed in aqueous solutions of strong acids and decomposes unimolecularly into the reaction products. It is assumed that the activity coefficient ratio $f_M/f^{\neq}$ is constant and the activity coefficients of the activated complex and the complex M are given by the equation

$$f_M = f^{\neq} = f_R^{\beta}\, f^{\alpha}_{H_3O^+}\ \mathrm{const},$$

where α and β are parameters independent of the medium,

$$k_{\mathrm{eff}} = \frac{k_{\mathrm{true}}}{K_X}\cdot c_{H_2O} + f_R^{(1-\beta)}\ f^{(1-\alpha)}_{H_3O^+},$$

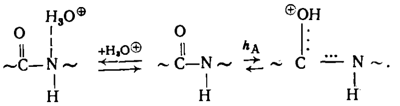
and f_R can be determined from solubility data. Thus the problem reduced to the determination of the parameters α and β alone.

In recent years Vinnik[51] formulated a general rule for the determination of the mechanism of the rate-limiting step in catalytic hydrolysis in aqueous solutions: the activity of the activated complex must be expressed in terms of the concentrations of different forms of the reactants in such a way that the multiplier involving the activity coefficients which appears in the kinetic equation does not vary with the concentration of the acid. Using extensive experimental data, Vinnik divided all the hydrolytic reactions in aqueous solutions of strong acids into four groups. In reactions of groups I and II, the activated complex is produced from the unionised form of the reactant, the hydronium ion, and the nucleophilic agent—water molecule (group I) or anion (group II). In the reactions of the other groups, the activated complex is produced from the protonated form of the reactant with or without the participation of a water molecule (group III) or with participation of the anion (group IV).

Thus, whereas a simple general equation, obtained within the framework of reasonable assumptions is available for unimolecular processes, such an equation does not exist for bimolecular processes and in each specific case additional information is necessary for the choice of the mechanism.

We shall consider the mechanisms of the decomposition of chemically unstable bonds in polymers.

The amide linkage. A characteristic feature of the hydrolytic reactions of compounds with an amide linkage in acid media is a maximum in the effective rate constant as a function of the concentration of the acid. Fig. 4 illustrates the variation of $\lg k_{\mathrm{eff},25°}$ for the hydrolysis of the cyclic caproamide trimer (a polymer model) as a function of the amide acidity function of aqueous solutions of sulphuric acid H_A.[15,52] The values of $\lg k_{\mathrm{eff},25°}$ for the hydrolysis of the polymer with M_V = 20 000 lie almost on the same curve. According to the proposed mechanism, the rate-limiting step of the process is the attack by the hydronium ion on the amide nitrogen atom; the protonation of the carbonyl oxygen leads to the formation of the unreactive form:



$$\sim\overset{\overset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle H}{|}}{\overset{\overset{\displaystyle H_3O^{\oplus}}{\vdots}}{N}}\sim \ \underset{\longrightarrow}{\overset{+H_3O^{\oplus}}{\longleftarrow}}\ \sim\overset{\overset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle H}{|}}{N}\sim \ \overset{h_A}{\rightleftarrows}\ \sim\overset{\overset{\displaystyle {}^{\oplus}OH}{\vdots}}{C}\ \overset{\cdots}{-}\ \underset{\underset{\displaystyle H}{|}}{N}\sim.$$

The variation of k_{eff} with thermodynamic parameter is described satisfactorily by the equation

$$k_{\mathrm{eff}} = \frac{k_{\mathrm{true}}\ c_{H_3O^+}}{1+\dfrac{h_A}{K_{BH^+}}}. \tag{8}$$

The continuous line in Fig. 4 was calculated theoretically from this equation.

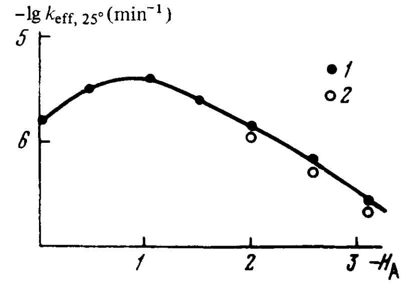


Figure 4. Variation of $\lg k_{\mathrm{eff},25°}$ for the hydrolysis of the cyclic caproamide trimer (1) and polycaproamide having $\overline{M}_V$ = 20 000 (2) with the amide acidity function of aqueous sulphuric acid solutions[15].

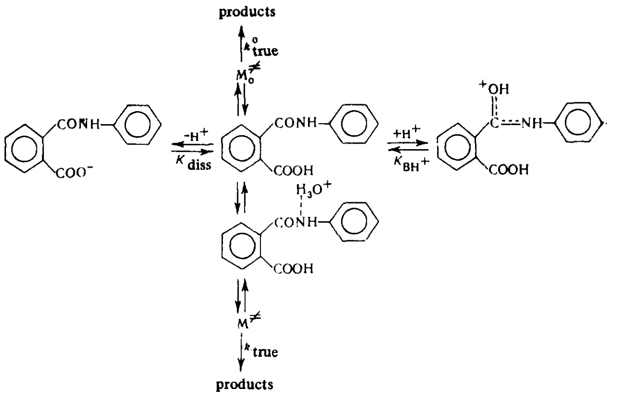
Thus the hydrolysis of compounds with an amide bond is described by the A-2 mechanism. Attention should be drawn to two facts of practical importance:

1. The hydrolytic stability of compounds with an amide linkage increases greatly in concentrated solutions of acids.
2. In polycaproamide the amide linkages are kinetically independent, since the five methylene groups completely prevent the transmission of the mutual polar influence of the amide linkages.

The study of the hydrolysis of o-substituted aromatic amides, simulating the non-cyclised units in heterocyclochain polymers, is of considerable interest. The presence of o-substituents is responsible for a number of characteristic features of the acid hydrolysis of these amides, namely the hydrolytic reaction may be accompanied by the cyclisation reaction and in dilute acid solutions intramolecular catalysis may occur.

Fig. 5 illustrates the variation of $\lg k_{\mathrm{eff},25°}$ with H_A for the hydrolysis and cyclisation of 2-benzamidophenol and the hydrolysis of 2-phenylbenzoxazole—the model compounds for polybenzoxazole[53]. Kinetic analysis of the results showed that the variation of k_{eff} is described by Eqn. (8) for all three reactions.

Fig. 6 presents kinetic data for the acid hydrolysis of N-phenylphthalamic acid—the model of aromatic polyamidoacids[54]. In order to interpret the experimental data, a mechanism was adopted according to which unreactive forms are produced on protonation of the carbonyl oxygen of the amide linkage and on dissociation of the carboxy-group. The reactive species is the unionised form, which may react either with the carboxy-group (intramolecular catalysis) or with a hydronium ion (specific acid catalysis).



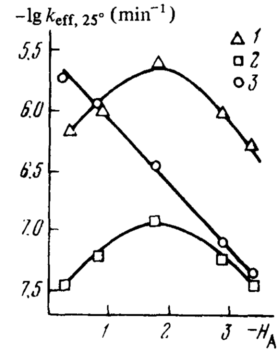


Figure 5. Variation of $\lg k_{eff}$ with the amide acidity function of aqueous sulphuric acid solution for the hydrolysis (1) and cyclisation (2) of 2-benzamidophenol and the hydrolysis of 2-phenylbenzoxazole (3).[53]

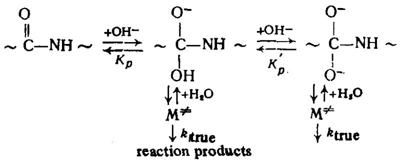
The general expression for k_{eff} is

$$k_{eff}=\frac{k_{true}\,c_{H_3O^+}+k^0_{true}}{1+\frac{K_{diss}}{h_A}+\frac{h_A}{K_{BH^+}}},$$

where k_{true} and $\overset{0}{k}_{true}$ are the true rate constants for hydrolysis via the specific acid and intramolecular catalytic mechanisms and K_{diss} is the dissociation constant of N-phenylphthalamic acid.

In alkaline media there is also a complex profile of changes in the alkaline hydrolysis of compounds with amide linkages. Fig. 7 illustrates the variation of $\lg k_{eff,25°}$ for the hydrolysis of N-methylacetamide with the alkalinity function of aqueous KOH solutions[55]. It has been shown by infrared spectroscopy that amides may exist both in the unionised form and as singly and doubly charged ions. The rate-limiting step in the process involves the interaction of these ions with a water molecule:



$$\sim\overset{O}{\overset{\|}{C}}-NH\sim \underset{K_p}{\overset{+OH^-}{\rightleftarrows}} \sim\underset{OH}{\overset{O^-}{C}}-NH\sim \underset{K'_p}{\overset{+OH^-}{\rightleftarrows}} \sim\underset{O^-}{\overset{O^-}{C}}-NH\sim .$$

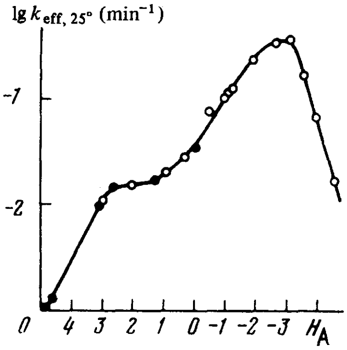


Figure 6. Variation of $\lg k_{eff,25°}$ with the amide acidity function of aqueous sulphuric acid solutions for the hydrolysis of N-phenylphthalamic acid[54].

The kinetic equation for the hydrolysis is

$$k_{eff}=\frac{k_{truc}\,a^2_{H_2O}\,K_p\cdot\frac{1}{b_0}+k'_{true}a_{H_2O}}{1+K'_p\frac{a_{H_2O}}{b_0}+K_pK'_p\frac{a_{H_2O}}{b_0^2}}, \qquad (9)$$

where b_0 is the alkalinity of the medium.

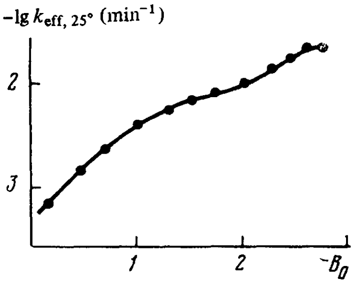

Figure 7. Variation of $\lg k_{eff,25°}$ with the alkalinity function of aqueous potassium hydroxide solutions for the hydrolysis of N-methylacetamide[55].

The validity of this equation has been demonstrated by an independent procedure involving a comparison of the changes in k_{eff} with the concentrations of the ionised forms of the amide[56].

The ester linkage. Numerous studies have been made on the acid hydrolysis of compounds with ester linkages, but there is as yet no unanimous view concerning the mechanism of the hydrolysis. The possible mechanisms of the hydrolytic reactions have been analysed in detail[51]. The hydrolysis of compounds with ester linkages in alkaline media proceeds via a mechanism[51] analogous to that described above for compounds with amide linkages.

The imide linkage. The hydrolysis of compounds with imide linkages takes place in acid and alkaline media via mechanisms analogous to those described for amides.

The acetal linkage. Compounds with acetal linkages are known to be stable in alkalis and to be readily hydrolysed in acids. The acid-catalysed hydrolysis of acetals is an example of the A-1 monomolecular mechanism[58,59]. The experimental data are described by the equation

$$k_{\text{eff}} = \frac{k_{\text{true}}}{K_{\text{BH}^+}} \cdot h_0,$$

where h_0 is the Hammett acidity function.

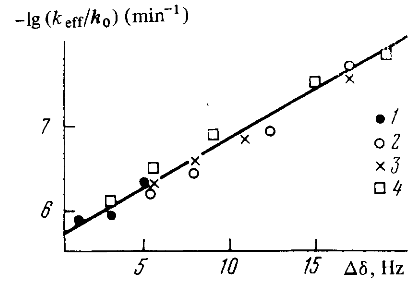

Figure 8. Experimental data represented by a plot of $\lg(k_{\text{eff}}/k_0)$ against $\Delta\delta$ for the hydrolysis of cellobiose in aqueous acid solutions: 1) HCl; 2) $HClO_4$; 3) H_2SO_4; 4) H_3PO_4.[61]

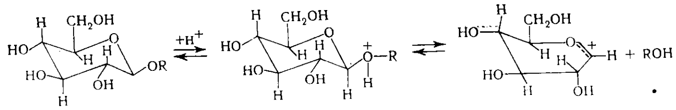
In the hydrolysis of cyclic hemiacetals (glycosides) the principle of correspondence between the structure of the protonated species and the activated complex does not hold. For example, the rate-limiting stage in the hydrolysis of cellobiose, a model of cellulose, includes a slow transition from the chair conformation (protonated form) to the half-chair conformation in the activated complex[60]:



The ratio $f_X/f^{\neq}$ in Eqn. (4) cannot then be regarded as constant. Evidently it will be larger the stronger the interaction between the cellobiose molecule and the medium.

The change in the activity coefficient ratio $f_{RH^+}/f^{\neq}$ can be estimated from the chemical shifts $\Delta\delta$ of the protons at the carbon atom in the 2-position[61]. The change in k_{eff} for the hydrolysis of cellobiose is described by the equation

$$\lg \frac{k_{\text{eff}}}{h_0} = \lg \frac{k_{\text{true}}}{K_{\text{BH}^+}} + p \cdot \Delta\delta,$$

where p is a proportionality coefficient. Fig. 8 presents experimental data in terms of the variables of this equation for aqueous solutions of different acids.

For the other linkages encountered in polymers, the evidence adduced for the hydrolytic mechanisms is not rigorous.

IV. PRINCIPAL TYPES OF DECOMPOSITION OF POLYMERIC MOLECULES

The structure of polymeric molecules determines the type of their decomposition. On the one hand, chemically unstable bonds can be equally reactive and, on the other, terminal bonds can exhibit enhanced reactivity, which complicates the chemical degradation process. Furthermore, polymers may contain bonds with enhanced reactivity—"weak bonds".

The kinetics (changes in the number of molecules and in the mass of the polymer) have been examined theoretically[62] for the principal types of decomposition of polymeric molecules in degradation processes. We shall consider the main types of decomposition of polymeric molecules in chemical degradation reactions.

a. Random Decomposition

This type of decomposition is frequently encountered in chemical degradation processes and can be illustrated by the examples in Tables 2 both for the reactions of the main polymer chain and for the polymer-analogue reactions involving the abstraction of groups of atoms without a change in the degree of polymerisation.

In cellulose the terminal hemiacetal linkages are somewhat more reactive than the "non-terminal" linkages. This is seen from a comparison of the rate constants for the acid-catalysed hydrolysis of cellulose and cellobiose (Table 2) and also from data[63] showing that the reactivities of the two hemiacetal linkages in cellotriose differ by 1.5. However, the difference between the reactivities of the terminal and non-terminal linkages is slight and the acid-catalysed hydrolysis of cellulose under homogeneous conditions can therefore be regarded as a random process to a first approximation.

b. Depolymerisation Decomposition

This type of decomposition is encountered extremely rarely in a pure form in chemical degradation processes; it is usually combined with the random decomposition of the polymer chain.

c. Decomposition of the Mixed Type

A typical example of such decomposition is the acid-catalysed degradation of polyoxymethylene, which is accompanied by the cleavage of the chain with formation of fragments having terminal hydroxy-groups and by the depolymerisation of these fragments.

d. The Cleavage of the Polymer Chain

The maximum in the reactivity of polyoxymethylene oligomers with terminal methoxy-groups (POM-OCH_3) in the acid-catalysed degradation process (Table 6) leads to the conclusion[64] that the terminal acetal linkages are more reactive than the non-terminal linkages and that the acid-catalysed degradation process includes two consecutive stages: (1) slow decomposition of the terminal acetal linkage in the oligomer; (2) rapid depolymerisation of the hemiacetal formed.

Table 6. Aliphatic reaction constants σ^* and the rate constants for the degradation of the $CH_3(OCH_2)_nOCH_3$ oligomers in aqueous sulphuric acid solutions[64].

n	R_1^a	R^a	$\Sigma\sigma^*$	$\lg K^b_{25°}$	n	R_1^a	R^a	$\Sigma\sigma^*$	$\lg K^b_{25°}$
1	CH_3	CH_3	0	−2.82	3	»	$(CH_2O)_2CH_3$	0.15	−2.64
2	»	CH_2OCH_3	0.52	−2.18	4	»	$(CH_2O)_3CH_3$	0.05	−2.74

[a] Substituents near the reaction centre.
[b] $k_{25°} = (k_{true}/K_{BH^+})_{25°}$, where k_{true} is the true rate constant for the decomposition of the protonated form of the reactant and K_{BH^+} is the basicity constant of the reactant.

The results are described satisfactorily by the Taft equation (Fig. 9) and make it possible to select methylal ($n = 1$) as a model of the terminal acetal linkage in POM-OCH_3 polymers.

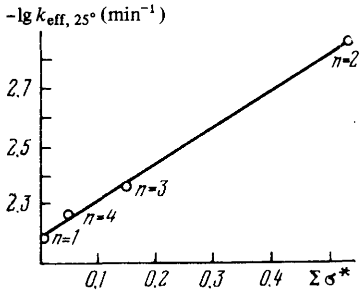


Figure 9. Correlation based on the Taft equation of the experimental data for the degradation of polyoxymethylene oligomers with terminal methoxy-groups in aqueous sulphuric acid solutions[64].

The reactivities of certain acetal linkages have been determined[65] from the change in the molecular weight of POM-OCH_3 in the course of degradation in a water–hexafluoroacetone solution of HCl. Table 7 shows that the terminal acetal linkages are approximately five times more reactive than the "non-terminal" linkages.

e. The Depolymerisation Reaction

This reaction occurs when the polyoxymethylene molecule contains terminal hydroxy-groups (POM-OH), which serve as active centres for the depolymerisation reaction.

Table 7. The rate constants for the decomposition of terminal and non-terminal acetal linkages and for depolymerisation in the acid-catalysed degradation of POM-OCH_3 in water–hexafluoroacetone solutions of HCl at 25°C.

	k, litre mole^{-1} min^{-1}		
water concn., M	decomposition of terminal bonds	decomposition of non-terminal bonds (random process)	depolymerisation
8.99	$(1.1\pm0.2)\cdot10$	2 ± 0.4	$(3\pm1)\cdot10$
55.5	$(3.1\pm0.2)\cdot10^{-3}$	—	6 ± 1

In stepwise depolymerisation of polymers with an exponential molecular weight distribution, the molecular weight remains almost constant, i.e. $(dM_n/dt)_{dep} \simeq 0$. When the decomposition of the polymeric molecules is a random process followed by depolymerisation (the length of the kinetic depolymerisation chain is much smaller than the number-average degree of polymerisation), we therefore obtain the following system of equations:

$$\frac{dm}{dt} = -2k_{rand}N - 2k_{dep}N; \tag{10}$$

$$\frac{dN}{dt} = k_{rand}m - 3k_{rand}N - \frac{2k_{dep}N^2}{m}, \tag{11}$$

where m and N are respectively the mass of the polymer and the number of molecules at time t, k_{rand} and k_{dep} are respectively the rate constants for random and depolymerisation decomposition. For the initial conditions $m = m_0$ and $N = 0$ with $t = 0$, Eqns. (10) and (11) have the following solution:

$$m = m_0 \exp\left\{\left(\frac{2k_{rand}}{k_{rand}} + 1\right)[\ln(2 - \exp - k_{rand}t) - k_{rand}t]\right\},$$

from which it is possible to calculate the depolymerisation rate constant (Table 7).

This relation between the rate constants for the decomposition of the terminal and non-terminal acetal linkages and for depolymerisation is responsible for the virtually identical effective rate constants determined from the accumulation of formaldehyde in the degradation of POM with different terminal groups in water–hexafluoroacetone solutions of HCl (Table 8). Thus the acid-catalysed degradation of POM in water–hexafluoroacetone solutions takes place in a complex manner; during the initial period, the random dissociations and the decomposition of the terminal acetal linkages lead to the formation of a considerable number of POM-OH molecules, which depolymerise with liberation of formaldehyde, the amount of POM-OH being almost independent of the molecular weight of the initial polymer and the nature of its terminal group.

It is noteworthy that the random decomposition and depolymerisation reactions have different mechanisms. The acetal linkage is decomposed via the A-1 mechanism[59,66], while the depolymerisation reaction proceeds via the A-2 mechanism[67]. Thus the relation between the rate constants for these reactions changes when there is an appreciable alteration of the acid concentration. An equation describing the variation of the effective rate constants for the degradation of POM-OH, determined from the accumulation of formaldehyde, in aqueous sulphuric acid solutions (5–50 wt.%) has been derived[67]:

$$k_{\text{eff}} = k_{\text{dep(true)}}\, c_{\text{H}_3\text{O}^+} \left(\frac{1}{M_{n_0}} + \frac{k_{\text{rand(true)}}\, h_0}{K_{\text{BH}^+}\, k_{\text{term(true)}}\, c_{\text{H}_3\text{O}^+}} \right),$$

where $k_{\text{dep(true)}}$ is the true depolymerisation rate constant and $k_{\text{term(true)}}$ the true rate constant for the destruction of active depolymerisation centres in consequence of the degradation of the polymer chain. When

$$\frac{k_{\text{dep(true)}}}{\overline{M}_{n_0}} \gg \frac{k_{\text{dep(true)}} k_{\text{rand(true)}}}{K_{\text{BH}^+}\, k_{\text{term(true)}}} \cdot \frac{h_0}{c_{\text{H}_3\text{O}^+}}$$

only the depolymerisation reaction takes place and is determined by the initial concentration of the OH terminal groups in POM-OH. This condition holds in dilute sulphuric acid solutions (<5 wt.%) for POM-OH ($\overline{M}_V$ = 7000). With increase of the acid concentration, the depolymerisation reaction, determined by the terminal groups formed on random cleavage of the polymer chain, begins to play a major role and when

$$\frac{k_{\text{dep(true)}}}{\overline{M}_{n_0}} \ll \frac{k_{\text{dep(true)}} k_{\text{rand(true)}}}{K_{\text{BH}^+}\, k_{\text{term(true)}}} \cdot \frac{h_0}{c_{\text{H}_3\text{O}^+}}$$

we obtain

$$k_{\text{eff}} = \frac{k_{\text{rand(true)}} k_{\text{dep(true)}}}{K_{\text{BH}^+}\, k_{\text{term(true)}}} \cdot h_0,$$

i.e. the acid-catalysed degradation process obeys the *A*-1 mechanism.

Table 8. The effective rate constants for the degradation of POM having different molecular weights and different terminal groups in 4.4 × 10^{-3} M HCl solution (8.99 M H_2O in hexafluoroacetone at 30°C [65]).

Polymer	$\overline{M}_V$	$10^2 k_{\text{eff}}$, min^{-1}	Polymer	$\overline{M}_V$	$10^2 k_{\text{eff}}$, min^{-1}
POM-OCH_3	1 500	3.8	POM-$OOCCH_3$	50 000	3.4
	6 500	3.6		100 000	3.4
	10 500	3.7	POM-OH	7 000	19*
	19 500	3.9		220 000	3.5

*Initially there is a large number of depolymerisation centres.

The type of decomposition of the molecules in the solid polymer may differ from that in solution. For example, according to one of the models, cellulose molecules have a folded conformation in the protofibrils and in each fold there are about eight elementary units[68]. On the basis of this structure, Manley and coworkers[69] suggested that the hemiacetal linkage at the tops of the folds exhibit an enhanced reactivity. To confirm this, experiments were performed on the acid-catalysed degradation of different types of cellulose under heterogeneous conditions and molecular weight distribution (MWD) curves were obtained for the acid-soluble degradation products and for the insoluble residue at different time intervals up to 70% conversion. In the course of the degradation process, the cellulose molecules broke down into fragments with an average degree of polymerisation of about 8 regardless of the type of polymer and the MWD of the unreacted component of the cellulose did not change. The results confirm the hypothesis of the presence in cellulose of at least two types of linkage differing appreciably in their reactivities; hemiacetal linkages at the tops of the folds are more reactive than the hemiacetal linkages in the remaining portions of the folds.

Thus in the decomposition of polymers in corrosive media there is a possibility in the general case of sets of bonds having different reactivities. This in fact determines the type of decomposition of polymeric molecules.

V. DIFFUSION OF CORROSIVE MEDIA INTO POLYMERIC MATERIALS

In order to determine the mechanism of the degradation of polymeric materials in corrosive media, it is necessary to know how the corrosive medium diffuses into the polymer and what is its state within the polymer, i.e. to what extent the electrolyte is dissociated into ions and how much the latter are solvated by the solvent.

Since the diffusion of corrosive media into polymers is of considerable theoretical and practical interest (for example in connection with the prediction of the protective properties of polymeric coatings, the permeability of biological membranes, etc.), it will be necessary to consider in this section the general characteristics of the diffusion of corrosive media into polymeric materials. There is at present no general quantitative theory relating the diffusion coefficients of electrolytes in polymers to any structural parameters of the latter. Polymers are usually divided into two classes: hydrophilic and hydrophobic; the principal characteristics of the diffusion of electrolyte solutions into such polymers have been described in a number of studies[70–72].

It is useful to examine the diffusion of electrolytes into polymers as a function of their content of the solvent, for example water. Polymers can be divided arbitrarily into three groups:

(a) polymers readily dissolving water (50–80 wt.%);

(b) polymers dissolving water to a limited extent (1–50 wt.%);

(c) polymers dissolving water sparingly (<1 wt.%).

One should bear in mind that polymers in groups (a) and (b) are as a rule hydrophilic and those in group (c) are hydrophobic.

Polymers of Group (a)

A typical polymer of this group is poly(vinyl alcohol); the solubility of water in this polymer lies in the range 60–80% depending on the method of synthesis. The influence of the polymer on the diffusing species is slight and largely reduces to the bending of the polymer molecules by the diffusing substance. The Mackie–Meares theory[73], which takes into account such bending, makes it possible to calculate the diffusion coefficients fairly rigorously. As a rule electrolytes dissociate into ions in such polymers to the same extent as in aqueous solutions[74]. If the electrolyte in the polymer matrix is not completely dissociated, then in the general case the effective diffusion coefficient depends on the electrolyte concentration. This effect is associated with the different mobilities of ions and undissociated molecules in the polymer matrix[74].

its time variation is described by one of the adsorption equations.

(c) The attainment of a steady concentration of the diffusing substances on the surface of the polymeric article is determined by certain mass-transfer laws, the simplest of which is

$$j = \beta (c_S - c_V),$$

where j is the flux of the diffusing substance, c_S and c_V are respectively the concentration of the substance on the surface and in the bulk of the corrosive solution, and β is the mass-transfer coefficient.

Solution of the Equations for Polymeric Articles of Different Shapes

Most of the practical problems reduce to the description of degradation processes in bodies of simple shape. Polymeric films and coatings are modelled by layers of infinite extent, fibres are modelled by a cylinder, etc. The solutions of Eqns.(12)–(14) for a layer of infinite extent will be considered below. Depending on the ratio of the rates of diffusion and chemical reaction, chemical degradation can proceed under different conditions:

(a) the rate of diffusion of the corrosive medium is comparable to the rate of the chemical reaction (the degradation process takes place in a reaction zone whose size increases with time, and reaches in the limit the dimensions of the polymeric article), i.e. the reaction takes place in the internal diffusion-kinetic region.

(b) The rate of diffusion of the corrosive medium greatly exceeds the rate of the chemical reaction. After the entire polymer has swollen in the corrosive medium, the degradation process takes place throughout the bulk of the polymer, i.e. in the internal kinetic region.

(c) The rate of diffusion of the corrosive medium is much lower than the rate of the chemical reaction. In this case the degradation process takes place in a thin surface reaction layer, which is usually described as reaction from the surface of the article, i.e. in the external diffusion-kinetic region.

b. Internal Diffusion-kinetic Region

The simultaneous solution of Eqns.(12)–(14) constitutes a difficult mathematical problem, which can only be solved with the aid of a computer.

Consideration of the diffusion of the corrosive medium in polymers showed that the diffusion of the solvent is frequently much faster than the direct diffusion of the catalyst (acid or base), i.e. $D_{\text{solv}} > D_{\text{cat}}$; one can therefore assume that the concentration of the solvent in the reaction zone of the polymeric article is constant and equal to its solubility in the polymer (c^0_{solv}), i.e.

$$c_{\text{solv}} = c^0_{\text{solv}} \,. \tag{17}$$

Thus the problem simplifies and reduces to the solution of Eqns.(12) and (13), the first of which assumes the following form when account is taken of Eqn.(17):

$$\frac{dc_n}{dt} = kc^0_n c^0_{\text{solv}}\, c_{\text{Cat}} = k_{\text{eff}} \cdot c_{\text{Cat}}, \tag{18}$$

where

$$k_{\text{eff}} = k\, c^0_n\, c^0_{\text{solv}}.$$

For simplicity, we shall confine ourselves to only one term in Eqn.(13) and shall put $c_i = c_n$.

Consider the case where $K_p \to \infty$, i.e. the functional groups formed during degradation react almost completely with the catalyst. When account is taken of the fact that this reaction proceeds much faster than the degradation reaction, Eqn.(13) becomes

$$\frac{\partial c_{\text{Cat}}}{\partial t} = D_{\text{Cat}} \frac{\partial^2 c_{\text{Cat}}}{\partial x^2} - k_{\text{eff}}\, c_{\text{Cat}}\,, \tag{19}$$

where x is the diffusion coordinate.

The solution of Eqn.(19) subject to the boundary conditions $c_{\text{cat}} = c^0_{\text{cat}}$ when $x = 0$ and l and the initial condition $c_{\text{cat}} = 0$ when $t = 0$ and $0 \leqslant x \leqslant l$ is the following:

$$c_{\text{Cat}}(x, t) = c^0_{\text{Cat}}\left\{1 - \frac{4}{\pi} \sum_{m=1}^{\infty} \frac{\sin b_m x}{(2m-1)(b^2_m D_{\text{Cat}} + 1)} \times \right.$$
$$\left. \times [k_{\text{eff}} + b^2 m D_{\text{Cat}} \exp - (b^2_m D_{\text{Cat}} + k_{\text{eff}})\, t]\right\}, \tag{20}$$

where $b_m = \pi(2m-1)/l$, c^0_{cat} is the solubility of the catalyst in the polymer, and l is the thickness of the film.

After substituting Eqn.(20) in Eqn.(18) and after double integration from 0 to t and from 0 to $l/2$, we obtain

$$c_n = k_{\text{eff}}\, c^0_{\text{Cat}} t \left\{1 - \frac{8}{\pi l} \sum_{m=1}^{\infty} \frac{k_{\text{eff}} t\, (b^2_m D_{\text{Cat}} + k_{\text{eff}}) + b^2_m D_{\text{Cat}} [1 - \exp - (b^2_m D_{\text{Cat}} + k_{\text{eff}})\, t]}{(2m-1)\, b_m (b^2_m D_{\text{Cat}} + k_{\text{eff}})^2\, t}\right\}. \tag{21}$$

Analysis of Eqn.(21) makes it possible to distinguish two cases:

(a) $b^2_m D_{\text{cat}} > k_{\text{eff}}$. In this case it is sufficient to retain only the first term of the series. A detailed solution in this instance will be described below.

(b) $b^2_m D_{\text{cat}} < k_{\text{eff}}$. Restriction to only the first term of the series is not permissible and one must bear in mind that, for fairly large values of t,

$$c_n = k_{\text{eff}} c^0_{\text{Cat}}\, t. \tag{22}$$

This case will also be analysed below.

When $K_p \to 0$, i.e. the functional groups formed during the reaction do not interact with the catalyst, Eqn.(19) becomes

$$\frac{\partial c_{\text{Cat}}}{\partial t} = D_{\text{Cat}} \cdot \frac{\partial^2 c_{\text{Cat}}}{\partial x^2}.$$

It solution, subject to analogous boundary and initial conditions, is

$$c_{\text{Cat}}(x, t) = c^0_{\text{Cat}}\left(1 - \frac{4}{\pi} \sum_{m=1}^{\infty} \frac{\sin b_m x}{2m-1} \exp - b^2_m D_{\text{Cat}}\, t\right). \tag{23}$$

After substituting Eqn.(23) in Eqn.(18) and after integrating between the same limits as for Eqn.(21), we obtain

$$c_n = k_{\text{eff}}\, c^0_{\text{Cat}}\, t \left\{1 - \frac{8}{\pi^2} \sum_{m=1}^{\infty} [1 - \exp - (2m-1)^2 y] \frac{1}{(2m-1)^4 y}\right\}, \tag{24}$$

where

$$y = \frac{\pi^2 D_{\text{Cat}}\, t}{l^2}.$$

When $y < 1$, this case obtains during the initial period of the degradation reaction for films of any thickness:

$$c_n = k_{\text{eff}}\, c^0_{\text{Cat}}\, t\, \frac{8}{\pi^2} \varphi(y), \tag{25}$$

where

$$\varphi(y) = \sum_{m=1}^{\infty} \frac{\exp - (2m-1)^2 y - 1 + (2m-1)^2 y}{(2m-1)^4 y}.$$

Polymers of Group (b)

These include, for example, polycaproamide, epoxy-resin, and ethylcellulose. The solubility of water in these polymers at 25°C is about 7–9 wt.% for the first two and 2 wt.% for the last[12].

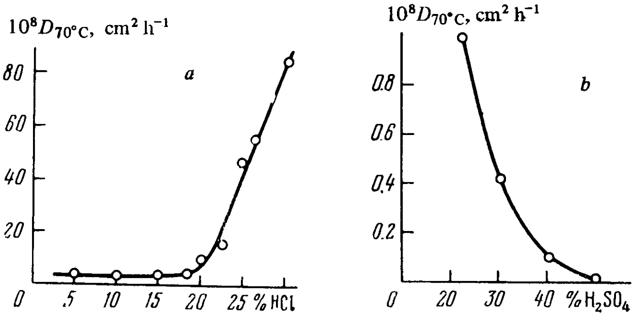

Figure 10. Variation of the diffusion coefficients of hydrochloric (*a*) and sulphuric (*b*) acids in epoxy-resin as a function of acid concentration[72].

Differences are observed in the behaviour in these polymers of electrolytes having high and low vapour pressures. Fig. 10 illustrates the variation of the diffusion coefficients of hydrochloric and sulphuric acids in epoxy-resin at 70°C as a function of the acid concentration[72].

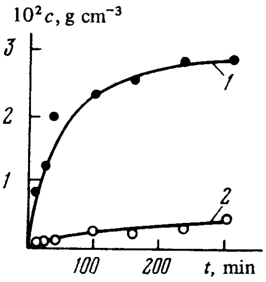

Figure 11. Variation of the concentration of water (1) and HCl (2) during the diffusion of the vapour of 28% hydrochloric acid into an ethylcellulose film at 35°C.[76]

Shterenzon et al.[75] believe that hydrogen chloride can exist in two-forms in polyethylene: in the non-hydrated form and as hydrates, the diffusion coefficient of the former being much higher. With decrease of the water content, there is a change in the ratio of the hydrated and non-hydrated forms of hydrogen chloride, which leads to an increase of the effective diffusion coefficient and in concentrated hydrochloric acid solutions the latter approaches that of gaseous hydrogen chloride.

In sulphuric acid solutions, diffusion coefficient and the water content in the polymer vary in parallel. In contrast to polymers of group (a), the polymers considered here sorb selectively the electrolyte and water.

Fig. 11 illustrates the variation of the concentration of water and HCl during the diffusion of the vapour of 28% hydrochloric acid solution into an ethylcellulose film at 35°C. The diffusion of the components of the corrosive medium proceeds with similar diffusion coefficients, but the ratio of the concentrations of water and HCl in the polymer is approximately ten times greater than in the gas phase[76].

Electrolytes are dissociated into ions in polymers of this kind, but quantitative data on the degree of dissociation are not available.

Polymers of Group (c)

This group includes the majority of industrially important polymers. Electrolytes with a high vapour pressure diffuse with diffusion coefficients close to those for polymers of groups (a) and (b). Electrolytes with a low vapour pressure diffuse into these polymers at very low rates[77].

VI. THE INFLUENCE OF THE SOLID STATE OF THE POLYMER ON THE DEGRADATION PROCESS

The degradation reactions in solid polymers have a number of characteristics which are associated both with the specific features of the structures of polymeric materials and with the specific features of the kinetics of heterogeneous reactions. We shall consider the characteristics of the structures of polymeric materials.

1. THE INHOMOGENEITY OF THE STRUCTURES AND PROPERTIES OF POLYMERS

The structural characteristics and properties of polymeric materials are almost always anisotropic with respect to volume, which is frequently referred to as spatial gradients[78]. For single-phase systems, the following examples of structural gradients may be quoted:

(a) vitreous and viscoelastic sections (copolymers of methyl methacrylate and methyl acrylate);

(b) strongly and weakly cross-linked regions (vulcanised elastomers);

(c) oriented and non-oriented regions (crystallising polymers);

(d) regions with different MWD (fractionated during shear flow);

(e) regions with different degrees of order in single-phase amorphous polymers (association).

The following structural gradients are characteristic of heterophase systems:

(a) amorphous and crystalline regions (crystalline polymers);

(b) regions with different degrees of microheterogeneity (stereoregular polymers);

(c) regions with different steric (*cis–trans* groups) or chemical structures (statistical copolymers).

In real polymeric materials there are in addition a wide variety of structural gradients established by added organic and inorganic substances: stabilisers, plasticisers, pore-forming agents, fillers (fibreglass in laminated glass plastics and carbon black in rubbers), dyes, etc.

The above structural gradients are responsible for the anisotropy of the chemical and diffusion properties of polymeric materials. At present there are no rigorous quantitative data concerning the influence of structural factors on the diffusion of corrosive media, on the one hand, and on the reactivity of the functional groups in polymeric materials, on the other. Isolated data on these problems have been published[79,80].

2. KINETICS OF THE DEGRADATION OF POLYMERS

The degradation of polymers in liquid corrosive media proceeds via the following principal stages:

(1) adsorption of the corrosive medium on the surface of the polymeric article;

(2) diffusion of the corrosive medium into the bulk of the polymeric article;

(3) chemical reaction of the corrosive medium with the chemically unstable bonds of the polymer;

(4) diffusion of the degradation products to the surface of the polymeric article;

(5) desorption of the degradation products from the surface of the polymeric article.

Examination of all the stages of the degradation process is difficult, because it is usually assumed that one or at most two stages are slow compared with the others, and therefore limit the rate of the entire degradation process. Stages (1) and (5) are usually faster than stages (2)–(4). The diffusion of the degradation products to the surface of the polymeric articles does not usually play a significant role in the estimation of the changes in the useful properties of the polymer during the degradation of polymeric articles, but it may limit, for example, the rate of biological degradation of the polymer in a living organism.

a. Fundamental Equations

In the general case (assuming that the law of mass action holds), the rate of decomposition of chemically unstable bonds in a polymer under the influence of a corrosive medium is

$$W = \frac{dc_n}{dt} = k(c_n^0 - c_n)\, c_{\text{Cat}}\, c_{\text{solv}}, \qquad (12)$$

where c_n^0 is the initial concentration of the chemically unstable bonds in the polymer, c_n the concentration of the dissociated bonds, c_{cat} the concentration of the catalyst in the polymer, and c_{solv} the concentration of the solvent in the polymer.

The concentration of the catalyst (for example an acid or a base) in the polymer can be found from Fick's equation:

$$\frac{\partial c_{\text{Cat}}}{\partial t} = D_{\text{Cat}} \nabla^2 c_{\text{Cat}} - \sum_i^0 c_{\text{Cat}}\, c_i\, K_{p_i}, \qquad (13)$$

where ∇^2 is the Laplace operator, c_i the concentration of the functional groups in the polymer capable of involvement in complex-formation or substitution reactions, and K_{p_i} are the equilibrium constants for the complex-formation or substitution reactions. The second term on the right-hand side of Eqn.(13) takes into account the possibility of reactions such as protonation, the conversion of carboxy-groups, etc.

If the solvent is consumed in the steps involving the decomposition of the chemically unstable bonds in the polymer (for example, water is consumed in hydrolytic reactions), then the concentration of the solvent can be found from the equation

$$\frac{\partial c_{\text{solv}}}{\partial t} = D_{\text{solv}} \nabla^2 c_{\text{solv}} - k(c_{n^0} - c_n)\, c_{\text{Cat}}\, c_{\text{solv}}. \qquad (14)$$

In order to formulate these equations, a number of assumptions must be justified:

(a) the polymer–corrosive medium system is as a rule extremely dilute with respect to the corrosive medium, i.e. one may assume that D_{cat} and D_{solv} are independent of the concentrations of the corresponding components in the polymer. When the corrosive medium is very soluble in the polymer, it is necessary to use the equation taking into account the relation between D and the concentration of the diffusant.

(b) k is constant. This is true for low solubilities of the corrosive medium in the polymer. In general, the influence of the corrosive medium on k can be reduced, to a first approximation, to the influence of the solvent on the rate of the chemical reaction and may be predicted on the basis of the existing theories[10].

(c) The decomposition of the chemically unstable bonds is almost irreversible. This condition holds for the degradation process in a thin surface layer, or in a reaction zone up to low degrees of conversion (<0.02). The concentration of the chemically unstable bonds then remains almost constant and $c_n^0 - c_n \simeq c_n^0$.

(d) The properties of the polymer are homogeneous with respect to volume. In reality there are regions in the polymer where the reactivity may be different (different values of k) and which exhibit a different capacity to sorb corrosive media and allow them to diffuse (different c_0 and D). The rigorous expression for the overall rate of the degradation process should therefore assume the following form:

$$W_\Sigma = \sum_i [k(c_n^0 - c_n)\, c_{\text{Cat}}\, c_{\text{solv}}]_i\, V_i, \qquad (15)$$

where V_i is the relative volume of each region. The use of Eqn.(14) involves considerable difficulties, so that in most cases one has to employ the concept of the average rate. We shall define it as the ratio of the overall rate of the process to the total volume of the polymeric article:

$$\overline{W} = \frac{\sum_i [k(c_n^0 - c_n)\, c_{\text{Cat}}\, c_{\text{solv}}]_i\, V_i}{\sum_i V_i}. \qquad (16)$$

This quantity will in fact be used subsequently except in special instances. Eqns.(13) and (14) can be formulated similarly.

Thus the problem of the determination of the rate of decomposition of chemically unstable bonds in the polymer under the influence of corrosive media reduces to the simultaneous solution of Eqns.(12)–(14).

Boundary Conditions

The following boundary conditions are usually encountered:

(a) the concentration of the diffusing substances on the surface of the polymeric article is constant. In practice this condition holds when a solution with a constant concentration of the diffusing corrosive medium flows rapidly around the article.

(b) The concentration of the diffusing substances on the surface of the polymeric article is a function of time, and

The following simple relation has been established with the aid of computer calculations:

$$\varphi(y) = 0.589 y^{1/2},$$

so that

$$c_n = \frac{4}{\pi^{1/2}} k_{\text{eff}}\, c^0_{\text{Cat}}\, D^{1/2}_{\text{Cat}}\, t^{3/2} l^{-1}, \tag{26}$$

i.e. during the initial period of the degradation the concentration of the ruptured bonds depends on the rate constant for the chemical reaction, the diffusion coefficient, the solubility of the catalyst, the thickness of the film, and time.

c. Internal Kinetic Region

The kinetic equation for this region can be obtained from Eqn. (24) with $y \gg 1$. This case obtains either for very thin films or very long times when the film has been saturated by the catalyst solution:

$$c_n = k_{\text{eff}}\, c^0_{\text{Cat}} t \left[1 - \frac{8}{\pi^2} \sum_{m=1}^{\infty} \frac{1}{(2m-1)^4 y}\right]. \tag{27}$$

In this case one can restrict the treatment to the first term of the series, whereupon

$$c_n = k_{\text{eff}}\, c^0_{\text{Cat}} t. \tag{28}$$

Thus the concentration of the ruptured bonds corresponding to low degrees of conversion is proportional to the rate constant for the chemical reaction, the catalyst concentration under saturation conditions, and the reaction time.

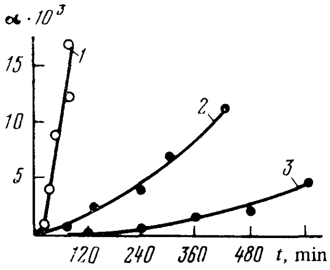

Figure 12. Time variation of the degree of conversion of ester linkages in the degradation of PETP films of different thickness in 53% H_2SO_4 at 116°C; film thickness (μm): 1) 5 ± 1; 2) 20 ± 2; 3) 80 ± 5.[81]

Fig. 12 illustrates the variation of the degree of conversion of the ester linkages α during the degradation of poly(ethylene terephthalate) (PETP) films of different thickness as a function of time[81]. For films 5 μm thick, there is a linear relation between α and time t starting from 30 min (by this time, the film has been saturated with the catalyst solution). Using Eqn. (28), we find the product $k_{\text{eff}} c^0_{\text{cat}}$. D_{cat} is determined from Eqn. (26) (Fig. 13).

We shall now consider certain characteristics of the degradation processes in the internal diffusion-kinetic and kinetic regions.

The Accessibility of the Functional Groups in Polymer Degradation Reactions

In polymeric materials with inhomogeneous structures (this applies primarily to heterophase systems), difficulties are frequently encountered in the definition of the terms "reactivity" and "accessibility" of the functional groups, because both terms are used to define the ability of the polymer to enter into a chemical reaction.

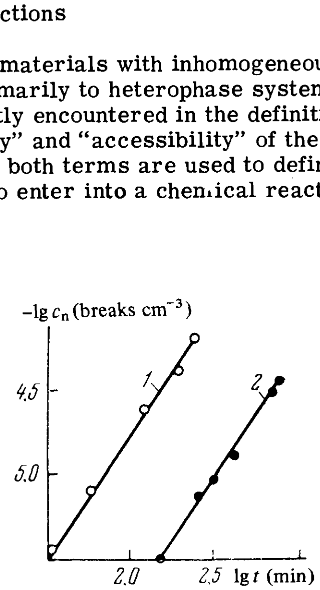

Figure 13. Variation of lg c_n with lg t for the degradation of PETP films of different thickness (1) in 53% H_2SO_4 at 116°C; thickness (l, μm): 1) 20 ± 2; 2) 80 ± 5.[81]

As already stated, the reactivity of the functional groups of the polymer can be accounted for on the basis of polar, resonance, and steric effects, and in most cases can be predicted quantitatively with the aid of correlation equations or by studying the kinetics of low-molecular-weight model reactions under corresponding conditions. Although there are as yet no rigorous quantitative data, presumably there should be no significant differences between the reactivities of the functional groups in regions with different structural inhomogeneities.

The accessibility of the "polymer" functional groups to molecules with which they should react is usually expressed quantitatively by the ratio $d = N/N_0$, where N_0 and N are respectively the total number of functional groups and the number of the accessible groups. It is reasonable to suppose that d will depend on the external conditions and on the method of determination. One should bear in mind that the "inaccessible" functional groups are involved in degradation reactions, but the rates of these reactions are low owing to the low concentration of the corrosive medium around these groups.

For polymers with mobile hydrogen atoms, a convenient method whereby the accessibility of the functional groups can be determined is provided by the H–D reaction, because during this reaction there is no change in the concentration of functional groups. The H–D exchange reaction has been investigated in detail in polycaproamide films[82,83]. The accessibility of the amide linkages is a function of temperature (Fig. 14). At 150°C all the amide linkages, including those in crystalline regions, are accessible to the H–D exchange reaction.

Most of the studies have dealt with the influence of the structure of cellulose on its reactivity in acid-catalysed degradation reaction[84]. The structure of the accessible regions in cellulose belonging to the structural type I has been studied in detail[85]. Small amounts of diethylaminoethyl substituents were introduced into the cellulose virtually without any alteration of the polymer structure (X-ray diffraction analysis was carried out); such substituents could be easily determined quantitatively in the soluble and insoluble products of the acid-catalysed hydrolysis by gas-liquid chromatography, which permits the determination of diethylaminoethyl groups in the 2-*O*-, 3-*O*-, and 6-*O*-positions of the D-glucopyranose residues.

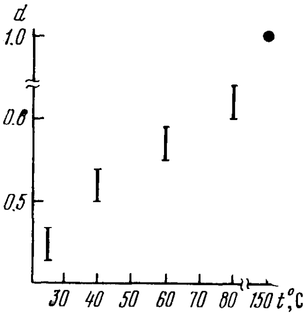

Figure 14. Temperature variation of the accessibility of the amide linkages in polycaproamide films.

The hydrolytic reaction takes place on the surface of the fibrils and there are two different types of accessible surfaces, called the "crystalline" and "disordered segments". According to BeMiller[86], the significant difference between the first-order rate constant for the formation of substituted D-glucopyranose residues in the acid-catalysed hydrolysis of cellulose at 25°C in 2.5 *N* HCl (Table 9) is due to the greater accessibility of the glycosidic linkages to protonation in the disordered segments and the greater ease of the transition from the chair to the half-chair conformation in these regions (the rate-limiting stage of the hydrolytic process).

Table 9. The first-order rate constants for the formation of various substituted D-glucopyranose residues in the acid-catalysed hydrolysis of cellulose at 25°C in 2.5 *N* HCl.[85]

D-Glucopyranose residue	Disordered segments; 10^3k, s^{-1}	Crystalline segments; 10^6k, s^{-1}	D-Glucopyranose residue	Disordered segments; 10^3k, s^{-1}	Crystalline segments; 10^6k, s^{-1}
Unsubstituted	1.1	6.5	3-*O*-Substituted	1.9	38.6
2-*O*-Substituted	4.8	15.8	6-*O*-Substituted	3.9	16,7

The distribution of the accessible surface between the disordered and crystalline segments, based on the content of the 2-*O*-substituted D-glucopyranose residues in these regions, is in the ratio 0.26 : 0.74 during the initial period of the reaction, changing to 0.36 : 0.64 as hydrolysis proceeds, because cellulose undergoes recrystallisation.

The surfaces of the crystalline and disordered segments of the fibrils are illustrated schematically in Fig. 15. In the crystalline regions (surfaces A and B), the segments are oriented and the hydroxy-groups are located in regularly repeating positions, the hydroxy-group in the 3-position being linked by a strong hydrogen bond to the oxygen in the ring of the neighbouring D-glucopyranose unit (Fig. 16). The bulk of the crystal structure defects due to twisting and bending of the fibrils and the presence of internal strain are concentrated in the disordered regions (surfaces C). The hydrogen bons 3-OH...5-O in these regions are least stable, which is the cause of the increase of the rate constant for the formation of 3-*O*-substituted D-glucopyranose residues.

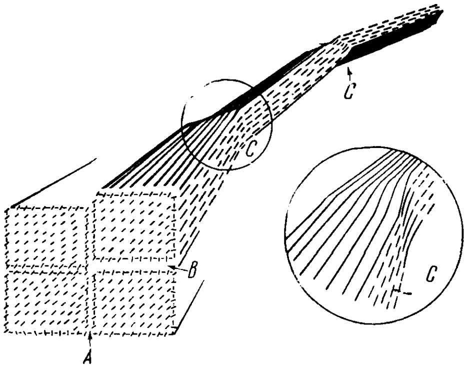

Figure 15. Schematic representation of the surfaces of the crystalline and disordered segments of cellulose fibrils[86].

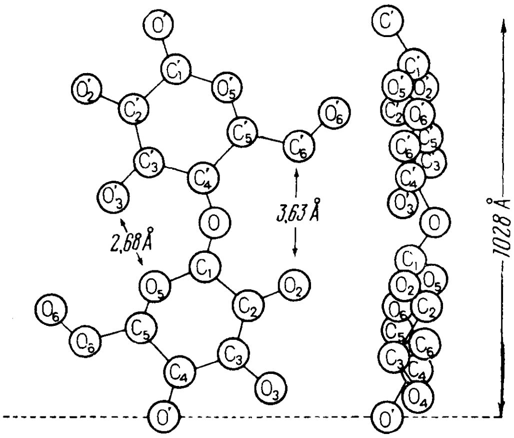

Figure 16. The conformation of the cellobiose segment of a crystalline cellulose chain[86].

Comparison of the Reactivities of the Functional Groups of Polymers in the Solid State and in Solution

Using as an example the degradation of cellulose derivatives, it is of interest to compare the kinetic parameters obtained for the solid state (degradation of ethylcellulose films in hydrochloric acid vapour)[76] and in solution (degradation of methylcellulose in aqueous hydrochloric acid solution)[61]. In the former case, the rate constants were calculated by Eqn.(28); ethylcellulose is an amorphous polymer and it was assumed that all the glycosidic linkages are equally accessible. In the latter case the rate constant under the conditions of an excess of hydrochloric acid was calculated from the equation for first-order kinetics but was referred to a single catalyst concentration (Table 10).

Table 10. Kinetic parameters of the acid-catalysed degradation reactions of methyl- and ethyl-cellulose.

Polymer	$k_{35°}$, mole $\min^{-1}$ cm^{-3}	E, kcal mole^{-1}	$\Delta S^{\neq}$ e.u.
Methylcellulose	$5.0 \cdot 10^{-6}$	30	4
Ethylcellulose	$1.2 \cdot 10^{-1}$	5.5	50

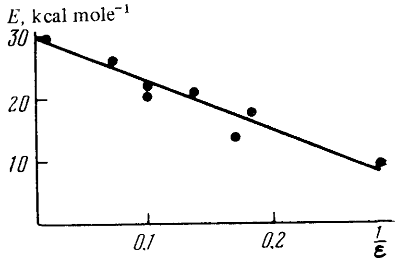

Figure 17. Variation of E with $1/\epsilon$ for the degradation of cellulose derivatives in various media[76].

To a first approximation, one may assume that the degradation of ethylcellulose takes place in "solution"; it is of interest to discover which properties of the solution are primarily responsible for the change in the kinetic parameters. Fig. 17 illustrates the variation of the activation energy for the degradation of cellulose ethers in various media as a function of the reciprocal of the dielectric constant[76]. The activation energy varies in opposition to $1/\epsilon$. Hence it follows that the chemical degradation processes in the solid state can be apparently simulated by reactions in solvents with similar physical parameters. To what extent this approach is valid will be established in the future when sufficient examples have accumulated.

d. The External Diffusion-kinetic Region

The degradation process in this region starts from the surface of the polymeric article. In this case we have

$$\frac{dc_n^S}{dt} = k(c_n^0 - c_n)^S c_{\text{Cat}}^S c_{\text{solv}}^S.$$

The superscript S denotes concentrations in the surface layer.

Regardless of the type of decomposition of the polymeric molecules, we have $(c_n^0 - c_n)^S \simeq (c_n^0)^S$. The state of the solvent and catalyst molecules in the surface layer has not been discussed in the literature. To a first approximation, one may assume that, under the conditions of adequate mixing, the thermodynamic parameters of the solvent and the catalyst in the surface layer and in the bulk of the liquid phase will be similar, so that

$$c_n^S = k_{\text{eff}}^S c_{\text{Cat}}^V c_{\text{solv}}^V,$$

where $k_{\text{eff}}^S = k(c_n^0)^S$ and the superscript V denotes bulk-phase concentration.

We shall consider how the mass of the polymer changes during degradation in this instance. Regardless of the type of decomposition of the polymer molecules, one can formulate an expression for the mass of the monomers formed:

$$m = k_{\text{eff}}^S c_{\text{Cat}}^V c_{\text{solv}}^V \, t \, S,$$

where S is the area of the polymer film. The thickness of the polymer film varies in accordance with the equation

$$x = l - \frac{k_{\text{eff}}^S c_{\text{Cat}}^V c_{\text{solv}}^V \, t}{\rho},$$

where ρ is the density of the polymer. The total decomposition time of the film is

$$\tau = \frac{m_0}{k_{\text{eff}}^S c_{\text{Cat}}^V c_{\text{solv}}^V \, S}.$$

The change in the mass of the polymer m_{pol} is described by the equation

$$m_{\text{pol}} = m_{\text{pol}}^0 \left(1 - \frac{t}{\tau}\right) = m_{\text{pol}}^0 \left(1 - \frac{k_{\text{eff}}^S c_{\text{Cat}}^V c_{\text{solv}}^V S t}{m_{\text{pol}}^0}\right). \quad (29)$$

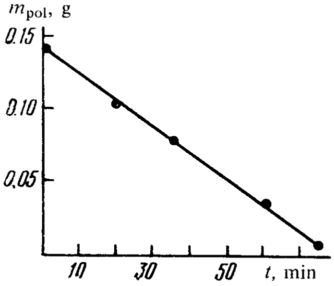

Figure 18. Time variation of the mass of the polymer in the degradation of a PETP film in 22.1% KOH solution at 88.2°C (l = 68 ± 8 μm, S = 14 cm²).[57]

When the degradation process takes place in the external diffusion-kinetic region, one must bear in mind that the polymer molecules in the surface layers have properties differing from those in the bulk of the specimen (molecular weight, degree of crystallinity, orientation, etc.). We have no data for the reactivities of polymer molecules in the surface layer. Progress in this field will be achieved by studying monolayers deposited directly on to the corrosive medium.

The change in the mass of PETP film during degradation is illustrated in Fig. 18. The following experimental observations have been made[57]:

(a) the reaction is of zero order with respect to the polymer;

(b) the molecular weight of the polymer film does not change until the end of the process;

(c) the multiple distorted total internal reflection infrared spectra contain no absorption bands due to the carboxy-groups formed in the decomposition of the ester linkages;

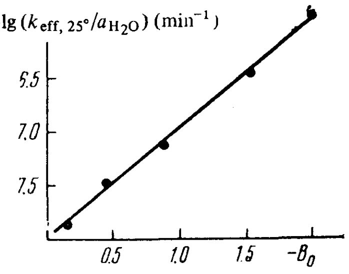

Figure 19. Variation of $\lg k_{\rm eff,25°}/a_{\rm H_2O}$ with the alkalinity function of aqueous potassium hydroxide solution for the degradation of PETP films 68 ± 2 μm thick[57].

(d) the values of $k_{\rm eff}^{\rm S}$ calculated by Eqn.(29) vary as a function of the thermodynamic parameters of the medium in accordance with Eqn.(9) (Fig.19), which describes the hydrolysis of low-molecular-weight compounds in aqueous solutions of alkalis.

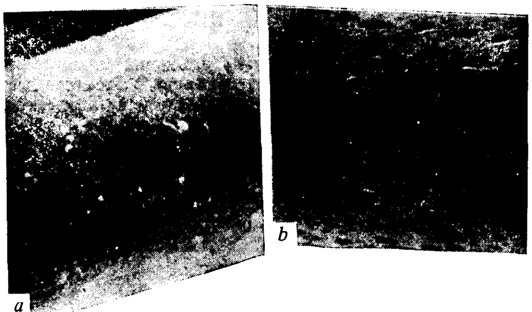

Figure 20. Photomicrographs (× 2100) [× 3000 in the Russian original] of PETP fibres during degradation in 22.1% KOH solution at 88.2°C: *a*) before degradation; *b*) after 5 min.

All these findings suggest that the reaction layer approaches a monolayer. The surface area of the films was estimated from profilograms. The variation of the surface area during the degradation process is illustrated in Fig.20. Photomicrographs of PETP fibres were obtained under a scanning microscope. In degradation of this type, structural gradients (degree of crystallinity and orientation) had almost no influence on the kinetic parameters.

---o0o---

The concepts described above and the examples discussed reveal the fundamental characteristics of polymer degradation processes in corrosive media. The review deals with the degradation reactions in polymeric materials in an unstrained state in corrosive media which have been most thoroughly investigated—aqueous solutions of acids and bases. These constitute only some of the degradation processes encountered in practice. The creation and development of a theory of the chemical degradation of polymeric materials in the strained state in different corrosive media is one of the immediate tasks in the modern science of polymer degradation.

The Present State of the Gas-chromatographic Analysis of Aminoacids

S.V.Vitt, M.B.Saporovskaya, G.V.Avvakumov, and V.M.Beliko

Problems of the general and enantiomeric gas-chromatographic analysis of aminoacid mixtures are considered. Data are presented concerning the accuracy, reproducibility, and linear range of the determination of aminoacids. The applicability of various types of derivatives is investigated from the standpoint of the suitability for quantitative analysis. Since analysis of aminoacids includes, apart from the chromatographic procedure and the final integration, their isolation from the natural material and the preparation of volatile derivatives, particular attention is devoted in the review to errors at each stage of the analysis and their contribution to the resulting reproducibility of the analysis.
The review is of interest to persons working in the field of the chemistry of natural products, biochemistry, medicine, as well as specialists developing analytical methods associated with the preparation of volatile derivatives.
The bibliography includes 111 references.

CONTENTS

I. INTRODUCTION

Considerable advances have been achieved in recent years in the biochemistry and chemistry of proteins and aminoacids as a result of the application of modern analytical methods based on column and thin-layer chromatography. Nevertheless the search for more sensitive and accurate quantitative analytical methods is being continued. The principal trend in this search involves gas-liquid chromatography (GLC). Although conditions for gas-chromatographic analysis of general utility have not so far been found, it is already clear that the GLC of aminoacids is significantly more accurate than other methods, has an exceptionally low sensitivity theshold over a wide linear range, and is susceptible to full automation.

In contrast to an aminoacid analyser, the gas chromatograph is a universal instrument and can be used for the analysis of not only aminoacids but also of a multiplicity of other biochemically important substances of different types. A gas chromatograph can be very successfully combined with a mass-spectrometer, which gives rise to unique possibilities for the identification of minor components and anomalies in aminoacids. Finally GLC is the most accurate method for the analysis of mixtures of optical isomers (aminoacid enantiomers).

However, one must stipulate immediately that all the advantages of GLC in the analysis of aminoacids can be achieved only when instruments of sufficiently high quality are used. Thus relatively insensitive detectors, metallic columns with a high percentage content of the liquid phase, and coarse carriers combined with isothermal separation conditions were used in early attempts, these features being in general characteristic of the state of GLC at the end of the 1950's and the beginning of the 1960's. These studies showed that aminoacid derivatives are thermally unstable compounds with a wide range of vapour pressures and their analysis is therefore possible only on columns with a very low content of the [liquid] phase and very inert carriers and phases combined with programmed temperatures. This required the use of highly sensitive detection with a low noise level and compensation of background changes, which is best achieved with the aid of flame-ionisation detectors in compensation (two-column) schemes. Stabilised phases of the type of very pure polysiloxanes and polyesters as well as special carriers, ensuring minimal adsorption combined with a high homogeneity of the surface and the dimensions and shapes of the particles and lacking catalytic activity, have been widely employed. These are diatomaceous carriers such as Chromosorb W, Supelcoport, Anachrome, Gas Chrom, etc. The advantages of not only glass columns but also of a seamless separating channel became apparent.

Overall, it became clear that the gas chromatography of aminoacids is one of the most difficult ("delicate") chromatographic tasks and is comparable in its complexity and requirements with regard to equipment and materials perhaps only to the GLC of steroids. In view of the complexity and importance of such tasks, special chromatographs began to be manufactured in recent years for their solution (the so called chromatographs of the biomedical class), which constitute the highest achievements of chromatographic engineering in a certain sense as regards the rationality [of the design] and the quality of the separating channel.

This does not of course imply that satisfactory results cannot be achieved on ordinary industrial or home-made apparatus of suitable design. It is important that such apparatus should be provided with a seamless glass separating channel and a sensitive linear detector and should be based on a two-column scheme (for experiments with programmed temperatures). A unit for reproducible programming of the temperature, preferably with provision for the automatic return to the initial isothermal conditions, is essential. For quantitative analysis, the velocities of all the gases must be stabilised by accurate flow-rate regulators. Electronic integration combined with monitoring of the drift of the base line is necessary. In the latest studies carried out using modern research techniques, the most reliable results have of course been obtained.

Several reviews exist of the GLC of aminoacids[1-5] and the early studies are fairly fully described in Blau's review[3]. The authors of the present review endeavoured to examine as fully as possible the latest and most important data concerning the development of the GLC method for aminoacids, concerning both the separation and preparation of derivatives and problems of quantitative analysis. Unfortunately not all the published studies have been performed at a sufficiently high quantitative level. This remark applies also to published reviews, since they discuss mainly problems concerning the preparation of derivatives and their chromatography rather than the characteristics related to the accuracy, reproducibility, sensitivity threshold, and linear range, i.e. all the factors which constitute the subject of the present review, which deals with standard protein aminoacids. Anomalous aminoacids, and their iodine- and selenium-containing analogues, have been considered in the review of Coulter and Hann[6].

II. VOLATILE AMINOACID DERIVATIVES AND THEIR CHROMATOGRAPHIC SEPARATION

a. Standard Protein Aminoacids

Since aminoacids are virtually involatile thermally unstable compounds, their direct gas-chromatographic analysis is impossible. It is therefore quite natural that the main bulk of published work on the analysis of aminoacids by GLC consists of studies on their transformation into volatile substances suitable for separation. The majority of these studies have been carried out at a qualitative or semiquantitative level, covering more than eighty types of aminoacid conversion products (see, for example, Blau[3]). Many of the results are of merely historical interest. However, on the whole they are useful both as a source of ideas for the solution of specific problems and the development of new methods for the identification and quantitative analysis of aminoacids.

There are several publications on the pyrolytic GLC of aminoacids in which the feasibility, in principle, of analysis based on the hydrocarbon or amine "profile" of the thermal decomposition products has been demonstrated. However, the complications arising from the fact that the same pyrolysis products are common to different aminoacids and the side reactions between the aminoacids and their decomposition products require special laborious investigations of the pyrolysis of aminoacid mixtures using a complex mathematical technique for the interpretation of the results, so that this procedure is on the whole rather unpromising as a standard method for the quantitative analysis of mixtures[3].

The development of the analysis of aminoacids by GLC followed a different pathway, involving chemical transformations of aminoacids into volatile compounds on the "one aminoacid–one derivative" principle, but attempts to employ oxidative, reductive, and other transformations of aminoacids into compounds of other classes (amines, aldehydes, aminoalcohols, etc.) did not yield satisfactory results, primarily because the methods are insufficiently universal and quantitative. The most promising procedures proved to be those based on the protection of the carboxy- and amino-groups as well as other functional groups.

However, here too serious difficulties arise owing to the fact that natural aminoacids are substances of an extremely wide variety of chemical types, the common feature of which is merely the amino-group in the α-position relative to the carboxyl. For this reason, as noted by Blau[3], it is difficult to find modifying reagents and conditions for quantitative reactions involving the synthesis of volatile derivatives which are common to all natural aminoacids. It is no less difficult to find conditions for the separation of such non-homologous mixtures.

Experiment has shown that only a very few of the proposed derivatives are really suitable for a simple and reliable quantitative analysis, i.e. satisfy the essential requirements listed below:

(1) simplicity, quantitative yield of derivatives, reproducibility, and, if possible, rapid conversion of all the natural aminoacids in the mixtures;

(2) optimal volatility of the derivative, suitable for chromatography without losses;

(3) stability of the derivative during the experiment and storage under the usual laboratory conditions;

(4) stability under the conditions of the gas-chromatographic experiment, i.e. on contact with the liquid phase and the solid carrier at temperatures up to 200–250°C;

(5) the possibility of obtaining individual peaks on the chromatogram on the "one aminoacid–one derivative–one peak" principle.

Requirements (4) and (5) determine the accuracy and reproducibility of the chromatographic analysis proper and taken together determine the accuracy and reproducibility of the entire method.

At the present time only two types of derivatives which satisfy sufficiently fully the above requirements are known. These are some of the alkyl esters of *N*-acylated (usually *N*-perfluoroacylated) aminoacids and to a lesser extent trimethylsilyl (TMS) derivatives. Subsequently we shall consider mainly studies using such derivatives as well as derivatives of other types which have been published after the publication of the reviews of Blau[3] and Coulter and Hann[6].

In essence, the gas-chromatography of aminoacids has begun to develop on the basis of Fischer's study[7] of the separation of methyl esters of aminoacids by a fractionation procedure. In 1957 Bayer et al.[8] separated a mixture of such esters. They also pointed out[9] the suitability for GLC of *N*-trifluoroacetyl (TFA) derivatives of methyl esters of aminoacids. Since then derivatives of this type have been studied very intensively. Formyl, acetyl, trifluoroacetyl, pentafluoropropionyl, heptafluorobutyryl and other groups have been used in various combinations for the protection of the amino-group (and also OH and SH groups) in methyl, ethyl, propyl, butyl, isopentyl, and other aminoacid esters. At the present time only butyl esters of *N*-trifluoroacyl derivatives can be separated on filled columns satisfying at the same time requirement (5), which is in fact the reason for their exceptional importance in quantitative analysis. As a result of studies mainly by Gehrke's school and also Darbre, Blau, and Islan[10], the n-butyl esters of *N*(*O*, *S*)-trifluoroacylated aminoacids (*N*-TFA n-butyl esters)† and to a lesser extent the corresponding methyl esters[12] have come to be used most frequently. The conditions for the preparation of these derivatives, giving the highest yields, the possible complications due to the presence of impurities and the oxidising action of atmospheric oxygen, stability during storage and gas-chromatographic analysis, and also optimal separation conditions have been studied in greatest detail.

---

†The *N*-TFA n-butyl esters have been proposed and separated for the first time by Zomsely et al.[11]

The alkyl esters of *N*(*O*, *S*)-acyl derivatives of aminoacids are usually prepared in two stages[13]. In the first stage, the aminoacid is converted into an alkyl ester by treatment with the corresponding alcohol in the presence of HCl. Methyl esters of aminoacids are also transesterified with higher alcohols[14]. After the removal of the excess reagent *in vacuo*, the product is acylated with a solution of the corresponding anhydride in methylene chloride, chloroform, or another suitable solvent.

It is noteworthy that new agents for the protection of functional groups have been discovered recently. In particular, Birkofer and Donike[15] recently suggested that bistrifluoroacetamide and its *N*-methylated analogue be used for trifluoroacetylation. The authors considered the application of these reagents in relation to various compounds, including certain aminoacids. The mildness of the acylation conditions, the possibility of obtaining mixed derivatives (the hydroxy-groups protected by trimethylsilyl groups are not affected during acylation), and the absence of the side reactions observed when trifluoroacetic anhydride is used have been noted among their advantages[16,17]. Both reagents are fairly volatile and emerge from the columns soon after the solvent.

The aminoacids must be freed from proteins, nucleotides, sugars, lipids, and other possible impurities before the synthesis of derivatives in the analysis of mixtures of natural products. Metal ions must also be eliminated, since most of them prevent a quantitative yield of the derivatives[18]. Furthermore, after entering the evaporator and the column, these ions catalyse the decomposition of the samples injected. The purification process and the complications arising in the analysis of aminoacids by GLC have been examined in detail[19].

The polyesters of ethylene glycol and neopentyl glycol with succinic, adipic, and sebacic acids exhibit the highest selectivity in the separation of the alkyl esters of *N*-acylaminoacids[13,20,21]. Neopentyl glycol sebacate, the phase with the highest thermal stability, is suitable for the separation of the *N*-TFA n-butyl esters of twenty protein aminoacids[21]. Columns with the mixed EGSS-X phase—diethyleneglycol succinate—have been used for the same purpose[22]. Polysiloxane phases (OV-1, OV-3, OV-7, OV-17, OV-25, OV-101, OV-210, OV-225, SE-30, SE-52, etc.) as well as their mixtures have been employed mainly for the analysis of mixtures containing heavy aminoacids, the separation of the derivatives of which on polar polyesters is difficult.

The majority of modern studies on the separation of *N*-TFA n-butyl esters culminated in the investigation by Stefanovic and Walker[23], who showed that the selectivity of columns with poly(ethylene glycol adipate) (PEGA) depends on the amount of phase deposited on the solid carrier. In particular, columns containing 0.65% of PEGA relative to the weight of the solid carrier (Chromosorb W) proved to be the most suitable for the separation of the *N*-TFA n-butyl esters of protein aminoacids (except tryptophan, arginine, histidine, and cystine). The optimal PEGA concentration for the separation of *N*-TFA n-butyl esters depends on the solid carrier employed—it amounts to 0.325% for Chromosorb G.[13]

Many modern studies on the separation of alkyl esters of *N*-acyl derivatives of aminoacids on columns with polar polyester phases with a low content of the phase have been carried out using a carrier heated to a specified temperature. Vitt et al.[24] showed that even a relatively inactive carrier, such as Chromosorb W, exhibits a sufficiently high capacity for adsorption, which is important for selective separation. It follows from the data in Table 1 that the free energy and enthalpy of solution on columns with a low content of the [liquid] phase are higher and that the order in which the *N*-TFA n-butyl esters emerge (i.e. the free energies of solution) under conditions of isothermal separation depends on the amount of the phase.

Table 1. The energies ΔG (kcal mole^{-1}) (at 126°C) and heats of solution ΔH (kcal mole^{-1}) (at 105–170°C) of the butyl esters of certain trifluoroacetylated aminoacids on columns with different PEGA contents on Chromosorb W(A.W.)[21].

Aminoacid	$-\Delta H$	$-\Delta G$	$-\Delta H$	$-\Delta G$
	0.8% PEGA		3% PEGA	
Glycine	15.0	5.5	14.9	5.4
Leucine	17.9	6.2	14.2	5.2
Methionine	20.2	7.4	18.0	6.9
Hydroxyproline	19.0	7.6	18.0	6.5
Phenylalanine	20.0	8.6	18.7	7.1

These data undoubtedly show that carriers with a low percentage of the phase behave in essence as modified sorbents a controlled selectivity of which is achieved by altering the content of the [liquid] phase or by heat treatment of the carrier. The separation on such carriers is sensitive to the type of temperature programme and the length of the chromatographic column. In particular, for a 3 m column with activated Chromosorb W, the optimal concentration ensuring the most effective separation of *N*-TFA n-butyl esters proved to be 0.58%[24] (for 1–1.5 m columns, Stefanovic and Walker[23] and Gehrke et al.[13] showed that the optimal PEGA concentration is 0.65%). The highest selectivity for a column length of 1.5–1.8 m is achieved at a rate of temperature rise of 2–4 K min^{-1} [13], while for a column 3 m long the optimum rate is 2–2.5 K min^{-1}.

According to our data, a change in the type of carrier for the stationary phase alters the nature of the separation. Presumably the future use of modified carriers of this type will extend the scope of the analysis of various volatile derivatives of aminoacids.

Gehrke et al.[25] proposed a scheme for the separation of *N*-TFA n-butyl esters of aminoacids based on the use of a single four-column apparatus or of two instruments, each comprising two columns. The first pair of columns with 0.65% of stabilised PEGA on Chromosorb W (A.W.), heat-treated for 12 h at 140°C, is used for the separation of *N*-TFA n-butyl esters of 17 aminoacids. The second pair of columns with 2% of OV-17 (OV-101) and 1% of OV-210 on silylated Chromosorb G is used for the separation of the *N*-TFA n-butyl esters of arginine, histidine, and cystine. Both pairs of columns can operate under the conditions of a single temperature programme and can therefore be combined in a single four-column apparatus, which permits the complete analysis of the protein aminoacids in a single cycle. The temperature programme is as follows: 70°C for 10 min followed by heating at a rate of 2–4 K min^{-1} to 235°C. The aminoacids are injected into the heated zone of the evaporator (at temperatures up to 240°C). According to the results of Vitt et al.[24], in the analysis of *N*-TFA n-butyl esters of aminoacids it is more convenient to employ a cold evaporator, having selected suitably the initial isothermal treatment.

Studies designed to choose conditions for the analysis of the *N*-TFA n-butyl esters of all twenty protein aminoacids on a single pair of columns are being continued. However, so far they have not been successful. Gerhrke and Roach[26] recently reported the analysis of the BTA derivatives of all twenty aminoacids on a single column with 10% of Apiezon M on Chromosorb W(HP), but, judging from the chromatograms presented, the separation of the *N*-TFA n-butyl esters was insufficient for accurate quantitative analysis; 13 peaks of the *N*-TFA n-butyl esters of protein aminoacids were incompletely separated.

The alkyl esters of pentafluoropropionyl and heptafluorobutyryl aminoacid derivatives, which became available subsequently, will probably prove more promising in this respect. Pollock and coworkers[27] were the first to suggest butyl esters of *N*(*O*, *S*)-pentafluoropropionyl derivatives of aminoacids and investigated their separation on silicone phases. Moss et al.[28] demonstrated the possibility of using n-propyl esters of heptafluorobutyryl derivatives of aminoacids. They carried out an analysis on a 3.6 m column with 3% of OV-1 on Chromosorb W(A.W.) treated with dimethylchlorosilane (DMCS), the temperature being programmed in the range between 100° and 250°C. In order to obtain a single histidine peak, the authors injected acetic anhydride together with the sample. We believe that, in order to convert monoacylhistidine into the diacyl derivative on the column, it would be necessary to inject together with the sample the anhydride used for the modification, as suggested for the first time by Gehrke and coworkers[29] for *N*-TFA n-butyl esters and as was done by Jonsson et al.[30] in the analysis of aminoacids in the form of the n-propyl esters of the *N*-heptafluorobutyryl derivatives.

Jonsson et al.[30] carried out the analysis on a short glass capillary column (6 m × 0.25 mm) to the walls of which a dimethylsiloxane polymeric phase has been grafted chemically. They achieved a satisfactory separation of derivatives of all the protein aminoacids except tryptophan; for the determination of cysteine, the latter was converted into the *S*-methyl derivative before modification.

Zanetta and Vincendon[14] demonstrated a satisfactory single-column separation of isopentyl esters of heptafluorobutyryl derivatives with the aid of 3% of SE-30 on Gas Chrom Q. Compared with *N*-TFA n-butyl esters, these derivatives are less volatile (which lowers the losses during evaporation), are less polar (which promotes a faster analysis), and give rise to symmetrical peaks.

Studies using alkyl esters of perfluoroacyl derivatives (particularly heptafluorobutyryl derivatives) lead at the same time to the possibility of a sharp reduction of the sensitivity threshold (down to 10^{-12}–10^{13} g) when an electron capture detector is used.

Despite the clear achievements in the separation and, as will be shown below, in the quantitative analysis based on esters of perfluoroacyl derivatives of aminoacids, the development of a single-stage method for the synthesis of volatile derivatives constitutes an attractive proposition. The studies by Rogozhin and coworkers[31], who showed that alkyl esters of *N*-acyl derivatives of aminoacids can be obtained in a single stage by condensing orthocarbonate esters with aminoacids, are of interest in this respect.

N- and *O*-Trimethylsilyl (TMS) derivatives can be obtained in a single stage. A fairly large number of studies have been made on the preparation and separation of TMS derivatives‡ of aminoacids[32-36]. In particular, new silylating agents have been proposed—bistrimethylsilylacetamide[36], bistrimethylsilyltrifluoroacetamide[34], etc.

These reagents give rise to a peak on the chromatogram which does not interfere with the peaks of the TMS derivatives of aminoacids. Furthermore, the use of bistrimethylsilyltrifluoroacetamide reduces the deposition of silica in the detector. The application of TMS derivatives of aminoacids in quantitative gas-chromatographic analysis is hindered by the fact that certain aminoacids form a mixture of silylation products, the proportions of which depend on the nature of the solvent employed[34].

In order to carry out the analysis of twenty protein aminoacids on a single column, Hardy and Kerring[37] used mixed derivatives—n-butyl esters of the *N*(*O*, *S*)-trimethylsilylated acids. The entire analysis on a ~2.5 m glass column with an internal diameter of 2 mm, filled with textured glass beads containing 0.2% of OV-7, was performed in less than 35 min.

The authors note that, in contrast to the free aminoacids, methylene chloride may be used as a solvent for the n-butyl esters in the silylation stage. On the one hand, the guanidino-group of arginine and the ω-amino-group of lysine are silylated under these conditions, which makes it possible to analyse the aminoacids, and, on the other hand, one can avoid the formation of the tristrimethylsilyl derivative of glycine, which emerges together with isoleucine derivatives during chromatography. However, as in the case of purely trimethylsilyl derivatives of aminoacids, the peaks of the serine and threonine derivatives are hardly separated at all, which naturally great complicates the quantitative analysis of these two aminoacids. Furthermore, the chromatograms show very small peaks corresponding to the trimethylsilyl derivatives of the non-esterified aminoacids, showing that the esterification reactions did not go to completion, which naturally constitutes an additional source of error in the analysis.

Thenot and Horning[38] used for GLC the alkyl esters of *N*-dimethylaminomethylene derivatives of aminoacids which are obtained in a single stage when *NN*-dimethylformamide reacts with aminoacid dialkyl acetals. They obtained derivatives of glycine, alanine, valine, leucine, isoleucine, aspartic and glutamic acids, phenylalanine, and lysine and separated them on filled and capillary columns with SE-30. We believe that, as long as the possibility of the rapid and quantitative formation of similar derivatives of "heavy" aminoacids (tryptophan, arginine, histidine, and cystine) has not been demonstrated, there is no point in trying to assess their practical value (with the exception, of course, of specific analytical problems). However, since the dialkyl acetals of *NN*-dimethylformamide do not react with hydroxy- and cercapto-groups under suitable conditions, the use of the above derivatives will always be limited.

The isopropylation of aminoacids has been recently proposed[39,40] as a single-stage reaction for the synthesis of derivatives to be used in GLC. However, these derivates have also scarcely found extensive applications, since satisfactory yields are obtained only for aminoacids without functional groups other than the carboxy- and α-amino groups. Furthermore, certain aminoacids give rise to several derivatives.

---

‡ The separation was as a rule carried out on silicone phases.

Mitchell's suggestion[41] that the Schiff bases of aminoacids, obtained by coupling benzaldehyde or penta-2.4-dione to methyl esters of aminoacids be used for GLC, has also apparently not found many applications. It is hardly possible to extend this method to all the protein aminoacids and to achieve sufficiently reproducible results.

Williams and Halpern[42] suggested that the gas-chromatographic analysis of aminoacids be carried out by pyrolysing in the evaporator of the chromatograph the trimethylanilinium salts of *N*-neopentylidene derivatives of aminoacids. These salts are obtained in a single stage by reaction with 2,2-dimethylpropanal and trimethylanilinium hydroxide in methanol for 15 min and 80°C in the presence of 3 Å molecular sieves. After being injected into the hot evaporator of the chromatograph, they decompose with formation of the *N*-neopentylidene derivative of the methyl ester of the corresponding aminoacid. The hydroxy-groups are also methylated. The nitrogen atoms in the proline molecule and in the indole component of the tryptophan molecule are likewise methylated. The derivatives obtained were successfully chromatographed on a ~2.5 m stainless steel column filled with 0.5% of OV-17 on Chromosorb W(DMCS). However, in this case too it is impossible to chromatograph all the protein aminoacids: histidine does not yield a volatile derivative. Furthermore, arginine and cystine give rise to several products. Incidentally, we believe that these difficulties may be obviated by replacing the column and particularly the evaporator by components made of glass and by a careful selection of the pyrolysis temperatures.

Finally, one should note that in recent attempts to discover a convenient single-stage method for the synthesis of volatile aminoacid derivatives various investigators have again shown interest in the preparation of cyclic aminoacid derivatives. Thus Grahl-Nielsen and Solheim[43] investigated the chromatographic behaviour of various 2-alkyloxazolin-5-one derivatives of leucine [44,45] and showed that, although these substances are extremely reactive, nevertheless their thermal stabilities make them quite suitable for chromatographic analysis. The authors recommend 2-trifluoromethyloxazolin-5-one, obtained by the reaction of leucines with trifluoroacetic anhydride, as the preferred derivative for the separation of leucine isomers. However, we believe that it is hardly possible to obtain similar derivatives of more complex aminoacids and to achieve quantitative yields. Furthermore, the high volatility of the derivatives, which facilitates chromatogrphy, may lead to significant losses at the unavoidable stage involving the distillation of the trifluoroacetic acid formed.

Husek[46] used the reaction of aminoacids with dichlorotetrafluoroacetone, which also yields in a single stage analogous derivatives[47,48], in order to determine tyrosine and its mono- and di-iodo derivatives. The use of this reaction is probably still more limited, since in this case additional reactions are needed to protect the hydroxy-, ω-amino-, etc. functional groups. (Husek protected the hydroxy-group of tyrosine by reaction with perfluorobutyric anhydride). However, one should recall that similar derivatives with a large number of halogen atoms in the molecule make it possible to reduce sharply the sensitivity threshold when an electron capture detector is used and may therefore prove to be extremely useful in the solution of specific problems.

The interest in the GLC of thiohydantoin derivatives of aminoacids is noteworthy. In general, these derivatives are not very suitable for gas-chromatographic analysis but are important in connection with the determination of the primary structure of peptides and proteins by the method of Edman and Begg. We shall not consider problems concerning the analysis of these derivatives, since a fairly complete review by Pisano et al.[49] was published recently. Furthermore, the application of GLC for the determination of *N*-terminal aminoacids of proteins and peptides has been examined by Rosmus and Deyl[50]. Among the latest studies, the analysis of phenylthiohydantoins on short capillary columns is noteworthy[51].

b. Aminoacid Enantiomers

Two methods for the separation of enantiomers by gas chromatography are known at present. The first is based on the quantitative conversion of the enantiomers into diastereoisomers under the influence of a dissymmetric agent. The diastereoisomers are then separated on a usual chromatographic phase[52–54]. The other method is based on the use of a dissymmetric stationary phase[55].

Weygand et al.[53] achieved for the first time the separation of diastereoisomeric aminoacid derivatives by the GLC of dipeptides; at the same time the possibility of determining the enantiomeric purity and the configurations by the GLC method was demonstrated by a number of investigators using as an example the much more suitable *N*-trifluoroacetyl (*N*-TFA) derivatives of the diastereoisomeric aminoacid esters[56–63].

In particular, the present authors[63], Pollock et al.[59], and Gil-Av and coworkers[56] described in 1965 the separation of *N*-TFA derivatives of aminoacid esters using optically active s-butyl alcohol and menthol[61]. After this, numerous investigations of this problem were published[63–78].

As regards the determination of the configuration by the GLC method, one should note the relation between the elution order of the diastereoisomeric derivatives and their configurations established by a number of workers. Thus, it has been shown that, in a series of aminoacid esters[59,64,65], the diastereoisomers with the *RR*- and *SS*-configurations have the lowest energies of solution in the chromatographic phase and hence the lowest retention volumes, while the highest retention volumes are characteristic of the *RS*- and *SR*-forms. The 2-butyl ester of phenylglycine[64], a non-natural aminoacid, is an exception. It has been established, for a series of amides obtained from aminoacid esters and amines, $\mathrm{RCH(NHCOCF_3)CONH{-}\underset{\displaystyle R''}{\underset{|}{C}}H{-}R'}$ (R′ = alkyl and R″ = alkyl or COOR), that the *SS*-diastereoisomer is eluted after the *SR*-form.[66] According to the authors, the explanation is that the *SS*-structure of amides has a more open form, as a result of which the amide hydrogen in this structure is more accessible for interaction with the carbonyl group of the polyester phase (it has been established that such interaction occurs[66]).

Although the *N*-TFA derivatives of s-butyl esters of aminoacids can be separated on both filled[68,69,71] and capillary columns[59,61,64,65], in practice only capillary chromatography yields satisfactory results, i.e. results suitable for quantitative analysis, which is due to the low value of $\Delta(\Delta G)$ for the majority of the phases investigated[69] (Table 2). Another disadvantage of the separation of aminoacids in the form of the *N*-TFA derivatives of their s-butyl esters is the low availability of the optically pure s-butyl alcohol. On the other hand, the separation of diastereoisomers of this type makes it possible to analyse the enantiomers of heavy aminoacids, which is difficult in the case of the more bulky L-menthyl derivatives.

N-TFA-L-menthyl derivatives of aminoacids have very high values of $\Delta(\Delta G)$ (Table 3)[69], which makes it possible to use the usual (filled) columns[63]. The preparation of the derivatives constitutes the difficulty in this instance. The value of $\Delta(\Delta G)$ is partly influenced by the conformational immobility of the groups.

Table 2. The values of $-\Delta(\Delta G)$ (cal mole^{-1}) for the s-butyl esters of *N*-TFA derivatives of aminoacids (at 125°C) on different chromatographic phases.

Aminoacid	PEGA	PEG	NPGA
Alanine	44.0	57.0	42.0
Valine	52.0	44.0	44.0
Leucine	45.0	57.0	50.0
Isoleucine	70.0	86.0	55.0
Norvaline	35.0	52.0	32.0
Norleucine	47.0	44.0	32.0
α-Aminooctanoic acid	67.0	39.0	—

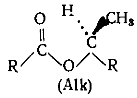
Note: PEGA = poly(ethylene glycol adipate), PEG = poly(ethylene glycol), and NPGA = neopentylglycol adipate.

In the chromatography of *N*-TFA-L-prolyl-2-methylindone, $\Delta(\Delta G^0) = 298$ cal mole^{-1}, which is the highest value noted in all instances of the separation of diastereoisomers, was obtained[72]. In this compound, the asymmetric centres are located in the ring, so that the conformational immobility of the groups linked to them is greater.

Table 3. The values of $-\Delta(\Delta G)$ (cal mole^{-1}) for the L-menthyl esters of *N*-TFA derivatives of aminoacids (at 160°C) on different chromatographic phases.

Aminoacid	PEGA	PEG	NPGA	APIEZON--L
Alanine	109.0	117.0	59.0	99.0
Valine	188.8	127.0	88.0	109.0
Leucine	145.0	—	124.0	108.0
Isoleucine	141.0	—	124.0	138.0
Norvaline	145.0	—	118.0	104.0
Norleucine	109.0	—	112.0	118.0
α-Aminobutyric acid	149.0	—	138.0	89.0

If the dissymmetric agent is acyclic, the groups linked to the asymmetric centre must be as large as possible. The point is that free rotation about the O–(Alk) bond in the molecule of the diastereoisomeric ester is hindered owing to the presence of the neighbouring carbonyl group.



When the substituent R′ is varied from CH_3 to t-C_4H_9, the separation is improved as a result of the decrease of the conformational mobility caused by the increase of the energy barrier to free rotation about the Alk–O bond[66,72].

As already pointed out, the other method for the gas-chromatographic analysis of enantiomers involves their separation on a dissymetric phase. The first reliable result was obtained by Gil-Av et al.[78] in 1967 in the separation of the ethyl, n-propyl, isopropyl, n-butyl, and 2-butyl esters of the *N*-TFA derivatives of alanine, valine, and leucine and the lauryl ester of *N*-TFA-L-isoleucine. Derivatives with a single asymmetric centre gave two peaks and those with two centres gave four peaks. The separation was specific: the methyl esters were not separated at all and only the cyclopentyl esters were fully separated.

Four types of dissymmetric stationary phases are now used for the gas-chromatographic analysis of enantiometric derivatives of aminoacids (Table 4):

I. Esters of *N*-TFA derivatives of aminoacids and C_6–C_{12} alcohols[78,79].

II. The ureide of the isopropyl ester of valine[55,80,81] (for the separation of amines and aminoacids).

III. Esters of *N*-TFA derivatives of dipeptides and C_1–C_6 alcohols[58,80–90].

IV. Amides[91,92].

The isopropyl esters of *N*-TFA-derivatives of aminoacids are most frequently separated. On peptide and ester L-phases, the D-isomer is eluted before the L-isomer, which makes it possible to determine the configurations of the aminoacids. On the ureide phase, the elution sequence of the enantiomers is related to the size of the alkyl substituents at the asymmetric centre and in the ester group of the enantiomer[80].

According to Gil-Av and coworkers[82,84,85], the mechanism of the separation process consists in the formation of diastereoisomeric complexes of the aminoacid enantiomer with the dissymmetric phase. It is suggested that the linkage between the molecules in these "complexes" is formed via hydrogen bond bridges. In other studies, hypotheses have been put forward concerning the structures of the "complexes" formed[79,84,85] and studies have been made in order to elucidate the role of the amide and ester components of the dipeptide[85,86,91] in the formation of the "complexes" with the enantiomeric aminoacid derivatives. Regardless of whether we attribute the dissolution of the aminoacid derivatives in the peptide phase to the formation of a "complex" or whether we explain the observed difference between the dissolution energies by specific solvation and a statistical distribution of different types of association, it is clear that the amide component of the dipeptide is in fact responsible for the stereoselective effect[86,91], although important secondary steric contributions are made by the ester end[85,86]. This is why tripeptide and even more so polypeptide phases proved to be less suitable for the separation of enantiomeric aminoacid derivatives than dipeptide phases[84,86].

Best results in the separation of aminoacid enantiomers (in terms of the highest values of $\alpha_{L/D}$[§]) have been obtained using dipeptide stationary phases of type (III), in which the hydrocarbon substituents at the asymmetric centres of the dipeptide and the ester groups are fairly bulky and branched (for example the cyclohexyl or t-butyl esters of the *N*-TFA derivatives of L-valyl-L-valine), and also on stationary phases of type (IV).

[§] $\alpha_{L/D}$ is the ratio of the retention volumes of the L- and D-enantiomers of aminoacids.

Table 4. The separation of derivatives of enantiomeric aminoacids on dissymmetric phases.

Aminoacids and their analytical forms	$\alpha_{L/D}$	Remarks
90°C; 50–100 m Pyrex column; d = 0.25 mm; chromatographic phase—lauryl ester of *N*-TFA-L-leucine [79, 82]		
2-Butyl esters of N-TFA derivatives of:		complete separation
D- and L-alanine	–	
D- and L-valine	–

* $\frac{n_1}{n_1 + n_2}$; n_1 and n_2 are the numbers of moles of (I) and (II).

It has been shown that the structure of the volatile aminoacid derivative is important for the separation[84,85,88,91]. Thus the following features were noted in the separation of isopropyl esters of *N*-TFA-aminoacids on the cyclohexyl ester of *N*-TFA-L-norvalyl-L-norvaline[88]:

(a) The successive increase in the length of the hydrocarbon group and the replacement of the isopropyl ester of *N*-TFA-alanine by the corresponding α-aminobutyric acid and norvaline derivative leads to a decrease of $\alpha_{L/D}$.

(b) The replacement of the protons in the methyl group of alanine (the same derivatives) by methyl groups gives rise to the following series in terms of $\alpha_{L/D}$ [83]:

alanine > α-aminobutyric acid > valine ≫ t-leucine

(c) For leucines, we have the following series in terms of the values of $\alpha_{L/D}$:

leucine, isoleucine > n-leucine ≫ t-leucine.

Parr and Howard[88] explained these characteristics by the steric hindrance in the formation of a complex with the chromatographic phase.

Proline, the *N*-TFA derivative of which does not contain amide hydrogen, yields the lowest separation factor among all the aminoacids on the available chromatographic phases[91,93]. The separation of aspartic acid enantiomers is also comparatively poor[93] (which cannot be said about glutamic acid).

All the volatile aminoacid derivatives which are capable of satisfactory resolution into enantiomers contain the group $-CONH\overset{*}{C}HR-CO-$. The quality of the separation is closely related to the presence of this structure[84], as shown by the finding that, on the isopropyl ester of *N*-TFA-L-valyl-L-valine, *N*-TFA-2-aminoheptane gives rise to only a slight inflection, while the isopropyl esters of *N*-(2,2,2,-trifluoroethyl)alanine [$CF_3CH_2NH-CH-COOCH(CH_3)_2$] and *N*-TFA-$\beta$-aminobutyric acid are not resolved at all[82]. According to the authors, these derivatives do not form "complexes" with the chromatographic phase and are involved in three hydrogen bonds. The statistical weight of the selective association of dipeptides (which have a high capacity for the formation of hydrogen bonds) via two or three bridges, for example in the case of *N*-TFA-2-aminoheptane, is very low[84].

Whereas the presence of the group –CO–NH–HCR–CO– (the acceptor and donor sections are located on either side of the asymmetric centre) is required for separation on a peptide phase, the presence of the group $-CO-NH-\underset{|}{\overset{|}{C}}{}^{*}$ is sufficient for the urea derivative obtained from L-valine,

$$\underset{\displaystyle\diagup \atop \displaystyle COOCH(CH_3)_2}{(CH_3)_2CH-CH}-NHCONH-\underset{\displaystyle | \atop \displaystyle COOCH(CH_3)_2}{CH}-CH(CH_3)_2$$

on which both amines and aminoacids can be separated[80]. Here it is significant that the elution sequence of the D- and L-isomers of the aminoacid derivatives $RCH(NHCOCF_3)CO_2R'$ is influenced only by the size of the R and CO_2R' groups and to a certain extent by the degree of branching of the hydrocarbon substituents.

Tripeptide phases have been used to separate enantiomers[84,86]. Here the working temperature is higher by about 10 K than the working temperature of the dipeptide phase and the separation factor is slightly lower. Furthermore, tripeptide esters can be used to make up binary phase compositions with m.p. <80°C.

Polypeptide phases have also been investigated; the separation on such phases proved to be poor, so that they can be scarcely used for the practical separation of enantiomers[86].

N-Pentafluoropropionyl and *N*-heptafluorobutyryl derivatives of dipeptide esters can be used to separate aminoacid enantiomers[86], while the corresponding *N*-acyl derivatives of aminoacid esters are more stable[85], the separation factors on these phases are higher, and the retention times are shorter than for the corresponding *N*-TFA derivatives[92].

The heats of reaction of the enantiomers with the dipeptide phases have been published in the literature[84,88,90,94]. For example, $\Delta(\Delta H)$ for the enantiomers of the *N*-TFA derivatives of the isopropyl esters of a number of aminoacids have the following values on the cyclohexyl ester of *N*-TFA-L-norvalyl-L-norvaline[88]:

Aminoacid	Aniline	α-Aminobutyric acid	Valine	Norvaline	Leucine	Isoleucine	t-Leucine
$-\Delta(\Delta H)\pm$ ±5, cal mole^{-1}	342	339	302	293	366	348	156

Table 4 lists the aminoacid derivatives and the phases used in the enantiomeric analysis of aminoacids on dissymmetric phases.

Summarising the results published hitherto concerning the use of dissymmetric phases for the separation of aminoacids, the following factors must be noted particularly.

1. The differences between the excess energies of the interaction of enantiomeric aminoacid derivatives with the phases described in the literature range from several cal mole^{-1} to 150 cal mole^{-1} depending on the enantiomer–chromatographic phase pair selected and the experimental temperature (values calculated from the retention parameters)[93].
2. Effective separation of aminoacid enantiomers during a reasonable period is possible despite the fact that high values of $\alpha_{L/D}$ are obtained on capillary columns only (Table 4).
3. The attainment of effective separation of enantiomeric pairs has in many instances been accompanied by the superposition of the peaks of several aminoacids belonging to different enantiomeric pairs despite the large number of phases tested (Table 4).
4. Unfortunately, many phases have a narrow working temperature range (the lower limit of the range is determined by the melting point of the phase and the upper limit by its volatility or instability).

Gas-chromatographic determination of the enantiomeric composition of complex mixtures makes it possible to solve also the specific problem involving the determination of optical purity. In both instances gas chromatography has an undoubted advantage over polarimetry and NMR. This highly effective method of separation does not, in principle, entail a limit to the number of components of the mixture of both optically active and inactive components being analysed.

III. QUANTITATIVE ANALYSIS

Quantitative analysis is characterised by parameters such as accuracy, reproducibility, linear range of concentrations being determined, and the sensitivity limit. For a multistage analytical procedure (and the GLC of aminoacids is in fact such a procedure), these parameters are determined by the partial parameters of each stage: the isolation of aminoacids from a natural or synthetic mixture, the formation of derivatives, the chromatographic separation proper, and the determination of the areas of the chromatographic peaks. Comparatively few studies have been made on the determination of these parameters[24,95-102] and those which have been carried out were mainly concerned with the separation of the butyl esters of the trifluoroacetylated derivatives by the Stefanovic–Gehrke method[12,13] and trimethylsilane derivatives and the preparation of such derivatives.

a. Reproducibility of the Analysis

The literature data on this problem are the most numerous and contradictory (coefficients of variation $\bar{w}$ ranging from 0.02 to 35% are quoted). This is not unexpected—there is also a large scatter in data concerning the reproducibility of the ion-exchange analysis of aminoacids. The results obtained in the separation of aminoacid enantiomers in the form of the isopropyl esters of their *N*-TFA derivatives on the cyclohexyl ester of *N*-TFA-L-valyl-L-valine[95] under the conditions of isothermal separation on capillary columns, i.e. under conditions ensuring the optimum signal/noise and signal/drift ratios with adequate separation of the peaks and equal chemical stabilities and volatilities of the components separated, have been the most reproducible (to within 0.02%, Varian 480 integrator).

The reproducibility of the separation of aminoacids in the form of the butyl esters of their trifluoroacetylated derivatives is somewhat less satisfactory. According to the results of Vitt et al.[24], the separation of such esters of twelve aminoacids on a 3 m glass column with stabilised PEGA (0.58%) has $\bar{w}$ = 0.17 rel.% (Infotronics CRS-100 integrator), the error (as well as the error in the separation of the enantiomers) depending on the amount of the sample injected into the chromatograph (see subsection c of the present Section). According to Gehrke's data[96], the average chromatographic reproducibility for 19 aminoacids, obtained from three replicate determinations, is to within 1.3%. The chromatographic reproducibility of the separation of trimethylsilane derivatives is to within 1.1 rel.% (for 20 aminoacids) according to Gehrke et al.[33]

Talbot et al.[97] investigated the reproducibility of the calibration coefficients in the analysis of the butyl esters of trifluoroacetylated aminoacids and showed that the coefficients vary on passing from one column to another (even with the same chromatographic phase). Thus the calibration coefficients of the threonine differed from one another by a factor greater than 2.5. The reason for this may be that the author failed to reach the complete separation of the butyl esters.

There is no doubt that the dependence of the calibration coefficients on the properties of the column may be reduced under the conditions of unified procedures for the preparation of the columns and by improving the efficiency of the separation. According to the present authors' results (with α-aminooctanoic acid as the internal standard), the calibration coefficients for the majority of aminoacids vary on passing from one column with PEGA to another by not more than 3%, the variation increasing to 10% only for threonine and serine. The stability of the calibration coefficients was achieved by a reproducible preparation of the columns and their prolonged conditioning (for at least 60 h at 190–200°C in a stream of helium).

The reproducibility of the conversion and the degree of racemisation in the preparation of derivatives for enantiomeric analysis may be investigated on the basis of data for the final procedure—the gas-chromatographic separation. However, the best procedure for the synthesis of the butyl esters of trifluoroacetylated aminoacids (direct esterification–acylation) is as follows. A dry mixture of aminoacids (between 2 μg and 50 mg of all the aminoacids) is covered by 3 *N* HCl solution in thoroughly dry n-butyl alcohol and heated at 100°C for 15–35 min. The excess reagent and water are distilled off on a rotary evaporator or in a stream of pure nitrogen, the mixture being heated twice with anhydrous methylene chloride in order to remove the residual water. The acylation is carried out with a 10% solution of trifluoroacetic anhydride in methylene chloride at temperatures up to 150°C for 5–60 min. There is a wide range of conditions associated with the different reactivities and stabilities of various aminoacids. Thus, when the mixture does not contain isoleucine, 15 min is sufficient for esterification (the maximum yield of the n-butyl ester of tryptophan is also obtained under these conditions); the quantitative esterification of isoleucine requires an increase of the reaction time to 35 min. On the other hand, the n-butyl esters of certain aminoacids (particularly histidine) are trifluoroacetylated quantitatively at a sufficient rate only at 100–150°C.[13]

The literature data for the preparation of the butyl ester of trifluoroacetylated histidine are contradictory (see, for example, the review of Coulter and Hann[6]). Even the structure of the volatile derivative is unknown. In view of the difficulty of the direct determination of histidine in the form of the butyl ester of trifluoroacetylated derivative, its preliminary conversion into aspartic acid by ozonolysis was suggested[6]. For the same purpose, arginine may be hydrolysed to ornithine in the presence of arginase[6].

Other complications in the quantitative analysis of the butyl esters of trifluoroacetylated derivatives are associated with the fact that the prolonged esterification necessary for the complete conversion of all 20 protein aminoacids into their esters is accompanied by partial charring of tryptophan. Therefore the esterification conditions must be rigorously standardised as regards the concentrations and amounts of reactants, the duration of reaction, and temperature[98].

According to our results, the calibration coefficients for the majority of butyl esters of trifluoroacetylated aminoacids do not change on storage of the derivatives (at room temperature) in the presence of a 2% solution of trifluoroacetic acid in methylene chloride for two weeks; however, the butyl ester of trifluoroacetylated methionine decomposes rapidly under these conditions. Dilute aqueous solutions of methionine are also unstable. Therefore methionine-containing mixtures must be analysed rapidly.

Together with the rigorous requirements which must be met by the gas chromatograph (seamless glass separation channel, minimal contact with the metal in the path traversed by the gases between the end of the column and the flame, an absolutely dry and filtered carrier gas), it is suggested that special attention should be devoted to the purity of the vessels used, the quality of the rotary evaporator which must not contain metallic components, and the purity of the derivatives of the reactants and gases used in the synthesis.

Vitt et al.[24] reported that samples without histidine and arginine can be acylated quantitatively with a satisfactory reproducibility at room temperature by two treatments with trifluoroacetic anhydride (initially in the form of a 10% and then a 2% solution in CH_2Cl_2) with intervening distillation of the CF_3COOH formed and the solvent on a rotary evaporator.

The esterification of aminoacids by isopropyl alcohol is much slower than the esterification with n-butyl alcohol. Fig. 1 presents kinetic curves for the esterification of a number of aminoacids[95], from which it follows that there is virtually no complete conversion in the synthesis of these derivatives. The authors recommend that the esterification time be limited to 4 h, since after more prolonged esterification the change in the enantiomeric composition of the mixture in consequence of racemisation becomes comparable to the random chromatographic error.

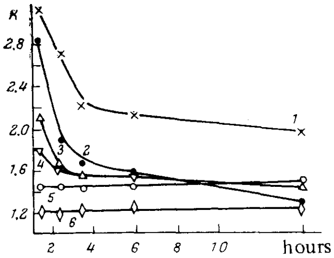

Figure 1. Dependence of the calibration coefficients of the isopropyl esters of *N*-TFA derivatives of aminoacids on esterification time; $K = S_{\mathrm{st}}(m_{\mathrm{i}}/m_{\mathrm{st}})s_{\mathrm{i}}$ (m_{i} is the aminoacid sample, m_{st} the sample of the standard, s_{i} the area of the aminoacid peak, and s_{st} the area of the peak due to the standard): 1) isoleucine; 2) valine; 3) threonine; 4) leucine; 5) glycine; 6) alanine.

In general aminoacid analysis, the reproducibility in the preparation of derivatives characterises the scope of the analysis of mixtures which do not require preliminary purification. The optimal overall reproducibility for two stages quoted in the literature[24] is $\bar{w}_{\mathrm{n}=4,\,\mathrm{m}=12} = 0.7\%$. According to the results of Gehrke and coworkers[96], the corresponding quantity for 19 aminoacids amounted to $\bar{w}_{\mathrm{n}=6,\,\mathrm{m}=19} = 1.5\%$. If the preparation of derivatives must be preceded by ion-exchange purification, the reproducibility of the analysis is impaired even more. Incidentally, this is no longer the "fault" of the gas chromatography—purification is a standard procedure also in analysis by ion-exchange chromatography.

Gehrke and coworkers[96,98] showed that the ion-exchange purification required for the isolation of the pure aminoacid fraction to be used in subsequent aminoacid analysis entails a partial loss of a number of aminoacids. The same workers established that arginine is completely lost in certain types of purification. The reproducibility of the gas-chromatographic analysis of synthetic and natural mixtures (urine, blood), obtained from three replicate determinations, amounted under these conditions to about 1.5% for synthetic mixtures and to 1.5–2.2% for natural mixtures. The reproducibility of the ion-exchange chromatography of the same specimens incorporating 17 aminoacids was to within 5–12%. Vitt et al.[24] obtained similar reproducibilities: 1.1% for the former case and 1.3% for the latter (for 12 aminoacids). Evidently the reproducibility of the ion-exchange purification is impaired for highly contaminated (natural) mixtures.

b. Accuracy of the Analysis

Strictly speaking the solution of the problem of accuracy is associated with the availability of standard procedures. Studies involving a standardisation procedure require standards whose purity approaches the reproducibility of the method and for this reason ion-exchange chromatography cannot serve as a standard for the determination of the accuracy of the gas-chromatographic analysis of aminoacids.

In all probability one must assume that gas chromatography itself constitutes the required standard procedure. The possibility of standardisation based on the equality of the concentrations of the compounds analysed was considered in the survey of Vitt et al.[95] Such instances include, for example, the equality of the concentrations of enantiomers in racemic mixtures. It has been shown that, in the chromatography of volatile D-aminoacid derivatives under isothermal conditions, a systematic error is observed, depending on the ratio of the peak variances and heights, i.e. on the concentration. This error is associated with the integration threshold—a sharp peak is integrated more fully than a broad peak. In the cases investigated the error was 0.02–0.3 rel.%.

When the internal standard method is employed (i.e. in general aminoacid analysis), the systematic error is determined by the purity of the standards and the operating point employed within the linear range of the method.

Under the conditions of large systematic errors which are known to exceed the uncertainty in the composition of the standards (this case is in fact characteristic of the stages involving the preparation of derivatives and particularly the purification on ion-exchange columns), the systematic errors can be readily determined from a small number of experimental results. This error (the average for 17 aminoacids) has been determined as 3.24 rel.% in the analysis of a standard mixture in the presence of urine aminoacids with removal of protein by ion-exchange[96]. The error can probably be reduced by extending the calibration over the entire analysis, including the purification stage.

In conclusion we shall consider the problem of the analysis of aminoacids in the case of overlapping peaks. The usual gas-chromatographic separation of the butyl esters of trifluoroacetylated aminoacids gives a satisfactorily resolved chromatogram for 18–20 natural aminoacids and is therefore suitable for an accurate quantitative analysis. Other methods, particularly the separation of enantiomers, where the number of peaks increases by a factor of two, do not exhibit this feature. The overall resolution depends in this instance on the separation of the components corresponding to various aminoacids and not on the selectivity of the separation within the enantiomeric pairs, i.e. is associated only with the efficiency of the column used. The reason is that the aminoacid mixtures are not homologous mixtures and therefore the retention volume of any one enantiomer of a single aminoacid may be close to the retention volume of other aminoacids. The likelihood of this situation increases with increase of the number of aminoacids present in the mixture. For a quantitative analysis of such partly resolved mixtures, simultaneous gas-chromatographic analysis on a column with a usual (not dissymmetric) stationary phase and the use of the available data for the aminoacid (but not enantiomeric) composition of the mixtures analysed has been suggested[95].

Then it follows from the experimentally demonstrated equality of the relative sensitivities of flame-ionisation detectors that

$$s_L + s_D = \omega s^*,$$

where $\omega = s_{\mathrm{st}}/s^*_{\mathrm{st}}$ is a proportionality coefficient, which remains unchanged for all the components in the given chromatographic experiment, s^* represents the peak areas for a column with a dissymmetric phase, s_{st} the peak area of the standard, and s the peak areas for a column with an optically inactive phase. Hence

$$\dot{S}_L = \omega s - \dot{s}_D.$$

In this case the systematic error depends on the accuracy of the determination of the peak areas under the conditions of chromatography on a usual phase.

c. The Linear Range and the Limits of Sensitivity

Depending on the concentrations being determined, the gas-chromatographic analysis of aminoacids in the form of the butyl esters of their trifluoroacetylated derivatives[13] is carried out using samples in the range 2 μg–50 mg. The size of the sample injected into the chromatograph then varies from 0.125 to 500 μg.

Chromatograms showing that individual peaks for 6–8 ng of aminoacids, injected into the gas chromatograph in the form of the butyl esters of their trifluoroacetylated derivatives, can be obtained using a flame-ionisation detector have been described in the literature[97]. In order to improve the signal/noise ratio, the bulk of the solvent vapour was discarded via a valve located between the analytical column and the fore-column[97].

According to the results of Vitt[110], the minimum amount of aminoacid which can be determined (in the form of the butyl ester of its trifluoroacetylated derivative) using an electron capture detector is 1–50 pg (evidently for a very narrow linear range).

It has been established[24] that the systematic and random errors in the gas-chromatographic analysis of the butyl esters of trifluoroacetylated aminoacids pass through a minimum (Fig. 2), i.e. there is an optimum concentration of the samples to be analysed as regards accuracy and reproducibility. The errors in the range of concentrations below the otpimum value are probably due to interference (noise and drift of columns), while the right-hand branch of the curve is due to the impairment of the resolution of the peaks with increase in concentration.

It follows from Fig. 2 that the linear range of the method is determined by the permissible concentrations and, conversely, the accuracy and reproducibility are determined by the linear range adopted and can be improved by operating within a narrower range of concentrations in the region of the minimum. The wide scatter of the literature values as regards accuracy and reproducibility is probably due to the fact that the investigators have not always worked in the concentration range corresponding to the optimum and also a satisfactory resolution and an adequately high signal/noise ratio were not always achieved. When the experimental parameters are incorrectly selected, the curve relating the errors to concentration is located at a higher level and has sharper minimum.

These limitations apply not only to the accuracy and reproducibility but also to threshold sensitivity: we are still unable to isolate aminoacids quantitatively and to obtain their derivatives at the level of 10^{-10} g.

Evidently relations between accuracy and reproducibility on the one hand and concentration on the other should also exist for processes involving the synthesis of aminoacid derivatives and the isolation of aminoacids from natural mixtures; in the region of low concentrations, there is a possibility of a sharp increase of errors owing to oxidation and residual sorption on glass and the materials of the columns[101]. One must recognise that, in a multistage procedure including gas chromatography, the stages preceding the gas chromatography proper are rate-limiting and have been least thoroughly developed.

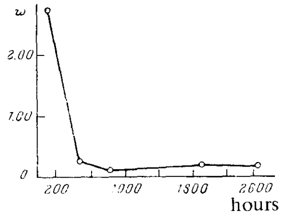

Figure 2. Variation of the reproducibility of the calibration coefficients of aminoacids with the concentration of the sample injected.

It follows from the above results that the accuracy and reproducibility of gas chromatography as a quantitative method are at least an order of magnitude higher than those of polarimetry and NMR in cases most favourable for these methods (in mixtures of two enantiomers, in determinations of optical purity). This can also be said of the sensitivity thresholds of the methods considered.

IV. EXAMPLES OF APPLICATIONS OF THE GAS-CHROMATOGRAPHIC ANALYSIS OF AMINOACIDS

In the first studies on the gas chromatography of aminoacids (see, for example, Gehrke et al.[13]), the analyses of natural mixtures (usually acid protein hydrolysates) were mainly carried out in order to demonstrate the applicability and reliability of the method, comparison with the results of ion-exchange chromatography being used as a criterion. As a result of numerous investigations, it became clear that the analysis of aminoacids by GLC is very accurate and reproducible and the number of studies in which GLC is used as an independent analytical method (not requiring a check by comparison with other methods) is at present increasing. Furthermore, certain investigations became possible (or at least became greatly facilitated) only after the application of the universal and highly sensitive gas-chromatographic method for the analysis of aminoacids.

We shall endeavour to demonstrate on a number of characteristic examples the present level of studies using GLC for the analysis of aminoacids and the scope of this method.

In 1971 Pellizzari and coworkers[13] used GLC to analyse blood plasma aminoacids in the form of the n-butyl esters of their *N*-trifluoroacetyl derivatives and carried out a statistical assessment of the results. They showed that only 0.2 ml of plasma is needed for the analysis and that the reproducibility of the results is quite satisfactory for clinical applications, for example for the diagnosis of metabolic disturbances (particularly in diseases associated with a disturbance of the aminoacid composition of proteins).

Subsequent studies confirmed the usefulness of GLC for the analysis of aminoacids in blood, urine, and other biological liquids in clinical tests.

For example the dynamics of aminoacid contents of the blood of patients operated on for cancer of the stomach and fed parenterally has been studied[69]. The aminoacids were determined in the blood plasma before the parenteral administration of the Aminosol preparation (1 g per kg of body weight in the form of a 10% solution) and in the course of its administration. It was found that the sum of the free analysable aminoacids in the blood plasma of the majority of the patients investigated decreased following the introduction of the aminoacid preparation into the blood supply, i.e. the injection of the mixture of aminoacids into blood accelerates sharply their assimilation. The blood plasma of the patients contained exclusively aminoacids having the L-configuration.

The increasing application of the GLC of aminoacids in biological studies is associated with the determination of the aminoacid composition and the primary structure of peptides and proteins and this is by no means the least important application. We have already noted[46] the success of the GLC of the thiohydantoin derivatives of aminoacids—the products of the stepwise degradation of proteins by the Edman method. The greater sensitivity of GLC compared with thin-layer chromatography makes it possible to use smaller amounts of the test substance and to determine the structures of proteins having higher molecular weights.

The advantages of gas chromatography may be even greater in the analysis of the composition of molecules of complex substances such as lipoproteins, protein–nucleic acid complexes, glycoproteins, etc. For example, Zanetta and Vincendon[14] showed that, in the case of glycoproteins, it is possible to analyse initially the hydrocarbon component and then the protein component of the same specimen. The universality of the GLC method is extremely convenient also in the analysis of products of aminoacid metabolism. Thus Albro and Fishbein[103] determined simultaneously with the aid of gas chromatography about 30 tyrosine and tryptophan metabolites—substances of very different chemical types.

In order to illustrate the scope of GLC in complex biological studies involving the determination of the aminoacid compositions, we may mention the study of Butler et al.[104], who used this method to analyse the aminoacids attached to tRNA.

Analysis of aminoacids by GLC has been used successfully in geochemical and paleontological investigations. Thus Pocklington[105] used this method for the quantitative analysis of the aminoacids in the water taken from the North Atlantic and Gardner and Lee[106] determined aminoacids in lake water. In both cases the aminoacid concentration was about 10^{-8} M (with respect to each aminoacid) and GLC proved to be a convenient and accurate analytical method. Gehrke's group[19] analysed the aminoacids in aqueous extracts of a specimen taken from the ancient Onverwacht chart (whose age is 3.4×10^9 years). GLC has demonstrated with a high degree of reliability the presence of aminoacids at the level of 10^{-8}–10^{-9} g. Bearing in mind that the minimum detectable amount of aminoacids has been reduced to 1–50 pg with the aid of the electron capture detector, the advantage of GLC in the analysis of aminoacids at an ultramicrolevel over other methods becomes clear. The new mass-spectrometric degradation method, usually called the "mass fragmentation" method, has a similar sensitivity limit. This technique has already been applied to the gas–liquid analysis of aminoacids in biological compounds[107] and in soil.

The unique possibility of determining by GLC the enantiomeric composition of aminoacid mixtures has been used in the analysis of collagen fossils[108], deposits on the sea bottom[109], and also the enantiomeric composition of the aminoacids in blood plasma and the hydrolysates and autolysates of baker's yeast[110].

The GLC of aminoacids will undoubtedly find extensive applications in studies associated with the origin of life on Earth and the possibility of life on other celestial bodies. Thus Raulin et al.[111] used this method to analyse the aminoacids formed in the photolysis of a gaseous mixture simulating Earth's primitive atmosphere. They showed that, in a single chromatographic experiment, it is possible to analyse together with the twenty main protein aminoacids also at least 18 non-protein aminoacids, which is particularly important in the study of chemical evolution and gives to gas chromatography an important advantage over aminoacid analysers.

The gas-chromatographic method has been used to seek aminoacids and other organic substances in the lunar dust supplied by the American Apollo spaceships[19,100] and we believe it will undoubtedly prove suitable for the analysis of soil specimens taken from the planets.

In conclusion we may note that the literature concerning the uses of the analysis of aminoacids by GLC is extremely extensive. This also shows that the reliability of the method and its suitability for the usual tasks in aminoacid analysis and for the solution of special problems requiring a universal, highly sensitive, accurate, and reproducible analytical procedure have been adequately demonstrated.

Kinetics and Mechanism of Electrode Reactions of Metal Complexes in Aqueous Electrolyte Solutions

V.I.Kravtsov

The kinetics and the mechanism of electrode reactions of metal complexes, which include rapid processes of reorganisation of outer and inner coordination spheres, are examined, and criteria for distinguishing between outer-sphere and inner-sphere mechanisms of the electrochemical stage are discussed. Published data provide the basis for a consideration of the mechanism of simple electrode reactions, uncomplicated by change in the composition of the inner coordination sphere of the reactant complexes, and of more complicated reactions, in which the composition of the inner coordination sphere of the complexes is partly or completely changed. Consideration is given mainly to electrode reactions of complexes containing electrochemically inactive ligands. A list of 258 references is included.

CONTENTS

I. INTRODUCTION

A central aspect of the kinetics of electrode processes, which is also the least studied, is the mechanism of the electrochemical stages, as well as the relation between the kinetic parameters of these stages and the properties of the reactant species, the electrode, and the medium. Discussion of the nature and the mechanism of the electrochemical and other stages of electrode reactions (in particular choice of a model for the transition state) must take into account available information on the kinetics and the mechanism of similar homogeneous reactions. The fruitfulness of such an approach has been noted several times [1-8] and has been confirmed experimentally [4,9-11] on several reactions of metal complexes. The relation between the rate constants of homogeneous and heterogeneous electron-transfer reactions of metal complexes has been discussed by several workers [5,12-17]. However, the vast quantity of data available on homogeneous reactions of metal complexes and their mechanism [18-30] are relatively little utilised in electrochemical kinetics. Nevertheless, such an approach is especially promising for studying the mechanism of electrode reactions of metal complexes, in particular for identifying the electrochemically active complexes directly involved in the electrochemical stage and the character of their interaction with the electrode [31]. One aim of the present Review is to illustrate this principle. The formal kinetics of the electrode reactions of metal complexes and diffusion hindrances have been discussed many times [4,32-34] and will not be considered in detail here. Nor will kinetic and catalytic currents be discussed, for they have been surveyed in monographs [33-36] and several reviews [4,32,37-39].

Attention will be paid mainly to electrode reactions of metal complexes complicated by outer-sphere association or by rapid reorganisation of the inner sphere, which may occur particularly in the adsorption of complexes on electrodes. Since it is important to compare the kinetic parameters of a cathodic process with those of the opposite anodic process in order to obtain sound conclusions as to the nature and mechanism of electrochemical stages of complicated electrode reactions [40-43], considerable attention will be paid to work on these lines. The Review discusses electrode reactions occurring in aqueous solutions and involving metal complexes formed by electrochemically inactive inorganic and simple organic ligands.

II. STATE OF METAL COMPLEXES IN ELECTROLYTE SOLUTIONS

Most investigations on homogeneous and heterogeneous reactions of metal complexes are conducted in the presence of foreign electrolytes. In concentrated solutions of so called "inert" salts the complexes exist as complicated aggregates [44-49], containing various numbers of ligands X, cations B and anions A of the supporting electrolyte, and water molecules. The total concentration of the frequently studied singly charged complexes MX_i, in which one central metal ion M^{z+} is accompanied by i ligands X, can be expressed†

$$[MX_i] = \sum_x \sum_y \sum_z [MX_i(B)_x(A)_y(H_2O)_z], \tag{1}$$

where the summation covers both inner-sphere and outer-sphere species. Published [50] concentration stability constants of complexes $\beta_i = [MX_i][M^{z+}][X]^{-i}$ are effective quantities describing complicated equilibria between various associated forms and species from which they are produced [44-49]. The diversity and varying reactivity of the complexes present in solutions are responsible for the complicated character of their reactions. Study of the mechanism of the latter should utilise the greatest possible variety of methods for determination of thermodynamic and kinetic parameters of the processes. Outer-sphere association can be conveniently studied on highly charged

---

†The possible charge on the ligands and the metal complexes is omitted for simplicity. Henceforward water molecules forming part of the metal complexes will sometimes not be written out.

inert complexes of the type $Co(NH_3)_6^{3+}$ and $Fe(CN)_6^{3-}$, in which substitution of outer-sphere ligands does not take place during a measurement[46-49].

Aggregates such as ion-pairs or outer-sphere complexes are formed by inner-sphere complexes with ions of the supporting electrolyte or with free ligands[45-51]. The term "ion-pairs" is applied to aggregates formed by the interaction of two oppositely charged ions, between which an interlayer of water molecules may be retained. If this is absent, so called "contact ion-pairs" are formed, whose stability may be determined not only electrostatically but also by specific donor-acceptor interactions. Contact ion-pairs in which a negatively charged inner-sphere complex is directly bound to a cation of the supporting electrolyte are essentially doubly charged complexes[47,48]. If a positively charged inner-sphere complex adds one or more anions of the supporting electrolyte or neutral ligands, outer-sphere complexes are formed, often characterised by specific interactions between outer and inner coordination spheres[45-49].

III. ELECTRODE REACTIONS OF METAL COMPLEXES AND THEIR STAGES

Electrode reactions occurring on electrodes are described by equations containing the initial species and the final products. Frequently only the inner sphere is taken into account in writing down the electrode reactions of metal complexes: i.e. electrochemical and inner-sphere chemical‡ stages are considered. This is partly due to insufficient study of outer-sphere association processes, which play an important part in many homogeneous[5,26-28] and heterogeneous[4,31] reactions, especially those involving highly charged species. Hence electrochemical kinetics must consider not only inner-sphere but also outer-sphere stages—the formation and break-down of ion-pairs and outer-sphere complexes, the rearrangement of outer-sphere solvent molecules, and other processes that may take place either in the bulk of the solution or at the electrode surface.

The isolation of electron-transfer stages from the overall reaction in the kinetic study of electrode and homogeneous redox reactions of metal complexes is based essentially on the Franck–Condon principle and Libby's principle of symmetry which follows from it[52,53]. According to the latter the electron-transfer stage involves complexes the structure of whose heavy particle (atomic nuclei) is intermediate between those of the ground states of oxidised and reduced reactant forms. Outer-sphere and inner-sphere electrochemical stages are distinguished by analogy with homogeneous electron-transfer reactions[4,5,7,31]. If surface atoms of the metal electrode are separated from inner-sphere ligands of electrochemically active complexes by one or more ligands (solvent molecules), an outer-sphere mechanism operates. If the surface metal atoms are directly bound to an inner-sphere ligand (ligands) of the electrochemically active complex or to its central ion, an inner-sphere mechanism operates[31] (e.g. in the ionisation of metal atoms).

Both inner-sphere and outer-sphere mechanisms may operate in the electrical reduction of complexes. With a slow electrochemical stage the rate of reduction of mononuclear complexes of a metal can in general be expressed

$$i=\sum_{j=1}^{n} k_j^0 [MX_j]_s \exp\left[-\frac{\alpha_j F(\varphi-\psi_1)}{RT}\right], \qquad (2)$$

where $[MX_j]_s$ is the concentration of electrochemically active complexes in the inner or outer Helmholtz planes, α_j is the apparent transfer coefficient, ψ_1 is the potential at the electrical centre of a reactant species in the transition state[54,55], φ the electrode potential relative to that of the reference electrode, and k_j^0 the rate constant. Under certain conditions, depending primarily on the nature of the reactant complexes, the material of the electrode and its potential, both inner-sphere and outer-sphere mechanisms may operate. If one type of complexes, e.g. the highest complexes MX_n, take part in the outer-sphere electrochemical stage, Eqn. (2) is converted into Frumkin's equation[54]

$$i=k[MX_n]\exp\left(-\frac{z_0F\psi_1^0}{RT}\right)\exp\left[-\frac{\alpha F(\varphi-\psi_1^0)}{RT}\right], \qquad (3)$$

where $[MX_n]$ is the bulk concentration of the complex MX_n and z_0 is its charge, while ψ_1^0 is the potential in the outer Helmholtz layer. Diffusion hindrances are assumed to be absent.

It is advisable to use the following criteria to distinguish between outer-sphere and inner-sphere mechanisms of the electrochemical stage[7,31]: (i) the effect of the structure of the double layer on the kinetics of the electrochemical reaction[54] is based on the use of Eqn. (3), which is valid for an outer-sphere mechanism and is widely employed in electrochemical kinetics[35,55]; (ii) a low rate of substitution of inner-sphere ligands in the complex and of species directly adsorbed on the electrode§ (in comparison with the rate of the electrochemical stage) indicates an outer-sphere mechanism; (iii) the kinetic parameters of the electrochemical stage should be more greatly dependent on the electrode material with an inner-sphere than with an outer-sphere mechanism, for specific interaction of reactant complexes with the electrode takes place with the former mechanism; and (iv) larger negative entropies of activation should be observed with an outer-sphere than with an inner-sphere mechanism (for similar reactions).

The last three criteria resemble those used in studying the mechanism of homogeneous electron-transfer reactions[6]. However, it must be stressed that conditions of formation of the transition state differ significantly between homogeneous and heterogeneous electron-transfer reactions involving inert complexes. If rapid electron transfer occurs between two inert complexes in solution, an outer-sphere mechanism is functioning[5,28,57]. With fast electrochemical reactions of inert complexes, however, both outer-sphere and inner-sphere mechanisms may operate, because of the lability of most ions and molecules (including solvent molecules) adsorbed directly on metal electrodes. Such a conclusion may be drawn from the generally sharp increase in mobility of inner-sphere ligands with decrease in degree of oxidation of the central metal ion, especially with singly charged cations[19,28]. Yet the formal charge per metal atom on the surface of a metal

---

‡Chemical stages of electrode reactions are those involving the rupture and formation of chemical bonds but not those involving charge transfer, which would entail interconversion of oxidised and reduced forms. The adsorption of ions and molecules on electrodes, involving partial transfer of charge, can be regarded as heterogeneous chemical stages.

§Ions and molecules directly adsorbed on the electrode surface can be regarded as the "inner coordination sphere of the electrode"[56], and adsorbed species as inner-sphere ligands.

electrode, at the usual departures from the zero-charge point, is a small fraction of unity. A very low mobility has been established for oxygen adsorbed on platinum in the first and second monolayers in the range of potentials of the oxygen portion of the charging curve[58,59].

Two groups of electrode reactions can be distinguished: (i) in simple reactions the composition of the inner sphere of the complexes remains unchanged; (ii) complicated reactions involve change in the composition of the inner sphere. Assignment of an electrode reaction to a particular group may be based on the dependence of the equilibrium potential of the system on the concentration of an inner-sphere ligand (ligands) or on chemical analysis. If the equilibrium potential can be measured, its dependence on the concentration of inner-sphere and outer-sphere species can be used to establish the composition of the complexes present in solution and also the optimum conditions for kinetic measurements[60].

The usual division of electrode reactions of metal complexes into those involving and not involving chemical stages[4,33,34] is less convenient for the discussion of experimental results, since it requires a knowledge of the reaction mechanisms, which are often dubious and may vary with the experimental conditions.

IV. ELECTRODE REACTIONS UNACCOMPANIED BY CHANGE IN THE COMPOSITION OF THE INNER SPHERE

The change in the charge of an inner-sphere complex resulting from an electrode reaction leads to rearrangement of the outer coordination sphere. Hence the rates of the electrode reactions may be determined by the rearrangement of outer-sphere aggregates[7,31] and the structure of the surrounding solvent[12-15,61], by the structure of the electrical double layer, and by adsorption phenomena[35,55], as well as in certain cases by rearrangement of the structure of the inner sphere of the complex[4]. As a consequence of the high rates of outer-sphere processes[62,63] rearrangement of the outer sphere takes place under reversible conditions.

The composition and the stability of outer-sphere aggregates present in solution must be known in studies of the reaction mechanism of charged complexes. Such information is obtained by investigating the equilibria of the corresponding bulk processes, in particular by electrochemical methods[46-49,64-67]. The study of bulk outer-sphere processes is important not only for establishing the stoichiometry of the overall electrode reaction but also for assessing possible similar outer-sphere interactions, which may take place in the double layer and precede the electrochemical stage.

The reactivity of outer-sphere aggregates often differs significantly from that of the unassociated species[68-70]. One reason is provided by the different conditions of solvation (hydration) of the reactant species. In non-contact ion-pairs, which appear e.g. on the interaction of trebly and less strongly charged anionic complexes with hydrated cations of alkali and alkaline-earth metals[46], the electric field of the ion-pair probably[70] exerts an ordering influence on the water molecules surrounding the inner-sphere complex. This leads to inhibition of the activation of complexes such as $IrCl_6^{3-}$ [71-74] and $IrBr_6^{3-}$ [75,76] by hydrogen ions and ions of alkali and alkaline-earth metals, the effect increasing with the atomic mass and the cationic charge.

Similarly, outer-sphere ions may also influence the rates of electrochemical stages[70]. If the charge on an inner-sphere complex increases as a result of an electrochemical reaction, prior association of the initial complex with an oppositely charged ion should increase the rate of the electrochemical stage, since the structure of the solvent in the ion-pair will approach that of the solvent surrounding the reaction product. The cathodic reduction of anions on negatively charged electrode surfaces provides an example of such reactions, the rate increasing in the sequence $Li^+ < Na^+ < K^+ < Cs^+$ and with increase in the cationic charge of the supporting electrolyte[77-85,33-35,55].

If the charge on an inner-sphere complex ion decreases as a result of an electrochemical reaction, prior association of the initial complex with an oppositely charged ion should inhibit the electrochemical stage, since the structure of the solvent surrounding the "free" complex is closer to the structure of the reaction product (in comparison with the ion-pair). An example of this type of reaction is the cathodic reduction of inner complexes such as $Co(NH_3)_6^{3+}$, whose reactivity diminishes when they form ion-pairs with anions of the supporting electrolyte[4,86-89]. The need to allow for orientation of water molecules surrounding ion-pairs in the transition state of an electrochemical reaction, and the influence of this factor on its activation energy, have been noted previously[90]. The structure of the electrical double layer greatly affects the rate of the cathodic reduction of negatively charged complexes and other anions[55,77-85]. Several recent publications[91-94] have discussed the influence of this structure on the kinetics of electrode reactions complicated by the formation of ion-pairs in solution.

Iron(III)–Iron(II) System

With sufficiently large negative surface charges, at which anions are electrostatically repelled by the electrode, the polarograms for the reduction of $Fe(CN)_6^{3-}$ at a dropping mercury electrode in solutions containing alkali-metal cations obey Eqn. (3) and the corrected Tafel relation which follows from it[95,96]. The linear sections of these corrected relations yielded transfer coefficients α of 0.16, 0.17, and 0.19 for lithium, potassium, and caesium ions respectively[95]. The corrected Tafel relations for the reduction of $Fe(CN)_6^{3-}$, as for that of $S_2O_8^{2-}$, are independent of the nature of the negatively charged electrode[85,97]. It has recently been shown[98] that the corrected relations for the cathodic reduction of $Fe(CN)_6^{3-}$ coincide on negatively charged bismuth, cadmium, lead, and indium. Together with earlier results[85] this demonstrates the absence of specific adsorption of the reactant complexes, i.e. an outer-sphere mechanism of the electrochemical stage.

The effect of the nature of cations of the supporting electrolyte on the rate of cathodic reduction of anions is attributed[78-82] to specific adsorption of the cations on the electrode. The adsorbed cations attract the reducible anions: i.e. they act as "bridges", diminishing the electrostatic repulsion of the anions by the negatively charged electrode surface and thereby accelerating the process.

Alkali-metal cations exert a similar accelerating effect[99] in 1 M solutions of their chlorides when hexacyanoferrate complexes undergo charge transfer on a positively charged platinum electrode. The exchange current density i_0 of the complex system increases by factors of ~3 and 15 in passing from 1 M lithium chloride to 1 M sodium chloride and from the latter to 1 M potassium chloride respectively: i.e. effects are observed analogous to those occurring on negatively charged electrode surfaces (at cation concentrations of ~10^{-3} M).[95,96]

The great effect of the nature of the alkali-metal cation in 1 M solution on the rate of charge transfer between negatively charged iron complexes on platinum (Table 1) is probably due mainly to differences in the nature of the outer-sphere aggregates of oxidised and reduced forms present in solution. According to published results[46,100,101] the association of hexacyanoferrate(II) complexes with alkali-metal cations is accompanied by breakdown of the hydrate sheath of the cation, which does not occur with the oxidised complex. Thus among alkali-metal ions lithium ions form the most stable aggregates with hexacyanoferrate(II) ions, and the least stable with hexacyanoferrate(III) ions, since the radius of the hydrated cation increases on passing from caesium to lithium[102]. In accordance with this the concentration of electrochemically active iron hexacyanide complexes, which according to the Franck-Condon principle should have the same structure of inner and outer coordination spheres, will increase from lithium to sodium and then to potassium ions. This is obviously responsible also for the increase in rate constant k_S (in exchange current density) in the hexacyanoferrate system on passing from 1 M lithium chloride to 1 M potassium chloride (Table 1). This explanation is consistent also with the smaller effect of the nature of the alkali-metal cation on the rate of charge transfer between $Fe(CN)_5X^{2-}$ and $Fe(CN)_5X^{3-}$ complexes ($X = NH_3$, H_2O)[99] (Table 1), which, like other doubly and trebly charged complexes, probably associate with hydrated alkali-metal ions. The stability of the resulting ion-pairs increases in the sequence $Li^+ < Na^+ < K^+$.[46]

Table 1. Standard heterogeneous charge-transfer rate constants k_S for iron complexes* at 25°C.

*Rate constants k_S for certain systems[99] were calculated from the exchange current density on the assumption that the sum of the transfer coefficients of cathodic and anodic processes is unity (transfer coefficients of the cathodic process α for the first and last systems above are respectively 0.50 [103] and 0.84 [105]).

Study of charge transfer in hexacyanoferrate and similar complexes of iron in 1 M solutions of foreign salts has revealed[99] a breakdown of the linear dependence of the exchange current density

$$\lg i_{ex} = \lg zFk_s + \beta \lg c_{ox} + \alpha \lg c_{red} \qquad (4)$$

on the concentrations of oxidised and reduced forms c_{ox} and c_{red} that follows from the slow-discharge theory. This is attributed[99] to the involvement of dimers—polymerisation products of iron(III) and iron(II) complexes—present in solution, in the charge-transfer processes. However, this conclusion is inconsistent with results[103] establishing the validity of Eqn. (4) over wide concentration ranges of hexacyano-complexes of iron(III) and iron(II). Values of k_S and α obtained in this work[103] agree with those of other investigators¶. The absence of appreciable quantities of dimers in hexacyanoferrate(III and II) solutions is indicated also by results for their homogeneous electron-transfer reactions[106], whose rates, however, are sensitive to the pH of neutral and nearly neutral solutions. A similar effect can probably occur on charge transfer in hexacyanoferrate complexes on electrodes. At a rotating graphite electrode[107] in the region of Tafel behaviour kinetic orders less than unity with respect to the reactant complexes are found, and apparent transfer coefficients of cathodic (0.2) and anodic (0.2) processes whose sum is significantly less than unity. In the vicinity of the equilibrium potential the apparent transfer coefficients are 0.5 on graphite[107] and platinum[103] electrodes. This indicates that the electrode potential has a significant influence on the conditions of charge transfer in relatively simple electrode reactions, uncomplicated by change in the composition of the inner sphere. It is concluded[107] that charge transfer in hexacyanoferrate complexes on graphite takes place in the adsorbed state.

The considerable dependence of the constant k_S on the electrode material found for charge transfer in trioxalato-iron complexes[104,105] indicates an inner-sphere mechanism of the electrochemical stage.

Cobalt(III)–Cobalt(II) System

Exchange current densities observed in charge transfer on a platinum electrode between higher complexes of cobalt(III) and cobalt(II) with ammonia[86,88,89], ethylenediamine (en)[87], diethylenetriamine (dien)[108,109], cyclohexanediamine (chn)[110,111], and phenanthroline (phen)[112] conform to Eqn. (4) provided that c_{ox} and c_{red} are the concentrations respectively of oxidised and reduced forms with the same composition of inner and outer coordination spheres and that the process suffers no retardation caused by adsorption of ligands, complexes, and their hydrolysis products. With increase in the concentration of a ligand X the exchange current increases initially owing to the formation in solution of higher complexes from lower complexes of the reduced form (e.g. of $Co\,en_3^{2+}$ from $Co\,en_2^{2+}$), and then either ceases to depend on [X] or decreases (with increase in the concentration of diethylenetriamine, cyclohexanediamine, or phenanthroline). This is attributed to adsorption of the organic diamines, which block part of the electrode surface. The adsorption of hydrolysis products of cobalt(III) complexes has a similar effect. Other workers have also established[113,114] the electrochemical inactivity of $Co\,en_i^{2+}$ complexes in which $i < 3$ in an electrode reaction involving $Co\,en_3^{3+}$ and $Co\,en_3^{2+}$ complexes.

Table 2 shows that k_S decreases on passing from a chloride to a sulphate supporting electrolyte, and with trisethylenediaminecobalt complexes in the sequence $Cl^- > Br^-$, $SO_4^{2-} > S_2O_3^{2-}$. This sequence applies to the increase in stability of the outer-sphere complexes formed by the interaction of $Co\,en_3^{3+}$ with anions of the supporting electrolyte[117,118], which according to what has been stated

---

¶Table 1 gives values of k_S and α obtained[103] for the reduced surface of a platinum electrode. The values found for oxidised platinum are k_S = 0.028 cm s^{-1} and α = 0.46.

earlier in this Section are electrochemically less active than are the free Co en_3^{3+} complexes.

Information on the interaction of electrochemically active complexes of bi- and ter-valent cobalt with the electrode material is very limited. From an analysis of the Faraday impedance of the system comprising the complexes Co en_3^{3+} and Co en_3^{2+} with a mercury electrode Laitinen and Randles concluded[115] that both adsorbed and unadsorbed cobalt complexes take part in the reaction. From this it may be assumed that two mechanisms—inner-sphere and outer-sphere—operate in the electrochemical stage in this system. The close similarity in the values of k_S determined for trisethylenediaminecobalt and bisdiethylenetriaminecobalt complexes at mercury and platinum electrodes (Table 2) is consistent with the hypothesis that the electrochemical stage takes place either entirely or largely by an outer-sphere mechanism.

Values of k_S obtained for hexammine- and triphenanthroline-cobalt complexes (Table 2) and the rate constants of the corresponding homogeneous electron transfers conform[89,112] to the Marcus relation[12], which should hold for an outer-sphere mechanism. With the trisethylenediamine complexes, however, this relation is not satisfied, which is attributed[87] to a possible complicating influence on the electrochemical stage by either hydrolysis products or the electrode surface, which may change for instance[89] the spin multiplicity of the complexes. The high-spin and low-spin configurations respectively of the cobalt(II) and cobalt(III) complexes that predominate in solution ($t_{2g}^5 e_g^2$ and t_{2g}^6) compel rearrangement of the electronic configuration of the reactant complexes, which is responsible[†] for the slow transfer of electrons between cobalt(III) and cobalt(II) complexes having inner spheres of the same composition in homogeneous[20,28,121,122] and perhaps heterogeneous[4] electron-transfer reactions.

As the Marcus relation[12] between the rate constants of homogeneous and heterogeneous electron-transfer reactions is not obeyed in the Cr $bipy_3$–Cr $bipy_3^+$ system, other available data on the relation between electron-transfer rate constants have been discussed[123].

Other Systems

The heterogeneous rate constants k_S for the MnO_4^{2-}–MnO_4^- system at platinum, palladium, gold, and graphite electrodes (0.012, 0.0064, 0.008, and 0.02 cm s^{-1} respectively) and the corresponding transfer coefficients for the cathodic process (0.30, 0.30, 0.35, and 0.25), determined[124] with rotating disc electrodes in 1 M potassium hydroxide (at 20°C), are little affected by the electrode material. In view of this, the high k_S values, and the inertness of the complexes and oxygen atoms adsorbed in the region of the equilibrium potential of the redox system [0.610 V (n.h.e.) in 1 M sodium hydroxide[125]], at least in the case of a platinum electrode, it may be concluded that the electrochemical stage has an outer-sphere mechanism. Analysis of cathodic and anodic polarisation curves obtained for different concentrations of manganate and permanganate ions (in 1 M sodium hydroxide) indicated[125,126] that the electrochemically active complexes were in an adsorbed state, their adsorption on the electrode being accompanied by partial transfer of charge[55,127-137]. An outer-sphere mechanism of the electrochemical stage does not exclude specific interaction between electrode and species reacting on it (by analogy with outer-sphere complex formation in the bulk of the solution).

It is a complicated problem to establish the mechanism of electrochemical stages in the potential range corresponding to high rates of exchange with the solution of species directly adsorbed on the electrode. In such cases systematic investigations of the influence of the structure of the double layer, the material of the electrode, the nature of foreign electrolytes, and other parameters on the kinetics of the electrode reaction are necessary. Kinetic investigation of charge transfer between aquo-complexes of europium(III) and europium(II) at a mercury electrode in 1 M potassium chloride and iodide solutions, allowing for the effect of the structure of the double layer, indicates that electrochemically active complexes are localised in the region of the outer Helmholtz plane[138], i.e. that the electrochemical stage has an outer-sphere mechanism.

Comparison of the kinetic parameters of similar homogeneous and heterogeneous electron-transfer reactions may sometimes indicate the mechanism of the electrochemical stage. Thus the rate of reduction at a mercury cathode of the inert complexes $CoX(NH_3)_5^{2+}$ (where X is a singly charged anion) and other similar cobalt(III) complexes depends on the nature of the inner-sphere ligand X in the same way as does the rate of their reduction by the inert complexes $Ru(NH_3)_6^{2+}$. Since an outer-sphere mechanism operates in the latter case, a similar mechanism was deduced[10] for the reduction of cobalt(III) complexes at a mercury electrode. An outer-sphere mechanism for such electrochemical reactions had been suggested previously[4].

V. ELECTRODE REACTIONS ACCOMPANIED BY CHANGE IN THE COMPOSITION OF THE INNER SPHERE

The sequence of chemical and electrochemical stages in complicated electrode reactions depends primarily on the nature of the reactant complexes and may vary with

---

[†] The slow exchange of electrons between cobalt(III) and cobalt(II) complexes of similar composition had earlier been attributed[119] to a considerable change in the cobalt–ligand bond length with change in the valency state of the cobalt. However, it was later established[120] that the difference in bond lengths between the hexammines is 0.15 Å, which differs little from other similar systems.

the experimental conditions, e.g. with change in the electrode potential. Thus nitrilotriacetate complexes of cadmium[139,140] and other metals[32] are directly reduced on a dropping mercury electrode at sufficiently negative potentials, but at more positive potentials the electrochemical stage of the cathodic process is preceded by detachment of an anion of nitrilotriacetic acid.

The occurrence of preceding chemical stages and their reversibility are usually assessed from the effect of the ligand concentration on the rate of the electrode reaction[4,32-35]. In order to diminish (or eliminate) the complicating influence of the diffuse structure of the electrical double layer such investigations are usually made at a high and constant solution concentration (ionic strength μ). In interpreting the order of the electrode reaction with respect to the ligand it is usually assumed that the equilibrium constants of the chemical stages remain unchanged over the range of ligand concentrations studied, but with a variable ionic strength or a considerable change in solution composition this requires special proof.

We shall first discuss reactions involving oxidised and reduced forms dissolved in the electrolyte, i.e. so called redox systems, and then the electrodeposition and the anodic dissolution of metals.

1. Redox Systems

Titanium(IV)–titanium(III) system

Irreversible cathodic and anodic waves are observed on charge transfer between titanium ions at a dropping mercury electrode in acid chloride[141-144], bromide[144,145], and sulphate[146] solutions. The dependence of the half-wave potential on the concentrations of hydrogen and chloride ions with $\mu = 1$ suggests[141-144] the electrochemical stage

$$\mathrm{Ti(OH)Cl^{2+} + e \rightleftarrows Ti(OH)Cl^{+}}, \tag{5}$$

the electrochemically active complexes in which are formed in preceding reversible chemical stages from the oxidised and reduced forms $Ti(OH)_2Cl_2$, $TiOCl^+$ and Ti^{3+} that predominate in solution. The sum of the transfer coefficients $\alpha' + \beta' = 1.00 \pm 0.05$ (where α' varies from 0.34 to 0.45). Charge transfer between titanium ions was studied[144,145] in 1 M HBr + KBr and in 0.06 M HBr + xM KBr (where $x = 0.02$–0.80), i.e. with a variable ionic strength in the latter case. It was concluded that the electrochemical stage involved the complexes $TiBr^{3+}$ and $TiBr^{2+}$, produced reversibly from the respective forms $Ti(OH)Br_2^+$ and Ti^{3+} that predominate in solution. The apparent transfer coefficients vary slightly with the solution composition, their sum being $\alpha' + \beta' \simeq 1.1$–$1.2$. In acid sulphate and sulphate–perchlorate electrolytes ($\mu = 1$)[146] the electrochemical stage involves the complexes $TiHSO_4^{3+}$ and $TiHSO_4^{2+}$, which are in equilibrium with the complexes $Ti(OH)HSO_4^{2+}$ and Ti^{3+} that predominate in solution.

Chromium(III)–chromium(II) system

The oxidation of labile hydrated Cr^{2+} ions at a mercury electrode is catalysed by halide and other anions, the catalytic effect diminishing in the sequence $I^- > Br^- > Cl^-$ [147,148], i.e. the sequence in which the specific adsorption of halide ions on mercury decreases. In the presence of sufficiently high chloride-ion concentrations the oxidation product is the inert complex $CrCl^{2+}$ [147-149]. In the presence of bromide ions inert complexes of Cr^{3+} and $CrBr^{2+}$ are formed, their concentration ratio depending on the electrode potential[148]. The composition of the reaction products, together with chronopotentiometric and other measurements, show that chloride and bromide ions adsorbed on mercury act as bridging ligands in the electrochemically active complexes $Hg\ldots X\ldots Cr^{II}$. The latter arise directly on the surface of the mercury electrode, not by the adsorption of CrX^+ complexes formed by a preceding homogeneous chemical reaction, as might be supposed[6]. The results show[148] that, in the oxidation of Cr^{2+}, chloride and bromide ions are non-bridging ligands which have a great influence on the kinetics of homogeneous electron-transfer reactions[150-158], in particular in the chromium(III)–(II) system[151,152,154-158]. Non-bridging ligands may influence the rate of electrochemical reactions[157].

An inner-sphere mechanism operates in the oxidation of Cr^{2+} on mercury in the presence of thiocyanate ions[159]. The inert $Cr(NCS)_i^{3-i}$ complexes contain 1–5 thiocyanate ions, the number increasing as the potential becomes more positive and with increase in the thiocyanate-ion concentration. The products *cis*-$Cr(NCS)_2^+$ and $Cr(NCS)_3$, formed when $CrNCS^+$ complexes are almost completely absent from the solution, indicate that polybridging electrochemically active complexes take part in the electrochemical stage. Here chromium ions are attached to nitrogen atoms in two or three thiocyanate ions, which in turn are attached to mercury through the sulphur atom. The chromium(III) complexes formed are adsorbed more strongly on the positively charged mercury surface than are thiocyanate ions. A detailed kinetic investigation of the electrochemical reduction on mercury of the inert complexes $Cr(NCS)_3.(H_2O)_3$ [160] and other similar chromium(III) complexes[161] included an independent study of the adsorption of the reactant complexes. Activity coefficients both of the predominant adsorbed complexes and of the transition state of the electrochemical stage must be taken into account in the kinetic equations[160].

Many processes involving the cathodic reduction of inert chromium(III) complexes have been studied[4,65], including subsequent chemical stages resulting in change in the composition of the inner sphere of the labile chromium(II) complexes formed[162-170].

Europium(III)–europium(II) system

Kinetic examination of the reduction of europium(III) at a mercury electrode in solutions of different concentrations of thiocyanate ions (mainly $\mu = 1$ with sodium perchlorate), allowing for the ψ_1 effect[54], indicates[8] comparable participation of Eu^{3+} and $EuNCS^{2+}$ ions in the cathodic process when present in comparable quantities in the solution. The $EuNCS^{2+}$ complex has a considerably larger standard heterogeneous rate constant than does the hydrated Eu^{3+} ion (respectively 8×10^{-4} and 4×10^{-5} cm s^{-1}). On passing from the bulk of the solution to that adjacent to the negatively charged electrode, however, the ratio $[Eu^{3+}]/[EuNCS^{2+}]$ increases. This is responsible for the comparable contributions by the two ions to the cathodic process, which had been disregarded hitherto[171]. Results[8,171] indicate an outer-sphere mechanism of the reduction of Eu^{3+} and $EuNCS^{2+}$. The latter complex loses the NCS^- ligand, probably after the electrochemical stage.

In the presence of excess of ethylenediaminetetra-acetic acid at pH 9.5 monoligand complexes $Eu^{III}L$ and $Eu^{II}L$ take part in the electrochemical stage, while $Eu^{III}L_2$ and $Eu^{II}L_2$ predominate in solution (where L is the anion of the complexone)[172].

Platinum(IV)-platinum(II) system

Steady-state polarisation and other measurements[173-185] indicate slowness of the electrochemical stage of charge transfer in PtX_6^{2-} and PtX_4^{2-} complexes (X = Cl, Br, I)[173-183,185] and other structurally similar complexes[181-184] at a platinum electrode. Study of the process in chloride complexes of platinum at platinum, rhodium, and iridium electrodes (0.4–1 M NaCl, 3 M H_2SO_4) suggested[176,180] that the electrochemical stage involved adsorbed complexes of the type $M\ldots Cl_{ads}\ldots PtCl_5^{3-}$ and $M\ldots Cl_{ads}\ldots PtCl_5^{-}$ (anodic and cathodic processes respectively), where M represents a metal atom on the electrode surface. It was assumed that the planar $PtCl_4^{2-}$ complex associates reversibly with a chloride ion adsorbed on the electrode and a free chloride ion, which bring its configuration to an octahedron[176,180]. An analogous mechanism was suggested[181] for the anodic oxidation of $Pt(NH_3)_4^{2+}$ in the presence of chloride and bromide ions, as well as for other platinum(II) complexes[177, 182-184]. It is consistent with the approximately first order of the oxidation of PtX_4^{2-} with respect to the ligand (Cl^-, Br^-) observed at high concentrations (~0.3–1 M) of chloride and bromide ions[174-177,180]. At low concentrations halide ions are subject to competition by water molecules, which is more successful with negatively charged platinum(II) complexes than with positively charged and neutral complexes of the type $PtX_{4-i}(NH_3)_i^{i-2}$, where X = Cl, NO_2 and $i = 2,4$.[181,182]

The oxidation of $PtCl_4^{2-}$ complexes on platinum has different mechanisms in the double-layer region of the charging curve and at more positive potentials, at which oxygen is adsorbed (1 M NaCl, 3 M H_2SO_4 [185,186]). On passing from potentials of 0.7–0.85 V (n.h.e.), at which chloride ions act as bridging ligands, to ~1.1–1.3 V the apparent transfer coefficient of the anodic process decreases from 0.9 to 0.48.[185] This is attributed[186] to a decrease in the effective negative charge of the adsorbed chloride ions, which stabilises electrons in d_{z_2} orbitals in adsorbed platinum(II) complexes, and these are transferred in the electrochemical stage. At ~1.1–1.3 V oxygen atoms (hydroxide ions) having a considerable negative charge appear owing to deprotonation of adsorbed water molecules on the platinum. This is probably responsible for their preferential involvement as inner-sphere bridges in the anodic oxidation of $PtCl_4^{2-}$ complexes. Hence the complexes $PtCl_4(H_2O)_2$ and $PtCl_6^{2-}$ (70% and 30%) have been detected by thin-layer voltammetry[179] among the products of the oxidation of $PtCl_4^{2-}$ complexes in 1 M hydrochloric acid at ~0.8–1.0 V. The change in state of water molecules adsorbed on platinum, on passing from the double-layer range to a more positive potential, is probably responsible for the similar change in mechanism of the anodic process in the $SbCl_6^-$–$SbCl_4^-$ [187] and arsenic(V)–(III) [188] systems.

The inhibiting effect of the ligand X on the cathodic reduction of PtX_6^{2-} complexes (X = Cl, Br) on platinum is attributed[176,185] to a preceding reversible heterogeneous chemical reaction

$$M-X+PtX_6^{2-}\rightleftarrows M\ldots X\ldots PtX_5^{-}+X^{-}, \qquad (6)$$

which may occur by an exchange type of mechanism. The surface complex formed by reaction (6) takes part in a slow electrochemical stage. The closely similar transfer coefficients for cathodic and anodic processes in the $PtCl_6^{2-}$–$PtCl_4^{2-}$ [174-176] and $PtBr_6^{2-}$–$PtBr_4^{2-}$ [177] systems, whose sum in the double-layer potential range of the platinum electrode is ~2, indicate simultaneous or almost simultaneous transfer of two electrons in the electrochemical stage. A similar mechanism had been suggested earlier[189-193] for the transfer of electrons between octahedral platinum(IV) and planar platinum(II) complexes in the bulk of the solution.

The great instability of platinum(III) complexes is indicated by the simultaneous transfer of two electrons from chromium to platinum via a bridging inner-sphere chloride ion when quadrivalent platinum complexes $PtCl(NH_3)_5^{3+}$ are reduced by Cr^{2+} ions[194,195]. The unstable quadrivalent chromium complex formed, $CrCl^{3+}$, is then reduced by bivalent chromium. The hypothesis of a successive transfer of electrons in electrode reactions of platinum(IV) and platinum(II) complexes[173,183,184] therefore requires further support. The lack of influence of chloride ions (at concentrations of 0.3–1 M) on the rate of electrochemical reduction of $PtCl_6^{2-}$ and the small apparent transfer coefficient of the cathodic process (0.44) suggest that the mechanism of the reduction of $PtCl_6^{2-}$ complexes[183] differed from that suggested[176,180], perhaps owing to different surface states of the platinum electrodes. The effect of the chemisorption of foreign species on the kinetics of electrode reactions of platinum complexes has been investigated[184].

Other systems

The cathodic reduction of inert cobalt(III) and rhodium(III) complexes[4,64-66,169,196,197], like that of chromium(III) complexes, usually involves subsequent chemical stages leading to rearrangement of the resulting labile complexes of the reduced forms. Reversible chemical stages have recently been established[198], as a result of which the forms of bi- and tervalent iron predominating in acetate solution are converted into their acetate complexes, and these take part directly in the slow electrochemical stage on a platinum electrode. During charge transfer between ferrous and ferric ions at a platinum electrode in the presence of salicylate ions (0.01–0.1 M) and an acetate buffer the electrochemical stage involves $FeSal^+$ and FeSal complexes formed by preceding reversible chemical reactions from the oxidised and reduced species $FeSal_2^-$ and Fe^{2+}, which predominate in solution[199].

2. Electrodeposition and Anodic Dissolution of Metals

The electrodeposition and the anodic dissolution of metals in complexing solutions, as in non-complex media[40-43,200], may involve successive electrochemical stages. We shall consider initially the simpler one- and two-electron electrode reactions, which include a single electrochemical stage uncomplicated by crystal growth or disintegration. Gerischer[60] regarded such processes, occurring on the surface of metal amalgams, as macromolecular reactions of the type

$$M^{(z)}X_k+ze\rightleftarrows M+kX, \qquad (7)$$

where $M^{(z)}X_k$ is a complex directly involved in the electrochemical stage. With $k > 1$, however, a single-stage mechanism is improbable for reaction (7) [32,33]. A similar structure must be expected for the activated complexes of the single electrochemical stage of cathodic and anodic processes[52]. In view of this and the fact that the stage of ionisation of metal atoms is preceded by formation of their complexes on the electrode surface (adsorption of ligands)[201-203] the anodic reaction occurring on the electrode can be represented[204] by the sequence of stages

$$\mathrm{E{-}M^{(0)}} + k\mathrm{X} \rightleftarrows \mathrm{E{-}M^{(0)}X}_k\,, \tag{8.1}$$

$$\mathrm{E{-}M^{(0)}X}_k \rightleftarrows \mathrm{E{-}M^{(z)}X}_k + z\mathrm{e}, \tag{8.2}$$

$$\mathrm{E{-}M^{(z)}X}_k + (n-k)\mathrm{X} \rightleftarrows \mathrm{E} + \mathrm{M^{(z)}X}_n, \tag{8.3}$$

where E is the electrode to which are directly bound the ionising, formally "zero-charged" metal atoms and their complexes $M^{(0)}$ and $M^{(0)}X_k$. The adsorption of ligands and complexes is accompanied by displacement of water molecules or other species adsorbed on the electrode, which for simplicity is ignored in Eqns. (8.1)–(8.3). The concentration of the metal complex $M^{(z)}X_n$ predominating in the solution will be regarded as identical with the total concentration of metal ions in the solution.

If anodic and cathodic processes involve the same stages (8.1)–(8.3), slow occurrence of the electrochemical stage (8.2) and reversibility of the chemical stages (8.1) and (8.3) should lead to satisfaction of the equation[204]

$$\left|\partial\lg\frac{i}{i_{d,c}-i}\Big/\partial\lg[\mathrm{X}]\right|_{(\varphi-\varphi_0)<0} + \left|\partial\lg\frac{i}{i_{d,a}-i}\Big/\partial\lg[\mathrm{X}]\right|_{(\varphi-\varphi_0)>0} = n, \tag{9}$$

where i is the polarising current density at the electrode potential φ, with $i_{d,c}$ and $i_{d,a}$ the limiting diffusion currents of cathodic and anodic processes respectively, and φ_0 is the equilibrium potential of the $M/M^{(z)}X_n$ system. It is assumed that $[X] \gg [M^{(z)}X_n]$ and that the coverage of the electrode surface by electrochemically active complexes is insignificant. Relation (9) should be satisfied independently of whether the equilibrium constants β_{0k} and β_{kn} of the heterogeneous chemical stages (8.1) and (8.3) are functions of the electrode potential. If the dependence of these constants on φ can be neglected, the relation

$$\left|\partial\lg\frac{i}{i_{d,c}-i}\Big/\partial\varphi\right|_{(\varphi-\varphi_0)<0} + \left|\partial\lg\frac{i}{i_{d,a}-i}\Big/\partial\varphi\right|_{(\varphi-\varphi_0)>0} = \frac{zF}{2{,}3RT} \tag{10}$$

should also be satisfied, since with a single electrochemical stage the sum of the apparent transfer coefficients is equal to the total number of electrons transferred[40-42].

Formulae (9) and (10) can conveniently be used as criteria in study of the mechanism of the electrodeposition and the anodic dissolution of metals in complex electrolytes. Since the electrochemically active complexes in the ionisation of metal atoms contain metal–metal bonds, the opposite cathodic process should correspond to a transition state of similar structure, in conformity with the mechanism (8.1)–(8.3). Examination of published data shows that relation (9) is satisfied more often than is (10). A probable reason is the dependence of the equilibrium constants of reactions (8.1) and (8.3) on the electrode potential[204], which may be due in particular to variation in the ψ_1 potential.

Table 3 lists parameters of electrode reactions in which, in conformity with the mechanism (8.1–8.3), integral or nearly integral orders‡ are observed with respect to the ligand in cathodic and anodic processes, and formula (9) holds. The satisfaction of relations (9) and (10) in the first four systems in Table 3 supports the mechanism (8.1)–(8.3), which includes the inner-sphere electrochemical stage (8.2). Variation of the electrode potential either has no effect on the concentration of electrochemically active complexes or has opposite effects on the slopes of cathodic and anodic Tafel lines in these systems, and such effects balance out.

Table 3. Parameters (at 25°C) of electrode reactions for which Eqn. (9) is satisfied*

Au/Au(I), CN^-	$Au(CN)_2^-$	1	0.50	0.45	210, 211
Pd/Pd(II), Cl^-	$PdCl_4^{2-}$	2	0.84	0.84	208
Pd/Pd(II), Br^-	$PdBr_4^{2-}$	2	0.82	0.82	209

*k = number of ligands in electrochemically active complex; α' and β' are the apparent transfer coefficients of cathodic and anodic processes.

The dependence of the exchange current density measured near the equilibrium potential of amalgams of zinc[60], cadmium, and other metals[33,34] on the concentration of the complexes and the species forming them is also consistent with the mechanism (8.1)–(8.3).

The proportionality between the rate of cathodic reduction of the complexes $PdCl_4^{2-}$ [208,212-214] and $PdBr_4^{2-}$ [209,212,215] and their concentration, established with palladium[208,209,214] and dropping mercury§ electrodes[212,213,215], indicates that the electrode surface is only slightly covered by the reducible complexes.

A second order with respect to the chloride ion had been observed earlier for the anodic ionisation of palladium[216,217]. Nearly integral values (–2) of the order with respect to the ligand are observed for the cathodic reduction of PdX_4^{2-} (where X = Cl [208,213], Br [209,215,218]) at palladium and dropping mercury electrodes. Complexes of $PdCl_2$ are considered[219,220] to undergo direct reduction in the electrodeposition of palladium.

The sum of the apparent transfer coefficients $\alpha' + \beta'$ for the Pd/Pd^{II} system is slightly <2 (Table 3), which, on the hypothesis of the simultaneous involvement of two electrons in the slow electrochemical stage, can be attributed to a decrease in the concentration of electrochemically active complexes with increase in the polarisation of the electrode. Thus increase in the positive potential of a palladium anode may be accompanied by a decrease in the concentration of surface PdX_2^{2-} complexes owing to displacement of their X^- ligands by water molecules[204]. The coefficient α' determined from the Tafel relationship may be underestimated because of a breakdown of equilibrium in the preceding chemical stage.

---

‡The kinetic order departs considerably from an integral value for the ionisation of zinc from its amalgam in a pyrophosphate electrolyte (the order of the anodic process with respect to $P_2O_7^{4-}$ is 0.76 at –1.28 V s.c.e.). The corresponding value $\beta' = 1.26$ (Table 3) was obtained with $[P_2O_7^{4-}] = 0.025$ M. [205]

§At $PdCl_4^{2-}$ and $PdBr_4^{2-}$ concentrations $\gtrsim 2 \times 10^{-4}$ M their reduction at a dropping mercury electrode is inhibited by the reduction products, which accumulate on the mercury drop during its lifetime[212,213,215].

The slow occurrence of this stage in the cathodic reduction of $PdCl_4^{2-}$ complexes on a palladium electrode with a high concentration of chloride ions is indicated by a decrease in the product $i\tau^{\frac{1}{2}}$ with increase in the polarising current density i (where τ is the transition time)[221]. Detachment of a chloride ion from the complex $PdCl_4^{2-}$ is the slow stage, for which application of a galvanostatic method[221] gave the rate constant as 500 s^{-1} (for 0.06–1 M HCl and 3 M H_2SO_4 at 25°C). Smaller values of k^- (in s^{-1} at 25°C)—8.9 ± 0.8 (in 0.5 M $HClO_4$ by a spectrophotometric method)[222] and 5.6 ± 0.5 [in 0.3 M $(Li, H)ClO_4$ by the temperature-jump method][251]—have been found for the homogeneous aquation

$$PdCl_4^{2-} + H_2O \xrightarrow{k^-} PdCl_3H_2O^- + Cl^- . \qquad (11)$$

This discrepancy may be due to a catalytic effect of the surface of the palladium electrode on the rate of dissociation of chloride complexes of palladium. Since it has been concluded[221] that the preceding chemical stage has a homogeneous character, this problem requires further investigation.

The diffusion nature of the limiting currents observed in the reduction of $PdCl_4^{2-}$ complexes at a dropping mercury electrode suggests[213] that the preceding chemical reaction may be catalysed by mercury ions or atoms. The rate of cathodic reduction of $PdCl_4^{2-}$ and $PdBr_4^{2-}$ complexes increases sharply on passing to a palladium electrode, which indicates an inner-sphere mechanism of the electrochemical stage. It probably involves complexes, adsorbed on the electrode surface, which contain two halide ions and palladium atoms directly attached to metal atoms on the electrode surface[213,215], which is consistent with the mechanism (8.1)–(8.3).

The participation of two electrons in the slow electrochemical stage of the reduction of $Pd\,py_4^{2+}$, $Pd(NH_3)_4^{2+}$, and $Pd\,en_2^{2+}$ complexes (py = pyridine) was deduced from an analysis of non-stationary galvanostatic curves[223]. The apparent transfer coefficient of the cathodic process was determined[223] to be respectively 0.91, 0.85, and 1.46 for these complexes, and the absence of preceding slow chemical stages was established. Oscillopolarographic oxidation of the reduction products of $Pd(CN)_4^{2-}$ complexes at a mercury cathode reveals intermediate complexes of univalent and zerovalent palladium[224], probably stabilised by cyanide ions. A similar situation is found in the cathodic reduction of cyanide complexes of cobalt(II)[225] and nickel(II)[226], as well as other similar complexes formed by strong-field ligands[4]. Yet the Tafel slopes corresponding to the reduction on mercury of ammine (ammonia is a weak-field ligand) nickel(II) complexes (42 mV[227] and 60 mV[228]) indicate the simultaneous transfer of two electrons in the electrochemical stage. The latter involves $Ni(NH_3)_2^{2+}$ complexes formed by a rapid chemical reaction from higher ammine complexes, which supports the mechanism (8.1)–(8.3).

The kinetic parameters determined[207,229–231] in a study of irreversible cathodic and anodic processes for the $Zn(Hg)/Zn(OH)_4^{2-}$ system, in contrast to the systems listed in Table 3, conform neither to Eqn. (9) nor to (10). This is explained[229,230] by differences in the nature of the electrochemical stages of cathodic and anodic processes. The approximate orders of −2 and 1 with respect to hydroxide ions for the two processes suggest that the complexes $Zn(OH)_2$ and $ZnOH^-$ are involved in their slow electrochemical stages. Near the equilibrium potential of the system the anodic process is of second order with respect to hydroxide ions[60]. An approximate halving of the order for the ionisation of zinc atoms with respect to the ligand on passing from low to high anodic polarisations is observed also when zinc amalgam dissolves in the presence of ammonia molecules[206] and for zinc in a citrate electrolyte[232]. This is probably due to competition with the adsorbed ligands by water molecules, a considerable proportion of which, at the low negative surface charges on the electrode characteristic of high anodic polarisations, are oriented with the oxygen atoms towards the surface zinc atoms, which should decrease the concentration of electrochemically active complexes and the order of the anodic process with respect to the ligand. The approximate halving of the apparent transfer coefficient of the anodic process which accompanies[206,232] the decrease in order with respect to the ligand may be due to a transition from a slow two-electron stage to a one-electron stage. The apparent transfer coefficients of cathodic and anodic processes (0.82 and 0.34) found for the $Zn(Hg)/Zn(OH)_4^{2-}$ system in 4 M K(OH, F) solution¶ are attributed[231] to a stepwise transfer of electrons in cathodic and anodic processes. However, these values are consistent also with a two-electron electrochemical stage during cathodic polarisation and slow detachment of the first electron at high anodic polarisations. It has been concluded that intermediate univalent zinc species are adsorbed on zinc during its electrodeposition and anodic dissolution in the presence of malonate ions (pH 6–7)[233] and in alkaline solutions[234,235].

Consecutive transfer of electrons probably always occurs in three-electron reactions, whose stage-by-stage mechanism has been studied in detail on the $Bi(Hg)/Bi^{III}$ and $In(Hg)/In^{III}$ systems[41–43,200]. The kinetics and the mechanism of the anodic dissolution of indium in various media have been surveyed[200]. The cathodic reduction of indium(III) complexes is complicated by slow chemical stages and also by the dependence of the concentration of adsorbed complexes and ligands on the electrode potential (see reviews[38,200,236]), which adds to the difficulty of determining the kinetic parameters of the cathodic process and of subsequent analysis based on Eqns. (9) and (10).

The three-electron cathodic reduction of rhodium(III) complexes also involves one- or two-electron stages[223,237–241]. With $RhCl_6^{3-}$ and $RhCl_5H_2O^{2-}$ complexes on mercury[238,241] and rhodium[240] electrodes the slow electrochemical stage is preceded by reversible detachment of some of the chloride ions from the initial complexes. The rapid replacement of inner-sphere ligands in inert complexes may be due to catalysis by the electrode surface or intermediate products. Heterogeneous catalysis of the replacement of ligands in inert complexes has been studied[242] on cobalt(III) complexes.

The bond between electrochemically active complexes and the electrode may vary significantly in character for different electrochemical stages of the same many-electron reaction. According to the above considerations the last electrochemical stage of electrodeposition, with formation of metal atoms (their surface complexes), should have a non-bridging inner-sphere mechanism, which occurs e.g. in the sequence of stages (8.3), (8.2), and (8.1). In the case of the initial electrochemical stages of electrodeposition, as a result of which intermediate uni- or bi-valent metal complexes are formed from the initial complexes, an outer-sphere or a bridging inner-sphere

---

¶Apparent transfer coefficients $\alpha' = 0.80$ and $\beta' = 0.52$ were determined[207] by a potentiodynamic method for the $Zn(Hg)/Zn(OH)_4^{2-}$ system in 3 M (KOH + NaCl) solution.

mechanism may operate†. The presence of bridging ligands in bivalent zinc, cadmium, and lead complexes adsorbed on a mercury electrode[243-246] (see also references in Refs. 247 and 248) does not exclude a non-bridging inner-sphere mechanism of the electrochemical stage in the reduction of these complexes. Complexes adsorbed through the ligand, which predominate on the electrode surface, may be converted by a preceding rapid chemical reaction into electrochemically active complexes containing a metal–metal bond.

It follows from the above considerations that, with a slow electrochemical stage complicated by complex formation, the main features of the electrochemical kinetics are the same on liquid and solid electrodes. The kinetics of practically important processes of the electrodeposition of solid metals from complex electrolytes have been examined in a monograph[249]. A review has recently been published[250] on the electrodeposition of noble metals.

oOo

A very important but little studied problem is the relation between the kinetic parameters of an electrode reaction and the electronic structure of the complexes. The electrode reactions discussed above involved the transfer of electrons from the electrode to orbitals localised mainly on the metal ion or in the reverse direction[4]. The transfer of t_{2g} electrons from or to low-lying orbitals of a metal occurs more rapidly than that of e_g electrons[252,253]. This is explained by the greater change in metal–ligand bond length in the latter case, and hence the greater energy of rearrangement of the inner coordination sphere (while its composition remains unchanged).

In the electrochemical reduction of complexes electrons may be transferred also to orbitals of inner-sphere ligands. In order to elucidate the reaction mechanism in such cases it is necessary to make a parallel kinetic study of the cathodic reduction of coordinated and free ligands[254-257].

The kinetic investigations on electrode reactions of trisbipyridyl and similar complexes of iron in water and dimethylformamide[258] and of trisbipyridyl complexes of ruthenium, osmium, chromium, titanium, vanadium, and molybdenum in dimethylformamide[254-256] have revealed two groups of electrode reactions. One group of complexes, with which a t_{2g} electron is transferred, have rate constants $k_S = 0.8–1.3$ cm s^{-1}. The other group of complexes, with which an electron localised on a π^* orbital of a ligand is transferred, correspond to $k_S = 0.1–0.3$ cm s^{-1}. The fact that k_S is relatively unaffected by the nature of the electrode (mercury, platinum), the solvent (water, dimethylformamide), the state of oxidation of the metal, or the charge on the complex indicates the decisive role of rearrangement of the inner coordination sphere in determining the rate of the electrochemical stage[256]. Electron transfer to orbitals of the ligand is suggested in the second group of complexes by the closeness of their k_S values to those found for the bipy/bipy$^-$ system (0.13 and 0.21 cm s^{-1} for mercury and platinum electrodes respectively). The redox properties of ligands coordinated by metal ions has recently been studied intensively. This topic is of intrinsic interest, and will not be considered here.

---

† With a bridging inner-sphere mechanism one or more inner-sphere ligands of the electrochemically active complex are attached directly to metal atoms on the electrode surface. In both heterogeneous and homogeneous electron-transfer reactions bridging ligands may fill various functions[5].

Polarography of Organoelementary Compounds of Non-transition Elements

S.G.Mairanovskii

The electrochemical behaviour of many organoelementary derivatives containing a non-transition element is described. The mechanism of the electrode processes and the effect of the conditions of electrolysis are reviewed, mainly at a dropping mercury electrode. A list of 156 references is included.

CONTENTS

Although polarography is used fairly widely in the study of organoelementary compounds, published data have not yet been collected together. The present Review attempts to summarise and systematise very briefly the results of numerous investigations on derivatives of non-transition elements.

I. ORGANOMERCURY COMPOUNDS

These compounds are of especial interest for polarography, since they can be formed by the reaction of mercury with certain depolarisers (e.g. halogeno-derivatives, sulphur-containing compounds, certain aldehydes and ketones), as well as intermediate and final products of electrode processes, e.g. in the reduction of iodonium salts[1]. If sufficiently rapid, the formation of organomercury compounds changes substantially the character and the mechanism of the electrode process, which must therefore always be borne in mind in the study of electrode processes.

The first detailed studies of the behaviour of arylmercuric salts RHgX [2,3] revealed the presence of two one-electron waves on the polarograms in 50% aqueous-ethanolic solutions, with the half-wave potential of the first wave appreciably affected by the nature of the anion X^-.[2,4] Organomercury salts are able to dissociate[5,6]:

$$\mathrm{RHgX} \overset{K_1}{\rightleftarrows} \mathrm{RHg}^+ + \mathrm{X}^- \ . \qquad (1)$$

If an electrolyte containing a common anion X^- is present in solution, complexes are formed:

$$\mathrm{RHgX} + \mathrm{X}^- \overset{K_2}{\rightleftarrows} \mathrm{RHgX}_2^- . \qquad (2)$$

Reduction of the cation RHg^+ is reversible[4]:

$$\mathrm{RHg}^+ + e \rightleftarrows \mathrm{RHg}^{\cdot} . \qquad (3)$$

The resulting radical $RHg\cdot$ dimerises to give an extremely unstable "organic calomel" R_2Hg_2. Formation of the latter was suggested[7,8] after comprehensive discussion of the possibilities for the cathodic reduction of organomercury salts. It has been proved by chronopotentiometric investigations[9], in particular establishment of the nature of the products of interaction of organomercury salts and their reaction with metallic mercury, and of interaction between various disubstituted mercury derivatives[10,11], as well as study of the products of the simultaneous reduction of two different organomercury salts and of reduction of a salt on an electrode covered with the adsorbed symmetrical organomercury compound[10-12].

The organic calomel is converted by disproportionation (which is probably reversible[10,13]) fairly rapidly into the symmetrical organomercury compound:

$$\mathrm{R_2Hg_2} \rightleftarrows \mathrm{R_2Hg} + \mathrm{Hg} \ . \qquad (4)$$

It is reduced irreversibly at the electrode[2,10,14-16]:

$$\mathrm{R_2Hg_2} + 2e + 2\mathrm{H}^+ \rightarrow 2\mathrm{RH} + 2\mathrm{Hg}, \qquad (5)$$

corresponding to the second wave on the polarograms of organomercury salts.

Another possibility is that an organic calomel may be formed by a so called "electrochemical desorption mechanism", in which a radical formed at the electrode reacts with the initial substance and simultaneously acquires a second electron from the electrode, as well as, though less probably, by a "hydride" mechanism, in which the product RHg^- of the addition of two electrons to the initial organomercury cation at the potential of the first wave reacts with the initial cation RHg^+.[13]

The lifetime of the organic calomel R_2Hg_2 (before its disproportionation by reaction 4) decreases according to the nature of R in the sequence[12]
$C_2H_5 >$ cyclo-$C_5H_9 >$ n-$C_3H_7 >$ iso-$C_3H_7 \simeq$ n-$C_5H_{11} \gg$ 2,4,6-$(CH_3)_3C_6H_2 >$ 2-$C_{10}H_7 > C_6H_5 \gg CH_2:CH$
It has been established[13] that neither the organic calomel $(RHg)_2$ nor the unsymmetrical calomel ArHgHgAlk is able to dissociate into free radicals.

The reversible character of transfer of the first electron and the accompanying chemical reactions are responsible for the form of the first wave and the influence of various factors on its parameters[4,15]. Thus if X is not a halogen, the wave in the absence of halide ions in solution is described[4] by the equation for a reversible one-electron process followed by rapid bimolecular interaction of the electrode products in the adjacent layer of solution[16]:

$$E = \varepsilon_0 - \frac{RT}{nF} \ln \frac{i^{2/3}}{i_d - i}, \tag{6}$$

where ϵ_0 is the so called characteristic potential, independent of concentration[16].

When RHgX, where X is a halogen, undergoes reduction in the absence of halide ions in solution, such ions appear at the electrode surface as a result of the electrode process (1), their concentration being greater the stronger the current. The resulting halide ions undergo reaction (2) with the initial salt RHgX, which makes the potential more negative, as occurs with bulk catalytic waves in unbuffered media, when hydroxide ions are formed provided that the wave height is still proportional to the catalyst concentration[16]. In both these cases the wave form is described by the formula

$$E = \text{const} - \frac{RT}{F} \ln K_2 - \frac{RT}{F} \ln \frac{i^{5/3}}{i_{\text{lim}} - i},$$

where a tenfold increase in the depolariser concentration makes the half-wave potential more negative by 40 mV.

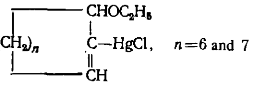
The form of the polarographic wave obtained for an organomercury halide in a solution containing excess of this halide ion is described by Eqn. (6), owing to the occurrence of reaction (2), as with bulk catalytic waves in buffered solutions. The quantity ϵ_0 becomes more negative with increase in the concentration of halogen in the solution[4]. For the ethylmercury halides the half-wave potential of the first wave becomes more negative in the sequence of derivatives Cl → Br → I.

The half-wave potential of the first reversible reduction wave of pyrid-3-ylmercuric acetate becomes less negative with lengthening of the drop period of the electrode and with increase in the depolariser concentration[15], in conformity with the Koutecký–Hanuš theory[17] for a reversible process followed by rapid dimerisation of the electrode products. In just the same way, in agreement with the theory[18] of irreversible electrode processes, for which the rate of electron transfer competes with a bimolecular reaction of the species involved in the electrochemical reaction, the half-wave potential of the second wave becomes more negative with increase in the depolariser concentration[15]. However, organomercury salts exhibit an additional shift in the half-wave potential, due to inhibition of the process by adsorbed reaction products.

The nature of the radical R influences the ease of reduction, the characteristic potential ϵ_0 (or the half-wave potential) becoming less negative with decrease in the acidity pK_a of the corresponding hydrocarbon RH.[19] However, there is no linear relation between these quantities. Negative values of ϵ_0 for the first wave of organomercury perchlorates with 0.1 N tetraethylammonium perchlorate as supporting electrolyte in dimethylformamide at 25°C are 0.612, 0.594, 0.613, 0.535, 0.544, and 0.370 V (s.c.e.) when R represents respectively methyl, ethyl, n-propyl, n-pentyl, phenyl, and benzyl[19].

With derivatives of phenylmercury salts not only cations of the initial compounds but also free radicals formed by electron transfer to them are adsorbed on the electrode[20]. Dimerisation of the radicals is then a surface process: i.e. the radicals undergo dimerisation when adsorbed on the electrode. The wave is then described not by Eqn. (6) but by the corresponding expression containing the square root of the current in the numerator of the antilogarithm[21]. Rate constants of surface dimerisation (or those of formation of the symmetrical compound, for it is assumed[20] that formation of an organic calomel is a very rapid reversible process, followed by the slower direct reaction (4) of the free radicals of phenylmercury and several of their derivatives with substituents in the benzene ring have been determined[20] by voltammetry with a linearly varying potential and reversal of the current. The rate constant for free phenylmercury radicals at 25°C is ~ 10^{13} cm^2 s^{-1} mole^{-1}. The rate of dimerisation increases or decreases on the introduction of electron-donating or electron-accepting substituents into the benzene ring, with a satisfactory correlation between the logarithm of the rate constant and the σ-parameter of the substituent[20].

cis-1-Chloromercuri-9-ethoxycyclononene and *cis*-1-chloromercuri-10-ethoxycyclodecene. When the group R in an organomercury salt RHgX is very large, the rate of dimerisation of the free radical RHg· is so slow that it ceases to influence the polarographic characteristics of the waves. This situation is probably present[22] in the reduction of these two compounds



$$(\text{CH}_2)_n\text{—CHOC}_2\text{H}_5\text{—C(HgCl)=CH—},\quad n=6 \text{ and } 7$$

which in 50% aqueous dioxan each give two waves, representing reduction to the free radical and its further reduction with separation of metallic mercury. The first wave is reversible, its form being described by the usual Heyrovský–Ilkovič equation for reversible waves with one transferable electron; its half-wave potential is independent of the concentration of depolariser in the solution, and both factors indicate absence of rapid dimerisation of the radicals. When a solution of these compounds in dimethylformamide is electrolysed at the temperature of liquid nitrogen, it acquires a deep yellow colour, which remains for a long time; when the solution warms up to room temperature, however, the colour characteristic of the free radicals disappears after a few minutes[22]. This is also an indication of the comparative stability of the radicals. The second wave on polarograms of these compounds is irreversible, its half-wave potential becoming more negative with increase in the depolariser concentration. For both waves these potentials depend on the pH. Although the investigators[22] speak of the diffusion nature of both waves, the first wave is appreciably lower than the second ($i_{\text{lim}}'/i_{\text{lim}}'' \simeq 2/3$) and has a comparatively high temperature coefficient (increasing from 2.2 to 3.8% deg^{-1} with rise in temperature from 21 to 42°C). The first wave probably has partly kinetic restriction.

trans-1-Chloromercuri-11-methoxycycloundecene and *trans*-1-chloromercuri-13-methoxycyclotridecene. These compounds have been studied under the same conditions[23] (n = 8 and 10 in the above general formula, with the ethoxy-group replaced by methoxyl). They each give two one-electron waves, whose limiting currents are independent of pH, while the half-wave potentials vary with pH. The first wave is reversible, and the second irreversible; free radicals appear in the first stage, and either dimerise or acquire a second electron, eliminate mercury, and form an unsaturated compound. The change from *cis*- to *trans*-isomers and the increase in size of the ring result in less negative half-wave potentials of both waves[23]. These potentials for the first waves of ring-substituted bromomercuriphenyl acetates do not correlate with the Hammett σ-constants[24]. Such correlation between the half-wave potentials of the first waves and the nature of the substituents is absent also from other α-oxomercuric halides[24].

Fluorinated aliphatic organomercury salts. These give two waves representing reduction of the carbon–mercury bond, but in some cases more than two electrons are involved, probably owing to electrochemical cleavage of a carbon–fluorine bond[14].

Perfluorophenylmercuric bromide. In 30% aqueous methanol with 1 M sodium perchlorate as supporting electrolyte this fluorinated compound gives two waves having half-wave potentials (with a depolariser concentration of 2×10^{-4} M) of respectively −0.02 and −0.31 V (relative to an aqueous saturated calomel electrode). It has been shown galvanostatically that the first stage of reduction gives perfluorodiphenylmercury, which is able to form up to ten adsorbed layers on the electrode[25].

Pyrid-3-ylmercury chloride and acetate. In buffered aqueous solutions each of these compounds gives two one-electron diffusion reduction waves (the first of which is reversible), whose half-wave potentials become more negative at pH > 5.0 (at pH 4 these potentials are respectively 0 and −0.37 V independently of the nature of the anion). The waves are distorted by adsorption of the reaction products, so that hysteresis is observed on the polarograms[15].

2-Piperidinoethylmercuric and 2-diethylaminoethylmercuric chlorides. These compounds are reduced in two one-electron stages (whose half-wave potentials in 50% aqueous ethanol are −0.345 and −0.70 V for the former chloride, and −0.35 and −0.62 V for the latter); these potentials are appreciably more negative in dimethylformamide[26]. The reduction products are a symmetrically disubstituted mercury derivative in the first stage, and a secondary amine (piperidine or diethylamine) and ethylene in the second stage. Only traces of tertiary amines were detected among the products of electrolysis[26].

Thien-2-ylmercuric chloride. In buffered solutions this compound gives two one-electron waves (at pH < 8 the first wave is concealed by the anodic mercury-dissolution current).[15] The half-wave potentials become more negative with increase in pH; at pH > 9 that of the second wave ceases to depend on pH, its value then being $E_{\frac{1}{2}} = -0.86$ V (s.c.e.). The first wave is reversible in character, and its half-wave potential is influenced by subsequent dimerisation of the electrode products.

5-Acetylthien-2-ylmercuric bromide. In a 30% aqueous dimethylformamide solution of 1 M sodium perchlorate this compound gives three reduction waves, of which the first two (half-wave potentials −0.06 and −0.73 V s.c.e.) are one-electron diffusion waves corresponding to reduction of the organomercury moiety, and the third represents reduction of the keto-group in the acetylthiophen formed by the first two processes[27]. Galvanostatic study of the bromide shows that it forms adsorbed multilayers on the surface of the mercury electrode.

2-Methoxyethylmercuric salts. Products of the addition of mercury(II) salts to alkenes in methanol, of the type $CH_3O.CHR.CH_2.HgX$ (where X is an acid radical), behave similarly to other organomercuric salts when polarographed: they give two reduction waves on the polarograms, the first of which is reversible and corresponds to formation of the radical R′Hg· adsorbed on the mercury (its half-wave potential does not depend on the pH but is affected by the nature of the anion); the second wave is an irreversible reduction of the radical (or "calomel") to R′H with the liberation of Hg^0.[28]

2-Hydroxyethylmercuric salts. In neutral or alkaline buffered solutions these compounds HOC_2H_4HgX give two pH-independent one-electron diffusion waves with half-wave potentials of −0.45 and −1.10 V for the chloride, and −0.63 and −1.30 V for the acetate. On acidification of the solutions the height of the first wave increases at the expense of the second, so that at pH < 5 a single two-electron wave remains[29]. Preparative electrolysis at potentials corresponding to the first wave give the symmetrical bishydroxyethylmercury[30]. At those of the second wave ethanol and ethylene are formed, the proportion of the alcohol increasing when the solution is made alkaline; in acid solutions, however, the yield of ethylene approaches 100%.[29] The formation of ethanol may be due to reduction of the symmetrical bishydroxyethylmercury formed on electrolysis[30].

2-Chloromercuri-3,3,3-trifluoropropan-1-ol. In a solution of 0.1 *N* potassium chloride in 80% ethanol this compound and its ethers $CF_3CH(HgCl)CH_2OR$ give two one-electron diffusion waves (with half-wave potentials of −0.37 and −0.080 V (s.c.e.) for the propanol). On acidification the first wave grows at the expense of the second, so that in acid medium only a single wave appears with $E_{\frac{1}{2}} = -0.37$ V.[31] Electrolysis in acid medium at the potential of the first wave entails protonation of the intermediate radical with further transfer of a second electron, as a result of which the ether bond is ruptured and the alkene $CF_3CH:CH_2$ is formed. At the potential of the second wave in neutral or alkaline media carbon–mercury and carbon–fluorine bonds are broken with formation of difluoroallyl alcohol (or an ether $CF_2:CHCH_2OR$).[31]

o-Chloromercuriphenol. The usual two one-electron diffusion waves are observed in buffered aqueous solutions. With a buffer containing nitric acid (0.05 M HNO_3 + 0.45 M $NaNO_3$), however, waves of unusual character are observed owing to the very sparing solubility of the intermediate formed on the electrode by transfer of the first electron[32]: the half-wave potential of the first wave becomes more negative with increase in the depolariser concentration, owing to retardation of the process by a reaction product; and in the second wave the current in the lower part is independent of the depolariser concentration, whereas the upper part of the wave is almost rectangular, the ascending portion of the wave passing abruptly, at an angle, into a limiting-current plateau. The absence of dependence of the current in the lower part of the wave on the concentration of the starting material is attributed[33,34] to a constant surface concentration of the reactant, due to its great adsorbability and very low solubility. The equations deduced[32] for both waves and the dependence of the half-wave potential of the first wave on the depolariser concentration reproduce correctly the peculiarities of the reduction waves for *o*-chloromercuriphenol in aqueous nitric acid.

Ferrocenylmercury salts. Both these compounds and mercury salts of manganese and rhenium cyclopentadienyltricarbonyls are reduced similarly to ordinary organomercury salts[35]. However, here two-step reduction waves (with respect to mercury), each corresponding to the transfer of one electron, can be obtained only in a 0.1 M solution of tetraethylammonium perchlorate in 90% dioxan (under these conditions neither ferrocene nor the manganese and rhenium atoms in the above compounds are involved in the electrode process). In the same medium a carboranylmercury salt gives two two-electron waves, the first corresponding to reduction to Hg^0 and carborane, and the second to reduction of the latter. As was to be expected, the introduction of substituents into the ferrocene ring system affects the half-wave potentials of both waves on polarograms of ferrocenylmercuric chloride, but the shifts are very small[35], which is consistent with the low-transmission of the induction effect of one ferrocene ring into the other.

It has recently been shown[36] that transfer of the first electron may occur either reversibly or irreversibly depending on the conditions. Thus allyl- and phenylmercuric halides give reversible waves in aqueous ethanol (1 : 1) and in ethanolic benzene (1 : 1), whereas in aqueous dimethylformamide and acetonitrile the first waves are irreversible with their half-wave potentials independent of the nature of the halide.

As already noted, the second reduction waves on polarograms of organomercury salts correspond to reduction of the "organic calomel" by reaction (5). Their half-wave potentials often depend on pH in acid media, but not in alkaline media[2]. In view of the possible reversible disproportionation (4) it might be expected that the symmetrical organomercury compounds R_2Hg formed by this reaction would be reduced at the same potentials as are the $RHg\cdot$ radicals. In fact, however, the waves of symmetrical organomercury compounds are usually situated at more negative potentials than are those of R_2Hg_2. The presence of separate R_2Hg_2 and $R_2Hg\cdot$ waves is due to the comparatively low rate of establishment of equilibrium (4).

The difference between the half-wave potentials for the reduction of HgR_2 and $RHg\cdot$ is smaller the lower the absolute value for the former[35]. If an organomercury salt is reduced very readily, the difference between the half-wave potentials of first and second waves becomes small, so that sometimes (e.g. with carboranylmercury salts) the two waves coalesce into a single two-electron wave[35].

A linear relation exists between the half-wave potential of the second reduction wave of RHgX and the electron affinity of the radical $R\cdot$. This enables the electron affinity of the radical to be estimated from polarographic data[35].

Symmetrical organomercury compounds. These are reduced irreversibly in a single stage involving two electrons[37]:

$$R_2Hg + 2e + 2H^+ \rightarrow 2RH + Hg.$$

The half-wave potential is usually unaffected by solution pH. Such an effect, i.e. preceding protonation, occurs only when R contains basic groups (e.g. carbonyl).

In some cases a symmetrical compound adsorbed on the mercury electrode reacts quite rapidly with the mercury to form free radicals $RHg\cdot$ or an organic calomel[9], which are reduced at less negative potentials. Two waves are then observed on the polarograms, the second corresponding to reduction of the symmetrical compound that has not reacted with mercury[9].

The ease of reduction of R_2Hg depends on the polarity of the R–Hg bond: the more polar this bond, the more readily does reduction take place[37]. Organomercury compounds containing an α-oxo-group are reduced most easily. Thus for the reduction wave of $(C_6H_5CHCOOC_2H_5)_2.Hg$ in 0.1 M sodium tetrafluoroborate in 50% aqueous methanol $E_{\frac{1}{2}} = -0.36$ V (s.c.e.), whereas the corresponding potential for dibenzylmercury under the same conditions is -1.64 V.[37] In 0.1 M tetraethylammonium perchlorate in dimethylformamide diphenylmercury gives a wave with $E_{\frac{1}{2}} = -2.21$ V (relative to 0.1 M $(C_2H_5)_4NI/Hg_2I_2$ in dimethylformamide).

The most positive value $E_{\frac{1}{2}} = -0.18$ V (s.c.e.) has been obtained for the reduction wave of mercury dicyanide in water, the wave being reversible[38], in contrast to other symmetrical organomercury compounds. Diferrocenylmercury, in contrast, is reduced at extremely negative potentials (in 0.1 M tetrabutylammonium perchlorate in dimethylformamide $E_{\frac{1}{2}} \simeq -2.68$ V aq.s.c.e.).[35]

Diphenylmercury. In tetrabutylammonium perchlorate dissolved in dimethoxyethane this compound gives a wave with $E_{\frac{1}{2}} = -3.32$ V (relative to an $Ag/AgClO_4$ (10^{-3} M) electrode). The half-wave potentials for the reduction of perchlorodiphenylmercury and perfluorodiphenylmercury under the same conditions are respectively -2.63 and -1.81 V.[14]

Perfluorodiphenylmercury. In a 1 M solution of sodium perchlorate in 30% aqueous methanol the polarograms contain one two-electron diffusion wave with $E_{\frac{1}{2}} = -1.06$ V (s.c.e.) independent of pH. The galvanostatic reduction of multilayers of perfluorodiphenylmercury adsorbed on the mercury electrode exhibits only one arrest at low current densities, but two at high current densities, the first corresponding to reduction of the first layer, and the second to reduction of the remaining layers[25]. Perfluorodiphenylmercury has been used as model compound to study the effect of the structure of the electrical double layer on the reduction of an adsorbed depolariser[39], as well as the effect of partial desorption of the depolariser on the capacitive section of the charging curve in the galvanostatic reduction of a substance adsorbed on the surface of a suspended mercury drop[40].

Bis-5-acetylthien-2-ylmercury. In a 1.0 M solution of sodium perchlorate in 30% aqueous dimethylformamide this gives two waves, the first of which ($E_{\frac{1}{2}} = -1.29$ V) corresponds to rupture of carbon–mercury bonds, and the second to reduction of the acetylthiophen formed[27].

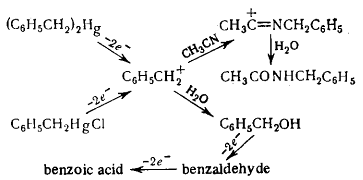
Bis-2,5-diphenyl-1,3-oxazol-4-ylmercury. With linear variation of the potential at a stationary platinum disc electrode in dimethylformamide the volt–ampère curves contain three reduction peaks[41]. With a rate of change of the potential $V = 20$ mV s^{-1} the potential of the first peak $E_p = -1.96$ V (s.c.e.) becomes more cathodic with increase in V, which indicates an irreversible chemical reaction following reversible electron transfer. The ratio of the peak current to $V^{\frac{1}{2}}$ increases with V, which is characteristic of a process with weak adsorption of the depolariser[42]. The first peak corresponds to rupture of carbon–mercury bonds; the other two peaks represent reduction of the mercury-free oxazoline derivative formed.

Bis-2-piperidinoethylmercury. In 50% aqueous ethanol this is reduced to piperidine ($E_{\frac{1}{2}} = -1.5$ V), but it gives no reduction waves in dimethylformamide[26].

The slopes of the waves (i.e. the experimental apparent transfer coefficients $\alpha_{\exp}$) vary greatly for different organomercury compounds. This is one reason for the absence of a strict correlation between the half-wave potentials and the Taft (or Hammett) σ-values of substituents. However, derivatives of dibenzylmercury with various substituents in the ring (when $\alpha_{\exp}$ remains approximately constant) satisfy the correlation $E_{\frac{1}{2}} = 2\sigma\rho$ fairly well, where σ is the Hammett constant of the substituents, the factor 2 reflects the presence of two groups in both benzene rings, and $\rho = +0.49$ V.[37] A good correlation is observed also between the product $\alpha_{\exp}E_{\frac{1}{2}}$ and the acid dissociation exponent pK_a of the hydrocarbon RH formed by the radical R.[19,37] It formed the basis of a proposed acidity scale for CH acids of saturated, aromatic, and unsaturated hydrocarbons, polyfluorinated and carbonyl-containing compounds, barenes, and certain other compounds[43]. However, it has been found[44] that the pK_a of CH acids correlate better with $E_{\frac{1}{2}}$ than with the product $\alpha_{\exp}E_{\frac{1}{2}}$; values of p$K_a$ have been estimated[44] for ferrocene and for the cyclopentadienyltricarbonyls of manganese and rhenium.

The polarographic method has been used to study the kinetics and the equilibria in the reaction of diphenylmercury with mercury dicyanide, bistrichloromethylmercury, and mercury bisphenylacetylide[45], as well as of diphenyl- and di-*p*-methoxybenzyl-mercury with certain symmetrical carbonyl-containing organomercury compounds in dimethylformamide solution[46].

Application of a linearly varying potential to a rotating platinum anode in acetonitrile with 0.1 M sodium perchlorate as supporting electrolyte gives with organomercury compounds clear oxidation waves having half-peak potentials (with $V = 20$ V s^{-1}) of 1.28, 1.53, 1.58, 1.95, and 1.84 V (relative to silver in 0.01 *N* silver perchlorate) for n-propylmercuric chloride, benzylmercuric chloride, dibenzylmercury, phenylmercuric tetrafluoroborate, and diphenylmercury respectively. The waves are completely irreversible. The results of preparative electrolysis in acetonitrile alone and with water (10%) suggested the following schemes



i.e. the first stage always involves rupture of a carbon–mercury bond and formation of a carbonium cation. In the presence of water the process is influenced by the anions of the supporting electrolyte[47].

II. ORGANOMAGNESIUM COMPOUNDS

Dialkylmagnesium derivatives. When dissolved in dimethoxyethane these compounds R_2Mg give anodic oxidation waves having $n = 2$ (the products are R_2Hg and Mg^{2+}), but are not reduced: reduction waves (with $n = 1$) are observed only when R forms a comparatively stable carbanion[48]. Half-wave potentials for reduction (relative to the 10^{-3} M $AgClO_4/Ag$ electrode) are −2.74, −2.65, and −2.50 V when R is respectively benzyl, allyl, and cyclopentadienyl. The mechanism of the process can be written[48]

$$R_2Mg + e \rightarrow R^{-}: + RMg^{\cdot} \rightarrow Mg^0 + R^{\cdot}\left[\begin{array}{l} \xrightarrow{\text{detachment of } H^{\cdot}} \\ \xrightarrow{\text{dimerisation}} \\ \xrightarrow{\text{disproportionation}} \end{array}\right.$$

Grignard reagents. Both the "natural" and the "synthetic" reagents, RMgX and $R_2Mg + MgX_2$ mixtures, give two reduction waves except with $R = CH_3$, when only one wave is observed. Coulometric electrolysis on the current plateau of both first and second waves gives $n = 1$, with the half-wave potential of the first wave close to that of MgX_2 (−2.47 V), and that of the latter lying between −2.70 and −2.80 V. The mechanism of the process was explained[48] in terms of rapid establishment of the Schlenk equilibrium

$$2RMgX \rightleftarrows MgX_2 + MgR_2 \qquad (7)$$

and reduction of MgX_2 in the first stage.

A pulsed galvanostatic study (with reversal of current) of a Grignard reagent at a magnesium electrode in diethyl ether indicates the occurrence of both cathodic and anodic processes (formation and dissolution of Mg^0). The introduction of oxygen, acetone, or bromoethane into the solution changes the form of the curves[49]. In ether and oxolan the reduction of Grignard reagents at a bright platinum cathode gives metallic magnesium; on anodic oxidation alkanes and alkenes are formed[50].

Polarisation curves have been determined for the oxidation of alkylmagnesium chlorides at rotating platinised and smooth platinum and also gold electrodes in oxolan solutions[51]. Fairly high concentrations (0.2–0.6 M) of the depolarisers were taken to ensure adequate electrical conductivity of the solution without addition of an inert electrolyte. Oxidation takes place most readily on platinised platinum, with rather greater difficulty on a gold electrode, and with the greatest difficulty on smooth platinum. The sequence of diminishing ease of oxidation of Grignard derivatives containing different groups is t-butyl > ethyl > isopropyl, vinyl > n-butyl > methyl > phenyl. The course of the reduction by these Grignard reagents in oxolan of naphthacene (at concentrations of 5×10^{-6} M and 5×10^{-4} M) to the radical-anion was followed by the determination of current–potential curves at rotating platinum and gold electrodes. The sequence of diminishing ease of oxidation of RMgCl coincides with their decreasing ability to reduce hydrocarbons[51].

Current–potential curves have been obtained at a rotating platinised platinum electrode in argon and in a mixture of argon with hydrogen at different pressures of the latter (i.e. at a hydrogen electrode) in oxolan with lithium and tetrabutylammonium perchlorates, as well as in the absence of a supporting electrolyte (for high depolariser concentrations), for several Grignard reagents and disubstituted organomagnesium compounds[52]. The oxidation of such reagents can be described by the general equation

$$2RMgCl \rightarrow R{-}R + 2e + 2MgCl^+,$$

or

$$2RMgCl \rightarrow R_{H(-1)} + RH + 2e + 2MgCl^+,$$

i.e. with dimerisation and dimutation respectively of the radicals formed ($R_{H(-1)}$ denotes an alkene formed from R).

The current observed on cathodic polarisation in argon probably corresponds to the process

$$\mathrm{RH} + \mathrm{MgCl}^{+} + e \rightarrow \mathrm{RMgCl} + \frac{1}{2}\mathrm{H}_2,$$

where RH has been formed owing to decomposition of RMgCl by traces of moisture[52]. Introduction of hydrogen into the solution leads to a clear anodic wave, whose height increases with the partial pressure of hydrogen. For methylmagnesium chloride this wave probably corresponds to the process

$$\mathrm{CH_3MgCl} + \frac{1}{2}\mathrm{H}_2 \rightarrow \mathrm{CH}_4 + e + \mathrm{MgCl}^{+},$$

i.e. to the oxidation of hydrogen catalysed by the Grignard reagent (the concentration of the latter far exceeds that of hydrogen), so that the height of the wave corresponds to a diffusion current of dissolved hydrogen. This anodic wave, together with the cathodic wave for the reduction of methane catalysed by MgCl^{+}, represents a redox system, in which the zero-current potential at the hydrogen electrode corresponds to the equilibrium potential of the system. Under otherwise similar conditions the latter depends on the basicity of the Grignard reagent (or, in view of the Schlenk equilibrium (7), to $\mathrm{R_2Mg}$), which in turn enables the basicity of a series of Grignard reagents to be determined quantitatively from current–potential curves at a hydrogen electrode[52]. An alkylmagnesium chloride was found to be rather more basic than the bromide. In oxolan some dissociation of RMgX to RMg^{+} and X^{-} takes place[52].

At a lead anode in 0.25 M tetrabutylammonium perchlorate in oxolan diethylmagnesium and ethylmagnesium bromide give very clear oxidation waves having half-wave potentials of −1.72 and −1.73 V (relative to Ag/0.01 M $\mathrm{AgClO_4}$ in oxolan). The wave heights are around one-tenth of the diffusion currents and are determined by reactions with the lead electrode. Tetraethyl-lead is the final product in both cases[53]. Chemical interaction of these depolarisers with lead explains their far greater ease of oxidation on a lead than on a platinum anode[53].

III. ALUMINIUM DERIVATIVES

Sodium tetraethylaluminate. At a lead microelectrode in 0.25 M tetrabutylammonium perchlorate in oxolan this compound $\mathrm{NaAl(C_2H_5)_4}$ gives a sharp oxidation wave with $E_{\frac{1}{2}} = -1.25$ V (relative to Ag/0.01 M $\mathrm{AgClO_4}$ in oxolan). The height of the wave is limited by preceding chemical reaction of the depolariser and the intermediate product with the lead electrode. The final anodic oxidation products are triethylaluminium and tetraethyl-lead[53].

Triethylaluminium. Under the same conditions this compound is not oxidised at a lead electrode up to potentials at which lead dissolves (−0.6 V).[53]

Aluminium isopropoxide. At high concentrations (down to 0.1 M) in absolute propan-2-ol, with lithium chloride as supporting electrolyte, this derivative gives at a dropping mercury electrode a small kinetic cathodic wave representing discharge of hydrogen atoms with $E_{\frac{1}{2}} = -1.45$ V (relative to silver in the same solution).[54]

IV. BORON COMPOUNDS

Tetraphenylborate ion. Two oxidation peaks are obtained at a graphite anode in aqueous solutions[55,56]. The first peak corresponds to the process

$$\mathrm{B(C_6H_5)_4^{-}} - 2e \rightarrow \mathrm{(C_6H_5)_2} + \mathrm{B(C_6H_5)_2^{+}},$$

$$\mathrm{B(C_6H_5)_2^{+}} + \mathrm{H_2O} \rightarrow \mathrm{B(C_6H_5)_2OH} + \mathrm{H^{+}}.$$

This wave is independent of pH, and its half-peak potential $E_{p/2} = 0.216$ V (relative to a saturated NaCl–calomel electrode). The second peak represents the process

$$\mathrm{B(C_6H_5)_2OH} - 2e + 2\mathrm{H_2O} \rightarrow \mathrm{B(OH)_3} + \mathrm{(C_6H_5)_2} + \mathrm{H^{+}},$$

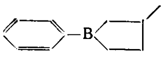
its half-peak potential depending on the pH:[56]

$$E_{p/2} = 0.92 - 0.057\mathrm{pH}.$$

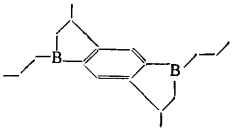
At a graphite anode two waves are obtained also in anhydrous acetonitrile and dimethylformamide with lithium perchlorate as supporting electrolyte[56]. At a platinum anode only one wave can be observed[57], but after appropriate anodic treatment of the electrode surface both oxidation waves of the tetraphenylborate ion can be observed also on platinum[58].

1,2′-Bis(diphenyl)borate ion. This gives a single two-electron wave on current-potential oxidation[59].

Dialkylborons and diarylborons. A compound such as $\mathrm{R_2B}$ behaves as a pseudometallic ion[60]. Its complexes with acetylacetone (AcAc) in tetrabutylammonium perchlorate in monoglyme give irreversible one-electron diffusion waves with half-wave potentials (V, relative to 1mM $\mathrm{Ag^{+}/Ag}$ electrode) of −2.16, −2.40, and −2.66 for the diphenylethynyl, diphenyl, and diethyl derivatives[60]. Electrolysis of $\mathrm{(C_6H_5)_2BAcAc}$ at −2.48 V gave a product which, on anodic oxidation at −0.3 V, regenerates the initial compound $\mathrm{(C_6H_5)_2BAcAc}$. Complexes of $\mathrm{BR_2}$ with 1,3-diphenylpropane-1,3-dione all give two one-electron waves, with half-wave potentials of −1.60 and −2.66 V for diethylboron, and −1.90 and −2.80 V for diphenylboron[60].



(I)



(II)

Phenylborolan (I) and diborindacene (II). With 0.1 M tetrabutylammonium iodide in anhydrous dimethylformamide methyl derivatives of (I) and derivatives of (II) give reversible one-electron waves corresponding to formation of the radical-anion, with half-wave potentials respectively of −1.96 and −1.46 V (relative to the mercury at the base of the cell); the corresponding potentials for the naphthalene and anthracene waves under the same conditions are −1.94 and −1.48 V. Thus the introduction of boron facilitates appreciably transfer of an electron to the aromatic π-electron system[61]. Polarograms of diborindacene contain also a second reduction wave, representing an irreversible electrode process.

Dibutyl benzeneboronate and tetrabutyl benzene-*p*-diboronate. The products $\mathrm{C_6H_5B(OC_4H_9)_2}$ and $\mathrm{(C_4H_9O)_2BC_6H_4B(OC_4H_9)_2}$ of the atmospheric oxidation or the hydrolysis of the preceding compounds are also reduced under the above polarographic conditions, with half-wave potentials of −2.02 and −1.93 V respectively[61].

Barenes (carboranes). These are polyhedral aromatic systems containing boron $B_{10}H_{10}C_2RR'$. In 0.1 *N* tetraethylammonium perchlorate in dimethylformamide they give diffusion reduction waves, with half-wave potentials of −2.51 and −2.8 V (s.c.e.) for barene (*o*-barene) and neobarene (*m*-barene) respectively[62], whereas *p*-barene gives no wave[30]. Substitution of phenyl at position 1 (at a carbon atom) facilitates reduction appreciably (half-wave potentials of −1.95 and −2.45 V for 1-phenyl-*o*-barene and 1-phenyl-*m*-barene), but 3-phenyl-*o*-barene (−2.59 V) is reduced with greater difficulty than is *o*-barene itself[62]. Study of many derivatives has established that the effect of substituents on half-wave potentials is more marked with *o*- than with *m*-barenes[62]. It is noteworthy that the reduction of *o*-barene is facilitated by introduction of a 1-methyl group[62,63]. The reduction of barenes involves transfer of a single electron, probably with formation of a radical-anion[63].

C-Halogenated barenes. Polarograms obtained in dimethylformamide usually contain two waves, the first of which, representing electrochemical cleavage of the carbon–halogen bond, is double the height of the second wave. Derivatives of *o*-barene are most readily reduced, and those of *p*-barene with the greatest difficulty[63]. In contrast to the situation with halogen derivatives of benzene and benzyl, 1-chloromethyl- and 1-bromomethyl-*o*-barenes (with half-wave potentials of −2.03 and −1.21 V s.c.e.) are reduced with greater difficulty than are 1-chloro- and 1-bromo-barene respectively (−1.19 and −0.56 V).[63] 1,12-Dihalogeno-*p*-barenes give two two-electron waves representing the detachment of halogen[63]. The half-wave potentials become more negative on passing from *C*-iodo- to *C*-bromo- and *C*-chloro-derivatives of barenes. For example, values for the 1-halogenated *p*-barenes in dimethylformamide with tetradecylammonium perchlorate as supporting electrolyte are respectively −0.53, −0.99, and −2.14 V (s.c.e.).[64] It is interesting that these compounds are not reduced at a platinum electrode.

B-Halogenated barenes. These derivatives are reduced with very great difficulty, and their half-wave potentials are almost independent of the nature of the halogen. Thus for 10-halogeno-*o*-barenes in 0.1 M tetrabutylammonium bromide in dimethylformamide they are close to −2.18 V (s.c.e.).[64]

Di-*o*(and *m*)-barenylmercury. These compounds and their derivatives give reduction waves in dimethylformamide, whose half-wave potentials have been used[65] to estimate the acidity of carbon–hydrogen bonds in corresponding derivatives of *o*- and *m*-barenes. For the same purpose several dibarenylmercury derivatives (*ortho*, *meta*, and *para*) have been investigated polarographically in various solvents[66].

Phosphacarboranes. These are reduced somewhat more readily than are carboranes, the ease of reduction diminishing as with the latter in the sequence of isomers *ortho*, *meta*, and *para*.[67] For *o*-phosphacarborane in dimethylformamide with 0.1 M tetrabutylammonium perchlorate $E_{\frac{1}{2}} = -2.30$ V (s.c.e.).

Arsacarboranes. The half-wave potentials become more negative in the sequence *meta*, *para*, *ortho*. On the polarogram of the *ortho*-isomer the main wave is preceded by a prewave hump. *m*- and *p*-Arsacarboranes are reduced somewhat more readily than are the corresponding isomeric phosphacarboranes[67].

V. THALLIUM COMPOUNDS

Dialkylthallium bromide. In 30% aqueous propan-2-ol buffered to pH 7 the polarograms for the n-propyl and n-butyl derivatives R_2TlBr contain three waves of approximately the same height, the first and the third of which are diffusion waves. The first wave is preceded by an adsorption prewave[68], and corresponds to the process

$$2R_2Tl^+ + 2e \rightarrow (R_2Tl)_2$$

with half-wave potentials respectively of −0.922 and −0.895 V. Diethylthallium bromide, in contrast to its homologues, does not give prewaves on the polarograms, and its first wave ($E_{\frac{1}{2}} = -1.000$ V) corresponds to the transfer of two electrons, probably with the formation of ethylthallium(I).[68] In aqueous Britton–Robinson buffers of pH < 7 dialkylthallium bromides give a sharp one-step wave, whose half-wave potential is independent of pH and becomes more positive with growth of the alkyl chain, from −1.07 V for methyl to −0.92 V for n-pentyl. At pH > 7 a second wave is observed, and is attributed to reduction of hydrolysis products[69]. In dimethylformamide dialkylthallium bromides give four cathodic waves, the third and fourth of which become more positive on addition to the solution of phenol (as a proton donor). In excess of the donor only two waves are observed, the ratio of whose heights is 1 : 2, which corresponds to reduction to $R_2Tl\cdot$ and then to Tl^0 respectively[69]. In the absence of proton donors the primary product of one-electron reduction $R_2Tl\cdot$ either disproportionates to Tl^0 and R_3Tl or is reduced further to Tl^0. In the presence of such donors dialkylthallium cations are rapidly regenerated:

$$R_3Tl + H^+ \rightarrow R_2Tl^+ + RH\ .$$

Therefore a one-step reduction wave of R_2Tl is observed in acid aqueous solutions[69].

Trialkylthallium derivatives. In dimethylformamide such compounds are probably reduced[69] in two stages:

$$2R_3Tl + 2e \rightarrow [R_6Tl_2]^{2-},$$

$$[R_6Tl_2]^{2-} + 4e \rightarrow 6R^- + 2Tl^0.$$

Triphenylthallium(III). In dimethylformamide this gives two waves, with half-wave potentials −1.76 and −2.55 V.[69]

Diphenylthallium chloride. With 0.05 M tetraethylammonium perchlorate in dimethylformamide this gives two waves, having half-wave potentials −0.79 and −2.58 V (aq. s.c.e.) respectively[70]. After such a solution has stood over mercury for a long time (several days), however, the [first] wave falls, and a new wave ($E_{\frac{1}{2}} = -0.46$ V), corresponding to the discharge of Tl^+ ions, appears in front of it. Thus diphenylmercury may be formed at a mercury electrode not only by the cathodic reduction of diphenylthallium (see below) but also as a result of its reaction with mercury[70].

Diphenylthallium(III) cation. Polarograms obtained in aqueous phosphate buffers contain three reduction waves, the heights of the first two being proportional to the depolariser concentration and restricted by diffusion, while the third wave tends to a limit with increase in concentration[71]. The half-wave potentials of the first and third waves become more negative with increase in the diphenylthallium concentration, whereas that of the second wave becomes more positive; those of the second and third waves vary with pH, but that of the first wave does not. Electrocapillary curves obtained during the drop period indicate strong adsorption of the starting material and still greater adsorption of intermediate reduction products. On preparative electrolysis at the limiting-current potentials of all three waves 1 mole of Tl^0 is formed as an amalgam and various quantities of diphenylmercury per mole of the initial substance, accompanied on the second and third waves by benzene[71]. The primary process is transfer of a single electron:

$$(C_6H_5)_2Tl^+ + e \rightarrow Tl^{\cdot}(C_6H_5)_2.$$

The resulting radical reacts in several ways: it interacts with mercury

$$(C_6H_5)_2Tl^{\cdot} + Hg \rightarrow (C_6H_5)_2Hg + Tl^0,$$

or disproportionates in the adsorbed state on mercury, giving diphenylmercury, Tl^0 and triphenylthallium, which is rapidly hydrolysed to benzene and diphenylthallium (reduction of the latter is the reason for the > 1 electrons determined coulometrically for the first wave). The radical $(C_6H_5)_2Tl\cdot$ may also be hydrolysed to benzene and inorganic thallium derivatives, which are reduced at the dropping mercury electrode. The second wave corresponds to the transfer of one electron to the diphenylthallium radical with formation of benzene and phenylthallium (I), which reacts rapidly with mercury

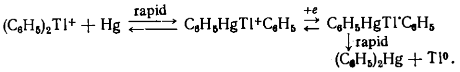
$$2Tl(C_6H_5) + Hg \rightarrow (C_6H_5)_2Hg + Tl^0.$$

The third wave corresponds to the process

$$C_6H_5Tl + e \xrightarrow{H^+} C_6H_6 + Tl^0.$$

Half-wave potentials in 1 mM solution at pH 7 are respectively −0.62, −0.94, and −1.42 V (s.c.e.).[71]

Diphenylthallium derivatives. A different interpretation has been given[70] of the mechanism of reduction. Derivatives with *para*-substituents (methoxy, methyl, chloro, methoxycarbonyl) and the *m*-tolyl derivative exhibit three reduction waves in aqueous 1 M potassium acetate, the first two of which are diffusion waves, whereas the limiting current of the third wave is determined by adsorption phenomena. The first wave is regarded[70] as preceded by very rapid reaction between the thallium derivatives and mercury, to give a product that acquires an electron reversibly:



$$\begin{array}{l} (C_6H_5)_2Tl^+ + Hg \underset{}{\overset{\text{rapid}}{\rightleftarrows}} C_6H_5HgTl^+C_6H_5 \overset{+e}{\rightleftarrows} C_6H_5HgTl^{\cdot}C_6H_5 \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \downarrow \text{rapid} \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (C_6H_5)_2Hg + Tl^0. \end{array}$$

The second wave corresponds to further reduction of $C_6H_5HgTl(C_6H_5)\cdot$ involving two electrons. However, the height of the second wave does not reach the diffusion current corresponding to the transfer of two electrons (probably because of retardation of the electrode process by substances, mainly diphenylmercury, adsorbed on the electrode). Desorption of diphenylmercury takes place at the potential of the third wave, so that the latter corresponds to reduction of depolariser that has not been reduced under the conditions of the second wave; a jump in the capacitive current due to the desorption of diphenylmercury is superimposed on the Faraday current of the third wave. This scheme of reduction is supported by the results of a chronopotentiometric study of diphenylthallium derivatives[70].

At a platinum microcathode in anhydrous dimethylformamide the diphenylthallium cation gives two irreversible diffusion waves, with half-wave potentials of −0.85 and −1.70 V (s.c.e.). The first corresponds to the transfer of one electron and the formation of diphenylthallium radicals, which disproportionate to give metallic thallium and triphenylthallium. Reduction of the latter gives the second wave, whose height is double that of the first wave[73]. The reduction of triphenylthallium yields Tl^0 and benzene. The primary products of electrolysis at −30°C are Tl^0 and $(C_6H_5)_4Tl^-$.[73]

Phenylthallium(III). Polarograms obtained in aqueous media contain an adsorption prewave and three one-electron diffusion waves. The half-wave potentials of the first and second waves are independent of depolariser concentration and of pH (−0.01 and −0.50 V (s.c.e.) respectively). That of the third wave becomes more negative with increases in both factors. Electrolysis at the limiting current of the first wave gives diphenylmercury and Tl^+; at that of the second wave Tl^0 accompanies diphenylmercury; and the third wave corresponds to reduction of phenylthallium(I) formed in the preceding stage[72]. In dimethylformamide diphenylthallium bromide and phenylthallium dichloride give two waves, the first representing reduction to Tl^0, and the second ($E\frac{1}{2} = -2.55$ V) reduction of diphenylmercury[69].

VI. DERIVATIVES OF GROUP IV ELEMENTS—THE SILICON SUBGROUP

Organochlorosilanes. Reduction waves were obtained[74] in anhydrous acetone, though their reproducibility was poor. Waves that can be used for the quantitative determination of organochlorosilanes were obtained in pyridine and its aqueous mixtures[74]. The wave then corresponds to discharge of the pyridinium ion formed by solvolysis of the organochlorosilane.

Ethyltrichlorogermane. In a benzene–methanol (3 : 2) mixture with 0.1 *N* lithium chloride as supporting electrolyte a sharp three-electron diffusion wave is obtained, corresponding to detachment of all the chlorine atoms and formation of the radical $C_2H_5Ge\cdots$, which gives a polymeric product. The wave observed in acidic aqueous solutions (to pH 4.0) is distorted by strong adsorption of the initial depolariser and the reaction products; with increase in depolariser concentration the height of the wave reaches a limit (at $c > 0.5$ mM), while its half-wave potential becomes more negative. Electrocapillary and current–time curves showed that rearrangement of the adsorbed layer occurs in the lower part of the wave at −1.06 V (s.c.e.): depolariser on the electrode surface is replaced by the reaction product. In methanolic benzene neither the depolariser nor the reaction product is adsorbed on a mercury electrode[75].

Mono- and bis-trimethyl-silyl, -germyl, and -stannyl derivatives of biphenyl. Derivatives with the substituents in positions 4 or 4 and 4′ give in anhydrous dimethylformamide reversible waves corresponding to the formation of radical-anions; the half-wave potentials lie in the range −1.94 to −2.07 V relative to the potential of the mercury at the bottom of the vessel (the supporting electrolyte is not indicated). Silicon derivatives are rather more electropositive than the germanium derivatives, while the tin derivatives are the most electronegative[76].

Bistrimethyl-silyl and -germyl derivatives of polyphenylenes. In dimethylformamide these derivatives $(CH_3)_3M[C_6H_4]_mM(CH_3)_3$ (where m = 1–4 and M = Si, Ge) give reversible one-electron waves, except in the case of *p*-bistrimethylgermylbenzene, which is polarographically inactive. Polyphenyl derivatives give a second one-electron wave, corresponding to formation of a dianion. The instability of the latter, leading to detachment of trimethylsilyl or trimethylgermyl groups, is responsible for the incomplete reversibility of the second wave. The half-wave potential of the first wave becomes more positive with increase in m, while the reversibility of the second wave improves[77].

In order to determine how the silyl bridge influences conjugation between two diphenylyl groups, ordinary and a.c. polarograms (with recording of the signal from the principal and second harmonics) have been obtained[78] on several compounds. The first waves correspond to reversible transfer of one electron (redox potentials E^0 given in parentheses for the first reduction waves in dimethylformamide with 0.1 M tetrabutylammonium perchlorate as supporting electrolyte and silver in a saturated dimethylformamide solution of tetrabutylammonium iodide as reference electrode). The compounds investigated were 4-trimethylsilylbiphenyl (−1.897), 4,4′-bistrimethylsilylbiphenyl (−1.805), dibiphenyl-4-yldimethylsilane (−1.853), 4,4′-bisbiphenyl-4″-yldimethylsilylbiphenyl (−1.750), and for comparison the hydrocarbons biphenyl (−1.999), dibiphenyl-4-ylmethane (−2.019), and 4,4′-di-*p*-phenylbenzylbiphenyl (−2.024). Thus introduction of a silyl group shifts the redox potential to less negative values than for the corresponding hydrocarbon. However, comparison with the ultraviolet spectra indicated[78] that a silyl bridge largely prevents conjugation between two biphenylyl groups.

1-Naphthylpolysilanes. A study has been made[79] of the polarographic behaviour of the compounds (Ar = 1-naphthyl and Me = CH_3)—$ArSiMe_3$, $ArSiMe_2Ar$, $ArSi_2Me_5$, $Ar[SiMe_2]_2Ar$, $ArSi_3Me_7$, $Ar[SiMe_2]_3Ar$, and $ArCH_2SiMe_3$—as well as of naphthalene and 1-methylnaphthalene for comparison. With 0.05 M tetrabutylammonium iodide in dimethylformamide mononaphthyl derivatives give one reversible one-electron diffusion wave, and dinaphthyl derivatives two such waves. Half-wave potentials for the above compounds (measured by a three-electrode scheme relative to Ag/0.1 M $AgNO_3$ in dimethylformamide) are respectively (values for the second wave given in parentheses) −2.845, −2.781 (−3.038), −2.842, −2.816 (−2.983), −2.838, −2.822 (−2.924), −3.006, −2.946, and −2.964 V. Introduction of a trimethylsilyl group facilitates electron transfer to the naphthalene ring system; facilitation is still greater on introduction of a second naphthalene ring system at the end of the silyl chain. With increase in length of this chain, however, the effect of the second ring system diminishes (the half-wave potential becomes more negative), while transfer of a second electron to the second ring system is facilitated, which indicates diminished transmission of the effect through the silyl bridges[79].

1,4-Bistrimethylsilyl(and germyl) naphthalenes. These give a single reversible one-electron wave. The silicon derivatives are reduced rather more easily than are the germanium derivatives[77]. Introduction of a trimethylsilyl group into the naphthalene molecule shifts the reversible one-electron reduction wave (with 0.1 M tetrabutylammonium iodide in dimethylformamide) to less cathodic potentials (by ~ 50 and by ~ 10 mV in positions 1 and 2 respectively); reduction is still more facilitated by the introduction of two groups, reaching 150 mV with 1,4-bistrimethylsilyl derivatives. However, introduction into the naphthalene molecule of a t-butyl group (or of two such groups) impedes reduction: the maximum effect is ~ 110 mV with the 2,7-di-t-butyl derivative[80].

Iodotrialkylsilylalkanes. Cleavage of the carbon–iodine bond is somewhat facilitated by introduction of a trialkylsilyl group into an iodoalkane, although this effect may be due not only to the electronegative action of the group but also to enhanced adsorbability of the organic molecule[81]. An important consequence of such introduction is to stabilise the free radical[82] formed as intermediate in the reduction of iodo-derivatives. Such stabilisation results in division of the two-electron wave into two one-electron steps, the half-wave potentials of both of which correlate with the electronegativity of the trialkylsilyl substituent[82].

Other evidence indicates the electron-accepting properties of the trialkylsilyl group. Thus introduction of the group into the *para*-position of nitrobenzene facilitates reversible transfer of the first electron to the nitro-group (in anhydrous dimethylformamide) by ~ 100 mV.[83] Reduction of mono- and di-silanaphthenes in dimethylformamide is facilitated by 200–400 mV in comparison with naphthalene, whereas acenaphthene itself is reduced with rather greater difficulty than is naphthalene[84]. The silicon atom in 5,10-dihydro-5,5-dimethyldibenzo[*b*,*e*]silinone competes slightly[85] even with the carbonyl group, facilitating electrochemical reduction of the latter (the half-wave potential of the reversible one-electron wave in dimethylformamide is −1.64 V relative to mercury in 0.1 M tetrabutylammonium perchlorate solution).

Phenyltrimethylsilane. On reduction in anhydrous methylamine solution at a platinum cathode in the presence of lithium chloride in a cell with a diaphragm, products resulting from detachment of the trimethylsilyl group and hydrogenation of benzene are obtained. In the absence of a diaphragm the main reduction product is *p*-dihydrophenyltrimethylsilane resulting from the action of lithium methylamide formed at the anode[86].

Triphenylsilyl and triphenylgermyl chlorides. In anhydrous dimethoxyethane these compounds give a one-electron wave with half-wave potentials of −3.1 and −2.8 V relative to an Ag/$AgClO_4$ (1 mM) electrode. The products were regarded as formed by the replacement of chlorine by hydrogen atoms, but the source of the atomic hydrogen was not indicated[87].

Halogenated triphenylgermanes. In an extremely detailed study[88] 1,2-dimethoxyethane was used as solvent, with 0.1 M tetrabutylammonium perchlorate as supporting electrolyte and silver in a saturated solution of silver nitrate in the same solvent as reference electrode

Triphenylfluorogermane. The slope suggests that the single polarographic reduction wave is reversible, with $E_{\frac{1}{2}} = -3.1$ V and its height formally corresponding to a diffusion current with transfer of half an electron. When increasing quantities of an alcohol or water are introduced into the solution, a new wave appears and grows on the limiting-current plateau of the first wave (whose height and half-wave potential remain unaffected). The new half-wave potential is displaced to less negative values, so that in excess of these proton donors it reaches the height of the initial wave and merges with it to give a single irreversible one-electron diffusion wave.

Voltammetry with a linearly varying potential (in the absence of a proton donor) reveals only one cathodic peak, whose properties suggest that the process is irreversible. This implies that the process is in general quasi-reversible: the radical-anion formed by transfer of an electron to the initial molecule is assumed[88] to interact with another molecule of the initial compound to give an electrochemically inactive dimeric radical-anion, which explains the "half electron". The absence of an anodic peak of the radical in voltammetry with the application of triangular pulses indicates that the rate constant of formation of the dimer $[(C_6H_5)_3Ge(F)...GeF(C_6H_5)_3]^{\cdot}$ exceeds 10^5 M^{-1} s^{-1}. The dimer is obviously unstable, being slowly converted in solution into more stable compounds; this apparently explains the formation of a deposit of hexaphenyldigermane when the solution is allowed to stand after electrolysis.

Immediately after electrolysis bistriphenylgermyl oxide $[(C_6H_5)_3Ge]_2O$ was isolated, having been formed by reaction of the dimeric radical-anion with water or a peroxide, certain quantities of which are always present in the solvent. The anodic peak due to fluoride ions, present on current–voltage curves with reversal of potential, indicates quite rapid interactions of the dimeric radical in which fluoride ions are liberated. On the introduction of proton donors into the solution the dimeric radical-anion is protonated, after which it or a conversion product acquires a new electron, which corresponds to appearance of the new wave on the polarogram.

Triphenylchlorogermane. This gives an irreversible one-electron reduction diffusion wave having $E_{\frac{1}{2}} = -2.85$ V.[88] Addition of water or an alcohol does not affect the cathodic wave, but results in the appearance of an anodic one-electron diffusion wave. The cathodic process produces a triphenylgermyl radical and a chloride anion. The radicals dimerise to hexaphenyldigermane (the principal product of preparative electrolysis at high concentrations of the starting material), and react with peroxides to form triphenylgermyl hydroxide $(C_6H_5)_3GeOH$ and hexabiphenylyldigermyl oxide (the main product at low concentrations of the initial substance). A certain quantity of triphenylgermane is also formed on electrolysis, apparently as a consequence of abstraction of a hydrogen atom from the solvent (dimethoxyethane) by the germyl radical.

The anodic wave is due to interaction with mercury (which is absent at a platinum electrode):

$$(C_6H_5)_3GeCl \underset{Hg}{\xrightarrow{-e}} (C_6H_5)_3Ge^+ + \frac{1}{2}Hg_2Cl_2,$$

$$(C_6H_5)_3Ge^+ + ClO_4^- \rightarrow (C_6H_6)_3GeOClO_3.$$

Formation of a perchlorate with a covalent bond has been proved by ultraviolet spectroscopy of the product isolated after electrolysis on the current plateau of the anodic wave. Both this product and specially prepared triphenylgermyl perchlorate give a cathodic wave with $E_{\frac{1}{2}} \simeq -1.6$ V on the polarograms, whereas the corresponding potential for the cathodic wave of the solution immediately after anodic oxidation is -0.2 V. This is regarded[88] as indicating that the germanium cation formed gives initially with the perchlorate anion an ion-pair, which is then converted into the covalent compound.

Triphenylbromogermane. This behaves similarly to triphenylchlorogermane, with the sole exception that it gives an anodic wave even in the absence of water or an alcohol[88]. Half-wave potentials are -2.63 and -0.14 V for the one-electron cathodic diffusion wave and for the anodic wave respectively.

Triphenyliodogermane. The polarograms contain two cathodic waves with half-wave potentials of -1.9 and -2.45 V (the first is kinetically restricted, and the two waves give an aggregate diffusion current with $n = 1$) and a one-electron anodic wave with $E_{\frac{1}{2}} = -0.36$ V.[88] On the addition of water to the solution the first cathodic wave grows at the expense of the second; the anodic wave also diminishes, but a new anodic wave appears and grows ($E_{\frac{1}{2}} = -0.95$ V), and was shown to be due to an anodic process involving free iodide anions. The second wave also diminishes on electrolysis at the potential of the first cathodic wave; the sole product of electrolysis is hexaphenyldigermane oxide. The second wave corresponds to detachment of an iodide anion and formation of a triphenylgermyl radical; the first is attributed[88] to the processes

$$(C_6H_5)_3GeI + H_2O \rightleftarrows [(C_6H_5)_3GeIH]^+ + OH^-,$$

$$[(C_6H_5)_3GeIH^+] + e + OH^- \rightarrow (C_6H_5)_3Ge^{\cdot} + I^- + H_2O.$$

In excess of water the initial substance undergoes hydrolysis with formation of an iodide anion and triphenylgermyl hydroxide.

Alkylhalogenotin derivatives. These compounds $R_{4-x}Cl_xSn$ ($x = 1-3$) have been studied by many investigators[87,89-104], but the mechanism of their reduction has not yet been finally elucidated. Their electrode behaviour is complicated by very strong adsorption on the electrode both of the initial substances and of the reaction products[94,96,97,100-104], as well as by dissociation, which is responsible for the appearance of kinetic restrictions of the current[99,100,102]. Thus for dimethyldichlorotin[100] the height of the first wave (disregarding the adsorption prewave) falls with rise in pH along a curve resembling a dissociation curve (expressing the pH dependence of the concentration or proportion of the undissociated acid). At the same time a second wave appears and grows, so that the polarographic $pK'_a = 9.05$, which exceeds the potentiometrically determined exponents for the stepwise substitution of the chloride ion by the hydroxide ion ($pK_a = 4.5$ and 8.0[100]).

It has been shown for dichlorodiethyltin as example[100] that the total wave height corresponds to the transfer of only one electron, so that the process can be represented by the scheme[87,96,98]

$$R_2SnCl_2 + e \rightleftarrows R_2Sn^{\cdot}Cl + Cl^-, \quad (8)$$

$$2R_2Sn^{\cdot}Cl \rightarrow \underset{Cl}{\underset{|}{R_2Sn}}-\underset{Cl}{\underset{|}{SnR_2}}. \quad (9)$$

Addition of the electron occurs reversibly[96], with the resulting radicals dimerising on the electrode surface itself. The wave form (at low depolariser concentrations) is therefore[105] described by the equation[96]

$$E = \varepsilon_0 - 0.065\lg\frac{i^{1/2}}{i_{\text{lim}} - i}. \tag{10}$$

The system R_6Sn_2/R_3Sn^+ is reversible on a platinised platinum electrode in methanol alone and mixed with benzene ($R = C_6H_5$, CH_3, C_2H_5, C_4H_9).[106] With increase in the concentration of the depolariser (diethyldichlorotin) the wave separates into several steps[96-98], the first of which is similar in nature to a Brdička prewave (Brdička adsorption prewaves appear on polarograms with strong adsorption on the electrode of a reaction product or a complex with the initial depolariser, their height increasing with the depolariser concentration to a certain value corresponding to complete coverage of the electrode surface by a monolayer of the adsorbate, after which the prewave height remains unchanged with further increase in depolariser concentration). The appearance of two adsorption prewaves may be due[107] to layer-by-layer coverage of the surface.

A very important feature[98] of the polarographic behaviour of a dialkyldichlorotin is a gradual increase in the ratio of the total wave height to the depolariser concentration with increase in the latter, and also an increase in the number of electrons determined microcoulometrically, especially in acid media, which is attributed[98] to partial regeneration of the depolariser by the reaction

$$(R_2Sn)_2Cl_2 + 2HCl \rightarrow 2R_2SnCl_2 + H_2.$$

Other workers[61], however, assign the one-electron process (8) followed by dimerisation by (9) merely to reduction of the trialkylhalogenotin (incidentally, hexaphenylditin is formed[108] on the cathode during the electrolysis of triphenyltin chloride), whereas complete reduction of butyltrichlorotin and dibutyldichlorotin has been regarded[99] as involving respectively three and two electrons. Two-electron reduction of a dialkyldichlorotin has been assumed also in other investigations[94,100,109]. We shall now examine the behaviour of individual organotin compounds.

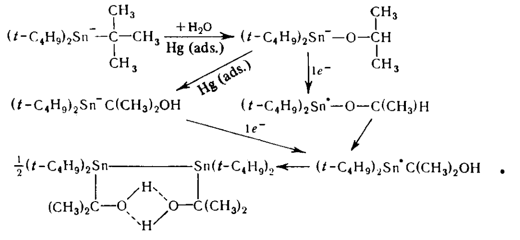
Trimethylchlorotin. In aqueous solutions two one-electron waves are obtained, whose heights are independent of pH, whereas the half-wave potentials become more negative with increase in pH (that of the second wave only in strongly alkaline medium).[103] An adsorption prewave precedes the second wave. With increase in depolariser concentration in an unbuffered medium the first wave divides into two steps, the first of which corresponds to reduction of the cationic form of the substance, and the second to that of trimethyltin hydroxide, which dissociates very slowly. The first wave represents formation of free radicals $(CH_3)_3Sn\cdot$, which dimerise to the water-insoluble hexamethylditin (the latter remains unreduced at a mercury electrode in oxolan up to −2.7 V). The second wave[103] is due to reduction of the radical to the anion $(CH_3)_3Sn^-$ (which then adds a proton), not to reduction of hexamethylditin; a similar process is suggested for the second wave in the reduction of triphenyltin chloride[87].

Di-t-butyltin. Very dilute solutions of the depolariser $(C_4H_9)_2Sn^{2+}$ in aqueous perchloric acid give polarograms having one diffusion reduction wave with $E_{\frac{1}{2}} = -0.55$ V, which is reversible and independent of pH.[110] Addition to the solution of increasing quantities of chloride ions shifts the wave to more negative potentials, divides it into two, and diminishes its height, conferring on it a kinetic character, and in 5 M hydrochloric acid almost completely eliminating the wave owing to the formation of a series of complexes. Studies have been made of complex formation also in buffered acetate, carbonate, and ammonium chloride solutions. Millimolar solutions of d-t-butyltin exhibit an adsorption prewave and two one-electron waves; the first stage involves formation of free radicals, which give dimeric products. The polarograms are greatly distorted by adsorption of the depolariser and especially of the electrode products. The presence of two t-butyl groups attached to tin facilitates transfer of the first electron and hinders that of the second electron in comparison with the diethyl or dimethyl derivatives, as well as stabilising considerably the four-coordinate state of tin[110].

t-Butyldiethyltin halides. With acid supporting electrolytes in 20% ethanol these give a reversible one-electron wave with an adsorption prewave; for the wave $E_{\frac{1}{2}} \simeq -1.1$ V (s.c.e.) at pH 4.6. With rise in pH the wave becomes less reversible and shifts to more cathodic potentials; a second, irreversible wave appears, lower than the first. In 1.0 *N* caustic soda the half-wave potentials are −1.45 and −1.70 V.[111] Preparative electrolysis shows that at the potential of the first wave the radicals formed dimerised to di-t-butyltetraethylditin. The same product occurs also at the potential of the second wave: the butyldiethylstannane $C_4H_9SnH(C_2H_5)_2$ formed in the second stage of the process probably reacts partly with the initial depolariser to give the dimer.

Di-t-butylethyltin bromide. The polarograms in acid solutions containing 20% of ethanol show two cathodic waves (half-wave potentials −1.05 and −1.45 V (s.c.e.) at pH 4.6) preceded by an adsorption prewave. The first, diffusion wave is reversible and corresponds to the transfer of one electron. The character of the second wave has not been established; the wave disappears on introduction of a surface-active substance into the solution. One one-electron wave occurs in alkaline medium, with $E_{\frac{1}{2}} = -1.55$ V in 1 *N* caustic soda. The waves are distorted by strong adsorption of the initial substance and the products, so that their form varies with increase in the depolariser concentration. Electrolysis yields tetra-t-butyldiethylditin.

Tri-t-butyltin. The behaviour of the cation differs appreciably[112] from that of mono- and di-t-butyl derivatives. A reversible main wave ($E_{\frac{1}{2}} = -0.6$ V at pH 1.9) and an adsorption prewave are found in acid solutions in 20% methanol. The limiting current is partly kinetic in character, although coulometric determination indicates a one-electron wave. When the solution is allowed to stand over mercury, the wave slowly diminishes, and at about −1.1 V a new wave grows to the one-electron level. Three waves are observed in alkaline medium: the sum of the first two corresponds to the transfer of one electron, and the height of the third wave also corresponds to such a process. Electrocapillary curves indicate strong adsorption of the initial depolariser and of the reaction products. Study by infrared and nuclear magnetic resonance spectroscopy of the products of preparative electrolysis suggests a general scheme involving comparatively rapid reaction between water and the depolariser adsorbed on the electrode, with elimination of a methyl group as methane and formation of an oxygen bridge; the product, which gives a wave having $E_{\frac{1}{2}} = -0.6$ V at pH 1.9, rearranges slowly in the adsorbed state to give the compound (wave with $E_{\frac{1}{2}} = -1.1$ V):



The half-wave potentials become in general more negative with increase in the number of alkyl groups attached to tin[92,95]: no reduction waves could be observed with tetra-alkyltins[109]. With increase in the length of the alkyl substituents the half-wave potentials of the reduction waves of organotin salts become less negative[92].

Butyltrichlorotin, dibutyldichlorotin, and tributylchlorotin. These compounds have been studied also by a.c. polarography[104]. Their adsorbability on the mercury electrode increases with the number of butyl groups. Tributylchlorotin has been investigated in greatest detail; the product of its reduction on the first wave is adsorbed far more strongly than is the initial depolariser, and the second reduction step gives an unadsorbable product. The height of the peak corresponding to the second stage of reduction increases sharply with rise in temperature, which confirms its kinetic nature. The electrochemical reaction at the second stage is irreversible, and the presence of a peak on the a.c. polarograms is attributed to change in the capacity of the double layer caused by reduction of a surface-active intermediate to an inactive end-product[104]. On the addition of propan-2-ol to the aqueous solution the peak height corresponding to the first wave becomes somewhat lower, whereas the peak corresponding to the second stage of reduction shifts abruptly to more cathodic potentials without significant change in height. It is interesting that the peak potential corresponding to desorption of propan-2-ol, located in front of the peak of the second wave, varies in almost the same way. In the presence of tributylchlorotin this desorption peak drops sharply, which is attributed to competitive adsorption of two substances; the effect increases with rise in temperature.

Aquodiethyltin. Voltammetry with a linearly varying potential shows that $(C_2H_5)_2Sn^{2+}.nH_2O$ gives on reduction extremely short-lived diethyltin biradicals, which are rapidly polymerised. The lower polymers can be oxidised anodically to the initial aquodiethyltin; oxidation of the higher polymers is accompanied by loss of some of the ethyl groups[113].

Triphenyltin. With tetrabutylammonium perchlorate in dimethoxyethane the chloride gives two waves[89], the first of which (one electron, $E_{\frac{1}{2}} \simeq -1.6$ V) corresponds to the formation of radicals that are rapidly converted into a dimer, whereas the second wave, which develops at extremely negative potentials, corresponds to reduction of the dimer (hexaphenylditin) to triphenyltin anions. In aqueous solution triphenyltin fluoride gives one irreversible one-electron wave representing reduction to hexaphenylditin, which is strongly adsorbed on the electrode[101].

The most detailed study has been made[102] of the behaviour of triphenyltin (acetate and hydroxide) in buffered solutions prepared in 50 vol.% ethanol. The polarograms contain three waves over a wide pH range: the heights of the first two waves are independent of pH; the third wave becomes visible at pH 4.75, reaches its maximum height at pH 7.3, and then falls along a kind of dissociation curve with further increase in pH. The half-wave potentials of first and second waves become more negative with rise in pH (in neutral and alkaline solutions $\Delta E_{\frac{1}{2}}/\Delta pH \simeq -60$ mV), their values at pH 7 being respectively −0.62 and −0.90 V (s.c.e.); that of the third wave is independent of pH ($E_{\frac{1}{2}} = -1.35$ V). On introduction of a tetrabutylammonium salt into the solution the third wave disappears, and the second becomes more extended. The first wave was shown to be an adsorption prewave; the total height of the first two waves corresponds to a one-electron diffusion current. The second wave is reversible in character, and the third irreversible. At high depolariser concentrations the heights of the second and third waves cease to increase with concentration. The first stage involves formation of the strongly adsorbable triphenyltin radical, which is either dimerised to electrochemically inactive hexaphenylditin or reduced further (the third wave) to the triphenyltin anion (after electrolysis at the potentials of the limiting-current plateau of the third wave an anodic wave with $E_{\frac{1}{2}} = -0.4$ V appears on the polarograms of the solution, and this corresponds to oxidation of triphenylstannane $(C_6H_5)_3SnH$ to the initial triphenyltin cation; no anodic wave appears after electrolysis at the potential of the second wave).

A method has been suggested[102] for determining microquantities (down to 10^{-8} M) of triphenyltin by the accumulation of adsorbed radicals by preliminary electrolysis of the test solution at a rotating mercury-coated platinum wire (at −1.0 V (s.c.e.) for 2 min) followed by anodic oxidation of the adsorbed radicals. With increase in time of pre-electrolysis or rise in concentration of the initial compound the height of the anodic peak ceases to increase, probably owing to dimerisation of some of the triphenyltin radicals to inactive hexaphenylditin; dimerisation is not observed at low surface concentrations of the radicals.

Hexaphenylditin. In dimethoxyethane this gives a two-electron wave at −2.9 V (relative to a 1 mM $AgClO_4$/Ag electrode), corresponding to formation of triphenyltin anions[87]. In aqueous–alcoholic medium, however, hexaphenylditin is electrochemically inactive[102].

Oxygen-containing organotin compounds. Trialkylstannyl methacrylates and ethers $R_3SnOSnR_3$ ($R = C_2H_5$, C_4H_9) in buffered aqueous solutions give two cathodic waves having half-wave potentials lying between −1.40 and −1.50 and between −1.74 and −1.78 V (s.c.e.) almost independent of the nature of the compounds, which is probably explained by their ready hydrolysis, e.g.

$$(C_2H_5)_3SnOSn(C_2H_5)_3 + H_2O \rightarrow 2(C_2H_5)_3SnOH) .$$

The first wave is rather more negative with ethyl than with butyl[114].

A polarographic method developed[115] for determining extremely small quantities (down to 3.4×10^{-7} M) of organotin compounds used as fungicides involves electrolysing the test solution in 12% hydrochloric acid at a suspended mercury drop cathode at −0.8 V (s.c.e.) for 5 min. The anodic current–potential curve for dissolution of tin from the amalgam is then recorded (rate of variation of potential 0.6 V min^{-1}), and the concentration of the organotin compound in the initial solution is calculated from the height of the peak. The method has been tested on benzyltin trichloride, octyltin trichloride, and dibenzyltin dichloride, as well as on benzylstannic acid.

Organolead compounds. One of the earliest studies[89] recorded polarograms for triethyl-lead chloride in aqueous potassium chloride. One-electron transfer was assumed to yield a triethyl-lead radical.

Aquodiethyl-lead. This species $(C_2H_5)_2Pb^{2+}.nH_2O$ is reduced[116] with the transfer of two electrons to biradicals, which partly disproportionate

$$2\,(C_2H_5)_2Pb^{\cdot\cdot} \rightarrow (C_2H_5)_4Pb + Pb^0$$

(this is favoured by increasing the concentration of the starting material), while the rest react with mercury

$$(C_2H_5)_2Pb^{\cdot\cdot} + Hg^0 \rightarrow (C_2H_5)_2Hg + Pb^0.$$

Trialkyl-lead bromides. These compounds have been studied in 30% isopropyl alcohol[117]. Triethyl-lead bromide gives two waves, the first ($E_{\frac{1}{2}} \simeq -0.7$ V) corresponding to the transfer of one electron followed by dimerisation of the resulting radicals to hexaethyldilead. With increase in the depolariser concentration this wave is split, the first step appearing as an adsorption prewave. The second wave on the polarograms of triethyl-lead bromide, with $E_{\frac{1}{2}} \simeq -1.35$ V (s.c.e.), forms a hump, and was attributed[117] not to the reduction of hexaethyldilead but to an unestablished process involving the initial compound. A detailed study was made[109] of the behaviour of trialkyl-lead chlorides.

Triethyl-lead hydroxide. In buffered aqueous solutions this compound gives two waves independent of pH, with half-wave potentials of −0.73 and −1.50 V (s.c.e.).[118]

Hexaethyldilead. A sharp wave is obtained[119] in anhydrous ethanol with tetraethylammonium iodide as supporting electrolyte (half-wave potential lying between −1.8 and −2.0 V relative to the mercury at the base of the cell). This compound can be determined polarographically as an impurity in tetraethyl-lead, which is polarographically inactive[109].

Phenyl-lead triacetate. Three one-electron diffusion waves, with respective half-wave potentials +0.1, −0.4, and −0.8 V (s.c.e.), are obtained[120] in 20% aqueous methanol in acid medium. A slight prewave occurs at −0.9 V, owing to the increase in the capacitive current resulting from desorption of reaction products. The first two waves are reversible, and the third is irreversible. After electrolysis at the plateau potentials of first and second waves diphenylmercury and bivalent lead were obtained, resulting from slow breakdown of products—$C_6H_5Pb(COO)_2^{\cdot}$ and $C_6H_5Pb(COO)^{\cdot\cdot}$ respectively—formed on the electrode; the kinetics of the breakdown of these radicals was studied. After electrolysis at the potential of the third wave only traces of diphenylmercury were found. When the solutions had stood for a few days, the first wave had diminished and divided, while the second wave had also split, this being explained by the replacement of acetate by hydroxyl groups. The products of electrolysis of the solutions after standing included not only diphenylmercury and Pb^{2+} but also phenol and metallic lead, formed by the reaction

$$C_6H_5Pb^{2+} + H_2O \rightarrow C_6H_5OH + H^+ + \frac{1}{2}(Pb^0 + Pb^{2+}).$$

Diphenyl-lead diacetate. In buffered acid and strongly alkaline solutions containing 20% of methanol this compound gives[121] an anodic oxidation wave, two two-electron reduction waves, and a prewave, which become more negative with increase in the depolariser concentration and with rise in pH (the substance is very sparingly soluble over the pH range 5–12). Owing to variation in the diffusion coefficient the waves are rather lower in alkaline than in acid medium. At a concentration of ~ 1 mM in 1 M perchloric acid the half-wave potentials are ~ +0.1 (anodic), −0.10 (prewave), −0.40, and −0.53 V (s.c.e.). Diphenyl-lead diacetate reacts comparatively rapidly with a mercury electrode ($k = 1.55 \times 10^{-4}$ cm s^{-1}) to form diphenylmercury and Pb^{2+}, so that preparative electrolysis cannot be accomplished at a mercury cathode. An extremely unstable diphenyl-lead biradical is assumed to be formed on the first wave, and to undergo rapid dismutation to hexaphenyldilead and metallic lead (Pb^0), and also reaction with mercury to yield diphenylmercury and metallic lead. On the second reduction wave the biradical gives benzene and metallic lead[121].

Triphenyl-lead hydroxide. In buffered solutions in 20% methanol reduction takes place in two stages, whose corresponding waves are preceded by an adsorption prewave[121]. The total wave height corresponds to a diffusion process with the transfer of four electrons. For a 1 mM solution in 1 M perchloric acid the half-wave potentials are respectively −0.17 (prewave), −0.43, and −0.55 V (s.c.e.). With decrease in depolariser concentration the half-wave potential of the prewave becomes less negative, and that of the second wave more negative, while that of the first wave remains unchanged. With rise in pH the half-wave potential of the first wave remains unchanged to pH 9 and then becomes more negative, whereas that of the second wave becomes more negative to pH 5.5, and is independent of higher pH. The first wave corresponds to the transfer of one electron with formation of a triphenyl-lead radical, which reacts rapidly with mercury to give diphenylmercury and metallic lead. The main reduction products at the potential of the second wave are benzene and lead.

The anodic oxidation of triphenyl-lead hydroxide yields bivalent lead, diphenylmercury, and phenylmercury ions[121]. The polarograms are distorted by adsorption phenomena (especially strongly at high depolariser concentrations). The second wave exhibits hysteresis: waves obtained with forward and reverse variation of the polarising voltage do not coincide.

Triphenylchlorolead and diphenyldichlorolead. In dimethoxyethane these compounds react with mercury to give diphenylmercury and metallic lead[87], but the corresponding acetates do not react with mercury under the same conditions. Diphenyl-lead diacetate gives[87] two one-electron waves (half-wave potentials of −1.1 and −1.6 V relative to $Ag/AgClO_4$—1 mM in dimethoxyethane). Electrolysis at the limiting-current potential of the second wave gives a quantitative yield of diphenylmercury.

Triphenyl-lead acetate. On the first one-electron wave (−1.4 V) in dimethoxyethane this gives the triphenyl-lead radical, but electrolysis at the limiting current of this wave gave diphenylmercury, not hexaphenyldilead: i.e. reaction of these radicals with mercury is considerably more rapid than their dimerisation[87]. The second wave ($E_{\frac{1}{2}}$ = −2.2 V) corresponds to the transfer of two electrons to the radical (to give a triphenyl-lead anion). The ease of addition of an electron increases in the sequence of compounds of silicon → germanium → tin → lead[87].

Hexaphenyldilead. In dimethoxyethane a two-electron wave is obtained representing formation of the triphenyl-lead anion ($E_{\frac{1}{2}}$ = −2.0 V relative to 1.0 mM $AgClO_4/Ag$).[87] At a platinised platinum electrode in a mixture of methanol and benzene the $(C_6H_5)_6Pb_2/(C_6H_5)_3Pb^+$ system is reversible.[122]

VII. DERIVATIVES OF PHOSPHORUS, ARSENIC, ANTIMONY, AND BISMUTH

Trisubstituted phosphines. Only the triaryl derivatives undergo reduction when polarographed[123-125]. With 0.09 M tetraethylammonium iodide in dimethylformamide $E_{\frac{1}{2}}$ = −2.670 V (s.c.e.) for the reversible one-electron wave of triphenylphosphine. The primary product is the radical-anion[123-126]. Preparative electrolysis yields diphenylphosphine and benzene.

Benzyldiphenylphosphine. This gives a two-electron wave corresponding to detachment of the benzyl group. Reduction is facilitated appreciably by replacing the phenyl by naphthyl groups[125].

Triphenylarsine, triphenylstibine, and triphenylbismuthine. These give two-electron waves[123]. The half-wave potential for triphenylarsine in dimethylformamide is −2.790 V (aq. s.c.e.).[125]

Triphenylphosphine, diphenylphosphine, and phosphinoacetates. These compounds, especially the last group, cause the catalytic evolution of hydrogen. The catalytic waves are greatly enlarged by the addition of cobalt(II), cobalt(III), and nickel(II) salts, except to triphenylphosphine solutions. In the presence of cobalt(III) even unsubstituted phosphine PH_3 produces a catalytic hydrogen wave, which in acid solutions (pH 3–5) is visible even with 10^{-7} M phosphine[127].

Triarylphosphines, triarylarsines, and triarylstibines. Half-wave potentials have been determined for the oxidation of several of these compounds in 0.1 M lithium perchlorate in acetonitrile. Values obtained for the triphenyl derivatives were respectively 0.12, 0.43, and 0.46 V (at 25°C relative to aqueous saturated KCl–AgCl/Ag). The wave heights correspond to the transfer of one electron. Preparative anodic oxidation gave the product $[Hg(Ar_3X)_2](ClO_4)_2$, where X = P, As, Sb.[128]

Diphenyl-phosphinous, -arsinous, -stibinous, and -bismuthinous halides, acetates, and perchlorates. In dimethoxyethane these compounds give irreversible reduction waves[129]. Only one one-electron wave, with $E_{\frac{1}{2}}$ = −3.3 V (relative to 1 mM $AgClO_4/Ag$), is observed for diphenylphosphinous chloride[129]:

$$(C_6H_5)_2PCl + e \rightarrow Cl^- + [(C_6H_5)_2P]^{\cdot} \xrightarrow{\text{solvent}} (C_6H_5)_2PH.$$

Diphenylarsinous bromide gives two one-electron waves, with tetraphenyldiarsenic as intermediate[129]:

$$(C_6H_5)_2AsBr \xrightarrow{e} Br^- + \frac{1}{2}(C_6H_5)_2As{-}As(C_6H_5)_2 \xrightarrow{e} (C_6H_5)\,As^-$$

with half-wave potentials of −0.9 and −2.7 V (relative to 1 mM $AgClO_4/Ag$). Reduction occurs in the same way with diphenylstibinous iodide (−1.0 and −2.5 V) and with diphenylbismuthinous chloride (−1.0 and −2.3 V), but the diphenylbismuth anion is unstable and decomposes with the separation of metallic bismuth[129].

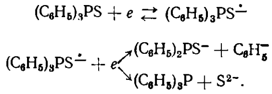
Phenylphosphonous and phenylarsonous dichlorides. In dimethoxyethane these compounds are reduced in a single two-electron stage:

$$C_6H_5PCl_2 + 2e \rightarrow 2Cl^- + [C_6H_5P]^{\cdot} \xrightarrow{\text{solvent}} C_6H_5PH_2.$$

The corresponding half-wave potentials are −2.5 and −0.9 V.[129]

Triarylphosphine oxides. In dimethylformamide these compounds give one reversible one-electron wave[125,126]. They are more easily reduced than are the corresponding phosphines. Thus the half-wave potential for triphenylphosphine oxide in dimethylformamide is −2.490 V (aq. s.c.e.)[125]. This oxide is strongly adsorbed from aqueous solution on a mercury electrode, and is therefore widely used to inhibit electrode processes[130]; it exhibits inhibiting properties, though less strongly, also in aqueous–methanolic[131] and methanolic[132] solutions. A detailed study has been made[132] of the effect of the nature and concentration of an inert salt and also the presence of a depolariser (azobenzene) on the adsorption of triphenylphosphine oxide from methanolic solution on a mercury electrode.

Triphenylphosphine sulphide. This gives three waves, with half-wave potentials −2.415, −2.530, and −2.700 V (aq. s.c.e.). The process corresponds to the scheme[125]



$$(C_6H_5)_3PS + e \rightleftarrows (C_6H_5)_3PS^{\dot{-}}$$

$$(C_6H_5)_3PS^{\dot{-}} + e \begin{array}{l} \nearrow (C_6H_5)_2PS^- + C_6H_5^- \\ \searrow (C_6H_5)_3P + S^{2-}. \end{array}$$

The third, small wave on the polarograms corresponds to reduction of triphenylphosphine.

Triphenylphosphine selenide. In dimethylformamide this gives one-electron waves with half-wave potentials of −2.145 and −2.690 V.[125]

Triarylarsine oxides and sulphides. These are reduced in dimethylformamide with the production of two waves. The half-wave potentials of the first wave are less negative than with the corresponding initial triarylarsines[125].

Aryldiethylarsine oxides. In dimethylformamide these give two-electron waves corresponding to detachment of the aryl group[133]. Addition of phenol to the solution causes the wave to grow and divide, so that two two-electron waves are produced in the presence of a fourfold to fivefold excess of phenol. The second wave then corresponds to reduction of the oxygen of the protonated species[133].

Quaternary phosphonium, arsonium, and stibonium salts. Many polarographic studies have been made of these compounds. A detailed summary will be found in Ref. 134, together with the polarographic characteristics of many phosphonium and arsonium salts in aqueous solution.

Tetraphenylphosphonium cation. Three reduction waves are obtained on the polarograms, the first corresponding to the transfer of one electron with the formation of triphenylphosphine and a phenyl radical, and the third to the reduction of phosphine[123], but the nature of the second wave was not established. Doubt has been cast on this mechanism[126]. In dimethylformamide the first wave is irreversible (according to results obtained with a Kalousek reversing switch)[126], but by analogy with the reduction of quaternary ammonium compounds[135], and on the basis of the slope of the lower part of the semi-logarithmic graph of the wave in aqueous medium[134,136], transfer of the first electron can be regarded as reversible or semi-reversible. From the inflexion in the upper part of the semi-logarithmic graph (Fig. 3 in Ref. 134) and the considerable shift in the half-wave potential to less negative values with increase in the depolariser concentration and the drop period of the electrode, it can then be supposed that electron transfer is followed by rapid bimolecular surface reaction (phosphines are strongly adsorbed on the electrode[127]) of the free radicals formed, yielding triphenylphosphine, phenyl radicals, and biphenyl, which was detected after electrolysis[124].

It has recently been shown[137] that minute quantities of hydroxide ions present in certain anhydrous media (if special measures are not taken to remove them) have a marked effect on the processes involved in the reduction of tetraphenylphosphonium salts. On polarography in dimethylformamide from which hydroxide ions (formed on storage in a glass vessel) have been specially removed the second wave on the polarogram of the tetraphenylphosphonium cation corresponds to reduction of triphenylphosphine oxide. If small quantities of hydroxide ions are present in the organic-solvent solution, the height of the second wave increases, and the limiting current of the first wave is smaller than the diffusion current corresponding to transfer of one electron, the number of electrons being less than unity by the concentration ratio $[OH^-]/[(C_6H_5)_4P^+]$ in the solution. This is due to occurrence of the very fast reactions

$$(C_6H_5)_4P^+ + OH^- \rightleftarrows (C_6H_5)_4POH, \qquad (11)$$

$$(C_6H_5)_4POH + OH^- \rightarrow (C_6H_5)_4PO^- + H_2O, \qquad (12)$$

followed by the comparatively slow process

$$(C_6H_5)_4PO^- \rightarrow (C_6H_5)_3PO + C_6H_5^-,$$

which under certain conditions (e.g. at very low temperatures) restricts the height of the second wave, and then the reaction

$$C_6H_5^- + H_2O \rightarrow C_6H_6 + OH^-.$$

Since dimethylformamide and acetonitrile usually contain a small quantity of water (0.1–0.2% and 0.4% respectively), the first stage of reduction (in the absence of hydroxide ions in the solution) takes place according to the scheme

$$(C_6H_5)_4P^+ + 2e + H_2O \rightarrow (C_6H_5)_3P + C_6H_6 + OH^-.$$

The hydroxide ions formed then react with a second molecule of the initial cation according to Eqn. (11), so that the height of the first wave corresponds formally to the transfer of one electron. In the preparative electrolysis of a tetraphenylphosphonium salt at the plateau potential of the first wave in dimethylformamide and acetonitrile not containing hydroxide ions, therefore, triphenylphosphine and its oxide are obtained in ~ 50% yield and benzene in 100% yield, which supports the above scheme. In conformity with this scheme the addition to dimethylformamide of formic acid, which suppresses reactions (11) and (12), raises the height of the first wave to a two-electron diffusion current. A similar but considerably smaller effect is produced by lithium ions (which combine with hydroxide ions) and also by water. The explanation for the latter[137] is that hydrated hydroxide ions are far less active than those solvated in dimethylformamide or acetonitrile.

The reversible character of transfer of the first electron to various phosphonium salts containing three phenyl groups has been shown in Ref. 138.

The half-wave potential of tetraphenylphosphonium in aqueous solution is −1.680 V (s.c.e.)[134], which becomes more negative on the successive replacement of phenyl by methyl or ethyl groups. Thus the potentials on passing from methyltriphenylphosphonium to trimethylphenylphosphonium are successively −1.862, −2.087, and −2.271 V.[134] When a phenyl group in tetraphenylphosphonium is replaced by other groups the half-wave reduction potentials become more negative in the sequence of substituents[136]

$$C_6H_5CH > (O)CH_3C_6H_4 > C(CH_3)_3 > C_6H_5 > C_2H_5 > CH_3.$$

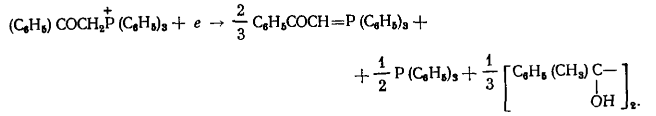
Diphenylmethyltriphenylphosphonium cation. With 0.1 M tetraethylammonium perchlorate in acetonitrile this gives two one-electron waves[139], corresponding to formation of an ylide and its reduction respectively. Addition of phenol (a proton donor) to the solution doubles the height of the first wave and suppresses the second. With tetrabutylammonium iodide as supporting electrolyte a third wave is observed, corresponding to triphenylphosphine. With the same supporting electrolyte these three waves are present on the polarogram obtained in dimethylformamide. The process can be represented by the general scheme

$$(C_6H_5)_2CH\overset{+}{P}(C_6H_5)_3 + e \rightarrow \frac{1}{2}(C_6H_5)_2C{=}P(C_6H_5)_3 + \frac{1}{2}(C_6H_5)_3P + \frac{1}{2}(C_6H_5)_2CH_2.$$

The appearance of an ylide is attributed[139] to abstraction of a proton from the initial cation on its interaction with a very strong base—the diphenylmethyl anion—formed on the electrode by transfer of an electron to the diphenylmethyl radical, which in turn appears together with triphenylphosphine as a result of comparatively slow decomposition of the primary electrode product—the free radical formed by reversible transfer of one electron to the initial cation. In the presence of a proton donor the usual two-electron rupture of a carbon–phosphorus bond takes place.

Benzyltriphenylphosphonium cation. This behaves similarly to the previous cation, giving two waves in acetonitrile with a tetra-alkylammonium salt as supporting electrolyte, and three waves in dimethylformamide or hexamethylphosphoramide with a tetrabutylammonium salt[139].

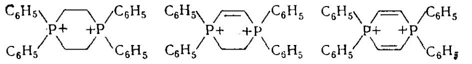
Phenacyltriphenylphosphonium cation. In acetonitrile this gives[139] three waves: the first corresponds to the transfer of one electron; the unusually low second wave was proved to represent reduction of the intermediate acetophenone (to "benzpinacone" [2,3-diphenylbutane-2,3-diol]; and the third wave, higher than the first, corresponds to reduction of the ylide and further reduction of acetophenone. The general scheme of the process is



$$(C_6H_5)\,COCH_2\overset{+}{P}(C_6H_5)_3 + e \rightarrow \frac{2}{3}\,C_6H_5COCH{=}P(C_6H_5)_3 + \frac{1}{2}\,P(C_6H_5)_3 + \frac{1}{3}\left[C_6H_5(CH_3)\underset{\displaystyle OH}{\underset{|}{C}}-\right]_2.$$

Polymethylenebistriphenylphosphonium salts. These compounds $[(C_6H_5)_3P[CH_2]_nP(C_6H_5)_3]Br_2$ having small values of *n* are reduced more easily than are the usual salts. With increase in *n* the half-wave potential becomes more negative, from −1.195 V when $n = 1$ to ~ −1.8 V when $n = 4-6$, after which it becomes more positive again[134].

1,1,4,4-Tetraphenyl-1,4-diphosphorinium salts. These salts, those containing the corresponding dihydro- and tetrahydro-rings



and numerous derivatives have been studied in dry dimethylformamide at a dropping mercury and a platinum microelectrode[140] with the use of 0.1 M tetraethylammonium perchlorate as inert electrolyte. The diphosphoniahexane derivative gives one two-electron wave with $E_{\frac{1}{2}} = -1.84$ V (s.c.e.) at a mercury electrode. The corresponding hexene and hexadiene derivatives are reduced considerably more readily: the first waves are reversible and correspond to the transfer of one electron forming radical-cations, with half-wave potentials respectively of −0.75 and −0.56 V. An especially detailed study has been made of a 2,5-di-t-butyl-1,1,4,4-tetraphenyl-1,4-diphosphoniacyclohexa-2,5-diene salt, which gives two one-electron waves ($E_{\frac{1}{2}} = -0.723$ and −1.08 V), the first being reversible and the second not. Addition of up to 10% of water to the dimethylformamide does not affect the height of the first wave, but in the presence of traces of perchloric acid the latter grows at the expense of the second wave, so that with increase in the acid concentration a single two-electron wave remains with $E_{\frac{1}{2}} = -0.675$ V.

The transfer of two electrons is regarded[140] as yielding a hitherto unknown compound—a diphosphabenzene derivative—which possesses basic properties and can be protonated at the carbon atoms; it resembles a diylide in character. Electrochemical reduction of the initial salt in aqueous-ethanolic medium gives a product without ring cleavage—a 1,4-diphosphoniacyclohexane derivative[141]—which is considered[140] to confirm the intermediate formation of diphosphabenzene. Substitution at positions 2 and 5 in the diphosphoniacyclohexadiene ring produces a change in half-wave potential in conformity with the inductive effect of the substituents (apart from di-t-butyl). Replacement of the *P*-phenyl groups by other substituents or substitution in the phenyl rings acts similarly. The waves are better defined at a platinum electrode, since they are distorted on mercury by adsorption phenomena[140].

Triphenyltriphosphine dianion. With tetrabutylammonium perchlorate in oxolan this species $(C_6H_5P)_3^{2-}$ gives an anodic oxidation wave at −1.4 V (relative to 0.1 *N* Ag^+/Ag), the product being probably[142] pentaphenylcyclopentaphosphine and hexaphenylcyclohexaphosphine $(C_6H_5P)_5$ and $(C_6H_5P)_6$. Mainly from the electrochemical behaviour of the triphenyltriphosphine dianion it was concluded that this compound has a linear structure, not the cyclic structure assumed earlier[143].

Pentaphenylcyclopentaphosphine and hexaphenylcyclohexaphosphine. With tetrabutylammonium perchlorate (concentration not indicated) in oxolan these compounds show the same electrochemical behaviour[142], giving at a dropping mercury electrode an irreversible two-electron reduction wave with $E_{\frac{1}{2}} = -2.62$ V (0.1 *N* Ag^+/Ag reference electrode) and a semi-logarithmic graph of slope corresponding to 63 mV. Cyclic voltammetry at a spherical platinum microelectrode gives a cathodic peak with $E_{p/2} = -2.8$ V, and on reversal of polarisation three anodic peaks with −1.9, −1.4, and −1.0 V, the second anodic peak being identical with the oxidation peak of the triphenyltriphosphine dianion. It is suggested that reduction yields an unstable dianion $(C_6H_5P)_n^{2-}$ ($n = 5,6$), which rapidly decomposes, so that the anodic peaks correspond to oxidation of the products formed.

Similar electrochemical behaviour is observed also with tetraphenylcyclotetraphosphine, as well as with alkyl derivatives of polycyclophosphines[144], for which the $E_{p/2}$ of the cathodic peak correlates well with the Taft σ-constants of the alkyl groups (the $E_{p/2}$ of the phenyl derivatives also lie on the straight line obtained).

Arsonium salts. These behave like phosphonium salts, but are more easily reduced, their half-wave potentials being ~ 0.3 V more positive than those of the corresponding phosphonium derivatives[134]. One or two reduction steps are observed depending on the nature of the substituents.

Hexaphenylhexa-arsine. Like the phosphorus analogue, $(C_6H_5As)_6$ on cyclic voltammetry at a platinum electrode gives a cathodic peak with $E_{p/2} = -2.8$ V, and on anodic polarisation three oxidation peaks with −2.0, −1.5, and −1.2 V.[142] Exhaustive electrochemical reduction yields a new substance, whose reduction gives $E_{p/2} = -3.0$ V, probably neutral diarsine. The corresponding diphosphines are electrochemically inactive.

Tetramethylstibonium. In aqueous solution the polarograms contain a single irreversible two-electron wave with $E_{\frac{1}{2}} = -1.490$ V (s.c.e.), corresponding to formation of trimethylstibine and methane[145].

Trimethylphenylstibonium, dimethyldiphenylstibonium, methyltriphenylstibonium, and tetraphenylstibonium. In aqueous media these give two one-electron diffusion waves[145]. The first wave corresponds to reversible electron transfer with formation of a tetrasubstituted stibine radical, which reacts rapidly with mercury to give a trisubstituted stibine and an organomercury radical, the latter disproportionating to a disubstituted organomercury derivative. The half-wave potential of the first wave has the respective values −1.195, −0.900, −0.710, and −0.635 V (s.c.e.) for the above compounds. The second wave is irreversible.

The half-wave potentials of both waves are independent of pH over the range studied (4–12). Electrolysis on the limiting-current plateau of both waves yields a trisubstituted stibine and a hydrocarbon (benzene or methane), but formation of the latter is not a consequence of reduction of the organomercury radical (as supposed[134] from the identity of the half-wave potentials for the second wave of tetraphenylstibonium and the phenylmercury ion). This follows from the simultaneous detachment of methyl and phenyl groups on electrolysis, in different ratios at the potentials of the first and second waves. In contrast to alkylaryl-phosphonium and -arsonium ions the nature of the group split off on the cathodic reduction of tetrasubstituted stibonium ions is determined by the stability not only of the resulting hydrocarbon radical but also of the stibine derivative[145]. The second wave corresponds to transfer of an electron and then also a proton to the tetrasubstituted stibine radical, to yield a trisubstituted stibine and a hydrocarbon.

The adsorbability of methylphenylstibonium ions on a mercury electrode is considerably enhanced with increase in the number of phenyl groups.

Preparative electrolysis of a tetraphenylstibonium solution at the potential of the first-wave plateau gave only triphenylstibine and diphenylmercury (neither benzene nor biphenyl was detected among the products). The second wave on the polarograms of tetraphenylstibonium corresponds to reduction of diphenylmercury formed in the first stage[146].

Tetratolylstibonium. In aqueous solution this gives two one-electron waves, the first of which is reversible[147].

Tetraphenylbismuth cation. Unpublished results indicate[145] two one-electron waves in aqueous solution.

Pentaphenylphosphorane. With 0.1 M tetrabutylammonium iodide in dimethylformamide this gives one irreversible wave[137]. The peak potential on voltammetry (with linear variation of potential) is −2.75 V (aq. s.c.e.).

Phosphoric esters. Only a capacitive cathodic spur appears on the $dE/dt = f(E)$ oscillopolarograms obtained in 1 M aqueous potassium chloride for the esters from trimethyl to triphenyl phosphates.

Trialkyl phosphites. These give an additional spur caused by the formation of compounds with mercury[148].

Tri-*p*-nitrophenyl phosphate. Of the five reduction waves the first represents an adsorption effect, the second is a diffusion wave with the transfer of two electrons, the third is kinetic, and the fourth and fifth waves are strongly distorted maxima, whose nature has not been established. On the second wave the dianion $[(NO_2C_6H_4O)_3PO]^{2-}$ is formed, and is slowly converted by interaction with the solvent into *pp'*-dinitrobiphenyl and nitrophenyl dihydrogen phosphate $NO_2C_6H_4OPO(OH)_2$.[149]

Di-*p*-nitrophenyl hydrogen phosphate. In dimethylformamide this ester $(NO_2C_6H_4O)_2POOH$ gives three waves. The second is a diffusion wave with the transfer of two electrons and formation of a dianion converted by reaction with the solvent into *pp'*-dinitrobiphenyl and phosphoric acid[150].

Phenyl- and *β*-styryl-phosphonic and -phosphinic esters. In dimethylformamide these give one or two one-electron cathodic waves, the first of which is reversible[126,151]. The styrylphosphonates are reduced more readily than styrene itself by almost 0.5 V. It is interesting that the half-wave potentials are almost the same for the styrylphosphonate and a styrylphosphinate (−1.45 and −1.81 compared with −1.45 and −1.85 V relative to mercury in 0.08 M tetraethylammonium iodide).[151]

Vinylphosphonic and divinylphosphinic esters. In dimethylformamide these compounds $CH_2:CH.PO(OC_2H_5)_2$ and $(CH_2:CH)_2POOC_2H_5$ have one-step two-electron reduction waves with respective half-wave potentials of −2.02 and −1.87 V (relative to mercury in 0.08 M tetraethylammonium iodide).[126]

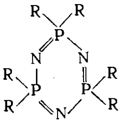
Diethyl aroylphosphonates. On reduction at a dropping mercury electrode in acetonitrile these esters $ArCO.PO(OC_2H_5)_2$ give diethyl phosphonates and benzoin. In the presence of benzoic acid diethyl *α*-hydroxyarylmethylphosphonates are formed[152].

Diethyl *α*-diazobenzylphosphonate. With 1 M lithium perchlorate in 20% aqueous dioxan this ester $C_6H_5.CN_2.PO(OC_2H_5)_2$ and its *para*-substituted derivatives give one irreversible two-electron diffusion wave ($E_{\frac{1}{2}} = -1.18$ V (s.c.e.) for the unsubstituted ester), corresponding to replacement of the diazo-group by two hydrogen atoms[153]. The corresponding potentials of the substituted derivatives vary in conformity with the Hammett equation containing the constant $\rho = +0.098$. Under the same conditions ethyl *α*-diazophenylacetate gives a wave having $E_{\frac{1}{2}} = -1.17$ V: i.e. the effect of the diethoxyphosphinyl group on reduction of the diazo-group is almost the same as that of the ethoxycarbonyl group[153].

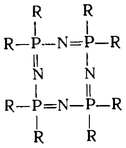
At a rotating platinum disc electrode the above phosphonates give one-electron diffusion waves, which with certain derivatives are reversible.

Acylphosphine oxides. In dimethylformamide and acetonitrile these compounds RCO.PORR′ acquire the first electron irreversibly when R = CH_3 and reversibly when R = C_6H_5.[154]

Organocyclophosphazines. Compounds having a six- or eight-membered ring (III) or (IV) or the polymeric linear structure (V)



(III)



(IV)

(V)

($n \simeq 15$; R = C_6H_5, OC_6H_5, OCH_2CF_3, etc.) are reduced in dimethylformamide in the presence of 0.1 M tetrabutylammonium iodide, giving a one-electron first wave followed, immediately before discharge of the supporting electrolyte, by another, very indistinct wave corresponding to transfer of a second electron[155]. The size of the ring is almost without effect on the half-wave potential of the first wave (with R = C_6H_5 structures (III) and (IV) have the values −2.65 and −2.67 V s.c.e.). Coulometric electrolysis of (III) at the limiting-current potential of the first wave showed complete regeneration of the depolariser: i.e. the first wave is catalytic in character. Cyclic voltammetry indicates the instability of the radical-anions formed on transfer of the first electron[155].

The present Review has given the principal information available on the polarographic behaviour of organoelementary compounds of non-transition elements. A brief summary of results for derivatives of transition metals can be found in the recently published Russian translation of the book by Mann and Barnes[156].

Advances in Fluorine Calorimetry

V.S.Pervov and N.S.Nikolaev

The development of a new area of thermochemistry (the calorimetry of fluorination reactions) is reviewed. The high reactivity of fluorine offers some important advantages over alternative reagents, but at the same time it introduces some experimental difficulties. We have attempted to generalise the practical problems of fluorine calorimetry by systematically examining a number of specific thermochemical investigations by the most widely adopted modification of the method: fluorine bomb calorimetry. Current developments and possible new applications are reviewed, and the basic experimental procedures and apparatus are described. 86 references.

CONTENTS

I. INTRODUCTION

The method known as "fluorine calorimetry" includes two main modifications, differing in the details of the calorimetric measurement. The first modification relies on combustion of the sample in fluorine within a calorimetric bomb ("fluorine bomb calorimetry"). This is the latest and most important development in the fundamental thermochemical procedure of bomb calorimetry. The second modification relies on combustion in fluorine with formation of a flame in a special flow-through calorimeter ("fluorine flame calorimetry"). Its applications are more limited, since it is assumed that only gaseous products are formed.

The term "fluorine calorimetry" includes all thermochemical studies of fluorination reactions, whether or not the fluorine is in the elemental state. The replacement of fluorine by a fluorine compound of comparable oxidising power (inert gas fluorides, oxygen fluorides, halogen fluorides) is a mere extension of the method without any fundamental difference.

Thermochemical studies of fluorination reactions were first reported[1] in the 1930's, but precise measurements of the heats of reactions were not attempted until approximately 1960. In 1959 Gross[2], of the Fulmer Research Institute in Great Britain, published the results of his calorimetric measurements of the heats of formation of SF_6(g) and TiF_4(c), obtained by burning sulphur or titanium in fluorine in a special glass bomb. Important contributions to the development of the fluorine bomb came from Hubbard and coworkers[3] of the Argonne National Laboratory, USA, and from Armstrong and coworkers[4] of the National Bureau of Standards, USA. These workers demonstrated the precision attainable by this method, they developed new apparatus for general application, and they proposed new combustion procedures. At the same time Armstrong developed and successfully applied the method of "fluorine flame calorimetry".

Work on reaction calorimetry by using fluorine in a bomb began in the Soviet Union in 1967 at the Kurnakov Institute of General and Inorganic Chemistry of the USSR Academy of Sciences and also at the High Temperatures Institute of the USSR Academy of Sciences.

Whereas the combustion method using fluorine in a bomb has been used successfully in several laboratories in the USA, Great Britain, West Germany, France, and the Soviet Union, the work using fluorine flames remains the prerogative of a single laboratory (the National Bureau of Standards in the USA). Partly because of its limited applications, and partly because of the lack of direct experience in our own laboratory, we have thought it preferable not to include a discussion of fluorine reaction calorimetry in flames in the present review.

There can no longer be any doubt that fluorine calorimetry offers entirely new possibilities in experimental thermochemistry, since it allows the study of reactions involving substances too unreactive to be investigated by other methods. From the thermochemical point of view reactions with fluorine are more attractive than reactions with oxygen because of the higher oxidising power of elemental fluorine. They are more exothermic and more readily initiated under the conditions of a calorimetric experiment. Fluorides tend to have more definite compositions than oxides. In the great majority of cases combustion in a bomb under a high pressure of fluorine gives the higher fluoride, whereas calorimetric combustion in oxygen can yield crystalline or glassy protective oxide films which make the reaction diffusion-limited and can lead to products of indefinite composition such as mixtures of oxides or phases of variable composition. Effects of this type are responsible for the low precision of oxygen bomb measurements on compounds containing silicon, boron, germanium, and some multivalent transition elements.

Fluorides are "low-temperature" compounds compared with oxides. Most of the higher fluorides have a significant vapour pressure at normal temperature. The presence of gaseous or distillable products in the calorimetric bomb makes their identification and analysis much simpler.

For these reasons reliable values of the standard heat of formation of many compounds were not available before the advent of fluorine calorimetry. Precise measurements of the heats of formation of fluorides by the direct thermochemical method (reaction between the element and fluorine) are important in their own right because of the major role played by these compounds in chemistry, chemical technology, and industry.

The compounds which have been studied by fluorine calorimetry up to the time of writing are listed in the Table. It can be seen that combustion in a fluorine bomb is the main form of the fluorine calorimetry method, having been used successfully to measure the heats of formation of higher and lower fluorides, oxides, refractories, and some other compounds. After the fluorides, the most important group of compounds in the list includes those of silicon (SiO_2, SiC), germanium (GeO_2, GeS), and boron (Zr, Hf, Nb, and Ta borides, and B_2O_3), i.e. the compounds which cannot be studied accurately by oxygen combustion for the reasons stated above. The bomb combustion methods in which fluorine is replaced by other fluorinating agents are likely to be developed further.

Compounds whose heats of formation have been studied by fluorine calorimetry*.

* Compounds within each group are listed in order of appearance of the first publication. The basis of the classification is stated in the Notes.

The use of fluorine compounds such as the inert gas fluorides often brings a number of advantages. However their exploitation requires some preliminary work: in particular, accurate measurements of the heats of formation of these fluorides, and the development of methods for causing combustion and for analysing the combustion products. Fluorine flame calorimetry is useful for determining the heats of formation of some reactive gaseous fluorides.

II. SPECIAL FEATURES OF COMBUSTION IN FLUORINE IN A CALORIMETRIC BOMB

The high reactivity of fluorine and fluorides can induce various side reactions, leading to systematic errors in the measurement of the heat of the main reaction. One of the main features of fluorine calorimetry is the need to develop procedures for avoiding these side reactions or accurately correcting for them. We shall discuss this aspect in detail for the special case of combustion in fluorine within a calorimetric bomb.

Obviously, one of the main problems is to avoid side reactions involving fluorine. The fluorine is present in the bomb at a relatively high pressure, and it can interact with the container material. Corrosion of the apparatus during the measurement can be a serious problem†, but it can be minimised to a level which produces a negligible error (thermal effect of the corrosion reaction less than 0.01% of the thermal effect of the main reaction)[10,11] by suitable choice of materials and methods of passivation, and also by careful design and operation of the calorimetric bomb. Heavy corrosion of the other parts of the apparatus (connecting tubes, taps, storage vessels) is also unacceptable because the fluorine can be contaminated with oxygen and other impurities if it is allowed to come into contact with an oxidised metal surface. On the other hand, metal surfaces covered by a passivating film of fluoride can show increased adsorption and a tendency to hydrolysis. A passivating fluoride film on the inner wall of the calorimetric bomb may interact with the products of the main reaction.

The experimental substance can begin to react with the fluorine in the bomb even before the start of the main period of the calorimetric experiment. Hence the thermochemical experiment must be supplemented by tests for this interaction, and if necessary the bomb must be provided with two compartments or other means of isolating the reactants. All these precautions relate, to a greater or lesser extent, to apparatus design. Accurate measurements of the heat of fluorination reactions cannot be attempted without special fluorine-handling equipment, made of the smallest number of fluorine-resistant materials, and operated with careful attention to the special requirements of this procedure.

Let us now consider the possibility of side reactions with impurities in the fluorine used for the calorimetric experiment. A survey of all the papers published on fluorine bomb calorimetry shows that the purity of the fluorine used by different authors varies in the range 99.0–99.99 vol.%. The earlier workers[9,10,35] tended, as a rule, to purify their fluorine by low-temperature distillation[69]. By using laborious procedures with distillation apparatus operated under laboratory conditions they were able to prepare very pure fluorine containing only a few hundredths of one per cent of oxygen and nitrogen as the main impurities[9].

---

†Some measurements[66,68] by fluorine flame calorimetry have had to be corrected for the corrosion of the apparatus in OF_2 and ClF_3. In the ClF_3 experiment[68] the correction amounted to 0.33% of the measured thermal effect of the $ClF_3 + H_2$ reaction.

At the same time, Domalski and Armstrong[23] measured the heat of formation of AlF_3 with fluorine containing 1 vol. % of impurities (0.9% O_2, 0.08% N_2, 0.01% CO_2, traces of SiF_4, HF, and fluorocarbons). Later the same workers[70] gave detailed information on the impurity content of two samples of commercial fluorine (99.40 vol. % F_2 and 99.79 vol. % F_2) which they used for calorimetric combustions of aluminium borides and graphite. Thus, both specially purified fluorine and fluorine of commercial purity have been used in fluorine calorimetry. The tendency to use the latter is explained by recent improvements in industrial processes, which now enable a level of purity in excess of 99.5% to be reliably obtained in commercial fluorine. However, the spectrum of impurities in the material is not constant, and depends on many factors including the grade of the starting material and unavoidable process variations. We must therefore consider the extent to which various possible impurities could take part in side reactions during the calorimetric experiment.

There is general agreement[69-72] that the commonest impurities in fluorine are O_2, N_2, HF, oxygen fluorides, fluorocarbons, CO_2, SiF_4, NF_3, SF_6, SO_2F_2, and Ar. An analysis[68,69] of many samples of commercial fluorine suggests that the predominant impurities are O_2, N_2, SiF_4, and CO_2. For example, the combined amount of these impurities in two fluorine samples containing 0.60 and 0.21 vol. % of total impurity was found to be[70] >98% of the total. Although the most reactive impurities (oxygen fluorides and hydrogen fluoride) are not usually detected, it cannot be assumed that their concentration is so low as to guarantee freedom from side reactions, since the occurrence (or otherwise) of these reactions depends also on the chemical properties of the substance under study. For example, according to Leonidov and coworkers[32] tungsten reacts spontaneously in the bomb if the fluorine contains ~1 vol. % of oxygen impurity. Spontaneous reaction was not observed when the oxygen content was decreased to 0.1 vol. %. Similar effects may occur with other impurities in the fluorine, which may therefore affect the result to different extents depending on the use to which the fluorine is put.

Thus the required level of purity of the fluorine may vary according to the nature of the impurities and that of the experimental substance. It is not enough to have access to high-purity fluorine: a qualitative and quantitative analysis of the impurities is essential, both before and after the calorimetric experiment‡. This presupposes that a high-precision method of analysis of fluorine and of the impurities in the gas is available. The need exists even if fluorine of the highest purity is used (such as fluorine purified by low-temperature distillation). Thus, Gillardean and coworkers[73] have shown that even very low (> 0.1 vol. %) concentrations of oxygen in the fluorine can affect the mechanism of fluorination of metallic copper.

It follows that an accurate method of fluorine analysis must be available, in addition to suitable calorimetric apparatus, in any laboratory attempting to use fluorine calorimetry.

The third essential precaution to avoid systematic errors through possible side reactions in the calorimetric bomb is a proper choice of the conditions under which the sample is burned in fluorine (combustion procedure).

The best combustion conditions in "oxygen" bomb calorimetry are those for which the oxidation reaction proceeds with a full yield of products of well-defined composition. When the sample is burned in a fluorine bomb calorimeter there is an additional requirement: freedom from side reactions by the fluorine or by the resulting fluorides. This requirement can introduce serious difficulties into the choice of the optimum method of combustion in fluorine. The combustion conditions cannot be really satisfactory unless the initial pressure of fluorine is as low as possible, since the probability of side reactions increases rapidly with pressure. The choice of optimum conditions for combustion in fluorine is further complicated by the likelihood of spontaneous reaction. Because of all these difficulties, we shall attempt a general discussion of the special features of calorimetric combustion in fluorine in relation to the type of sample used, and we shall make some general recommendations on the best experimental conditions in each case.

Thus, the following sections will deal in detail with the analytical determination of fluorine and its impurities, with non-standard apparatus for calorimetric work with fluorine, and with combustion methods for various substances. Since the measurement procedure, the design of the calorimeter, and the calculation of the calorimetric results do not differ in any way from those used, for example, in calorimetric combustions in oxygen[74], we shall not dwell on these problems in the present review§.

III. FLUORINE ANALYSIS

The mercury method, consisting in chemically absorbing the fluorine in metallic mercury and measuring the volume of residual gases, is generally used for fluorine analysis in calorimetric work. Klyuev[81] has given a full review of all the published work on the mercury method. This is undoubtedly the most accurate chemical method of analysis of high-purity fluorine. It is relatively simple and convenient under laboratory conditions. The method is applied in a variety of forms, differing in the method of measuring the volume of residual gas, in the design of the apparatus, and in the attainable precision. We shall briefly outline the published work on the application of this method to fluorine calorimetry.

Armstrong and Jessup[4] analysed fluorine of 97–99 vol.% purity by the following procedure. A quartz vessel 50 cm^3 in volume containing 1–2 cm^3 of pure mercury was evacuated to a pressure of 0.01 mmHg, and filled with fluorine at atmospheric pressure through a special micro-valve. The valve was shut, the vessel was disconnected from the gas lines, and it was manually shaken for 10–15 min.

---

‡As well as measuring the concentration of impurities in the fluorine before and after the calorimetric experiment, special experiments are necessary to prove that there has been no reaction of the main sample with the various impurity components. Thus Domalski and Armstrong[23], having used fluorine containing 0.9 vol.% of oxygen for the calorimetric combustion of aluminium, also burned a sample of aluminium in an equimolar mixture of fluorine and oxygen to show that aluminium oxide is not formed even at that concentration of oxygen.

§Most of the calorimetric measurements of fluorine bomb calorimetry (see Table) were carried out in standard water calorimeters with an isothermal enclosure (with the exception of the work of Gross and coworkers[2,13,15,35,36,41], Hayman[17], and Schröder[6]). The only non-standard component of the calorimetric system was the bomb itself.

Complete absorption of the fluorine was judged from the cooling of the vessel and from the change in colour of the mercury surface. The residual pressure was measured with a U-tube manometer filled with fluorocarbon oil. The manometer reading was corrected for the expansion of the gases into the auxiliary volumes (manometer limb, connecting tube) and the volume of the residual, non-absorbed gas was calculated. A reproducibility of 0.05% in a short series of measurements is claimed[4]. A similar procedure was used in calorimetric experiments by Stein and coworkers[69], Armstrong and coworkers[67,70], and Hubbard and coworkers[3]. Stein[69] describes an i.r. spectral method of estimating HF, OF_2, CF_4, C_2F_6, C_3F_8, NF_3, and CO_2 impurities in the residual gas. Domalski and Armstrong[70] reported some measurements of the impurity content of commercial fluorine samples (see above) by a mass spectrometric identification of the residual gas components. The same method was used to analyse fluorine of 99.95% purity, purified by low-temperature distillation[3]. Subsequently King and Armstrong[67], and also Pervov and coworkers[75], used gas chromatography to determine oxygen and nitrogen impurities in the gas which was not absorbed by mercury.

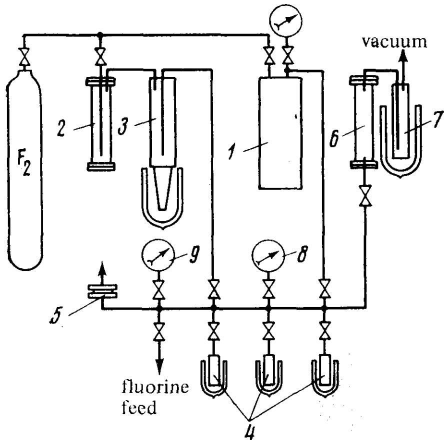

Figure 1. Apparatus for fluorine purification: *1*) storage vessel, *2*) granulated NaF absorber for removing HF, *3*) low-temperature condenser with nickel packing, *4*) receivers for fluorine condensation, *5*) pressure relieving valve, *6*) tube packed with metallic silicon for fluorine absorption, *7*) trap for SiF_4, *8*) manometer, *9*) vacuum gauge.

However, in spite of their good reproducibility (0.05–0.10%), many of the reported analytical results for fluorine[3,67,69,70] have doubtful precision. Most of the early work on the mercury method includes several sources of systematic error which affect the results of the fluorine analysis. For example, later workers[71,76] have identified the reaction between some impurities (HF, OF_2) and mercury as the main source of systematic error. According to Miller and Bigellow[77] the main contribution to the lack of precision comes from the pressure measurements (both the initial pressure of fluorine and the final pressure of the residual gases). A recent paper[75] suggests that the analytical results can be affected by the adsorption of impurities on the mercury fluoride, by temperature changes during the reaction between fluorine and mercury, and by the mixing conditions.

Pervov and coworkers[75] have made a thorough study of the effect of all these factors on the precision of the analysis of fluorine containing only oxygen and nitrogen impurities. They found that, because of the variability of the impurities in ordinary fluorine and of their chemical behaviour under the conditions of analysis by the mercury method, results of adequate precision can be obtained only if the analytical problem is simplified by a preliminary purification of the fluorine. They suggest a relatively simple method of purification, consisting in freezing out most of the impurities (except oxygen and nitrogen) in a flow-through trap at −170°. This procedure achieves two desirable ends: the reliability of the calorimetric results is improved by the use of purer fluorine, and the analytical data are more precise.

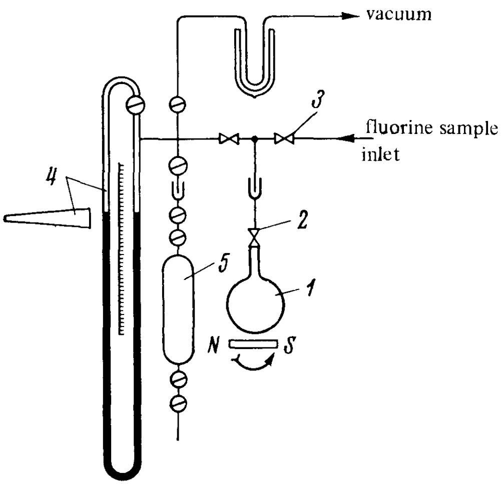

Figure 2. Fluorine analysis apparatus: *1*) flask, *2*) needle valve, *3*) tap, *4*) mercury manometer with cathetometer, *5*) gas burette for sampling residual gas.

The apparatus for removing impurities from the fluorine[75] except oxygen and nitrogen is shown in Fig. 1.

Fig. 2 shows an improved apparatus[75] for the analysis of the purified fluorine (>99.5 vol. % F_2) by the mercury method with a guaranteed precision. The total concentration of impurities is measured with a precision of 0.05 to 0.10 vol.%; identification is by mass spectrometric or gas chromatographic analysis of the residual gas. This form of the mercury method is ideally suited[4,75] to the analysis of high-purity fluorine (~99.9%), since in this case also the main impurities are oxygen and nitrogen[9], and there are no systematic errors from side reaction or adsorption of impurities. In either case the fluorine used in the calorimetric experiment can be analysed with a precision sufficient to give a reliable correction for the heat of the reaction with the oxygen and nitrogen impurities in the bomb, or alternatively to prove that the correction is unnecessary.

IV. APPARATUS

The equipment needed for fluorine bomb calorimetry includes the special calorimetric bombs¶ and apparatus for the preliminary purification and anslysis of the fluorine, for filling the bomb, and for sampling and separating the gaseous combustion products. Careful commissioning and operation of this specialised equipment is an essential prerequisite to the achievement of high precision in the measurement of heats of combustion in fluorine. A glass bomb for preliminary experiments on the optimisation of the conditions of combustion in fluorine should also be available because visual observations can be very valuable in this type of work†.

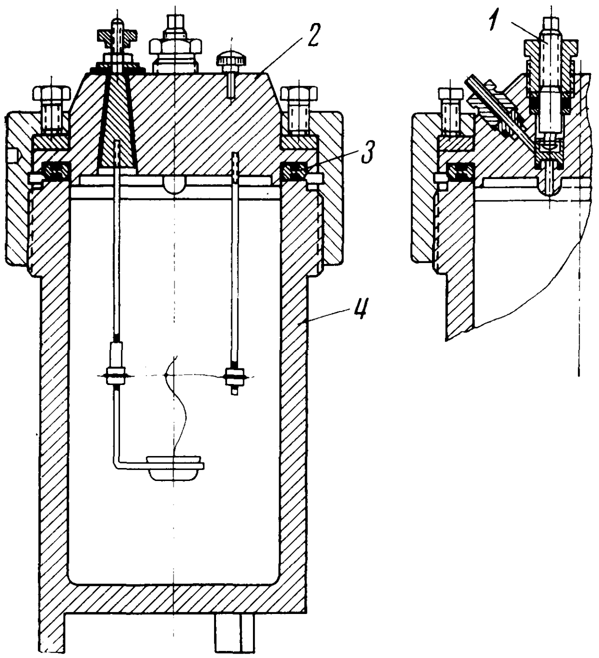

Figure 3. Single-chamber bomb calorimeter: *1*) valve, *2*) lid, *3*) seal, *4*) body.

The design of the calorimetric bomb must take account of a number of special requirements which are common to all fluorine-handling equipment. First and foremost, the bombs must be made of fluorine-resistant materials such as pure nickel, Monel metal, some high-alloy carbon-free steels of the Fe–Cr–Ni type, aluminium, gold, and Teflon (used to make sealing gaskets and partitions). Some types of ceramic can also be used (fluorite, fused alumina, and in some cases fused quartz[3,67]). Mechanical properties, operating conditions, and passivation regimes all have to be considered before finalising the choice of materials. For example, Teflon and quartz can ignite spontaneously in compressed fluorine at moderately high temperatures (50–100°). A reliable and simple operating procedure is another important requirement for equipment (including calorimeters) designed to handle fluorine under pressure.

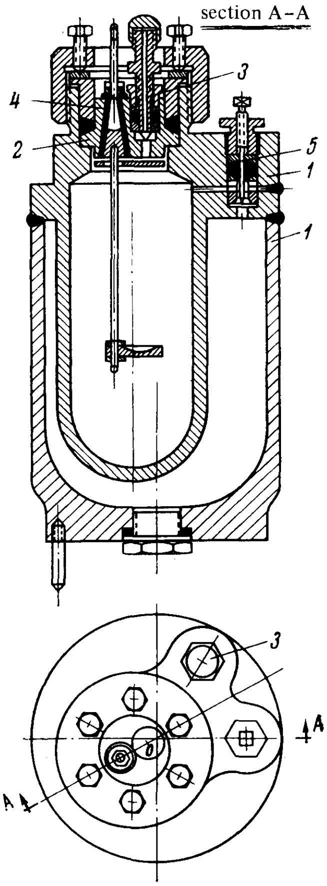

Figure 4. Double-chamber bomb calorimeter: *1*) body, *2*) lid, *3*) valve, *4*) electrical lead, *5*) mixing device with break seal.

The most critical elements of fluorine bomb calorimeters are the seals and the locking devices. Hubbard and coworkers used simple gold[9] and aluminium[10] gaskets, or gold–Teflon gaskets[8], to seal the lids of their single-chamber bombs; Armstrong and coworkers[67] used Teflon seals. A single-chamber calorimetric bomb of 350 cm^3 capacity[32,33], made of Monel metal, is shown in Fig. 3. It relies on aluminium seals with Teflon-filled channels. We have also used Teflon seals designed on the self-tightening principle[78,79]. Various other effective sealing arrangements for fluorine bomb calorimeters have been described[78-81].

¶The calorimetric bombs are designed to be used in conjunction with the most widely used type of calorimetric system: the water calorimeter with an isothermal enclosure.

†We shall not attempt to describe the glass apparatus for fluorine calorimetry used by Gross and coworkers[2,13,15,35,36,41] because of its limited pressure range, difficult operating procedure, and liability to attack on the glass. Some other unusual approaches[17,63] will also be ignored.

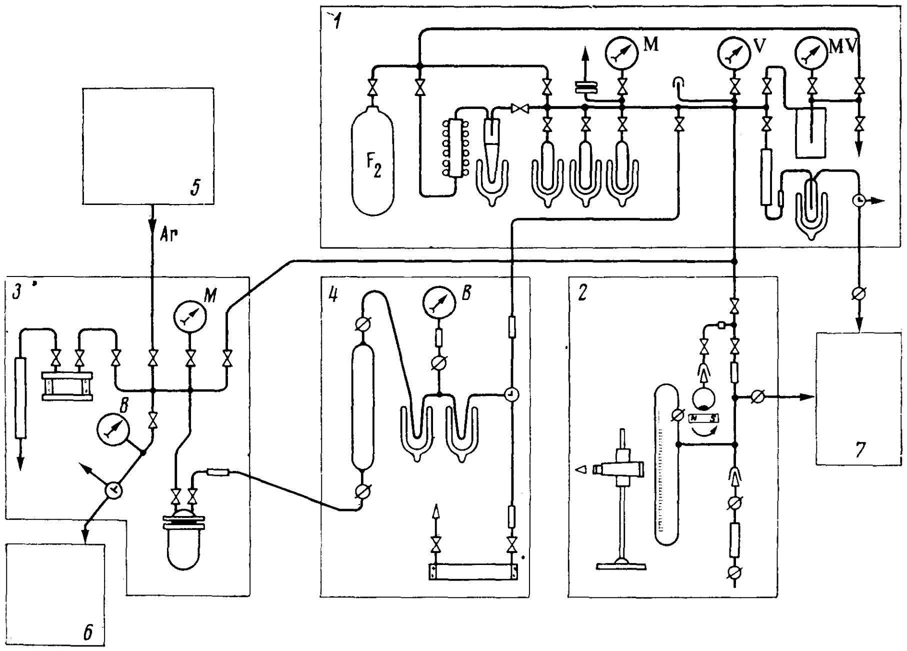

Figure 5. Fluorine handling apparatus for calorimetric work: *1*) purification and storage train, *2*) fluorine analysis, *3*) bomb filling assembly, *4*) assembly for collecting and separating the gaseous combustion products, *5*) argon purification, *6*) and *7*) backing pump and vacuum pump, M) manometer, V) vacuum gauge, MV) combined manometer and vacuum gauge.

As stated above, the possibility of spontaneous reaction can be a serious problem in calorimetric work with fluorine in a bomb. It may be necessary to prevent contact between the reactants until the beginning of the main period of the calorimetric experiment. The commonest solution of this problem is to use a two-chamber bomb. A widely used type of two-chamber bomb was designed by Hubbard and coworkers[82,83]; our own design (Fig. 4) is described in Ref. 79. The two-chamber bomb described by Barberi and coworkers[63] was not so successful. Alternative means of isolating the sample from the fluorine in a single-chamber bomb have also been proposed. Thus, Schröder and Sieben[6] measured the heats of combustion of tungsten pentafluoride and of elemental sulphur, which ignite spontaneously in fluorine, in a single-chamber bomb fitted with a nickel vessel and external means for opening and shutting the lid of this vessel. The weighed sample was placed in the nickel vessel, which remained filled with argon until the beginning of the main period. A similar device was used by Bisbee and coworkers[61,64] to measure the heat of the reaction between ClF_5 and hydrogen. A thin-walled Monel metal bulb, previously filled with ClF_5, was placed in the bomb and punctured with a special device, thus allowing the ClF_5 to react with the hydrogen filling of the main chamber.

Other methods, described in the following Section, use an auxiliary material (which does not react spontaneously with fluorine) to isolate the sample from the fluorine in a single-chamber bomb. The partition is ignited when contact between the sample and the fluorine is required.

Fig. 5 shows a typical assembly for handling fluorine in calorimetric work. It is more complicated than some other designs[3,68] because it includes all the necessary subsidiary facilities such as apparatus for purifying and storing the fluorine (*1*), for analysing the fluorine by the mercury method (*2*) including provisions for sampling the residual gases, for filling the bomb (*3*), and for sampling and separating the gaseous combustion products including provisions for duplicate analysis of the excess fluorine and for sampling gaseous fluorides (*4*). Facilities for purifying the argon used to purge the apparatus (*5*), and for producing a rough vacuum (*6*) and a high vacuum (*7*), are also shown. Items *1* and *3* are made of nickel, with stainless steel valves and taps. Items *2* and *4* are made of quartz and Pyrex glass. The glass vacuum joints are lubricated with a special perfluorinated grease.

We have already pointed out that corrosion of the apparatus and (particularly of the bomb) in fluorine can lead to major difficulties in high-precision measurements. The following precautions are taken to ensure that the results are not affected by side reaction of the construction materials with the fluorine or with the fluorides produced by the combustion. First, all the metal vessels and connecting tubes are tested under pressure, under vacuum, and they are then exposed for several days to fluorine at its working pressure‡. Furthermore, a number of "blank" combustions of the sample are carried out in the calorimetric bomb[31-34]. The products of these combustions are tested for the presence of products of any reactions between the fluorine and the bomb materials, the sample supports, and the passivating fluoride films which are formed on

---

‡Wise and coworkers[11] describe a method of passivating the calorimetric apparatus by heating it for several hours at 110° in the presence of fluorine at 1 atm pressure.

their surface[32,34]. The success of the passivating treatment is checked by separately weighing the internal components of the bomb[32].

Secondly, all operations (loading and unloading) with the passivated bomb are carried out in a "dry" box§ to avoid the danger of hydrolysis of the passivating fluoride film. The other parts of the apparatus are kept filled with dry argon after passivation[32]. Additional tests include check measurements of the water equivalent of the calorimetric system by calibration[85] before and after each series of experiments. Electrical calibration is preferred, but the combustion in oxygen of calorimetric standards such as benzoic acid is also acceptable[3,32,33].

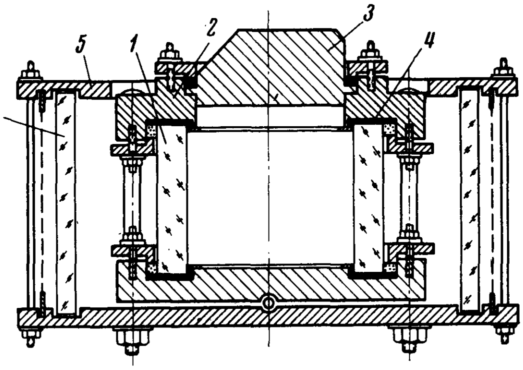

Figure 6. Glass bomb for experiments on the optimum conditions for fluorine combustion: *1*) glass body, *2* nickel flange, *3*) lid, *4*) seal, *5*) explosion guard.

A glass bomb for test combustions in fluorine is a valuable facility for auxiliary experiments aimed at selecting the best combustion conditions for the calorimetric bomb. The bomb (Fig. 6) has transparent walls through which the reactions in the chamber can be visually observed at fluorine pressures up to 10 atm. The apparatus was first used by Hubbard and coworkers[84]; our modification, shown in Fig. 6, was described in Ref. 78.

Special safety precautions are essential in all laboratory work involving liquid fluorine and gaseous fluorine under pressure. The danger of explosions and the high toxicity of fluorine and fluorides must be carefully considered in the design of the apparatus, the layout of the accommodation, and the choice of operating procedure[3,68,71,74,85].

V. COMBUSTION METHODS

The main consideration in the search for the optimum combustion conditions is the nature of the reaction between the sample and the fluorine. The geometry of the sample (assuming, of course that the sample is not gaseous) is of crucial importance. Hubbard[3] has made a special study of this problem, and has even suggested a classification of combustion methods based on sample geometry¶.

It can be seen from the Table that metals account for a significant proportion of the materials which have been investigated by this method. When metallic samples are burned in fluorine under bomb conditions the temperature can be high enough to melt the sample, at least partially. The effect depends markedly on the rate of reaction of the metal with fluorine. If the rate is high, and the resulting fluoride has a low boiling point (e.g. tungsten[6,31-33]), there is little danger of side reactions leading to analytical complications. On the other hand if the rate is relatively low, the thermal conductivity of the sample is high, and the resulting fluoride is involatile, the molten metal tends to break up into drops and to spatter, together with some of the fluoride formed by the reaction. This effect can have various undesirable consequences, particularly at the contact between the metal and the support. It can be avoided by diluting the fluoride with an inert gas so as to lower the temperature and the reaction rate.

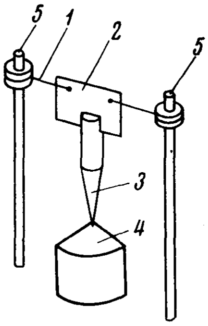

Figure 7. Combustion of metallic zirconium in fluorine: *1*) zirconium igniting wire, *2*) zirconium foil, *3*) pointed zirconium rod, *4*) massive nickel block.

Thus, in the first investigation by fluorine bomb calorimetry described by Hubbard and coworkers[8] the sample of zirconium metal (of the shape shown in Fig. 7) was burned from the top towards the bottom. The reaction stopped after ~75% of the sample had been burned, owing to the loss of heat to the massive nickel heat sink. Fusion of the zirconium was avoided by diluting the fluorine with helium (fluorine pressure 2000 mmHg, total pressure 12 atm). A similar method was used by Hubbard and coworkers in their calorimetric work with metallic uranium[16].

---

§However, it has been pointed out[11,37] that the water equivalent of the calorimetric system is practically unaffected by storing the passivated nickel bomb in ordinary air and by washing it in water.

¶There are, of course, other classifications, e.g. classifications according to the phase composition of the products (gaseous, fused, or solid), or according to the number of products (only the higher fluoride if the reactant is an element or a lower fluoride, but if the sample is more complex several products may be formed, and may have to be separated for analysis). Alternative methods of classification could be based on the use of auxiliary materials, on the ignition procedure, on the propensity to spontaneous reaction with fluorine, etc.

When metallic copper[33], zinc[21], cadmium[19], magnesium[22], or nickel[37] are burned in fluorine an acceptable rate of combustion is obtained only at temperatures in excess of the melting point of the metal. Several workers[19,21,22,24,26,37] have therefore been compelled to line the inner surface of the bomb and to use a substrate made from a fused fluoride of the metal under test. It was assumed that under these conditions no undesirable reactions can occur between the metal and the substrate in a fluorine atmosphere. However, oxygen evolution was observed in the bomb during the combustion of metallic nickel[37] in the presence of high pressures of fluorine (15–25 atm). Evidently the NiF_2 substrate still contained some nickel oxide in spite of having been carefully prepared by lengthy baking in HF and ClF_3. Side reactions with formation of copper monofluoride between molten copper and the CuF_2 substrate could not always be avoided in calorimetric combustions of metallic copper[33,86].

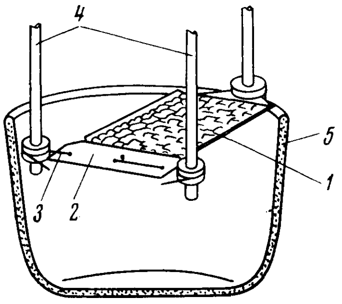

Figure 8. Combustion in fluorine of a copper sample with tungsten: *1*) copper sample (gauze), *2*) tungsten sheet, *3*) tungsten igniting wire, *4*) electrodes, *5*) fused alumina heat screen.

The possibility of forming lower fluorides and the difficulty of separating and analysing the combustion products can preclude the use of "inert" fluoride substrates. In these circumstances it is better to use an auxiliary material whose combustion can raise the temperature in the reaction zone. In this way the rate of the main reaction is increased, and the resulting fluorides are volatilised and condense on the cold walls of the bomb. Drop formation and spattering of the molten metal can be avoided by keeping the rate of fluorination high and the thermal conductivity of the sample low. Analysis and identification of the combustion products becomes much simpler if the conditions are chosen so that only gaseous products are formed in the combustion zone. Another important consideration is the possibility of working at much lower initial pressures of fluorine if an auxiliary material is introduced as an igniter.

We have used this procedure to measure the enthalpy of formation of CuF_2 by burning metallic copper in fluorine[33], and also in seeking the best conditions for the combustion of metallic nickel in fluorine. The type of copper sample[33] is illustrated in Fig. 8. The auxiliary material was metallic tungsten. The geometry of the sample ensures the maximum concentration of heat at the combustion front. Domalski and Armstrong used a similar method in their calorimetric combustions in fluorine of metallic aluminium[23], one of the boron carbides[52], and aluminium boride[48]. Their samples consisted of pressed disks of the powdered material (aluminium, aluminium borides, or boron carbide) mixed with powdered Teflon which they found to be a suitable igniter for these reactions[23,48,52].

Ill-defined reaction products, including lower fluorides, are occasionally obtained when some metals are burned in fluorine. As was pointed out above, this difficulty was encountered in our work on the combustion of copper[33]. In the determination of $\Delta H_f^\circ(UF_6, g)$ by the combustion of metallic uranium in fluoride[16] small amounts ($\sim$1%) of lower uranium fluorides were invariably produced in the bomb, requiring very accurate chemical analyses to enable the appropriate corrections to be calculated. Careful analyses of the solid "residues" of lower fluorides had to be made also in other investigations[10,29].

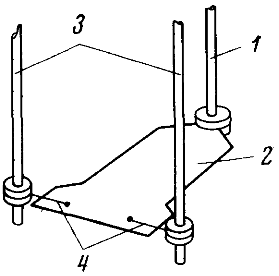

Figure 9. Combustion of a metallic tungsten sample in a fluorine bomb: *1*) holder, *2*) tungsten foil, *3*) electrodes, *4*) tungsten igniter wire.

In spite of these difficulties, it is often possible to choose a type of metal sample for combustion (foil, wire, or rod) which avoids or minimises the substrate problem. The geometry of the sample and the method of clamping the sample in the bomb are usually determined by the need to avoid direct contact between the combustion zone and the constructional materials (substrate, bomb fixtures). The design of tungsten foil sample shown in Fig. 9, used for calorimetric combustions at fluorine pressures up to 3 atm[32], satisfies all these requirements. The tungsten foil, 0.06 mm thick, can be burned completely without undesirable effects such as spattering or contamination of the combustion zone by falling fragments of the sample support.

When powdered samples are used for calorimetric combustion in a fluorine bomb they are usually contained in a simple nickel capsule or crucible. Contact between hot particles and the container material leads to local overheating and enhanced corrosion of the nickel. Various practical steps can be taken to minimise this effect. The burning rate of the particles can be decreased by diluting the fluorine with helium or argon, and by choosing the most appropriate particle size for the sample[11]. Alternatively, massive containers can be used to conduct the heat away from the reaction zone[50]. Occasionally it is possible to use a container material which avoids the danger of side reactions between the combustion products of the main sample and the passivating fluoride film of the constructional material. For example, Hubbard and coworkers[50] used a container of metallic zirconium in their study of zirconium diboride. Often the container material is chosen empirically. Containers of fused alumina or nickel had been found[11] to react with fluorine at the points of contact with a charge of crystalline boron powder. They were successfully replaced by a CaF_2 crucible. Combustible containers, which fulfil the role of igniter, have also been used[33,48,52].

A test for the absence of "premature" reaction between the sample and the fluorine is an essential part of the search for the optimum combustion conditions (unless of course the design of the bomb allows physical isolation of the two reactants). The test usually takes the form of repeated weighings of the sample after exposure to fluorine in the bomb at the working pressure. If the premature reaction is significant the simple test is followed by analytical determinations. Hubbard and coworkers burned metallic uranium[16], and niobium and tantalum[25], in a single-chamber bomb after determining the extent of the preliminary reaction with fluorine. They showed that this reaction (between uranium and fluorine) produces uranium tetrafluoride[16], and they were able to correct their calorimetric measurements accordingly.

We have already pointed out that the most effective and generally applicable precaution in the study of materials which ignite spontaneously in fluorine is to use a two-chamber bomb. The other methods of isolating the reactants mentioned in the previous Section are attempts at designing a "universal" bomb[6,64]. It is appropriate at this point to review the methods of isolating the reactants by using auxiliary materials as combustible partitions in one-chamber bombs. Thus, Margrave and coworkers[43,55] used a nickel vessel with a pressure-tight lid including a tungsten foil diaphragm. The vessel, containing a weighed amount of the sample, was filled with helium and inserted into the calorimetric bomb, which was filled with fluorine. At the beginning of the main period of the calorimetric experiment the foil was kindled with an igniter wire, thus allowing the fluorine to reach the sample. The review articles by Hubbard[3] and Armstrong[68] suggest the use of quartz bulbs[3] sealed by a small stopper of thin Teflon[68] or metal foil[3].

A number of conditions must be satisfied when auxiliary materials are used in calorimetric combustions in fluorine. The main condition is an appropriate choice of the auxiliary material itself. As well as being compatible with the chosen method of combustion, it must have an accurately known heat of combustion in fluorine. Also, its fluorination products should be inert towards the fluorination products of the main sample. The presence of an auxiliary material introduces additional measurement difficulties. In order to obtain accurate results the heat of combustion in fluorine of the auxiliary material must be determined in a separate series of experiments, using the same sample geometry and identical bomb conditions (initial fluorine pressure, amount of material, method of supporting the sample). These precautions ensure that the result is unaffected by impurities and by uncontrolled combustion conditions[23,33].

Preliminary measurements of the heat of combustion in fluorine of the auxiliary material were made in all the thermodynamic investigations listed in the Table which relied on an auxiliary material. Thus, Hubbard and coworkers measured the heat of combustion of sulphur in fluorine[5], and subsequently used this material to initiate the combustion of molybdenum and vanadium sulphides[44,56] and of niobium and tantalum borides[51] in a two-chamber bomb. Precise measurements of the heat of combustion of silicon in fluorine[18] enabled Hubbard and coworkers to use silicon as an initiator for graphite[39] and silica[18]. Armstrong and coworkers repeatedly measured the heat of combustion of Teflon in fluorine[23,38], and they used Teflon as the auxiliary material in their studies of the heat of combustion of aluminium, graphite, aluminium borides, etc.[23,38,48] Tests for possible interactions between the fluoride of the main sample and that of the auxiliary material are made by various methods, described below.

Other workers have used tungsten[33,43,55], sulphur[44,51,56,58], silicon[18,39], Teflon[23,38,48,55], phosphorus trifluoride[59], titanium[11], and molybdenum[12] as the auxiliary material. Tungsten, titanium, and molybdenum in the form of thin wires can be used to ignite samples by the electrical discharge method[11,12,33,43].

It is evident from the above discussion that the combustion of samples in fluorine in a calorimetric bomb can be carried out by very different procedures. The most important criterion for choosing the best combustion conditions is freedom from side reactions. Equally important is the provision of simple, reliable, and accurate methods of analysis of the bomb products.

It may be useful to dwell in some detail on some differences in the analytical techniques used to identify the products of combustion in fluorine. These differences arise mainly from the need to estimate the excess of fluorine and the gaseous products of the combustion in fluorine, as well as identifying any interactions with the bomb materials.

Analysis of the excess of fluorine involves the separation of the gaseous fluorides by low-temperature vacuum condensation. It has been shown[18,41,47,60,66] that the combustion of many oxides in a fluorine bomb produces the corresponding fluoride and oxygen; nitrogen is formed when nitrides[49,57] and some other nitrogenous compounds are burned (e.g. thiazyl trifluoride[59]). Most of the other elements burn with formation of higher fluorides. Thus the excess of fluorine may contain amounts of oxygen, nitrogen, and some fluorides (CF_4, BF_3, SF_6, etc.) corresponding to the stoichiometry of the reactions under study. Because the boiling points of these materials are not very different from that of fluorine we cannot expect complete separation by the low-temperature vacuum condensation method. The excess of fluorine may contain also additional amounts of oxygen, nitrogen, carbon tetrafluoride, etc. produced by the combustion in fluorine of impurities in the main sample. Hence a study of the composition of the residual gas after absorption of the fluorine in mercury is an essential analytical operation. For example, King and Armstrong[66] showed, by chromatographic separation of the components of the gaseous residue, that free oxygen is formed by the reaction between oxygen difluoride and hydrogen. I.r. and gas-chromatographic analyses of the residual gases enabled O'Hara and Hubbard to show[34] that phosphorus pentafluoride is the only product of the reaction between phosphorus and fluorine under calorimetric bomb conditions. Hubbard and coworkers[49] proved, by mass-spectrometric analysis of the gaseous residue, that free nitrogen and boron trifluoride are formed in the reaction between boron nitride and fluorine.

If the reaction under study gives rise to a mixture of volatile fluorides, which is invariably the case when auxiliary materials are used, the possibility of side reactions between the fluorides must be examined. This problem can also be solved by the analytical procedures described above. Special experiments are sometimes needed. Thus, the absence of interactions between boron trifluoride and tungsten hexafluoride during the combustion of tungsten borides in fluorine[58] was demonstrated by volumetric experiments with mixtures of these gases. Gross and coworkers[36] tested for interactions between phosphorus pentafluoride and boron trifluoride, in their work on the heat of formation of boron phosphide, by a series of calorimetric experiments in which equimolar mixtures of boron and phosphorus (and separate samples of boron and phosphorus) were burned in fluorine.

Gas chromatography is perhaps the most convenient method of analysis of the gaseous products of combustion in a calorimetric fluorine bomb (including the excess of fluorine)†.

The solid products of the reaction between the sample and fluorine can be analysed by chemical and X-ray diffraction methods[33,37]. Solid reaction products are separated from the unburned part of the sample by appropriate choice of combustion conditions. The extent of side reactions with the sample support materials is checked at the same time. If necessary, the results of these analyses are used to calculate corrections to be applied to the calorimetric measurement. The correction for attack on a nickel support has been specially discussed[34,58].

VI. CONCLUSIONS

The above discussion of the special features of reaction calorimetry in a fluorine bomb gives some insight into the aspects which must be considered before deciding to use this method in specific instances. The method is relatively complex and laborious, since it requires special experimental procedures and a large number of analytical checks. We have tried to make clear the extent to which thermochemically well defined conditions can be achieved in fluorine bomb calorimetry.

After applying the corrections for side reactions the calorimetric result is calculated by normal procedures[74]. However, there are some differences of detail in the calculation of the correction for standard conditions. Thus the determination of the Washburn corrections (for the change in internal energy of the system when converted to the standard conditions) can present some difficulty due to the lack of necessary data. A method of calculating the Washburn correction from the coefficient $(\partial E/\partial p)_g$ for fluorine and gas mixtures containing fluorine, measured in a separate experiment by Hirschfelder's method, has been described by Hubbard in detail[3]. Calculations of the correction for reactions with impurities in the sample usually assume that oxygen and nitrogen are evolved in the free state during combustion in fluorine. All other impurities are assumed to form higher fluorides[32,33,57].

When a double-chamber calorimetric bomb is used, the heat associated with the transfer of the fluorine into the combustion chamber has to be measured by a series of "blank" calorimetric experiments with a bomb containing the fluorine but not the main sample. The results are used to apply a correction to the calorimetric results of the main experiment[5,7,44,46].

One fundamental problem in the adoption of fluorine bomb calorimetry is the lack of a really satisfactory standard material. Calibration standards for combustion in fluorine should meet the following requirements[3]: their heat of combustion in fluorine should be reliably and accurately known, the combustion and analysis procedures should be simple and the reaction should be thermochemically well defined, there should be no side reactions with fluorine or with impurities in the fluorine, and lastly the material should be available in a high state of purity. We believe[33] that metallic tungsten satisfies all these requirements. The value $\Delta H^\circ_{f\,298\cdot15}(WF_6, g) = 411.4 \pm 0.2$ kcal mole^{-1} appears to be well established[32,33]. It agrees well with the results obtained in two other laboratories[6,31]. The procedure for burning tungsten in fluorine[32,33] is relatively simple (see Fig. 9): the only combustion product is gaseous tungsten hexafluoride, which can easily be separated from the excess of fluorine for subsequent analysis by vacuum condensation[31-33].

Standardisation of some of the auxiliary procedures (in particular, the fluorine analysis) would be desirable. Our procedure and apparatus[75], described in Section III, give accurate analytical results after a relatively simple purification of the fluorine, and can be recommended as the preferred method of fluorine analysis in calorimetric work. Our method of passivating the calorimetric bomb, and the operating conditions, can also be recommended. We also believe that the initial pressure of fluorine in the bomb should be as low as possible. We have shown that the maximum pressure of fluorine can be limited to 8–10 kg cm^{-2} even with samples of metallic copper and nickel, which can be classified as "difficult" because of their inertness towards fluorine. The tendency to use lower fluorine pressures is justified by the lower corrosion rate of the bomb materials in low-pressure fluorine.

This brief review suggests that the experimental problems encountered in the use of a fluorine bomb in reaction calorimetry have been solved to a large extent. More accurate and better standardised experimental approaches are needed to extend the range of applications of the method, which is still considered to be a laborious and specialised procedure, and to allow its advantages to be fully realised. It is clear from the results listed in the Table that although the stage of determining the heats of formation of simple fluorides is far from complete, there are already indications that the method can be applied to complex materials. Examples of the successful application of fluorine calorimetry in the study of compounds include the fluorine combustion of SiO_2, B_2O_3, and GeO_2, which provided the first reliable values of the enthalpy of formation of these compounds. The reaction with fluorine is the most convenient method of measuring $\Delta H^\circ_{f\,298}$ of several refractory compounds, especially borides and silicides, as well as the lower fluorides. We can expect the range of applications of fluorine calorimetry to continue to expand, and in future the method is likely to become one of the most widely used thermochemical procedures.

The Interaction of Organometallic Derivatives with Organic Halides

I.P.Beletskaya, G.A.Artamkina, and O.A.Reutov

The possible mechanisms of the reactions of organometallic derivatives with organic halides, including the metal-halogen and recombination (Wurtz) reactions, are examined. Particular attention is devoted to the analysis of the composition of the products and the stereochemistry of the reactions and to the results obtained using physicochemical methods. The bibliography includes 156 references.

CONTENTS

I. INTRODUCTION

The interaction of organometallic compounds RM with alkyl halides R′X is a complex process which may proceed as an exchange reaction (known for sodium, lithium, magnesium, and barium derivatives):

$$RM + R'X \rightarrow RX + R'M,$$

or as a recombination reaction (the well known Wurtz reaction involving RLi or RNa):

$$RM + R'X \rightarrow R{-}R',$$

accompanied by the formation of RR, R′R′, RH, R′H, R(−H), and R′(−H). The problem of its mechanism is still controversial and the possibility of heterolytic and radical pathways is being discussed.

A tendency has arisen in recent years to consider many reactions previously classified as nucleophilic or electrophilic substitution processes in terms of oxidation–reduction interactions. Within the framework of this concept, the interaction of a donor (nucleophile) and acceptor (electrophile) takes place as a result of electron transfer (*single electron transfer*, SET mechanism) and leads to the formation of radicals or radical-ions. There is no doubt that the objective cause of the development of this concept (and the reason why it has proved attractive) has been the appearance of physicochemical methods whereby one can detect the formation of radical-ion and radical species directly or indirectly the latter method includes chemically induced dynamic nuclear polarisation (CIDNP).

Naturally the attention of the supporters of this concept has been attracted primarily by organometallic compounds which can behave, by virtue of their high capacity for oxidation, as electron donors in relation to many organic and inorganic acceptors. The first attempts to consider certain reactions of organometallic derivatives with carbonyl compounds and alkyl halides from the standpoint of a radical mechanism were made as early as the beginning of this century on the basis of the composition of the observed products or the appearance of a colour in the reaction mixture, although the formation of "anomalous" products in many instances could be accounted for also within the framework of a heterolytic mechanism. However, the possibility of the simultaneous occurrence of reactions via several pathways was hardly ever considered, although the question of the possible change from an ionic to a radical mechanism frequently arose when the nature of the metal atom, the structure of the reactants, and the reaction conditions (primarily temperature and the solvent) were altered.

Attempts are now being made to unify the two mechanisms within the framework of the concept of single electron transfer (SET), as a result of which there is radical recombination with formation of RR′ (the classical Wurtz reaction) and the formation of products arising from the radicals R· and R′· liberated from the cage can occur.

From the standpoint of the SET mechanism, the general scheme for reactions of RM with R′X can be represented as follows:

$$RM + R'X \rightleftarrows \begin{bmatrix} R'^{\cdot} & X^{-} \\ R^{\cdot} & M^{+} \end{bmatrix} \longrightarrow \begin{cases} \xrightarrow{\;a\;} R{-}R' \\ \xrightarrow{\;b\;} R'M + RX \\ \xrightarrow{\;c\;} R'^{\cdot} + R^{\cdot} \end{cases} .$$

In this review we attempted to analyse all the mechanisms of both exchange and Wurtz reactions which are being discussed in the literature, without trying to cover the entire available data and all the synthetic aspects of these reactions. It was found that the simple SET mechanism cannot explain all the observed characteristics of the reaction between R′X and RM. This applies particularly to stereochemical data, since reactions of organometallic compounds with optically active halides, which lead not only to racemisation but also to inversion (in the Wurtz sense) and to racemisation with partial or complete retention of configuration (in the metal-halogen exchange reactions), are known.

II. REACTIONS WITH ORGANOMAGNESIUM COMPOUNDS

The first systematic study of the reactions of organomagnesium compounds with alkyl halides was apparently undertaken in 1913 by Späth[1], who proposed a radical mechanism, in contrast to Abegg's ionic mechanism[2]. In many cases the main reaction products were the hydrocarbons R_2, R'_2, R(–H), RH, etc., which had been previously regarded as side products, and not the mixed hydrocarbon RR′ (the product of the Wurtz reaction). It is interesting to note that the hydrocarbon RR′ was formed in a high yield when halogeno-derivatives of the allyl and benzyl types or derivatives with a tertiary group R were introduced into the reaction[1–4]. As will be shown below, the same effect is observed also in the corresponding reactions of organosodium and organolithium derivatives with yields of the hydrocarbon RR′ reaching 70–98%.[5–9] It is difficult to account for these results from the standpoint of a radical mechanism, since the extent of the liberation of the radicals from the cage should increase with increase of their stability. Indeed, when R = Ph_3C, a large amount of triphenylmethyl radicals of triphenylmethyl peroxide is always formed in the reaction[10–14]. For example, the yield of tetraphenylmethane in the reaction of Ph_3CCl with PhMgBr has been usually 0.5–5%[10] and the yield increased to 12% only under specially selected conditions (temperature, solvent, order of addition of reactants)†. The replacement of phenylmagnesium bromide by the corresponding iodide led to the formation of the triphenylmethyl radical and biphenyl alone (not even traces of Ph_4C were detected).[11] The yield of tetraphenylmethane in the reaction of PhMgBr with triphenylmethyl ethers Ph_3COR (R = Me, Et, or Ph) reached 10–12% for the first two groups and was more than 20% in the reaction with phenyl ether at 150°C. The last reaction occurred most readily, but the reduction of temperatures to about 35°C led to the formation of triphenylmethyl peroxide alone[10]. However, one should note that exceptionally high yields of Wurtz reaction products are formed even with triphenylmethyl halides when benzyl (or methyl) Grignard reagents are introduced into the reaction[1,2,15,16].

In certain early studies, the formation of R'_2 alone was observed when RMgX was allowed to react with R′X. Thus according to Schmidlin and Massini[17], the only product found in the reaction of phenylmagnesium bromide with β-chloromethylnaphthalene was symmetrical di-(β-naphthyl)ethane. A similar result was obtained by Fuson[18], who isolated the corresponding bibenzyl $(o\text{-}CNC_6H_4CH_2)_2$ after the reaction of methylmagnesium bromide with o-cyanobenzyl bromide. On this basis, he suggested that the Grignard reagent promotes the radical reaction of R′X.

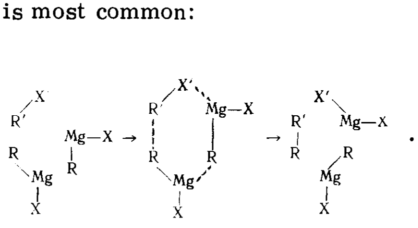
All the early studies suffered from one disadvantage—the lack of a complete analysis of the products and in the first place from the loss of volatile hydrocarbons. The first disadvantage was apparently overcome by Fuson[19], who analysed in detail the products of the reaction of MeMgI with benzyl halides (Hal = Cl, Br, or I) and showed that, apart from ethylbenzene and bibenzyl, which had been detected also by other investigators[1,4], ethane is formed in the reactions in equimolecular amounts with respect to bibenzyl. We may note that the yield of ethylbenzene decreased appreciably in the sequence $PhCH_2Cl > PhCH_2Br > PhCH_2I$ (by a factor of about 2.5 on passing from the chloride to the iodide); the amounts of ethane and bibenzyl increased under these conditions, albeit only slightly (to an extent of about 20%). These results can be accounted for from the standpoint of both the SET mechanism, i.e. by a change in the ease of rupture of the C–Hal bond in the above sequence and by the occurrence of two consecutive reactions—exchange and Wurtz reactions, since the possibility of the exchange processes also increases on passing from the chloride to the iodide. However, the author himself believed that the exchange reaction has no bearing on the formation of ethane, since he had shown for benzyl chloride that methyl chloride is absent from the reaction products:

$$PhCH_2Cl + CH_3MgI \rightarrow CH_3Cl + PhCH_2MgI,$$

and furthermore in the reaction of methyl iodide with CH_3MgI ethane is formed in a yield of only 21%:

$$CH_3I + CH_3MgI \rightarrow CH_3CH_3.$$

The possibility of a radical mechanism was considered by Gilman and Kirby[20], who observed that the reaction of diphenylmethylmagnesium bromide with dimethyl sulphate leads to the almost quantitative formation of tetraphenylethane. However, in their book dealing with organomagnesium compounds[21], Kharash and Reinmuth noted the possibility of a radical mechanism of the Wurtz reaction and expressed the view that this pathway probably occurs only rarely on the grounds that there is no statistical distribution of hydrocarbons in the reaction products (RR′, R_2, and R'_2) or the corresponding disproportionation products [RH, R(–H), R′H, and R′(–H)]. We may note that, from the standpoint of the SET mechanism, this argument appears unconvincing, since the ratio of the yield of recombination products and the extent of the liberation of radicals from the cage can vary within wide limits, depending on the stability of the radicals and the reaction conditions. As a second argument, Kharash and Reinmuth quote the fact that in real radical processes, which were believed to be the reactions of R′X and RMgX in the presence of transition metal salts, quite different products are formed. Finally, the main argument was the fairly high yields of the hydrocarbons RR′ observed for R = $PhCH_2$, $CH_2=CH-CH_2$, CH_3OCH_2, etc., i.e. in those reactions where fairly stable radicals should have been formed‡. Kharash suggested that there is no unique mechanism explaining all the observed instances of the reactions; he believed that the trimolecular "push-pull" mechanism is most common:



---

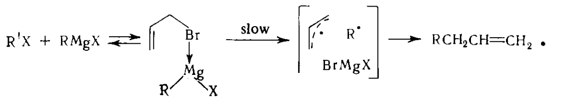
† Gilman and Jones[15] observed the formation of 47.7% of p-biphenylyldiphenylmethane (not detected by other workers), which undoubtedly confirms the presence of Ph· in the system.

‡ We may note that the absence of a β-hydrogen atom is a characteristic feature of all the groups enumerated as well as CH_3.

The view that, depending on the structure of the reactants and the conditions in the reaction, the mechanism of the latter may change, was questioned by Gough and Dixon[22], who investigated the kinetics of the reaction of allyl bromide with a series of organomagnesium compounds. In terms of their reactivity, the derivatives RMgX were arranged in the following sequence:

RMgX	PhMgBr	n-BuMgCl	s-BuMgCl	t-BuMgCl
$K_{\text{rel, 25°}}$	1	2.71	22.6	107

According to the authors, the observed sequence in which the reactivity varies and the applicability of the Taft equation with $\rho = -1.9$, the formation of 2,2,3,3-tetramethylbutane in the reaction with t-BuMgCl, and the ESR signal observed in the reaction with n-BuMgCl (although the yield of n-BuCH$_2$–CH=CH$_2$ was 90%) indicate the SET mechanism:



The conclusion that the reaction of phenylmagnesium iodide with iodobenzene has a radical mechanism was based on the detection of the label in the reaction product when deuterobenzene was used as a solvent (in admixture with ether).[23]

The composition of the products formed in the reactions of phenylmagnesium bromide and benzylmagnesium bromide with a series of arylalkyl chlorides is regarded[24] as proof of the SET mechanism, since, according to Gilman's data[15], exchange processes do not occur in these systems.

R'X	RMgX	Yield, % RR'	R'R'	RR	RH
PhCH$_2$Cl	PhMgBr	56	6	4	12
(Ph)$_2$CHCl	»	60	6	6	10
Ph$_3$CCl	»	46	5	4	10
Ph$_3$CCl	PhCH$_2$MgCl	55	5	15	—

The observed reactivity series Ph$_3$CCl > Ph$_2$CHCl > PhCH$_2$Cl, PhCH$_2$MgX > PhMgX, which is the same as the series based on the increasing stability of the groups R and R', is also consistent with the radical reaction mechanism. A similar mechanism has also been proposed[156] for the reaction of phenylmagnesium bromide with bromotriphenylmethane on the basis of the analysis of the composition of the products. When the reaction was carried out in ethyl ether, triphenylmethanol, triphenylmethane, biphenyl, ethylbenzene, and α-phenylethyl alcohol were detected in the reaction mixture, while in the presence of oxygen triphenylmethyl peroxide was found.

Finally, data confirming that alkyl radicals are formed even in the reactions of alkylmagnesium halides with "simple" alkyl halides have been obtained in recent years. This is indicated by data based on the CIDNP of the reaction products. Thus Ward et al.[25] observed CIDNP in the products of the reaction of t-butyl bromide with t-butylmagnesium chloride and of n-butyl iodide with n-butylmagnesium chloride in tetrahydrofuran (THF). The former reaction leads to the formation of isobutene (6%), isobutane (39%), and tetramethylbutane (6%), the vinyl protons of isobutene and but-1-ene and the methyl protons of isobutane being polarised, which suggests the formation of t-butyl and n-butyl radicals§.

CIDNP was likewise observed in the products of the reaction of diethylmagnesium with ethyl iodide and isopropyl iodide in THF.[26] The disproportionation products of the groups R and R' were mainly formed (ethane, ethylene, propane, and propene) with only a small amount of recombination products. The initial iodides were also polarised, which is associated, according to the authors, with a relay transfer of the radical in the chain process:

$$R'I + R^{\cdot} \rightarrow R'^{\cdot} + RI.$$

The authors believe that exchange processes can be hardly responsible for the observed polarisation of the halide, since in the reactions of iso-PrI with Et$_2$Mg the exchange process would have led to the formation of appreciable amounts of ethyl iodide, which was not observed under the conditions of the NMR experiment. However, the reaction of diethylmagnesium with iodobenzene occurred mainly as an exchange process:

$$\underset{}{Et_2Mg} + PhI \rightarrow \underset{72\%}{Ph_2Mg} + \underset{92\%}{EtI} + \underset{5\%}{PhH} + \underset{5\%}{PhEt},$$

The yield of ethylbenzene increased with time owing to the condensation of Ph$_2$Mg with EtI.

Ideas concerning the mechanism, including SET, of reactions involving ArHal (the Wurtz–Fittig reaction) have been put forward[27] on the basis of the detection by ESR of radical-anions in the reaction of phenylmagnesium bromide and phenyl-lithium with nitrosated halogenobenzenes.

When the results of the reactions are considered from the standpoint of the SET mechanism, then evidently the ratio of the radical recombination products and products arising as a result of the liberation of radicals from the cage should depend on the structure of the radical and also on the stabilities of the individual components of the radical-ion pair. For example, the reaction of 1-adamantyl bromide with a series of organomagnesium compounds RMgX can be analysed from this standpoint[28]. For R = Me, the Wurtz reaction was achieved with an 83% yield, but the latter fell sharply for R = PhCH$_2$ and became zero for R = t-Bu, where adamantane was formed in 84% yield. However, there exists an alternative explanation, which Osawa et al. in fact believe to be valid[28], namely that the reaction mechanism changes when the group R in RMgX alters.

---

§ The recently published study by Ward and coworkers[155] suggests that even a small admixture of transition metals present in magnesium can alter significantly the nature of the reaction of RMgX with R'X and can stimulate the development of a radical reaction pathway. The authors showed that the rate of reaction of iso-PrMgBr with iso-PrBr, leading to propane and propene, increases sharply following the addition of bromine, the effect being more marked when less pure magnesium (99.9 instead of 99.998%) is used; a considerable polarisation of the reaction products was observed at the same time. It is suggested that the process is catalysed by an oxidised form of the metal, for example the metal oxidised by the halogen present in R'X. We may note that in this version we are dealing with a Kharash reaction and not a Wurtz reaction. However, it is still not clear to what extent such admixtures can distort the results discussed above.

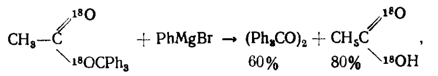
It is interesting that monobromonorcarane was obtained in high yield in the reaction of 7,7-dibromonorcarane with methylmagnesium bromide in THF,[29] which makes it possible to employ RMgX in such systems as a reducing agent for preparative purposes.

It is appropriate to mention here the reaction of organomagnesium compounds RMgBr (R = Ph, $PhCH_2$, or n-Bu) with (trichloromethyl)carbinyltoluene-*p*-sulphonates $\mathrm{R'-\underset{\underset{OTos}{|}}{C}HCCl_3}$ (R' = Alk or Ar) in ether, for which a free radical mechanism has been proposed[30]. The reaction results in a mixture of products, the composition of which in each specific case depends on the nature of RMgBr and the toluene-*p*-sulphonate derivative. For example, when R = R' = Ph, the products are *ββ'*-dichlorostyrene (78%), benzene (64%), styrene (42%), and ethyl *α*-phenylethyl ether (13%). In the presence of benzylmagnesium bromide, the corresponding ether was not detected, but bibenzyl was formed in a quantitative yield. The authors believe that the first reaction stage involves electron transfer:

$$\mathrm{RMgBr + R'\underset{\underset{OTos}{|}}{C}HCCl_3 \rightarrow R^{\cdot} + R'\underset{\underset{OTos}{|}}{C}H\dot{C}Cl_2 + MgBrCl + TosMgCl.}$$

All the products detected have been accounted for by further reactions of the above radicals (including their reactions with ether). The formation in the initial reaction step of the radical $R'CHCCl_3$ appears to be no less likely and its further reactions (together with those of R·) should naturally lead to the same composition of the products.

A mechanism including a reaction transfer stage has also been proposed for the reaction of phenylmagnesium bromide with triphenylmethyl acetate in ether, which proceeds in an unusual manner[31]. The use of acetate labelled with ^{18}O shows that the entire label passes to acetic acid:



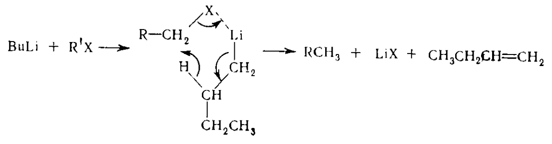
i.e. the reaction takes place with dissociation of the $O-CPh_3$ bond. Apart from trityl peroxide and acetic acid, acetophenone (14%), benzophenone (12%), triphenylmethane (23%), biphenyl (23%), and triphenylmethanol (about 5%) were detected in the reaction products.

III. REACTIONS WITH ORGANOSODIUM AND ORGANOLITHIUM COMPOUNDS

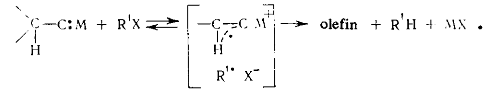
Ideas concerning the mechanism of the classical Wurtz reaction between RNa or RLi and R'X have undergone approximately the same development. In 1927 Marvell et al.,[32] who investigated the reaction of butyl-lithium with a wide variety of halogeno-derivatives, showed that the yield of RR' varies within very wide limits as a function of the nature of R'X. In many cases hydrocarbons of the type R'R' were isolated together with RR'. Thus *trans*, *trans*-1,4-diphenylbuta-1,3-diene was obtained together with 1-phenylhex-1-ene in the reaction involving *α*-bromostyrene. The authors showed that it is formed from the radical $PhCH{=}\dot{C}H_2$ and not as a result of exchange and subsequent recombination processes. This conclusion is based on the fact that the reaction with almost all the R'X was accompanied by the appearance of a colour (particularly pronounced for *α*-bromostyrene and chlorotriphenylmethane), which disappeared at the end of the reaction. The reaction of Ph_3CCl led to the formation of triphenylmethyl peroxide together with 1,1,1-triphenylpentane. An unexpected result, which is difficult to account for by differences in the structures of the R'X, was obtained in the reaction of butyl-lithium with isomeric bromotoluenes. For *p*-$BrC_6H_4CH_3$, the product of the Wurtz reaction was obtained in 76% yield, while the *m*- and *o*-isomers give almost quantitative yields of toluene.

We may note that, in the early studies on the Wurtz reaction as well as in the studies published much later than the investigation described above, the formation of products of the disproportionation of RH, R'H, R(–H), R'(–H), and (or) the symmetrical hydrocarbons R'_2 and R_2 was frequently observed together with that of the recombination product RR', but the possibility of a radical mechanism was either not discussed or was frequently ruled out on *a priori* grounds. For example, Morton et al.[33] stated that all the recombination and disproportionation products in the reactions of R'X with RNa can be explained without resorting to the hypothesis of the existence of radicals (although they did not rule out completely the possibility of a free radical pathway). Incidentally the conclusion that the hydrocarbons RH and R(–H) are not formed as a result of the disproportionation of radicals was based on the finding that in the reactions investigated the yield of RH as a rule greatly exceeded the yield of R(–H). Many other investigators also hold the view that the Wurtz reaction has an ionic mechanism (see, for example, Refs. 7 and 34–38). The stereochemical data discussed below constitute an important argument in this connection.

Defending the ionic reaction mechanism, Eastham and Gibson[39], wrote that the formation of the alkane RH and the alkene R(–H) does not by itself demonstrate the existence of the radical R·, i.e. it is the result of the hydride reduction of R'X by the *β*-hydrogen atom of the RM molecule and not of the disproportionation of the radical. In the reaction of butyl-lithium with 2-bromo-octane in hexane, which they investigated, octane (66%) and dodecane (32%) are formed, while in the reaction with bromocyclohexane the products are cyclohexane (56%), butylcyclohexane (32%), and cyclohexene (5%). Under these conditions, other halogeno-derivatives—1- and 2-chloro-octanes, 1-chloroisopentane, 4-chloroheptane, and fluoro- and chloro-cyclohexanes—were also reduced to alkanes. Using butyl-lithium labelled with tritium in the *β*-position, the authors obtained tritiated cyclohexane, which enabled them to suggest a mechanism for the reduction of halogeno-derivatives by the *β*-hydride atom of butyl-lithium:

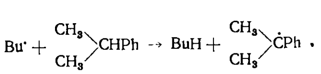


However, from our point of view, the hydride shift can also occur as a multistage process including an electron transfer stage:



This conclusion was based on the observation of the CIDNP of the methine proton of triphenylmethane in the reaction of Ph_3CX (X = Cl, Br, or ClO_4) with di-n-butyl or di-s-butyl-mercury and also with triethylsilane. In this case the results do not rule out the SET mechanism, which we believe can be invoked to account for the ease of reduction by metal hydrides of the C–Hal bond involving a bridgehead halogen[41]. We may note that Jefford et al.[41] assume that the reaction takes place as a result of cationoid abstraction of the halogen and the protonation of the resulting carbanion by the solvent.

Some evidence for the formation of radicals in the Wurtz reaction was obtained by Bryce-Smith[42]. He used cumene as a trap for the butyl radical formed in the reaction of the butyl derivatives of lithium and sodium with butyl halides:

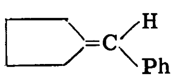


$$Bu^{\cdot} + (CH_3)_2CHPh \rightarrow BuH + (CH_3)_2\dot{C}Ph \ .$$

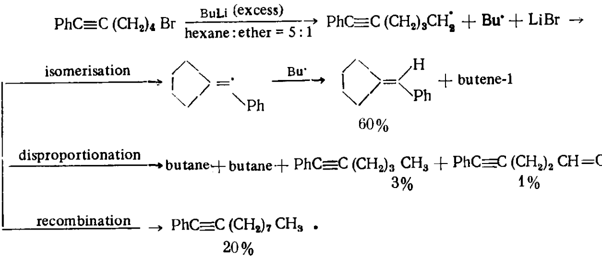
The resulting radical then dimerises to 2,3-dimethyl-2,3-diphenylbutane.

Sauer and Braig[9] also considered electron transfer as the first stage of the Wurtz reaction and showed that the reaction of 2-bromo-octane with allyl-lithium in ethyl ether or TMF (at 0°C) gives an 87–95% yield of the corresponding hydrocarbon RR′ and only trace amounts of octane, octene, and 7,8-dimethyltetradecane. The addition of cumene has no influence on the reaction. However, the interaction of the same bromide with ethyl- or n-propyl-lithium (at 0° or 35°C) leads to the formation of a mixture of the hydrocarbons R′H, R′(–H), RR′, and R′R′ in the proportions (0.6–0.9) : (0.6–0.9) : 1.0 : (0.5–0.6). When cumene is added, about 8% of bicumenyl is formed. According to the authors[9], the products detected are formed via the recombination or disproportionation of the radicals $R^{\cdot}$ and $R'^{\cdot}$ arising in the primary reaction step.

The possibility of a radical mechanism sometimes assumes special interest, for example in the reaction of $PhC{\equiv}C(CH_2)_4Br$ with BuLi, which leads to the cyclisation product[43,44]



Kandil and Dessy[43] suggested that it is formed as a result of the anionic cyclisation of the corresponding organolithium compound $PhC{\equiv}C(CH_2)_4Li$, arising in the exchange reaction. Ward[44] adduces convincing data in support of a radical mechanism of the cyclisation reaction:



Similar results have been obtained with ethyl- and t-butyl-lithium.

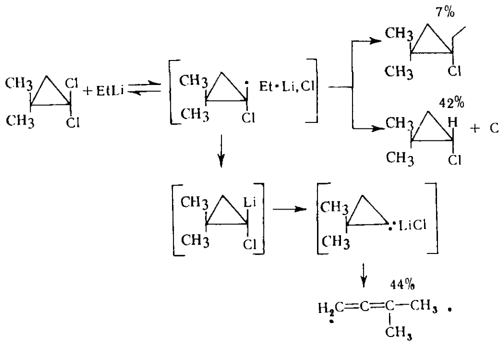
Direct detection of radicals by ESR in the reaction of ethyl-lithium with chlorotriphenylmethane was achieved by Shilov et al.[45] The concentration of triphenylmethyl radicals exceeded the equilibrium value, which undoubtedly indicated an SET mechanism. Ethane and ethylene were formed from methyl radicals; however, the absence of deuterium from ethane when the reaction was carried out in a deuteriated solvent forced the authors to assume that the ethyl radicals do not exist as kinetically independent species and that a complex with EtLi is formed in which disproportionation takes place. Ward[46] believes that there is a relation between the complex formation process and the state of aggregation of the organolithium compounds in solution.

Proof of the formation of radicals in the primary reaction step was obtained for simple alkyl halides by D'yachkovskii and Shilov[47] in a study of the reaction of ethyl-lithium with ethyl iodide, the products of which were ethane, ethylene, and butane, ethylene being formed according to the authors on disproportionation of the radical $R^{\cdot}$ in the cage. The relative yield of ethane decreased when the reaction was carried out in decalin with added anthracene and also in benzene and toluene, which are known to be capable of interacting with alkyl radicals. The relative yield of ethane falls even more when α-methyl-styrene is added to decalin (by a factor of ten compared with the yield of ethane in pure decalin). When experiments in deuteriated solvents were carried out, monodeuteroethane was detected: 2.3% in C_6D_6, 3% in C_6D_{12}, and 5.6% in $C_6D_5CD_3$.

A radical mechanism may also be considered for the exchange reaction between RLi and R′X. The exchange reactions of PhI with RLi, where R = alkyl, cycloalkyl, alkenyl, or aryl, have been used by Applequist and O'Brien[48] to estimate the relative stabilities of various compounds RLi (i.e. the stabilities of the carbanions), and data for the equilibrium positions in the system served as a basis for a method of determining the pK_a values for CH acids[49]. It has been suggested that the reaction is electrophilic. According to Wittig[50], the main argument has been the ease of carrying out this reaction with bromo-derivatives of bicyclic compounds containing bridgehead bromine, for example bromotriptycene, for which S_N2 and S_N1 reactions are hindered or even impossible. According to Wittig, the electrophilic attack is preceded by the nucleophilic attack of R^- on the bromine, which then expands its electron shell to a decet. Other investigators[51] also support the view that the exchange processes are heterolytic. However, the ease of exchange in such systems does not conflict with a radical mechanism, including SET, either.

Evidence for the radical mechanism of the exchange reaction was obtained with the aid of CIDNP studies[52–57]. Thus Ward and Lawler[52] observed the polarisation of protons in the but-1-ene and isobutene formed in the reaction of n-butyl-lithium and t-butyl-lithium with butyl bromide in hexane. The octane formed is probably also polarised, but the observation of the polarisation is hindered by the superposition of the signal due to the solvent and the reactants. In the almost "pure" exchange reaction between ethyl-lithium and iodobenzene[53] the methylene proton of the ethyl iodide formed in 80% yield are polarised. Similar results were obtained in a study of the reaction of ethyl iodide with ethyl-lithium (in benzene at 40°C), where the polarisation of the methyl and methylene protons of the ethyl iodide formed in the course of the exchange was observed[53]. Both iodides (s-BuI and n-BuI) were polarised in the reaction of n-BuLi with n-butyl iodide in consequence of the reversibility of the reaction. A similar situation was observed in the converse exchange reaction—the reaction of s-butyl-lithium with n-butyl iodide[53]—and in the reaction of n-butyl-lithium with n-butyl iodide and isopropyl iodide, where the vinyl protons of propene and but-1-ene were found to be polarised[54]. We may note that the polarisation of the protons in the molecule of the organolithium compound has not been observed in any of the reactions, in agreement with the data of

Shilov et al.,[45] showing the absence of ethyl radicals in the reaction of ethyl-lithium with chlorotriphenylmethane. Positive CIDNP has been observed in the products of the reaction of ethyl-lithium with 1,1-dichloro-2,2-dimethylcyclopropane[58], i.e. in 3-methylbuta-1,2-diene and 1-chloro-2,2-dimethylpropane.



Several instances of the observation of CIDNP in the products (RR′) of the Wurtz reaction proper, for example in the reaction of ethyl-lithium with *αα*′-dichlorotoluene[59], are known. This example is of interest, because it has been used to demonstrate the dependence of the observed polarisation of *α*-chloro-*α*-phenylpropane on the applied magnetic field. Polarised ethane was formed in the reaction of ethyl iodide with sodium in dimethoxyethane (DME), which enabled the authors[60] to treat the reaction of CH_3I with CH_3Na as a radical process; however, the polarisation of cyclobutane in the analogous reaction of 1,4-diiodobutane with sodium could not be observed.

The CIDNP of ^{19}F has been observed in the products of the reaction of n-butyl-lithium with *p*-fluorobenzyl chloride[56,57] and pentafluorobenzyl chloride[57]; in both cases, the reaction products are the corresponding symmetrical diphenylethanes and phenylpentanes (the product ratio $R'_2 : RR' = 1:5$ for the former reaction and 1 : 6 for the latter, as shown by the NMR spectra); intense polarisation was observed for both products[56]. The *p*-nitrobenzyl radical has been detected in the reaction of BuLi with *p*-$NO_2C_6H_4CH_2Cl$.[57]

A not altogether comprehensible result was obtained in a study by Ward[46], who showed that there is no polarisation in the exchange reaction in the t-BuLi–n-BuLi system at −70°C, but on raising the temperature CIDNP is observed in the recombination and disproportionation products. However, in the EtLi–iso-PrI system at 40°C both iodides (EtI and iso-PrI) are polarised, undoubtedly due to the exchange process, which Ward treats as the interaction of R· and R′I, in conformity with Russell's mechanism (see below).

The observation of the polarisation of all the products formed in the reaction of RLi with R′X (the metal–halogen exchange, the "normal" Wurtz reaction, and the formation of radical disproportionation products) makes it possible to describe all these processes in terms of the SET mechanism.

Russell[61], who succeeded in showing that one electron transfer may occur in the Wurtz and exchange reactions even when the yield of RR′ is fairly high, attributes a general significance to this mechanism. In a study of the reaction of RLi with R′X by ESR using a flow system, whereby detection approximately 0.03 s after mixing the reactants is possible, Russell obtained direct proof of the primary formation of radicals. In the reactions of n-butyl-lithium with R′I (R′ = Et, n-Pr, n-Bu, n-Oct, or t-Bu), only the R′· radicals, which arise before the metal–halogen exchange takes place, i.e. from the iodide molecule, were observed. However, the spectra of certain bromides and $PhCH_2Cl$ revealed only the signal of the n-butyl radical, while both possible radicals were found in the reaction of s-BuLi with EtBr and of n-BuLi with CH_3I.

According to Russell, the results agree best with the following mechanism

$$RM + R'X \xrightarrow{k_1} R^{\cdot} + R'^{\cdot} + MX; \qquad (1)$$

$$R^{\cdot} + R'X \xrightarrow{k_2} RX + R'^{\cdot}; \qquad (2)$$

$$R'^{\cdot} + RLi \xrightarrow{k_3} R'Li + R^{\cdot}; \qquad (3)$$

$$R'^{\cdot} + R^{\cdot} \xrightarrow{k_4} \text{alkanes and alkenes.} \qquad (4)$$

The particular radical detected in the spectrum depends on the rates of stages (2) and (3). On the other hand, the rates are naturally determined by the nature of the radicals R· and R′· and the anion X^-. For iodides (R = Bu and R′ = Et or Pr), the rate of stage (2) exceeds that of stage (3) and the radicals R′· have been observed. When $X^- = Br^-$ or Cl^-, the rate of this stage diminishes and only R· or a mixture of R· and R′·¶ ($k_2 \simeq k_3$) is observed. For allyl bromide, the spectrum reveals the presence of allyl radicals only. Russell states that reactions (2) and (3) constitute the possible mechanism of the metal–halogen exchange. However, he does not rule out the possibility of some contribution by the heterolytic process in such reactions.

It is seen from the examples quoted that the composition of the products formed depends on the nature of R, R′, X, and M. The result is determined to a significant extent by the nature of the solvent. In the study of Eastham and Gibson[39] already mentioned, it was shown that in a non-polar medium (hexane) butyl-lithium reacts with R′X via a hydride reduction mechanism, while in ether the usual Wurtz reaction takes place. The change in the mode of reaction as a function of the nature of the solvent has been illustrated[63] by a study of the reaction of butyl-lithium with benzyl chloride. In hexane and ether, the authors observed the formation of n-alkylbenzene and bibenzyl, while in THF *trans*-stilbene was found (20%). A significantly higher yield of the dimerisation products RR′ in the Wurtz reaction has been observed in benzene in relation to ether[64]. However, an increase in solvent polarity usually leads to an increase of the yield of the Wurtz reaction product. Thus it has been shown in a recently published study[65] that in the hexane : THF = 1 : 5 mixture the reaction of n-butyl-lithium and n-octyl-lithium gives satisfactory yields of the hydrocarbons RR′ even with aryl halides.

¶ The problem of the mechanism of the reaction between R and R′X can also be treated from different standpoints: as an S_N2 reaction involving the halogen atom or as the reduction reaction

$$R^{\cdot} + R'X \longrightarrow R^{+} + (R'X)^{\overset{\cdot}{-}} \longrightarrow RX + R'^{\cdot},$$

which naturally proceeds more readily with iodides. The results agree with those of Evans and Szwarz[62], who showed that the methyl radical abstracts the halogen from MeI 7 × 10^3 faster than from MeBr. This also applies to the reaction of R′· with RLi.

By tradition it has come to be accepted that an increase in the polarity of the C–M bond under the influence of the solvent facilitates the heterolytic process, which is indicated by the increase of the yield of RR′, and that the radical mechanism can be replaced by a heterolytic mechanism under the influence of the solvent[45,66–68]. Thus a detailed study has been made[66] of the reaction of butylmagnesium iodide with R′X in cumene or in higher alkanes and it has been shown that the hydrocarbons RH, R′H, R(–H), and R′(–H) are formed in all cases, while in cumene the formation of appreciable amounts of bicumenyl is observed in addition. On passing to DME, the situation changes sharply. The simplest RMgX and R′X readily enter into the "normal" Wurtz reaction in DME, although even in ether this reaction is not at all characteristic of these substances. The authors believe that, on passing from hydrocarbon solvents to DME, the mechanism of the reactions of organomagnesium compounds with R′X changes from radical to heterolytic.

Here one should note that the exchange reaction R′X + RM → R′M + RX, which is well known for the more reactive organolithium compounds, is believed to be generally atypical in the series of organomagnesium compounds and takes place only when the difference between the electronegativities of the groups R and R′ is large[21]. However, in strongly solvating solvents such radical exchange does occur also for the simplest alkyl or aryl-magnesium halides and alkyl halides[67]. For example, the degree of exchange in the reaction of n-$C_5H_{11}MgBr$ with CH_3I varies from 5.7% (1 h, 0°C, in ether) to 38% in DME. Since the ease of exchange increases with increase of the solvating capacity of the solvent, the authors treat this reaction as heterolytic. However, one cannot rule out the possibility that not only the amount of ionic character of the C–M bond but also the ability of the organometallic compounds to behave as an electron donor is altered by the solvent. From the standpoint of the unified SET mechanism, the influence of the solvent on the composition of the products (but not on the rate of reaction) should be manifested as a result of a change in the nature of the "cage" enclosing the radical-ion pairs formed and not as a result of the change in the nature of the dissociation of the C–M bond. Unfortunately, nothing is as yet known about the nature of this cage and about its influence on the stability of the radical-ion pair.

Thus, in recent years, particularly after the publication of CIDNP data and Russell's study[61] concerning the detection of radicals in the reactions of simple alkyl halides with alkyl-lithium, there has been a tendency to treat the exchange and Wurtz reactions from the standpoint of the radical mechanism. However, we believe that the conclusion that there is a single mechanism for all the processes involving the SET stage may prove to be premature. We have been led to this conclusion mainly by analysis of stereochemical data.

IV. STEREOCHEMISTRY OF THE EXCHANGE AND WURTZ REACTIONS

In the first place we shall consider the results obtained in the study of the stereochemistry of the exchange reactions. Unfortunately the stereochemistry of such processes, occurring at a tetrahedral unstrained carbon atom, has been hardly investigated. The only available stereochemical result for reactions of this kind is apparently the partial retention of configuration found by Letsinger in the s-butyl-lithium–optically active 2-iodo-octane system[69]. Only when the reaction was carried out at −70°C (in a petroleum ether–ethyl ether mixture) was the author[69] able to obtain the optically active 2-lithio-octane, but its activity was lost on raising the temperature to 0°C (after carboxylation, the acid proved to be fully racemic).

One cannot rule out the possibility that the racemisation of the organometallic compounds formed in the metal–halogen exchange in fact accounts for the formation of the racemic products RR′ in the reactions of R′Hal with simple alkyl derivatives of metals (see below), particularly if one bears in mind that the reactions are frequently carried out at fairly high temperatures (0°C and above). For example, Wittig[70] obtained virtually inactive 2,3-diphenylbutane in the reaction of the optically active α-bromoethylbenzene with phenyl-lithium in ether and explained its formation by the exchange reaction of the bromide with PhLi and the subsequent Wurtz reaction between  $\mathrm{Ph{-}\underset{\underset{\textstyle Li}{|}}{C}HCH_3}$ and $PhCH(Br)CH_3$. Thus, in principle, the reaction can take place with retention of configuration. The possibility of the retention of configuration in the metal–halogen exchange reaction has been confirmed also by the finding that the exchange takes place readily between 1-bromotriptycene and butyl-lithium (with formation of 1-lithiotriptycene)[50], i.e. in the system where the retention of configuration is predetermined by the structure of R′X and where processes of the S_N2 type, occurring with retention of configuration, are impossible.

The organolithium derivatives of the vinyl and cyclopropyl series are more stable, so that the stereochemistry of the metal–halogen exchange in such cases has naturally been investigated in greater detail. The organolithium compounds were not isolated or a configuration assigned in any instant and the stereochemical course of the reaction was inferred from the configuration of their conversion products, for example after carboxylation, Li–H exchange, the cleavage of $HgCl_2$, I_2, or Br_2, etc. (it is assumed that all these reactions are of the S_N2 type and take place with retention of configuration). Thus investigations have shown that all the reactions investigated take place with retention of configuration (Table 1), which is evidence against the involvement of free radicals in the exchange reactions. The retention of configuration in the exchange reactions of the *cis*- and *trans*-isomers of the cyclohexyl derivatives of lithium with methyl iodide and bromobenzene[71] also supports these conclusions.

We shall now consider the stereochemical data available for the Wurtz reactions involving organosodium, organolithium, and organomagnesium compounds. The results are compiled in Tables 2–4. The principal stereochemical results in Tables 2–4 may be summarised as follows. The reactions of organosodium and organolithium derivatives of the benzyl and allyl type with R′X proceed with preferential and sometimes complete inversion of configuration. However, in the reactions of the corresponding organomagnesium compounds, the percentage racemisation increases appreciably. On the other hand, the interaction of simple alkyl derivatives of sodium and lithium with RX′ results in racemisation, the only exception apparently being the reaction of lithium diphenyl cuprate with s-butyl bromide, which takes place with inversion of configuration to the extent of 84–92%†.[81]

---

† Naturally the mechanisms of the reactions of Ph_2CuLi and simple RLi and RNa with R′X are the same.

From general considerations, the stereochemical results of radical reactions presumably involve racemisation, possibly with partial retention of configuration. The retention of configuration under these conditions may be due to the recombination of radicals in the cage or the presence of a barrier to inversion. Only in the case of a stable radical, with a fairly high inversion barrier, can one expect the preferential retention of configuration. This probably actually accounts for the observed retention of configuration in the reaction of bromo-derivatives of the vinyl series with lithium dimethyl- or diphenyl-cuprates[81,82].

Table 1. Stereochemical results of the reactions of RLi with R'X.

RLi	R'X	Stereochemical result	References
s-BuLi	2-IC_8H_{17}	20% retention, 80% racemisation	69
n-BuLi	*cis-* and *trans-*  $p\text{-}ClC_6H_4(Ph)C{=}C(Br)Ph$	retention	72
»	*cis-* and *trans-* $PhCH{=}C(Br)Ph$	retention	73, 74
»	*cis-* and *trans-* 	retention	75
	cis- and *trans*	retention	76
»			
»			
	CH_3I	90% retention	71
	PhBr	85% retention	71
			

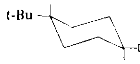


Table 2. Stereochemical results of the reactions of RNa with R'X.

RNa	R'X	Yield of RR', %	Stereochemical result	References
C_2H_5Na	2-BrC_8H_{17}	25	90% racemisation	35
n-C_4H_9Na		35	total racemisation	36
2-NaC_8H_{17}		—	ditto	37
s-C_4H_9Na	s-C_4H_9Br	—	"	37
C_2H_5Na	2-ClC_8H_{17}	—	inversion, 20% racemisation	77
2-NaC_8H_{17}	»	—	partial inversion, exact assignment of configuration unavailable	37
Ph_2CHNa	$PhCH(Cl)CH_3$	—	exact assignment unavailable, but only slight racemisation observed	78
$PhCH_2Na$	s-C_4H_9Br	65—69	74% inversion, 26% racemisation	5
»	2-BrC_8H_{17}	80	70% inversion, 30% racemisation	5
$CH_2{=}CHCH_2Na$	»	83	79-81% inversion, 13-21% racemisation	6
»	$PhCH(Cl)CH_3$	—	inversion (exact assignment unavailable)	79
$NaCH(COOEt)_2$	2-BrC_8H_{17}	—	inversion	34

Naturally the inversion of configuration cannot be interpreted from the standpoint of the radical mechanism. For this purpose, one would have to postulate the occurrence of S_N2 reactions which would result in inversion of configuration and which would include attack by $R^{\cdot}$ on the carbon atom:

$$R^{\cdot} + R'X \rightarrow RR' + X^{\cdot}.$$

Table 3. Stereochemical results of the reactions of RLi with R'X and of R_2CuLi with R'X.

RLi or R_2CuLi	R'X	Yield of RR', %	Stereochemical result	References
n-C_4H_9Li	s-C_4H_9Br	37	98% racemisation	80

	s-C_4H_9Br	30% (I)* 12% (II)	100% inversion	85

* (I) —  ; (II) — 
Furthermore, it is known[79] that such processes involve as a rule terminal atoms [Hal, M(I)]:

$$R^{\cdot} + R'X \rightarrow RX + R'^{\cdot}.$$

This stereochemical result of the reactions of RNa with R'X in fact forced Le Goff et al.[34] to conclude as early as

1958 that "there is almost no doubt about the ionic mechanism of the reaction".

Another stereochemical result, namely racemisation, which has been observed for many reactions of RLi and RNa with **R'X**, can be interpreted fairly simply by the radical mechanism. However, in this case there is a possibility also of an alternative explanation associated with the occurrence of metal–halogen exchange processes. One may suppose that the exchange processes involving simple alkyl derivatives of lithium and sodium proceed more readily than for the benzyl or allyl derivatives and this is the reason for the formation of the racemic products **RR'** (RLi or RNa, formed as a result of the exchange reaction, racemise; see above). On the other hand, if it is assumed that the exchange processes proceed via a radical mechanism, then evidently they must be accompanied by "losses" associated with the reactions of the radicals liberated from the cage. Indeed the yields of **RR'** are extremely low in the reactions of **R'X** with simple alkyl derivatives of lithium and sodium, while in the case of the allyl and benzyl derivatives they are nearly quantitative. However, it is at present extremely difficult to reach any conclusions, since an increase in the reactivity of RM, like that of **R'X** (for example on passing from chlorides to iodides), should increase the rates of both processes (although possibly to different extents).

On the other hand, it is difficult to account for data obtained for the Wurtz reactions involving RMgX from the standpoint of an ionic S_N2 mechanism. Exchange processes are known to be less typical for organomagnesium compounds than for organolithium or organosodium compounds[21,67]. Nevertheless, preferential racemisation, even in reactions with **R'X** incapable of reacting via the S_N1 mechanism although the yield of **RR'** are in fact highest in processes of this type, is often the stereochemical result of reactions involving allyl- or benzyl-magnesium halides. It is noteworthy that the available data for the stereochemistry of the Wurtz reaction with participation of RMgX are limited to only a few examples (Table 4).

It is evident from the data described that the Wurtz reaction and the metal–halogen exchange reaction cannot be described within the framework of a single mechanism, particularly since a change in the nature of M, R, R', and the halogen may alter the process mechanism. We shall now consider the possible mechanisms of the exchange and Wurtz reactions in the light of the available data (particularly stereochemical data) for these processes.

V. POSSIBLE MECHANISMS OF THE EXCHANGE REACTIONS

1. The mechanism proposed by Wittig to explain the ease of the exchange of the bridgehead halogen[50], which involves nucleophilic attack on the halogen (cationoid abstraction of the halogen) and which may be regarded as a mechanism involving electrophilic substitution at the carbon atom in **R'X**:

$$R'X + RM \rightarrow [R'\!:\ddot{X}\!:\ \,:\!R]^{-}M^{+} \rightarrow RX + R'M.$$

The stereochemical result of such a process should be retention of configuration. This mechanism is frequently invoked, particularly for reactions of organobimetallic compounds with **R'X**, to explain the retention of configuration in exchange reactions. However, exchange processes are as a rule accompanied by the formation of alkanes and alkenes, which cannot be explained within the framework of this mechanism (provided, of course, that the exchange reactions and the reactions involving the formation of these hydrocarbons have a common rate-limiting stage).

2. Electron transfer with formation of a radical-ion pair in which a redistribution of radicals may occur:

$$RM + R'X \rightarrow \begin{bmatrix} R^{\cdot} & M^{+} \\ R'^{\cdot} & X^{-} \end{bmatrix} \rightarrow RX + R'M.$$

The formation of alkanes (RH, and R_2 or R'_2) and alkenes can be explained from the standpoint of this mechanism by the liberation of $R^{\cdot}$ and $R'^{\cdot}$ radicals from the cage. If it is postulated that the radical distribution process takes place in the cage, one can thus account for the observed retention of configuration. However, in consequence of the inversion of the radicals in the cage, even in this case the process can occur with partial or even preferential racemisation.

3. The radical chain mechanism proposed by Russell[61]:

$$R^{-}M^{+} + R'X \rightarrow R^{\cdot} + R'^{\cdot} + MX; \tag{1}$$

$$R^{\cdot} + R'X \rightarrow RX + R'^{\cdot}; \tag{2}$$

$$R'^{\cdot} + RM \rightarrow R'M + R^{\cdot}; \tag{3}$$

$$R^{\cdot} + R'^{\cdot} \rightarrow RR' + \text{alkanes and alkenes.} \tag{4}$$

This mechanism probably gives at the present time the best explanation of the exchange process [stages (2) and (3)]. The formation of different hydrocarbons can be understood within the framework of this mechanism, although the stereochemical result of reactions (2) and (3) should be racemisation. In a few instances one can probably expect also the retention of configuration, for example for radicals of the vinyl and cyclopropyl series which have high inversion barriers. There is no doubt that the free-radical mechanism appears particularly attractive for the exchange reaction, which is in essence an oxidation-reduction process. However, one cannot explain within the framework of this mechanism the results of Mechinger's study, which has become a classical (and so far unique) example of this kind, showing the possibility, in principle, of the retention of the stereochemical configuration in exchange reactions involving an sp^3-hybridised uncharged carbon atom[69]. On the other hand, the observation of CIDNP in alkyl halides together with the observation of the polarisation of alkanes and alkenes shows that these products are formed via a mechanism involving an SET stage or a chain radical process. There remains only one possibility—to assume that in reality a combination of mechanisms [(1) and (2) or (2) and (3)] obtains. There has been only one investigation which throws doubt on the SET mechanism of radical exchange reactions (in halogen–metal systems). This is the study of Ward and coworkers[46] (whose results have been published in the abstracts of reports at the conference in Belgium in 1971), where the authors failed to observe CIDNP in the reaction of t-BuLi and n-BuI at −70°C involving exchange, but did observe CIDNP in the disproportionation products formed on raising the temperature, i.e. in the products arising under the conditions of the Wurtz reaction.

VI. POSSIBLE MECHANISMS OF THE WURTZ REACTION

1. The heterolytic mechanism of the S_N2 type[‡]

$$RM + R'X \rightarrow [M^{\delta+}R^{\delta-} \ldots R'^{\delta+}X^{\delta-}] \rightarrow MX + RR'.$$

The stereochemical result of this process is inversion of configuration. This mechanism has been frequently invoked in studies on the reactions of benzyl and allyl derivatives of lithium and sodium, since preferential inversion of configuration has in fact been observed in such cases. The reactions of lithium dimethyl- and diphenyl-cuprates with R'X also take place with inversion of configuration[81,82], probably owing to their pronounced nucleophilic properties in relation to the carbon atom.

This mechanism is probably also valid for the reactions of simple alkyl derivatives of sodium and lithium with R'X, which take place with racemisation, if it is assumed that the racemisation is a result of the loss of configuration by the organometallic compound RM during the exchange process and is not a consequence of the Wurtz reaction. This hypothesis is particularly likely, because simple alkyl derivatives of lithium and sodium should show the greatest tendency towards exchange reactions by virtue of their basicity, which is confirmed by the formation of R_2 and R_2' together with RR' in these reactions, in contrast to the reactions of benzyl and allyl derivatives of sodium and lithium, where compounds RR' are sometimes formed in nearly quantitative yields. However, the stereochemical result (racemisation) in the reaction of optically active R'X with RMgX (even of the allyl and benzyl types) remains inexplicable within the framework of this mechanism. Exchange processes are not characteristic of these reactions, because the latter have been carried out in hydrocarbon media or in hydrocarbon–ether mixtures, where hardly any exchange processes occur. Unfortunately the stereochemical data obtained for Wurtz reactions involving RMgX are extremely limited.

A change in the nature of R'X can lead to a change from an S_N2 to an S_N1 mechanism, which involves attack by RM on the carbonium centre of the carbonium ion R'^+ of the corresponding ion pair R'^+X^-. Racemisation accompanied by inversion of configuration when the ion pair is involved should be the stereochemical result of this reaction. However, one should recall that such reactions are usually carried out in ethereal solvents or in ether–hydrocarbon mixtures, which hardly promotes the ionisation of the R'X molecule and the operation of an S_N1 mechanism. On the contrary, an increase of the electron-donating capacity of the solvent (for example on passing from ether to DME of the glymes) promotes the ionisation of the organometallic compound molecule.

2. The mechanism of the S_Ni type:

$$RM + R'X \rightarrow \left[\begin{array}{ccc} R & — & M \\ & & \uparrow \\ R' & — & X \end{array}\right] \rightarrow \left[\begin{array}{ccc} R & \cdots & M \\ \vdots & & \vdots \\ R' & \cdots & X \end{array}\right] \rightarrow RR' + MX.$$

An attempt has been made to consider this mechanism for the Wurtz reaction of RNa with R'X; it is readily seen that it does not explain the formation of the observed products and stereochemistry, but it can obtain in reactions of covalent organometallic compounds, for example organomercury compounds (the reaction of RHgX or R_2Hg with R'X is discussed below). The stereochemical result of this reaction involves retention of configuration. However, when a fairly stable carbanion corresponds to the organic group R in the RM molecule, the rate-limiting stage of this process may become the ionisation of the RM linkage under the influence of nucleophilic coordination, i.e. the true mechanism is of the S_E1 type. The stereochemical result in this case may be racemisation, although one cannot rule out partial retention of configuration.

Finally one cannot rule out the possibility that both processes can involve electron transfer as a separate stage, which is rate-determining in an ionisation mechanism. The occurrence of SET in this instance would explain the formation of radicals in the reaction of Ar_2Hg with Ph_3CX (Beletskaya et al.[87]) and the CIDNP in the product Ph_3CCH_2Ar of the reaction of $(ArCH_2)_2Hg$ with Ph_3CX.[88] The stereochemical results of these reactions should involve retention of configuration or racemisation, but such data are so far unavailable in the literature.

3. Electron transfer as in the exchange reaction. When radicals recombine in the cage, one may expect the retention of configuration, but it is difficult to suppose that such recombination takes place only in the cage, particularly if one is dealing with fairly stable radicals of the allyl or benzyl type. On the other hand, one cannot explain within the framework of this mechanism the observed inversion of configuration which actually occurs in reactions involving RM of the benzyl or allyl type. The possible alternative explanation involving electron transfer in the oriented attack in the complex $[MR^{\delta-}\ldots R^{\delta+}{}'X]$[§] lacks any supporting evidence at the present time.

4. The radical chain mechanism in which the Wurtz reaction product is formed on recombination of the radicals R· and R'·. For the usual radicals, the natural stereochemical result should be racemisation. Analysis of the possible reaction pathways showed that, in order to account for the inversion of configuration in the Wurtz reaction, the absence of radical stages must be postulated.

At first sight the heterolytic mechanism in both the Wurtz and the exchange reactions is supported also by the finding that both reactions are appreciably accelerated in highly solvating media and that under such conditions the yield of hydrocarbons RH, R(–H), etc. is in fact reduced, while their amount increases sharply in hydrocarbon media, where there are virtually no products of the Wurtz reaction proper. These results can also be interpreted in a different way. An increase in the electron-donating capacity of the solvent leads to an increase of the basicity (and nucleophilicity) of the RM molecule and probably to a

---

[‡] The assignment of this reaction to processes of the S_N2 type is purely arbitrary. It could be just as successfully regarded as a reaction of the S_E2 type. In this case the assignment was made because the study of the stereochemistry of the reaction (on which attention has been mainly concentrated in this section) has been carried out on the optical or geometrical isomers of R'X. This applies also to mechanisms of the S_Ni and S_Ei types.

[§] The formation of radicals has been recently demonstrated in a typical S_N2 reaction involving inversion of configuration. This enabled the authors to postulate that the transition state is a "hybrid" of the usual transition state of an S_N2 reaction and a radical pair[89]. On this hypothesis, it is indeed found that electron transfer should take place from "the rear". However, the authors failed to take into account the fact that a synchronous S_N2 mechanism cannot lead to the formation of different products (radicals and nucleophilic substitution products) from the same transition stage.

facilitation of the electron transfer process. On the other hand, these solvents can increase the stability of the radical-ion pair by solvation, as a result of which the radicals are less able to emerge from the cage.

Thus the observed characteristics of the Wurtz reaction cannot be explained within the framework of a single mechanism either. In order to account for the inversion of configuration, it is necessary to invoke a heterolytic pathway, while the retention of radicals (Russell's data[61]) and CIDNP in the recombination products requires a radical pathway. On the other hand, the ratio of the contributions of these pathways in each specific case constitutes an independent problem.

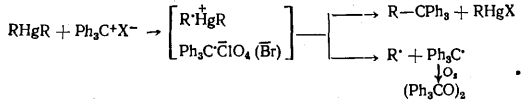
VII. REACTIONS OF OTHER ORGANOMETALLIC COMPOUNDS WITH ALKYL HALIDES

The formation of triphenylmethyl radicals has been demonstrated in a Wurtz-type reaction between organometallic compounds Ar_2Hg and triphenylmethyl bromide or perchlorate[87]. The ratio of the amounts of the Wurtz reaction products $ArCPh_3$ and triphenylmethyl peroxide depends strongly on the nature of the solvent and the substituent in the benzene ring of Ar_2Hg (Table 5).

Table 5. The yields of products in the reactions of Ar_2Hg with Ph_3CX.

p-X	Solvent	$(Ph_3CO)_2$, %	*p*-$XC_6H_4CPh_3$, %	*p*-X	Solvent	$(Ph_3CO)_2$, %	*p*-$XC_6H_4CPh_3$, %
H	benzene	15	85	CH_3O	DCE	90	10
H	DCE	60	40	Cl	»	20	80

In this case one can also postulate the occurrence of two simultaneous processes (radical and heterolytic), one of which may predominate. However, bearing in mind that the change in the rate of reaction following the alteration of X is described by the Brown–Okamoto equation (σ^+), the hypothesis of a single mechanism in which the rate-determining stage is electron transfer appears to be more probable:

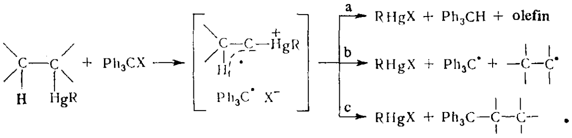


$$RHgR + Ph_3C^+X^- \rightarrow \left[\begin{matrix} R^{\cdot}\overset{+}{Hg}R \\ Ph_3C^{\cdot}\overline{C}lO_4\ (\overline{B}r) \end{matrix}\right] \rightarrow \begin{cases} R{-}CPh_3 + RHgX \\ R^{\cdot} + Ph_3C^{\cdot} \xrightarrow{O_2} (Ph_3CO)_2 \end{cases} .$$

One can attempt to explain the observed behaviour by the properties of the radical-cation formed initially, the stability of which should decrease in the sequence $CH_3O >$ H $>$ Cl; the higher the stability of these species the greater the "freedom" and ability to emerge from the cage acquired by its partner in the radical-ion pair, i.e. triphenylmethyl. On the other hand, the rate of reaction increases in the sequence methylene chloride $<$ CH_3CN $<$ benzene; the yield of triphenylmethyl peroxide increases in the same sequence. It may be that the radical-ion pair in π-donor solvents is more stable and this is responsible for the higher degree of recombination of the radicals in the cage; in the case of DCE, the radicals are more capable of leaving the cage (in all the solvents the formation of $Ph_3C^{\cdot}$ has been detected by ESR in the absence of oxygen, but in benzene the yield of the radical is low).

The validity of the proposed mechanism is demonstrated directly by the observation of CIDNP in $RCPh_3$ in the reaction of triphenylmethyl bromide with benzylmercury bromides p-$XC_6H_4CH_2HgBr$ (X = H or CH_3) and dibenzylmercury in DCE and methylene chloride[88].

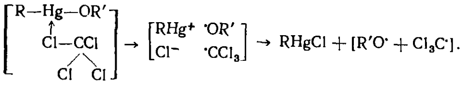
For alkyl derivatives of mercury containing a β-hydrogen atom capable of mobility as the hydride ion, the dominant mode of reaction with triphenyl methyl halides and perchlorates is known to be a hydride shift leading to triphenylmethane and not the formation of the Wurtz reaction products[90-92]. However, one may postulate that the elementary steps in the two outwardly different processes are of the same type. Indeed a considerable positive polarisation of the methine protons of triphenylmethane has been observed in the reactions of di-(n-butyl)- and di-(s-butyl)-mercury with Ph_3CX (X = Cl, Br, or ClO_4) in DCE.[93] On this basis, the following mechanism including the stage of one-electron transfer via the C–Hg bond to Ph_3CX has been postulated for the reactions under consideration:



In this mechanism triphenylmethane (pathway *a*) is a product of the abstraction of the β-hydrogen atom by the triphenylmethyl radical and not of the hydride shift as traditionally understood. The competing modes of reaction under these conditions are pathway *c* involving radical recombination in the cage and pathway *b* involving the liberation of the radicals from the cage, which becomes the main pathway when tri-(*p*-nitrophenyl)methyl bromide is used as the electrophilic agent (probably in consequence of the extremely high stability and low tendency towards recombination of the corresponding radical).

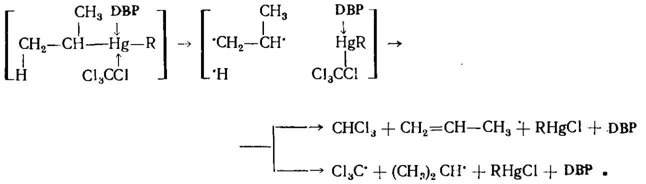
The SET mechanism in reactions of organomercury compounds with R′X may not be general and may obtain only in the specific case of the reaction with triphenylmethyl halides, owing to the ease of reduction of Ph_3CX and the formation of the stable triphenylmethyl radical. This hypothesis appears to be particularly valid, since in the general case the interaction of organomercury compounds with alkyl halides proceeds with extreme difficulty and a very low yield of RR′¶.

The mechanism including the SET stage has also been proposed for the reactions of mercury alkoxides RHgOR′ with polyhalogenomethanes and the reactions of dialkyl- and diaryl-mercury compounds with CCl_4 in the presence of di-t-butyl peroxide (DBP).[94] The organomercury compounds R_2Hg as a rule react with CCl_4 or $CHCl_3$ under severe conditions (heating to the decomposition temperature of R_2Hg) and the process has a free-radical mechanism. Following the replacement of R by an alkoxy-group, the reaction proceeds under milder conditions:



¶ This situation is analogous to that occurring in SN processes, where the usual SN2 reactions take place with inversion of configuration and cannot be simulated by the reaction of Ph_3CBr with t-BuO-(or PhO^-), which leads to radicals only[95].

DBP acts in the same way; its introduction into the reaction of alkyl or phenyl derivatives of mercury greatly accelerates the latter (the optimal conditions obtain when $R_2Hg:DBP = 1:1$). On the other hand, DBP itself is consumed in the reaction to an extent not greater than 5%. According to the authors[94], the catalytic role of DBP reduces to the formation of a complex with R_2Hg, as a result of which the Hg–C bond is polarised to such an extent that R_2Hg becomes reactive in relation to CCl_4. When CCl_4 reacted with Alk_2Hg in the presence of equimolar amounts of DBP, considerable amounts of chloroform and propene (more correctly, 1,1,1,3-tetrachlorobutane formed from propene after the addition of CCl_4) were found in the reaction mixture. The authors explain the formation of these products by an intermolecular hydride shift, which they believe also proceeds via an electron transfer stage:



However, the data quoted by the authors[94] do not show that this is the only reaction pathway.

The formation of racemic products in the reactions of phenyl- or α-naphthyl-cadmium chloride with α-bromopropionate esters and the observation of an intense signal in the ESR spectrum when the reactants are mixed, suggests that these reactions have radical mechanisms[96].

CIDNP (both emission and positive polarisation) has been recently observed in the reaction of ethyl-lead with hexachlorocyclopentadiene and hexachloroacetone (the solvents) at 140°C:[97]

$$Et_4Pb + C_5Cl_6 \rightarrow Et_3PbCl,\ EtCl,\ EtC_5Cl_5,\ C_5Cl_5H,\ C_2H_4,\ (C_5Cl_5)_2.$$

Analysis of the polarisation signs indicates the occurrence of CIDNP in the singlet radical pair ($R^{\bullet}\,{}^{\circ}Et$), but the authors do not regard electron transfer as the only possible reaction mechanism. Similar spectra have been observed in both solvents also for the reactions with $Et_2Pb(OAc)_2$ and Et_3PbOAc.

A wide variety of reactions involving organocopper compounds, including the reactions of RCu with organic halogeno-derivatives[98], have been investigated fairly vigorously in recent years. Some of these reactions have proved useful as regards syntheses; for example, the reactions of copper acetylides with a wide variety of halogeno-derivatives (acetylenic, vinyl, aromatic, etc.) are widely used for the synthesis of the corresponding hydrocarbons. In many instances thermally stable arylcopper compounds were introduced into the reaction with R′X. It is quite likely that some of these reactions proceed via a radical mechanism, but this problem has not been discussed in the literature. Furthermore, in many reactions, for example the reactions of arylcopper compounds with aromatic halides[99], a mixture of hydrocarbons is obtained, the formation of which can be readily explained by a radical mechanism. However, it is impossible to reach an unambiguous conclusion, because one cannot rule out the possibility that the formation of this mixture is associated with the occurrence of halogen–copper exchange processes, which has been demonstrated in many cases.

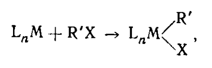
Somewhat more attention has been devoted (from the standpoint of the study of the mechanism) to the reactions of lithium (or magnesium) dialkyl- or diaryl-cuprates, which have higher thermal stabilities, with halogeno-derivatives[81,82]. The use of cuprates makes it possible to obtain high yields of the hydrocarbons RR′ in reactions with primary and even secondary RHal or ROTos (70–100%).

As already mentioned above, the reaction of lithium diphenyl- and dimethyl-cuprates with s-butyl bromide takes place preferentially (to the extent of 84–92%) with inversion of configuration, which shows that it proceeds via an S_N2 mechanism[81]. Similarly a 100% inversion of configuration is observed in the reaction of lithium diphenylcuprate with (+)-2-(s-butyl)toluene-*p*-sulphonate or ethanesulphonate in ether[100]. However, the reactions of cuprates with halogeno-derivatives of the vinyl series to form RR′ proceed with retention of geometrical configuration, which is clear evidence against an S_N2 mechanism. According to Whitesides et al.,[81] this mechanism is also relatively unsuitable for the explanation of the ease of reaction of lithium diphenylcuprate with aromatic halides (it is striking that the reaction may be regarded as a variant of the Ullmann reaction, for which both oxidation-reduction and heterolytic[101] mechanisms have been proposed). There is no doubt that, as in the reactions of organomagnesium and organolithium compounds, there may be a change of mechanism or a change in the contribution of the radical or heterolytic reaction pathway in the series of different cuprates, depending on their nature and that of R′X.

VIII. REACTIONS OF ORGANIC DERIVATIVES OF TRANSITION METALS WITH ALKYL HALIDES

The ability of certain transition metal complexes to undergo oxidative addition reactions (which includes the reactions with R′X) constitutes the basis of their catalytic activity in many processes, such as the homogeneous hydrogenation of unsaturated compounds, the oxidation of alkanes, etc., and also reactions involving the dissociation and reformation of carbon–carbon bonds.

The interaction of transition metal complexes with alkyl halides constitutes one of the most interesting methods for the formation of a carbon–metal σ-bond[102,103]. The reaction can proceed as oxidative addition, in which the state of oxidation of the metal and its coordination number change by two units (two-electron oxidation):



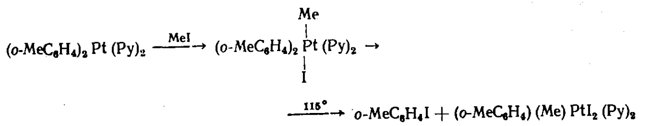
$$L_nM + R'X \rightarrow L_nM\begin{matrix}\diagup R' \\ \diagdown X\end{matrix},$$

where L is the ligand. In the presence of a fairly stable group to be eliminated from the alkylating agent (CH_3SbF_6, CH_3SO_3F), only one fragment R′ of the R′X molecule may add on[104,105] with formation of an alkylmetal cation, for example $[Pt(PPh_3)Me]^+$.

We shall naturally consider only reactions in which complexes of organic derivatives of metals are involved. The number of such reactions is small. The products of the addition of alkyl halides have been isolated for platinum(II) derivatives[106]; on heating, the complex decomposes with elimination of ethane:

$$[MePt(PEt_3)_2]I \overset{MeI}{\rightleftarrows} [Me_2PtI_2(PEt_3)_2] \xrightarrow{100^\circ} Me{-}Me + I_2Pt(PEt_3)_2.$$

It is postulated that the exchange of the *o*-tolyl group for methyl in the reaction[107]



$$(o\text{-MeC}_6\text{H}_4)_2\text{Pt(Py)}_2 \xrightarrow{\text{MeI}} (o\text{-MeC}_6\text{H}_4)_2\overset{\text{Me}}{\underset{\text{I}}{\text{Pt}}}(\text{Py})_2 \rightarrow$$

$$\xrightarrow{115°} o\text{-MeC}_6\text{H}_4\text{I} + (o\text{-MeC}_6\text{H}_4)(\text{Me})\text{PtI}_2(\text{Py})_2$$

proceeds via an intermediate of this kind.

The stereochemistry of the addition of MeI and CF_3I to platinum complexes, for example to *cis*-$Pt(Me_2)L_2$, has been studied[108]. The oxidative addition of methyl iodide to the triphenylphosphine complex of methylgold(I) proceeds via Me_2AuIL and the subsequent exchange of the alkyl halide with MeAuL gives a trimethylgold complex[109,110], which undergoes reductive elimination with formation of ethane:

$$\text{MeAuL} + \text{MeI} \underset{a}{\rightarrow} \text{Me}_2\text{AuIL} \xrightarrow[b]{\text{MeAuL}} \text{Me}_3\text{Au}^{\text{III}}\text{L};$$

$$\text{Me}_3\text{Au}^{\text{III}}\text{L} \underset{c}{\rightarrow} \text{Me—Me} + \text{MeAu}^{\text{I}}\text{L}.$$

Thus the complex MeAuL behaves as the catalyst in the dimerisation of alkyl groups[111]. A significant difference has been observed between the reactivities of the complexes in relation to oxidative addition (*a*) and alkyl exchange (*b*) processes as a function of the nature of the ligand. The complex Me_3AuPMe_3 is much more stable than Me_3AuPPh_3, so that it enters into a slow methyl–iodine exchange reaction with $IAu(PMe_3)$ or CH_3I without undergoing elimination.

It follows from the above mechanism that the oxidative addition reactions are assumed to have a polar mechanism. However, the possibility of a radical reaction pathway has been recently discussed in relation to an inorganic iridium(I) complex[112–114]. A free-radical chain mechanism is proposed for the process on the basis of the inhibiting effect of radical "traps" and the loss of configuration of the α-carbon centre in the reaction of $IrCl(CO)L_2$ with optically active ethyl α-bromopropionate[114].

There is another one-electron mechanism of the oxidation of transition metal complexes by alkyl halides:

$$2\text{L}_n\text{M} + \text{R}'\text{X} \rightarrow \text{L}_n\text{MR}' + \text{L}_n\text{MX}.$$

In this case the reaction undoubtedly proceeds via a free-radical mechanism:

$$\text{L}_n\text{M}^{\text{II}} + \text{R}'\text{X} \xrightarrow{\text{slow}} \text{L}_n\text{M}^{\text{III}}\text{X} + \text{R}'^{\cdot};$$

$$\text{R}'^{\cdot} + \text{L}_n\text{M}^{\text{II}} \xrightarrow{\text{fast}} \text{L}_n\text{M}^{\text{III}}\text{R}'.$$

The reactions involving the oxidation of iron(II) to iron(III) in porphyrins[115] and haemoglobin[116] by alkyl halides may serve as an example:

$$\rangle\text{Fe}^{\text{II}} + \text{R}'\text{X} \rightleftarrows \rangle\text{Fe}^{\text{II}}(\text{XR}') \rightarrow \rangle\text{Fe}^{\text{III}}\text{X} + \text{R}'^{\cdot}.$$

The fate of the radical depends on its nature; alkyl, benzyl, and propargyl radicals recombine to form R'_2. A further reduction of the radical with formation of alkanes is possible:

$$\text{R}'^{\cdot} + \rangle\text{Fe}^{\text{II}} + \text{H}^+ \rightarrow \rangle\text{Fe}^{\text{III}} + \text{R}'\text{H},$$

The alkanes are formed almost quantitatively when bromomalononitrile and diethyl bromomalonate are used as the alkyl halides[116].

The reactions of alkyl halides with cobalt[117,118] and chromium[119] complexes, leading to the formation of organic derivatives of these metals, have similar mechanisms. Generally speaking, these reactions involve the reduction of alkyl halides by metal salts (and not by organometallic compounds) and for this reason they are outside the scope of the review. We shall only mention that reactions of this kind include the alkylation of cobaloximes[120–122]:

$$2\text{Co}^{\text{II}}(\text{dmg})_2\text{L} + \text{R}'\text{X} \rightarrow \text{XCo}^{\text{III}}(\text{dmg})_2\text{L} + \text{R}'\text{Co}^{\text{III}}(\text{dmg})_2\text{L},$$

where dmg is dimethylglyoximate and L = Py, PPh_3, etc., and the reactions of R′X with vitamin B_{12s} [a cobalt(I) complex][123,124], which are biochemically important.

However, it is believed[122,123] that, in contrast to the reactions of $Co(CN)_5^{3-}$ (Halpern and Maher[117]) and cobaloximes[120], those of R′X with vitamin B_{12s} proceed as classical nucleophilic substitutions and do not involve electron transfer. This view is based on data for the influence of the nature of R′ on the course of the reaction. It is interesting to note that, according to the results of these investigations, vitamin B_{12s} is the most powerful nucleophile known (a supernucleophile[123]).

The stereochemical result of the reaction obtained in the alkylation of cobalt(I) cobaloximes by *cis*- and *trans*-1,4-dibromocyclohexanes, namely complete inversion at the carbon centre, also suggests that this process involves bimolecular nucleophilic S_N2 substitution[125].

IX. REACTIONS OF ORGANOBIMETALLIC COMPOUNDS† WITH ALKYL HALIDES

It is useful to examine briefly also data obtained for reactions of organobimetallic derivatives with alkyl halides, since in this case it is possible to note the same trend in the development of ideas concerning the reaction mechanism and the same difficulties in the determination of the mechanism which arise in the analysis of the results of studies on the reactions of RM with R′X. It is noteworthy that the reactions of $(R_{n-1}E_m)M$ with halogeno-derivatives constitute one of the methods for the formation of a C–transition metal σ bond.

Dessy et al.[126] investigated the reactivities of a series of compounds of the type $R_{n-1}E^-Bu_4N^+$ (where E are various Group IV and V metals and non-metals as well as transition metals, for example Fe, Cr, W, Mn, etc.) in relation to alkyl halides (MeI, EtBr, and iso-PrBr) in DME. The anions $R_{n-1}E^-$ were obtained via the electrochemical reduction of the corresponding derivatives, usually compounds of the type $(R_{n-1}E)_2$. Since no hydrocarbons of the type RH and R(–H) [or compounds of the type $(R_{n-1}E)_2$], which might have indicated a radical reaction mechanism, were detected in the products, the authors regarded the reaction as an S_N2 type process and the values of k_2 as a measure of the nucleophilic properties of the corresponding anions $R_{n-1}E^-$. However, the yields of bibenzyl (a "side" product) reached 47% in the reaction of trimethylsilylsodium with benzyl chloride, while the reactions of Me_3SiNa with butyl halides produced fairly large amounts of butane, the yield of which increased sharply on passing from the chloride to the bromide and to the iodide[127]. According to the authors[128], these results suggest the possibility of electron transfer with formation of radicals.

When triethylgermyl-lithium was allowed to react with chlorotriphenylmethane in benzene, the formation of the

---

† Any compounds of the type $(R_{n-1}E^-)_mM^+$, where *n* is the valence of the element E, which may be both a metal or a non-metal, and *m* is the valence of the metal M, we have defined arbitrarily as organobimetallic derivatives.

triphenylmethyl radical was observed (13%), its yield reaching up to 33% after the addition of ether to the reaction mixture. Other reaction products were triethyl(triphenylmethyl)germane (63%) and hexaethyldigermane. The authors explained the results from the standpoint of the mechanism involving electron transfer from triethylgermyl-lithium to triphenylmethyl chloride[127,129]:

$$Et_3GeLi + Ph_3CCl \rightarrow \begin{bmatrix} Li^+ & {}^\cdot GeEt_3 \\ Cl^- & {}^\cdot CPh_3 \end{bmatrix} \rightarrow LiCl + Ph_3C^\cdot + Et_3Ge .$$

The same mechanism apparently obtained also in the reaction of bis(triethylgermyl)cadmium with triphenylmethyl chloride in toluene[127,129]. In this case the reaction is a multistage process. The first, exothermic stage involves the formation of the triphenylmethyl radical (according to ESR data). In the second stage, which is completed in several days at 20°C, metallic cadmium is formed. According to the authors, the exothermic stage involves electron transfer from $(Et_3Ge)_2Cd$ to Ph_3CCl:

$$(Et_3Ge)_2\,Cd + Ph_3CCl \rightarrow \begin{bmatrix} Et_3GeCd^+ & {}^\cdot GeEt_3 \\ Cl^- & {}^\cdot CPh_3 \end{bmatrix} \rightarrow Ph_3C^\cdot + Et_3GeCdCl + Et_3Ge^\cdot ,$$

$$2Et_3Ge^\cdot \rightarrow (Et_3Ge)_2 \quad (48\%);$$

$$Ph_3C^\cdot + Et_3Ge^\cdot \rightarrow Et_3GeCPh_3 \quad (28\%).$$

The fact that the organobimetallic derivatives enumerated readily reduce compounds such as naphthalene (Me_2SiNa), tetracyanoethylene, and *o*- and *p*-chloranils, i.e. typical electron acceptors, is regarded as evidence in support of the likelihood of the SET mechanism in these reactions[127-129]. Nor is a possibility of processes of the S_N2 type complicated by exchange processes ruled out. For example, the products found in the reaction of Et_3GeLi with triphenylmethyl chloride can be accounted for equally successfully by the following mechanism:

$$Et_3GeLi + Ph_3CCl \rightarrow Et_3GeCPh_3 + LiCl;$$

$$Et_4GeLi + Ph_3CCl \rightarrow Et_3GeCl + Ph_3CLi;$$

$$Et_3GeLi + Et_3GeCl \rightarrow (Et_3Ge)_2 + LiCl;$$

$$Ph_3CCl + Ph_3CLi \rightarrow 2Ph_3C^\cdot + LiCl.$$

However, for the analogous mercury derivative $(Et_3Ge)_2Hg$, the authors give preference to a heterolytic four-centre mechanism, assuming that unstable bis(triphenylmethyl)mercury is formed in the reaction as an intermediate:

$$(Et_3Ge)_2\,Hg + 2Ph_3CCl \rightarrow 2Et_3GeCl + \underset{\displaystyle 2Ph_3C^\cdot + Hg.}{\underset{\downarrow}{(Ph_3C)_2\,Hg}}$$

The reaction products are in fact mercury (93%), chlorotriethylgermane (68%), and hexaphenylethane‡ (91%). Hexaethyldigermane and triethyl(triphenylmethyl)germane could not be detected in the reaction mixture[129]. The same four-centre mechanism has been proposed also for the reaction of $(Et_3Ge)_2Hg$ with simple alkyl or aryl halides[127-131] and for the reaction of $(Me_3Si)_2Hg$ with aryl halides[133]. The authors of the last investigation believe that virtually all the products can be accounted by an S_Ni mechanism; if the radical reaction pathway does occur, its contribution is very small. The reaction of triphenylstannylsodium with 1-bromoadamantane in liquid ammonia probably proceeds via a radical mechanism[134].

A mechanism including the SET stage has been proposed for the reaction of sodio- and potassio-dibutylboron with alkyl halides (MeI, n-HepI, $PhCH_2Br$, and $PhCOCH_2Br$). The formation of a mixture of RH, R_2, and Bu_3B was observed in all cases; the yield of the product of the Wurtz reaction proper was vanishingly small under these conditions (< 1%).[135]

X. STEREOCHEMISTRY OF REACTIONS OF ORGANOBIMETALLIC COMPOUNDS WITH ALKYL HALIDES

There have been several studies on the stereochemistry of reactions of organobimetallic derivatives of Group IV elements with alkyl halides (Table 6).

Table 6. Stereochemical data obtained for the reactions of organibimetallic compounds with various R'X.

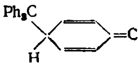
Jensen and Davis[136] observed the preferential inversion of configuration in the reactions of Ph_3EM (E = Si, Ge, Sn, or Pb) with optically active s-butyl halides (Hal = Cl, Pr, or I), the extent of inversion of configuration increasing from the iodide to the chloride. In conformity with the study of Dessy et al.,[126] the authors treat their results as a consequence of an S_N2 process. However, as already pointed out in the discussion of the stereochemistry of the Wurtz reaction, the S_N2 mechanism explains only the inversion of configuration; in order to

---

‡ The triphenylmethyl dimer[132] having the structure



is probably meant.

account for the observed partial racemisation (Table 6), one must invoke another mechanism or the parallel occurrence of an exchange process and the loss of configuration in the organometallic compound RM formed. An inversion of configuration has also been observed in the reaction of trimethylstannylsodium with *syn*-7-bromonorborn-2-ene in liquid ammonia, but the analogous reaction with the *anti*-isomer led to the formation of a mixture of *syn*- and *anti*-isomers[127]. The reaction of optically active 1-bromo-1-methyl-2,2-diphenylcyclopropane with Me_3SnLi takes place with retention of configuration[138].

The problem of the mechanisms of the reactions of organobimetallic compounds with **R'X** has been examined by Traylor et al.,[139] who investigated the stereochemistry of the reactions of trimethylstannyl-lithium with a series of halogeno-derivatives of cyclohexane, bi- and tri-cyclic compounds, and 4-t-butylcyclohexyltoluene-*p*-sulphonate (Table 6). The authors believe that the inversion of configuration is always a consequence of a reaction of the S_N2 type at the carbon atom. On the other hand, the observed retention of configuration can be accounted for on the basis of two mechanisms according to their view.

1. The metal–halogen exchange process, which the authors regard as an S_N2 reaction involving the halogen atom followed by a rapid Wurtz reaction:

$$R'Br + R_3SnLi \xrightarrow{\text{slow}} R'Li + R_3SnBr; \text{ (retention of configuration).}$$

$$R_3SnBr + R'Li \xrightarrow{\text{fast o}} R_3SnR' + LiBr.$$

The authors suggest that the first stage proceeds with retention of configuration and the second stage probably also takes place with retention of configuration as a process of the S_E2 type involving the carbon atom. Furthermore, the RLi formed in the reaction are not racemised, probably owing to the structure of the R group.

2. A mechanism involving the SET stage:

$$R'Br + R_3Sn^- \rightarrow [R'^{\cdot}Br^- \ {}^{\cdot}SnR_3] \rightarrow R'SnR_3 + \text{olefin.}$$

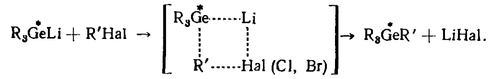
Both mechanisms also explain the formation of distannane observed in the reaction, but the authors give preference to the former on the grounds that the geometrical configuration is retained in the reaction with *cis*-4-t-butylcyclohexyl bromide, while under conditions allowing rotation in the radical-ion pair the R_3Sn^- group should have occupied the more stable equatorial position.

To a significant degree, the stereochemistry of processes of this kind can depend on the nature of the solvent and the atom of the metal M. The results obtained by Kuivila et al. for the reactions of the *syn*- and *anti*-isomers of 7-bromonorbornenes with Me_3SnM in a series of ethereal solvents[140] are presented below.

		Retention of configuration, %		
Isomer	M	THF	DME	THF–TG
syn-	Li	16	3	,3
	Na	90	18	9
	K	3	92	4
anti-	Li	96	98	96
	Na	85	93	99
	K	79	92	96

The authors regard the results obtained as confirmation of the view that the "freer" ion pairs react preferentially with inversion of configuration. Indeed, in the case of the *syn*-isomer the highest percentage inversion is observed in the THF-tetraglyme (TG mixture) and for the lithium derivatives, which are most highly solvated, in all the solvents. A particularly marked solvent effect has been observed in the reaction with Me_3SnNa, where the stereochemical result varies from 70% retention in THF to 91% inversion in the THF–TG mixture. However, incomprehensible results have been obtained for the *anti*-isomer—the reaction proceeds in all solvents with almost complete retention of configuration. The reactions of 1- and 2-bromoadamantanes with Me_3SnM also involve a complete retention of configuration[140]. Analysis of the possible reaction mechanisms led the authors to the conclusion that the retention of configuration can be most simply explained by a four-centre transition state, although the alternative two-stage process and the mechanism including an SET stage (Traylor's mechanisms 1 and 2[139]) are not ruled out. We may note that, in the Wurtz reaction between RM and optically active alkyl halides, the retention of configuration in the product **RR'** has not been observed with the exception of the reactions of **RM** with vinyl halides, which take place with retention of geometrical configuration.

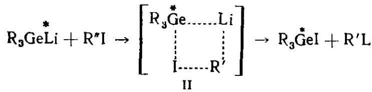
Finally, Eaborn and coworkers[141,142] studied the stereochemistry of the reactions of optically active ethylphenyl(α-naphthyl)germyl-lithium with a series of alkyl halides in ether and showed that the stereochemical result depends significantly on the nature of the halogen. Thus the reactions with chlorides and bromides took place predominantly with retention of the configuration at the germanium atom, while inversion of configuration was observed in the reactions with iodides. The configuration was retained also in the reaction with benzyl bromide. The authors explained the retention of configuration in this reaction by a four-centre transition state (I):



$$R_3\overset{*}{Ge}Li + R'Hal \rightarrow \left[\begin{array}{ccc} R_3\overset{*}{Ge} & \cdots & Li \\ \vdots & & \vdots \\ R' & \cdots & Hal \text{ (Cl, Br)} \end{array}\right] \rightarrow R_3\overset{*}{Ge}R' + LiHal.$$

(I)

On the other hand, they believe that in reactions with iodides the exchange process (II) takes place initially and is followed by the Wurtz reaction between R_3GeI and **R'Li**, which results in inversion of configuration, as shown by the same investigators[143]:



$$R_3\overset{*}{Ge}Li + R''I \rightarrow \left[\begin{array}{ccc} R_3\overset{*}{Ge} & \cdots & Li \\ \vdots & & \vdots \\ I & \cdots & R' \end{array}\right] \rightarrow R_3\overset{*}{Ge}I + R'Li;$$

II

$$R_3\overset{*}{Ge}I + R'Li \xrightarrow{\text{inversion}} R_3GeR' + LiI.$$

Thus analysis of the stereochemical data for the reactions of organobimetallic derivatives with **R'X** shows that the results cannot be accounted for by a single mechanism (as already stated, a similar situation was observed also for the reactions of **RM** with **R'X**).

XI. THE INTERACTION OF ORGANOMETALLIC COMPOUNDS WITH 'ONIUM SALTS

A radical mechanism has been proposed for the reactions of iodonium salts with Grignard reagents by Gragerov and coworkers[144] on the basis of the detection of triphenylmethyl radicals in the reactions of diphenyliodonium salts ($X = BF_4$, Cl, or I) with triphenylmethylmagnesium chloride and the detection of methane and ethane (5%) in the reaction of $Ph_2I^+BF_4^-$ with methylmagnesium iodide:

$$Ph_2I^+X^- + RMgX' \rightarrow Ph_2I^{\cdot} + R^{\cdot} + MgXX'.$$

However, the problem of whether the radical pathway is unique or whether it represents a side reaction, which becomes dominant for $R = Ph_3C$, remains unsolved.

A similar mechanism has been suggested also for reactions of t-butyl- and benzyl-magnesium chlorides with *p*-chlorophenyldiazonium fluoroborate in THF.[145] PhCl (40%), *p*-$ClC_6H_4N = NCMe_3$ (15,6%), isobutane (18%), isobutene (14%), and tetramethylbutane (77%) were detected in the former reaction. Furthermore, the polarisation of the vinyl protons of isobutene and of the methyl protons of isobutane was observed. The formation of chlorobenzene, toluene, and bibenzyl was noted in the reaction with benzylmagnesium chloride; chlorobenzene proved to be polarised. A study was also made of the interaction of diphenyliodonium bromide with methyl-, ethyl-, and phenyl-magnesium iodides and phenyl-lithium, toluene (59%), ethylbenzene (37%), and biphenyl (33 and 64% respectively) being observed. The authors were not particularly concerned with the study of the reaction mechanism, but they believe that the reaction is a process of the S_N2 type.[146]

The reaction of diphenyliodonium fluoroborate with α-bromomercuriphenylethyl acetate, which leads to the formation of a mixture of ethyl esters of phenylacetic, diphenylacetic, and 1,2-diphenylsuccinic acids, can only be treated from the standpoint of the SET mechanism[147]:

$$Ph_2IBF_4 + PhCH(HgBr)CO_2Et \rightarrow PhCH_2CO_2Et + Ph_2CHCO_2Et + (PhCHCO_2Et)_2.$$

Within the framework of the SET mechanism, an attempt could probably be made to treat the interaction of organolithium compounds with the sulphonium salts $Ph_3S^+BF_4^-$.[148-150] However, the experiments carried out using phenyl-lithium labelled with ^{14}C showed that, for the 1 : 1 reactant ratio, the isotopic label is distributed in equal amounts between the reaction products Ph_2 and Ph_2S, which agrees with the mechanism involving their formation from the intermediate sulphurane Ph_3Ph^+S, but can also be accounted for within the framework of the SET mechanism or on the assumption of the intermediate formation of dehydrobenzene[149]. Furthermore, the existence in solution at a low temperature (−78°C) of tetrakis(pentafluorophenyl)sulphurane, which decomposes on raising the temperature (−20° and 0°C) with formation of the corresponding fluorinated analogues of biphenyl and diphenyl sulphide, has been demonstrated. On the other hand, the addition of styrene or norbornene has no influence on the course of the reaction[150].

It is apparently of interest to investigate the reactions of organomagnesium compounds with sulphenyl chloride[151,152] for which an electron transfer stage may be postulated in certain cases, bearing in mind that sulphenyl halides are reduced much more readily than alkyl or aryl halides[153,154]:

$$ArSCl\ (AlkSCl) + Ar'MgX \rightarrow ArSAr'\ (AlkSAr') + MgXCl.$$

Unfortunately, a complete analysis of the products was not carried out in the above investigations[151,152] and only the yields of the corresponding sulphides are indicated (55–70%), which does not allow one to infer that radical stages occur in the reaction.

Polymerisation of Acetylenes. The Structure and Electrophysical Properties of Polyvinylenes

M.G.Chauser, Yu.M.Rodionov, V.M.Misin, and M.I.Cherkashin

The literature data on the radical and ionic linear polymerisation of mainly mono- and di-substituted acetylenes with a single carbon–carbon triple bond are considered and the known mechanisms of the acetylene polymerisation processes are discussed. Much attention is devoted to the copolymerisation of acetylenes with monomers of different types. The results of studies on molecular, supermolecular, and electronic structures of polyvinylenes are compared with their electrophysical properties. The bibliography includes 475 references.

CONTENTS

I. INTRODUCTION

There has been a considerable growth of interest in recent years in the study of the polymerisation reactions of acetylenic compounds which make it possible to synthesise linear and cyclic compounds with a wide variety of structures. Different aspects of the problem have been described in a number of reviews and monographs[1–25].

The aim of the present review is to consider the latest advances in the synthesis of linear polymers based on mono- and di-substituted acetylenic monomers with a single C≡C bond. A review of studies on the polymerisation of diacetylenes was published previously[26]. To facilitate the description and in view of the fact that the polymerisation mechanism has not been established in many cases, a systematic account is given of the available data in accordance with the initiator or catalysts employed in the synthesis of the polymers.

The unusual features of the reactivities of alkynes are determined largely by the high electron density in the triple bond, the cylindrical symmetry of the electron distribution relative to the molecular axis, and the weak polarisability of π electrons, which hinders electrophilic attack and facilitates nucleophilic attack on the triple bond[27]. Because of the above characteristics, alkynes readily form π complexes[15] and metal acetylides[15,27]. Thus one may expect the polymerisation of alkynes to occur most readily under the influence of anionic and complex catalysts based on transition metal compounds. On the other hand, one should bear in mind that the ease of elimination of the acetylenic proton promotes chain termination and transfer, while strong bases induce the acetylene–allene rearrangement[27,28].

The relative weakness of the multiple carbon–carbon bonds compared with a single bond is the driving force of the polymerisation of unsaturated compounds. The polymerisation usually leads to a decrease of entropy and sometimes also the enthalpy of the system[29]. In the polymerisation of acetylenes, the change in the enthalpy of the system is a consequence of the replacement of the triple bonds by the more stable double bonds and the stabilisation of the resulting polyconjugated system[30]. The conjugation energy per unit in the polyvinylene (polyacetylene) chain is a function of the number of units and increases continuously up to the limiting value of 0.55 β, where β is the resonance integral or 10 kcal. The overall enthalpy of polymerisation of acetylene to give a polymer stabilised by conjugation should be 46 kcal mole^{-1}.[31] According to an estimate[30], the negative entropy of polymerisation of acetylene is −34.5 e.u.

II. RADICAL POLYMERISATION

1. Thermal Initiation

The reactions of phenylacetylene (PA) have been investigated in greatest detail. From approximately 120°C, amorphous, soluble, and coloured linear polyene is formed from PA (together with 1–25% of triphenylbenzenes)[32–41]. The molecular weight of the polymer $\bar{M}_n$ depends little on the polymerisation conditions[33,42]. An approximately twofold increase of the number-average degree of polymerisation (up to $\bar{P}_n = 26$) has been observed in the polymerisation of PA in the presence of polyphenylvinylene (poly PA) obtained beforehand[43,44]. The polymerisation of PA under pressure (80–200°C, 1000–6000 atm) proceeds at a much higher rate than under normal pressure, but the degree of polymerisation hardly changes[45,46].

The thermal polymerisation of PA can be explained satisfactorily in terms of a bimolecular initiation mechanism[36,37]. It is believed that there is a possibility of the formation under these conditions of the two most stable biradicals: triplet (*trans*-1,4) and singlet (*cis*-1,3). The first leads to mainly the chain propagation of the linear polymer and the second the formation of triphenylbenzenes. The polymerisation reaction is of second or higher order with respect to the monomer (2 in nonane and cyclohexane[37,47], 2.20 in xylene[36], and 2.32 in benzene[48]). The deviation towards the trimolecular reaction is probably associated with the formation of considerable amounts of cyclic trimers on bimolecular initiation and first-order termination. The rate of polymerisation in bulk is proportional to the concentration of PA, possibly in consequence of the gel effect. The activation energies for the polymerisation process E_a are respectively 26.8 and 33.67 kcal mole^{-1} in bulk[36] and in solution [37,47]. The termination of the growing macroradical probably occurs via degradative chain transfer to the monomer. Chain termination in the course of intramolecular cyclisation has also been postulated[47].

Pyridylacetylenes[49] and 5-ethynyl-2-methylpyridine polymerise similarly to PA.[36] The polymerisation of 5-ethynyl-2-methylpyridine[36] (125–175°C, solution in *p*-xylene) is of second order with respect to the monomer (E_a = 20.4 kcal mole^{-1}).

A soluble polymer with $\overline{M}_n$ = 950 has been obtained from *p*-dimethylaminophenylacetylene (150°C, 24 h) in 66.5% yield; *p*-nitrophenylacetylene (200°C, 4 h) gives rise to a partly soluble polymer in 97% yield and *o*-nitrophenylacetylene polymerises explosively at 150°C.[50] The polymerisation of *o*- and *p*-nitrophenylacetylenes takes place under the influence of cold plasma[51].

Acetylenic derivatives of condensed aromatic hydrocarbons (ethynylnaphthalene[52], 9-ethynylanthracene[53], 9-ethynyl phenanthrene[54], 5-ethynylacenaphthene[55], the 1,2-dihalogenoacenaphthylene dehydrohalogenation product[56], and *N*-ethynylcarbazole[57]) polymerise comparatively readily at 100–220°C (9-ethynylanthracene even at room temperature).

Under normal pressure, propargyl alcohol does not polymerise up to 200°C, but at an elevated pressure (6000 atm) it is converted into a polyene in 11% yield at a temperature as low as 120°C.[58] With increase of temperature, the yield of the insoluble product formed as a result of cross-linking via intermolecular elimination of water also rises. Intramolecular and intermolecular cross-linking processes have also been observed in the polymerisation of propiolic acid under pressure[59–61]. The polymerisation of the ethers formed by the interaction of propargyl alcohol with phenol and its *m*-methyl- and *p*-*t*-butyl derivatives takes place with an induction period, which diminishes with increase of reaction temperature (45 h at 160°C, 1 h at 250°C) and leads to low-molecular-weight products[62]. *N*-Propargylmorpholine also polymerises with an induction period[63]. With increase of the length of the alkyl group, the yield of poly-(*N*-alkyl-*N*-propargylamines) (polymerisation in bulk at 200–250°C, $\overline{P}_n$ = 5–9) diminishes, probably owing to a steric effect and a change in the polarisability of the triple bond[64].

A substituted polyene with $\overline{M}_n$ = 2700 is formed from ethynyltriphenylgermane at 180°C.[65]

Phenoxyacetylene polymerises spontaneously even at room temperature. The resulting polyene chains are cross-linked via a Diels-Alder reaction to hydroaromatic derivatives, which are aromatised by the elimination of phenol[66]. E_a 23.1 kcal mole^{-1} for phenoxyacetylene and free-radical initiators do not influence its spontaneous polymerisation[67,68]. Phenylthioacetylene is less reactive and *p*-nitrophenoxyacetylene is much more reactive in polymerisation than phenoxyacetylene[67,68]. The structures of the polymerisation products of 2-methoxy-1-phenylacetylene[66] and ethoxyacetylene[66,69] have not been determined.

In contrast to arylacetylenes, alkylacetylenes polymerise under more severe conditions[46,70,71]. Cyclohexylacetylene oligomers with $\overline{M}_n$ = 400–500 (E_a = 32.7 kcal mole^{-1}) have been obtained at a temperature in excess of 230°C.[70] It has been suggested[72] that the thermal polymerisation of alkylacetylenes occurs only in the presence of an admixture of allenes, which initiate the process. But-2-yne gives rise (250°C, 23.5 kbar) to an insoluble resin containing non-conjugated double bonds according to infrared spectroscopic data, which may indicate the formation of a ladder structure[73].

Disubstituted acetylenes polymerise at higher temperatures than the monosubstituted derivatives. For example, tolane polymerises at 300–400°C [74,75] and $\overline{M}_n$ for the polymers increases from 850 to 1200 when the temperature rises from 300 to 400°C. A bimolecular initiation mechanism has been suggested.

The dimethyl and diethyl esters of acetylenedicarboxylic acid polymerise at temperatures in excess of 200° and 300°C respectively[76]. The polymerisation of β-iodophenylacetylene is extremely complex and is accompanied by the evolution of iodine[77,78].

When diiodo and dichloro-maleic anhydrides or diiodo-*N*-phenylmaleimide were dehalogenated, the products were polymers resulting from the dissociation of the triple bond in the hypothetical anhydride of acetylenedicarboxylic acid or its analogue[79].

2. Polymerisation in the Presence of Initiators

The initiated radical polymerisation of acetylenes has no advantages over the purely thermal process. This is indicated by the extremely limited selection of initiators, a significant contribution of thermal processes in many instances, hindering the study of the reaction kinetics, the low conversion of the monomer, the low molecular weight of the resulting polymer, and the contamination of the polymer by the initiator decomposition products.

The initiators employed were benzoyl peroxide (BP),[45,80–111] lauroyl peroxide[88,112], t-butyl peroxide[45,58,107–110], azobisisobutyronitrile (ABIN),[45,89–94,96–98,100–102,104–106,111–118], triisobutylboron[45], triisopropylboron[43,44,112,119–122], and triethylboron[123]. The benzoyl peroxide initiator does not undergo simple thermal dissociation (60–80°C) and is involved in a chain reaction with monomer molecules. It has been shown for PA [84,124] that two radicals are formed under these conditions, one of which propagates the polymerisation and the other abstracts hydrogen from the monomer with formation of benzoic acid and an inactive radical; this is confirmed by the kinetics of the decomposition of benzoyl peroxide in PA, deuterophenylacetylene, and methylphenylacetylene. ABIN does not undergo chain decomposition in the presence of PA.[111] The formation of isopropyl hydroperoxide on polymerisation of PA in the presence of triisopropylboron and oxygen appears to indicate a radical process mechanism[119]. In the absence of oxygen, PA does not polymerise under the influence of triethylboron.

The rate of polymerisation of PA is proportional to the concentration of the monomer and the initiator (benzoyl peroxide), one polymer molecule being formed on decomposition of one peroxide molecule[84,85]. With increase of temperature (60–130°C), the rate of polymerisation rises appreciably and $\overline{M}_n$ varies in the range 600–1500.[85] It is suggested[125] that E_a for the radical-initiated polymerisation of acetylenes should equal the decomposition energy of the initiator (about 21 kcal mole^{-1} in the polymerisation of PA).

Benzoquinone inhibits the polymerisation of PA under the influence of benzoyl peroxide, which is probably associated with the suppression of the above initiation reaction by benzoquinone[84]. On the other hand, benzoquinone apparently does not inhibit the growing radical, since the radiation-induced and ABIN-initiated polymerisation of PA proceeds also in the presence of benzoquinone[111]. The rate of polymerisation of PA in the presence of triisopropylboron is of first order with respect to the monomer. The initiator concentration hardly affects the yield of the polymer, which is strongly influenced by the reaction temperature. The break in the lg *k*–1/*T* curve, where *k* is the effective polymerisation rate constant, corresponds to activation energies of 78 and 29 kcal mole^{-1}, which has not been explained[43,119,120,122].

The rate of polymerisation of ethynylferrocene in the presence of benzoyl peroxide, lauroyl peroxide, and triisopropylboron in bulk at 140–200°C is proportional to the monomer concentration and $E_a \simeq 10$ kcal mole^{-1}. Up to 190°C, the concentration of benzoyl peroxide (0.2–1.6%) does not affect the yield of the polymer. The conversion passes through a maximum at 190°C and for soluble fractions $\bar{P}_n = 4$–7.[86,87,112] In contrast to benzoyl peroxide[126], t-butyl peroxide did not oxidise ethynylferrocene and did not cause the degradation of the polymer under the conditions employed (160–180°C; molar ratio initiator : monomer = 0.25 : 1).[107–110] It is suggested that the radical formed on decomposition of the initiator abstracts from the monomer the mobile acetylenic hydrogen. The monomeric radical is stabilised in the form of the dimer (diferrocenylbutadiyne) which polymerises and is methylated owing to the decomposition of some of the butoxy-radicals.

It has been shown for 1-chloro-1′-ethynylferrocene[88] that the chlorine atom located in a heteroannular position relative to the ethynyl group greatly reduces the capacity of the monomer for polymerisation. A linear polyene structure, which may be crossed-linked via chlorocyclopentadienyl rings, has been proposed for the polymer.

Propiolaldehyde polymerises via the mechanism[114]

$$n\mathrm{HC{\equiv}C{-}CHO} \xrightarrow[1.9\%]{\mathrm{AIBN}\ 60°,\ 19\mathrm{h}} -[-\mathrm{HC{=}C(CHO){-}}]_n- \quad .$$

Propargyl acrylate[89–93], methacrylate[90–92], crotonate[92], itaconate[91], and acetate[94] were polymerised in bulk and in solution under the influence of ABIN and benzoyl peroxide at 60–80°C. For the first three monomers, the rate of reaction is proportional to the initiator concentration raised to a power of 0.7 and 0.8 in the presence of benzoyl peroxide and ABIN respectively and to the monomer concentration raised to a power of 1.6 in both cases; $E_a =$ 16–21 kcal mole^{-1}. For conversions up to 20–30%, polymerisation takes place via the dissociation of the double bonds, after which the triple bonds also react with the consequent formation of three-dimensional systems.

Vinylacetylene polymerises in the gaseous state at 250–400°C in the presence of small amounts of oxygen[127,128]. The rate of reaction is proportional to the monomer concentration raised to the power 1.94; $E_a = 25.3$ kcal mole^{-1}. The polymerisation of vinylacetylene in the presence of benzoyl peroxide takes place in a more complex manner[80,81]. Oligomers (ABIN; $\bar{P}_n = 4$–15) of divinylacetylene were obtained; oxygen accelerates the process and oxidises the polymer[116,117].

Numerous studies have been made on the polymerisation of ethynyldimethylvinylmethanol and its esters and ethers. Polycyclobutene[1,5,129] or polycyclopentene[11,94–104,118] structures, resulting from cyclopolymerisation involving the double and triple bonds, were proposed for the resulting polymers. Other investigators believe that the polymerisation proceeds only with participation of the double bonds[105,106] or with participation of the double bonds in the isopropenylacetylene series and with formation of cyclopentene rings in the vinylacetylene series[130].

A soluble polytolane was obtained in low yield under the influence of a shock wave. It is suggested that this involves a special type of polymerisation—"polymerisation in the shock wave"[131].

3. Radiation-Induced Initiation and Photoinitiation

The radiation-induced polymerisation of PA has been investigated in greatest detail. It has been carried out over a wide range of temperatures (between −196° and 100°C) in bulk and in solution under the influence of initiating radiation at different dose rates (36–10^6 r min^{-1}) and over a wide range of doses (10^6–10^8 r). Radiation polyPA—a yellow-orange amorphous product, soluble in many organic solvents, with a softening temperature of about 200°C, and with $\bar{M}_n = 1200$—was obtained in a yield of 10–12%. The radiation-chemical yield of the polymer G (the number of polymerising monomer molecules per 100 eV) is 8–9 [124,125,132–134] for irradiation with accelerated electrons (1.6 MeV) and 8–13,[135,136], 13–30,[137] and 30–40 [138] for irradiation with cobalt-60 γ-rays.

The mechanism of the radiation-induced polymerisation of PA is determined largely by the process temperature. Gol'danskii and coworkers[124,125,132–134] suggested that PA polymerises via a radical mechanism in both liquid and solid phases. Japanese investigators[118] believe that ionic polymerisation takes place at low temperatures; the possibility of an "electronic" mechanism is not ruled out either[139].

The rate of polymerisation of PA is proportional to the rate of initiation, i.e. to the dose rate. The same dependence has been observed in the polymerisation of propiolic acid and its salts[60,140–143], propargyl alcohol[138,144–146], and propargyl bromide[138,148,149]. This indicates the absence of bimolecular termination of the macroradicals when a radical process mechanism is postulated, which can be accounted for by the loss of activity by the growing radical owing to the increase of the degree of delocalisation of the unpaired electron. Instead of separating the chain propagation and termination reactions, it was suggested that a single polymer chain "decay" process be considered[125]. Subsequently this hypothesis was refined; the importance of the mobile acetylenic hydrogen, terminating both the material and the kinetic chain in consequence of the formation of an inactive radical, was noted[134]. Another important characteristic of the radiation-induced polymerisation of PA is the low value of E_a (~700 cal mole^{-1}) and hence the virtual independence of the rate of the process of temperature, which is characteristic of the ionic polymerisation of olefins.

In the presence of oxygen, the yield of polyPA increases by a factor of 1.2–2.[120,132,133] The polymerisation is not inhibited by radical process inhibitors (benzoquinone), possibly owing to the fact that the interaction of the inhibitor with radicals at a high steady-state concentration, i.e. with delocalised macroradicals which have lost their activity, is the most likely process. When PA was polymerised in solution in nonane or ethyl acetate, an appreciable deviation from additivity was noted, which indicates an effective transfer of the irradiation energy absorbed by the solvent to the monomer[124,132]. A specific feature of the polymerisation of PA in the liquid phase is the independence of the yield of the polymer of dose rate (for a given dose)[125], which is characteristic of the radiation-induced solid-phase polymerisation of vinyl monomers. For polyPA's, $\bar{M}_n$ is almost independent of the polymerisation temperature, the rate of initiation, the form of the initiating radiation, the monomer concentration, and the phase state. The use of radiation-induced initiation made it possible to graft PA to fibreglass[149].

The radiation-induced polymerisation of alkylacetylenes (propyne, hex-1-yne, oct-1-yne, and cyclohexylacetylene) proceeds similarly[124,132–135]. The rate of reaction is proportional to the dose rate: $E_a \simeq 1$ kcal mole^{-1} and $\bar{P}_n = 10-13$. A white insoluble thermostable polymer, resistant to the action of concentrated acids and alkalis, was obtained in the polymerisation of perfluorobut-2-yne under the influence of cobalt-60 γ-radiation[150] or electrons with energies in the range 0.5–4 MeV.[151]

Radiation-induced initiation has many advantages compared with thermal initiation and photoinitiation in the case of propiolic acid and its salts (fewer side reactions, the radiolysis of the monomer does not exceed 1–1.5%).[60, 140–143] For a dose of 124 Mr about 30% of amorphous polymeric acid with $\bar{M}_n = 3000$ and $G = 35-40$ is formed. According to infrared spectroscopic data, the *trans*-transoid configuration of the polyene chain arises in solid-phase polymerisation and the *trans*-cisoid configuration arises in liquid-phase polymerisation. At −196°C polymerisation does not occur and, on increase of temperature to between −120° and −100°C, postpolymerisation is observed. The reactivity of propiolate salts is determined by the stability of the crystal lattice (the radius and valence of the cation).

In the study of the radiation-induced polymerisation of 59 different acetylenic monomers, polymeric products were obtained only from acetylenedicarboxylic acid and neopentylene dipropiolate[13].

An ethynylferrocene polymer with $\bar{M}_n = 1000-3000$ was obtained in a yield of about 4% (γ-irradiation, 270 Mrad).[152]

The photopolymerisation of PA,[153] methyl 4,4-dimethylpent-2-ynoate[154], tolane[155], and propargyl bromide[148] has been investigated very inadequately.

III. IONIC POLYMERISATION

1. Cationic Polymerisation

An unsuccessful attempt to polymerise vinylacetylene and 3-ethylvinylacetylene in the presence of BF_3 and $AlCl_3$ was reported in 1959.[156] However, later it proved possible to polymerise both vinylacetylenes $RC{\equiv}CCH{=}CH_2$†, where R=R, Et, $Me_2(OMe)C$, or $CH_2{=}OMe$ [BF_3,[157,158] $BF_3.OEt_2$,[159–161] CCl_3COOH,[158,161] CF_3COOH,[158] H_2SO_4,[159] and $SnCl_4$ [159,160]] as well as other acetylenic monomers: pent-1-yne [$SnCl_4$ [162]], phenylacetylene [BF_3,[163] $BF_3.OEt_2$,[39,164] CF_3COOH,[39,164] CCl_3COOH,[155,166] $SnCl_4$,[162] and AlX_3 with X_3 = Cl_3, $EtCl_2$, Et_2Cl, or Et_3 [167]], 9-ethynylanthracene [$TiCl_4$ [53]], *p*-methoxyphenylacetylene [$BF_3.OEt_2$ and CF_3COOH [38,164]], $Me_2NC{\equiv}CC(O)R$ with R = H or Me [$TiCl_4$, $SnCl_4$, H_2SO_4, HBF_4, $BF_3.OEt_2$, $Et_3N.HBr$, or CF_3COOH [168]], and $ROC{\equiv}CH$ with R = Me, or iso-Bu [Friedel-Crafts catalysts[169]].

In the reaction of acetylene containing a powerful electron-accepting substituent ($NC-C{\equiv}CH$) using $TiCl_4$, $Co(Acac)_3$ (Acac = acetylacetone), and $AlEt_3$ as catalysts, a polymer is formed only in the last case, its yield being much lower than in the Ziegler polymerisation[169]. PA reacts with $SnCl_4$ to form a stable complex; polymerisation takes place after the addition of hydrochloric acid, which behaves as a cocatalyst[162].

The main product formed in the reaction of PA in the presence of CCl_3COOH (in benzene at 30–55°C) is 1-phenylvinyl trichloroacetate formed as a result of the addition of CCl_3COOH to the C≡C bond of the monomer. Acetophenone and about 3% of a low-molecular-weight linear polymer with a conjugated system were also detected.

It has been suggested[165] that the catalyst participates in the reaction in a dimeric form $(HA)_2$ and forms with the monomer an intermediate of the solvated ion pair type (A = anion):

$$HC{\equiv}CPh + 2\,(HA)_2 \rightleftarrows (CH_2{=}\overset{+}{C}Ph\bar{A}HA)\cdot(HA)_2.$$

This ion pair leads to the formation of low-molecular-weight products and initiates the polymerisation of PA:

$$(CH_2{=}\overset{+}{C}Ph\bar{A}HA)\cdot(HA)_2 + HC{\equiv}CFh \rightarrow (CH_2{=}CPhCH{=}\overset{+}{C}Ph\bar{A}HA)\cdot(HA)_2;$$
$$(CH_2{=}CPh-[-CH{=}CPh-]_n-CH{=}\overset{+}{C}Ph\bar{A}HA)\cdot(HA)_2 \rightarrow$$
$$\rightarrow (CH_2{=}CPh-[-CH{=}CPh]_{n+1}A + (HA)_2 + HA.$$

The reaction of PA with CCl_3COOH in nitroethane solution is of first order with respect to the monomer and of third order with respect to the catalyst, about 15% of a linear polymer with $\bar{P}_n = 5-10$ being formed together with acetophenone (about 85% of the reaction product)[166]. The lifetime of the ionic substances involved in the reaction in benzene is probably much shorter than in nitroethane.

An analogous linear polymer was also obtained in the polymerisation of PA in the presence of $BF_3.OEt_2$ or CF_3COOH in methylene chloride[39,164]. Here $E_a = 9.7$ kcal mole^{-1} at 0° and 25°C and is independent of the molar ratio of the catalyst and the monomer. In the chain termination reaction, the polymer forms a protonated 1 : 1 complex with an excess of the acid as a result of the interaction of the polymeric cation with the CF_3COO^- counter-ion or another proton transfer reaction. The formation of the complex together with the dependence of the rate constants for the elementary reaction steps (with the exception of initiation) on the length of the polymer chain[39] constitutes the main difference between the polymerisation of PA and that of vinyl monomers.

When PA was polymerised under the influence of BF_3 at room or a reduced temperature in n-hexane, methylene chloride, or 2-bromopropane, a fraction partly soluble in organic solvents was obtained together with a soluble fraction having $\bar{M}_n \simeq 3000$. A linear structure was attributed to both fractions on the basis of infrared spectroscopic data[163]. A linear polymer with $\bar{M}_n = 1000-2000$ was also obtained in the polymerisation of PA in the presence of $AlHal_nR_{3-n}$ in solution or in a suspension in toluene at 30°C [167] or in solution in n-hexane in the presence of $TiCl_4$.[170] The activity of $AlCl_nR_{3-n}$ falls to zero in consequence of the decrease of its electrophilic properties when $n \rightarrow 0$. The yield of the polymer, amounting to 18, 39, and 55% in polymerisation in methylene chloride in the presence of $AlBr_3$, $TiCl_4$, and BF_3 fell when the reaction was carried out under the influence of $BF_3.OEt_2$, $SnCl_4$, and VCl_3 and also in solution in hexane.

In the presence of $BF_3.OEt_2$, *p*-methoxyphenylacetylene forms polymers giving rise to protonated complexes on reaction with an acid. When CF_3COOH was used, only low-molecular-weight products were obtained[38,164]. In the polymerisation of 9-ethynylanthracene, the conversion of the monomer and $\bar{M}_n$ of the products increase with the temperature of the synthesis (the experiments were performed at approximately 20°C and at −70°C).[53] In the course of polymerisation, the active centre isomerises, which leads to the appearance in the polymer chain of allenic 1,6- units and structures (apart from the main 1,2-structures) formed via the Diels–Alder reaction between the growing end of the macromolecule and the initial monomer.

---

† The catalysts are indicated in square brackets.

In ether, hexane, or methylene chloride at −78°C, alkoxyacetylenes give rise to linear oligomers with $\overline{M}_n$ = 500–600, which are converted into polyketones on subsequent treatment with hydrochloric acid[169]:

$$\underset{\substack{|\\ OR}}{-CH{=}C}-\underset{\substack{|\\ OR}}{CH{=}C}- \rightarrow -CH_2-\underset{\substack{\|\\ O}}{C}-CH{=}\underset{\substack{|\\ OR}}{C}- \rightarrow -CH_2-\underset{\substack{\|\\ O}}{C}-CH_2-\underset{\substack{\|\\ O}}{C}- .$$

Vinylacetylene and its derivatives polymerise[157–161] as a result of the simultaneous dissociation of double and triple bonds with formation of ladder polymers, while only double bonds are involved in the radical process.

The decrease of the reaction rate with time, usually observed in the cationic polymerisation of acetylenes, is not associated with side reactions of the monomer and is due to the deactivation of the catalyst on formation of the catalyst–polymer complex[171]. Because of this, the polymerisation is carried out in the presence of large amounts of catalyst or at elevated temperatures, which promote the dissociation of the complex.

2. Anionic Polymerisation

As noted above, the tendency of alkynes to interact with nucleophilic agents should make them more reactive in anionic polymerisation compared with radical and cationic polymerisation. This is confirmed by the anionic polymerisation of tolane under mild conditions[172], while its thermal polymerisation produces a polymer only at high temperatures[74,75]. Activated electrophilic acetylenes (hexafluorobut-2-yne[173–177], methyl esters of propiolic[178,179], acetylenedicarboxylic, and phenylpropiolic acids, ethyl tetrolate[179], acetylpropiolic anhydride which polymerises also in the presence of alkali[179,180], cyanoacetylenes[181–184], dicyanoacetylene[185], propiolaldehyde[186], propiolamide, tetrolamide, and *N*-methylpropiolamide[187]) polymerise even under the influence of weak nucleophilic agents such as cyanide, thiocyanate, and halide salts.

With increase of the electrophilicity of the substituents at the triple bond (phenylpropiolonitrile[188], cyanoacetylene[181–184,189], and dicyanoacetylene[185,190]), the reactivity of the monomers rises: phenylpropiolonitrile does not change in the presence of tertiary amines, while dicyanoacetylene polymerises readily in their presence even at −73°C.

A method has been proposed for the polymerisation of dialkylamides of acetylene-α-carboxylic acids having the general formula $RC{\equiv}CC(O)NR'_2$ (propiolic or tetrolic acid is best) in aprotic solvents [dimethylformamide (DMF), dimethyl sulphoxide (DMSO), or hexamethylphosphoramide (HMPA)] in the presence of 5–10 mole % of PhSNa, t-BuOK, and tertiary amines with formation of polymers having $\overline{M}_n$ = 2000–3000.[191] The introduction of electron-donating substituents into the propiolamide molecule decreases the reactivity of the monomer; only resinous substances are formed as the products[187].

The reactivity of alkynes has been found to decrease in the following sequences:

$$HC{\equiv}CH > MeC{\equiv}CH > EtC{\equiv}CH\ ^{192} \text{ and}$$
$$MeOOCC{\equiv}CCOOMe > HC{\equiv}CCOOMe > MeC{\equiv}CCOOEt >$$
$$> PhC{\equiv}CCOOMe\ ^{179}.$$

The dimethyl ester of acetylenedicarboxylic acid polymerises even in the presence of a weak nucleophilic agent such as Cl^-, while the methyl ester of phenylpropiolic acid forms a polymer in approximately 1% yield only in the presence of PhSNa.

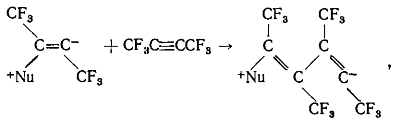
Together with the formation of a linear polyene, the occurrence of cyclotrimerisation processes has been noted[178,188,193–195]. A cyclic trimer is formed on polymerisation of propiolonitrile in the presence of BuLi, but not when sodionaphthalene is used[188]. For the ratio PA : n-BuLi > 20 in HMPA, triphenylbenzene was obtained instead of the linear polyPA.[195]

The polyene structure $-[-CH{=}C(CONH_2)-]_n-$ (polymerisation in bulk in the presence of triethylamine[189]) as well as the heterochain structure $-[-CH{=}CHCONH-]_n-$ (polymerisation in DMF solution in the presence of anhydrous NaCN[187]) has been proposed for polypropiolamide. The structure of polymers corresponding to the dissociation of monomer triple bonds only and analogous to the first of the two described above is produced on polymerisation of the dialkylamides of tetrolic and propiolic acids[196]. In this case the formation of a heterochain polymer is impossible owing to the absence of a mobile hydrogen atom in the amide group. Propiolaldehyde may be converted both into the copolymer $-[-HC{=}C(HCO)-]_x-$ $-[-OCH(C{=}CH)-]_y$ (at −40°C in the presence of NaCN in DMF[186] or at 0°C in the presence of pyridine in THF[114]) and into the homopolymer $-[-OCH(C{=}CH)-]_{x+y}-$ (at −78°C in the presence of pyridine or NaCN in THF[186]).

We shall consider in greater detail certain general features and characteristics of the elementary stages of the anionic polymerisation of acetylenes.

Initiation. Tolane[172], tetrolonitrile[197,198], phenylpropiolonitrile[188], dimethylaminopropynol and 4-dimethylaminobut-3-yn-2-one[168], benzoylpropiolic anhydride[180], acetylpropiolic anhydride[179,180], and dicyanoacetylene[185,190] have been polymerised using for initiation electron transfer from a metalloaromatic complex to the monomer. Such initiation takes place instantaneously and is accompanied by the formation of coloured products.

Polymerisation in the presence of phosphines[185,186,199], amines[184,185,189,199–203], and ammonia[189] presupposes a Zwitter-ionic initiation mechanism, which has been proposed, for example, for the polymerisation of propiolonitrile in the presence of triethylamine[184]. The formation of a dipolar ion is also postulated in the polymerisation of hexafluorobut-2-yne in the presence of Ph_3P, Et_2PH, and Me_3N[199]:



where Nu is a nucleophile.

In the presence of aromatic bases (pyridine, acridine, 3-aminopyridine, etc.), propargyl halides initially form quaternary salts, which then polymerise in the presence of the excess base[204]. Propargyl halides also polymerise in the presence of trialkylarsines, trialkylphosphines, or triarylphosphines[204].

Polar initiators, causing the dissociation of the triple bond of the monomer with formation of carbanions, constitute a large group of substances. The organometallic compounds in this class initiate the polymerisation of disubstituted acetylenes[168] and cyanoacetylenes[185,188,190,197,198]. Weak nucleophilic agents such as alkali metal salts and alkoxides initiate similarly the polymerisation of disubstituted[174–176,179,187,189] and monosubstituted acetylenes[178,180–184,186,187,196]. The polymerisation in the presence of alkali metal salts proceeds simultaneously via radical-anions and carbonium ions[179,205].

An unusual type of initiation reaction is observed in the polymerisation of monosubstituted acetylenes under the influence of strong nucleophilic agents: of 5-ethynyl-2-methylpyridine in the presence of a suspension of sodium[193]; of the mixed anhydrides of acetylene-α-carboxylic and other carboxylic acids[180]; of PA [194,206,207] and cyanoacetylene[183,184,208] in the presence of n-BuLi; of methyl-, ethyl-, and phenyl- acetylenes[192] and p-nitrophenylacetylene[50,209] in the presence of the lithium and sodium salts of DMSO. In this case the acidic acetylenic hydrogen atom is substituted by the metal and chain propagation takes place via the insertion of the monomer in the carbon-metal bond. This mechanism is supported by the polymerisation of acetylenes in the presence of alkali metal acetylides[183,192].

Whereas in non-polar solvents (benzene and toluene) and weakly solvated polar solvents PA does not polymerise in the presence of n-BuLi and gives rise to lithium phenylacetylide in HMP, n-BuLi adds to PA apparently with formation of butylstyryl-lithium, which behaves as the polymerisation initiator[195].

It has been suggested that the polymerisation of ferrocenylacetylene in the presence of a dispersion of sodium, which could not be achieved in the presence of n-BuLi, sodio-dimethyl sulphoxide, and sodionaphthalene, involves the initial dimerisation of the monomer with formation of diferrocenylbutadiyne and subsequent conversion into a ladder polymer[107–110].

Chain propagation. As in the anionic polymerisation of vinyl monomers, for acetylenes there probably exist various types of chain propagation active centres with different reactivities. A study of the polymerisation of acetylenes in DMSO showed[192] that chain propagation takes place at active centres which consist of a solvated complex of the carbanion and the monomer. The addition of a highly dissociated salt ($NaNO_3$, NaI) to the system hindered or stopped the polymerisation. A large excess of the salt suppressed also the initial coordination of the acetylide and the monomer. The results led to the conclusion that chain propagation in a highly solvating medium with a fairly high dielectric constant ($\epsilon \geqslant 23$) takes place preferentially via free anions.

The lack of experimental data on the synthesis of stereoregular polyenes even when the polymerisation is initiated by n-BuLi in a hydrocarbon medium is particularly noteworthy. Individual oligomeric stereoisomers[188] were detected in the polymerisation products of phenylpropiolonitrile in the presence of n-BuLi and sodionaphthalene in THF, which shows that the reaction is not stereospecific.

Chain termination. Chain termination may be due to various causes. A mass-spectrometric study of polyhexafluorobut-2-yne[210], obtained in the presence of CsF, showed that the process is initiated by the F^- ion, while proton transfer from the solvent to the carbanion is responsible for chain termination. Another type of chain termination has been observed in the polymerisation of $DC{\equiv}C{-}CN$.[181,183] According to infrared spectroscopic and NMR data for the low-molecular-weight fraction, the active centre is destroyed as a result of the transfer of deuterium from the monomer to the carbanion.

The absence of factors leading to chain termination presupposes the formation of "live" polymers. Indeed polyacetylene obtained in the presence of the sodium salt of DMSO retains for a long time the ability to form block copolymers with acrylonitrile, ethyl methacrylate, and styrene[192]. The activity series for the vinyl monomers then corresponds to the corresponding series for their anionic homopolymerisation.

Certain experimental facts suggest a decrease of the reactivity of the "live" polymer with increasing length of the polymer chain and an increase of the length of the polyene chain in equilibrium with the monomer when the temperature of the reaction mixture is reduced. Consequently even in "live" polymerisation chain propagation may cease as a result of the attainment of thermodynamic equilibrium in the system[‡]. In this case the change in the rate of polymerisation during the reaction can be explained only by the enhancement of the resonance stabilisation of the anion in the course of the propagation of the conjugated chain[23]. Calculations[202,212–214] confirmed these conclusions.

On the other hand, the observed self-inhibition in the polymerisation of phenylacetylene in the presence of n-BuLi in HMPA has been attributed to the formation of polymer-donor and monomer-acceptor charge-transfer complexes and not to kinetic termination or deactivation of the growing centre[195].

IV. POLYMERISATION OF ACETYLENES UNDER THE INFLUENCE OF TRANSITION METAL COMPOUNDS

Since cyclic and linear oligomerisation and polymerisation of acetylenes frequently accompany one another, the choice of reaction conditions is important for specific synthesis. This section deals mainly with studies whose aim has been to synthesise high-molecular-weight (oligomeric) linear polyene systems.

1. Catalysis by Transition Metal Salts and Their Complexes

Various reactions of acetylenes in the presence of copper(I) salts accompanied by the formation of cuprene analogues insoluble in organic solvents have been studied for a long time[2,6,215]. It has been suggested that polymerisation involving the conversion of PA into a soluble polyene with $M_n = 7000$ in the presence of CuO at 250–350°C proceeds via a stage involving the formation of a linear conjugated polyene which is converted into a three-dimensional product as a result of an intermolecular Diels-Alder reaction[216].

It has recently been established[217] that amine complexes of univalent and bivalent copper salts [CuCl, $Cu(OOCCH_3)_2$] polymerise butyne-2,4-diol and the diacetate derived from it. Linear polymerisation is accompanied by the intermolecular elimination of water or acetic anhydride. The complex spontaneous polymerisation of phenoxyacetylene is apparently accelerated in the presence of CdI_2. [66]

PA has been polymerised in the presence of rhodium salts [$RhCl_2$, [218] $RhCl_3$, [219,220] $RhCl_3.3H_2O$, [221,222] and $Rh(NO_3)_3$ [219]], while in the presence of the complex $RhCl.(PPh_3)_3$ PA, [223,224] hexafluorobut-2-yne[225], and α-ethynylnaphthalene[226] have been polymerised. The reaction is of first order with respect to the monomer and

---

[‡] The reversible nature of the polymerisation of acetylene was also observed on carrying out the reaction in the presence of a complex catalyst, where the degree of polymerisation increased with increase of the pressure in the system[211].

the catalyst[219,221], reaching a maximum value in the medium with the dielectric constant $\epsilon = 10$.[219] The activation energy for chain propagation remains constant (approximately 15 kcal mole^{-1}) in media with $\epsilon < 10$, increasing to 20.8 kcal mole^{-1} with increase of ϵ from 10 to 25.1. The dielectric constant was altered by carrying out the polymerisation in different solvents (benzene and its mixtures with ethanol, DMF, and DMSO). Consequently the coordination between the catalyst and solvent molecules determines the polymerisation process. With increase of the concentration of alcohol, there is merely an increase of the number of active centres, which leads to a rise of the rate of reaction without a change in the activation energy. DMF and DMSO, which have been used to obtain media with high dielectric constants, forms stable complexes with the catalysts, which results in an increase of the activation energy and a decrease of the rate of the process.

PA and methylacetylene polymerise over $PdCl_2$ [227] or its complexes with benzonitrile[227,228] and DMSO;[228] poly-(α-ethynylnaphthalene) has been obtained in the presence of the complex $(PdCl_2.PPh_3)_2$.[226] In solutions of rhodium and palladium salts, both catalytic and noncatalytic reactions of acetylenes are possible. The linear oligomerisation of vinyl- and phenyl-acetylenes with formation of σ-organo metallic polyenes has been observed by Temkin and Flid and coworkers[220]. The products are $Cl_mM-[C(R)=CR'-]_{n-1}-CH(R)C(O)R'$ in aqueous solutions and $ClPd-[C(R)=CR'-]_{n-1}-C(R)=C(R')Cl$ with $n = 18-20$ in non-aqueous solutions.

PolyPA with $\overline{M}_n = 3400$ has been synthesised in 67% yield at 20°C in the presence of $[Mo(OCH_3)_2Cl_2]_2$, obtained by dissolving $MoCl_5$ in absolute methanol[229].

The complexes of nickel cyanides with heterocyclic aromatic amines[230] or complexes of the type $NiX_2.(PR_3)_2$, where X = SCN, Cl, Br, or I and R = alkyl, cycloalkyl, aryl, or arylalkyl, have been used to synthesise linear polymers based on various mono- and di-substituted acetylenes[112,226,231-234]. An increase of the catalytic activity of the complexes has been observed in the series $NiCl_2 < NiBr_2 < NiI_2$, PA forming mainly a linear polymer, while propynol gives approximately equal amounts of linear polymers and aromatic trimers[231]. The polymerisation of the dibutyl ester of ethynylboronic acid in the presence of $NiBr_2(PPh_3)_2$ is accompanied by degradative-hydrolytic processes leading to a three-dimensional polymer with the probable structure $[-\overset{|}{C}=\overset{|}{C}-B(OH)OBu]_n$.[235]

In contrast to the complexes $NiX_2.(PPh_3)_2$ discussed above, in the presence of $(PPh_2)_2Ni(C_5H_7O_2)_2$ ethynylferrocene polymerises with difficulty and the structure of the polymer differs from that of the polyethynylferrocenes obtained in the presence of triphenylphosphine complexes or radical initiators[112]. The platinum complexes $(Ph_3P)_2.Pt(R)Cl$ (R = Cl or H), in the presence of which PA,[234,236] 2-methylbut-3-yn-2-ol[237,238], and α-ethynylnaphthalene[226] polymers have been obtained, are less active in the polymerisation of acetylenes.

2. Group VI–VIII Metal Carbonyls

A number of nickel[25,239-243], chromium, molybdenum, and tungsten[242,244] carbonyls or their complexes, for example $Mo(CO)_6$, $Mo(CO)_5.PPh_3$, $Mo(CO)_3.3PyH$, $Ni(CO)_2.(PPh_3)_2$, etc. have been used in the polymerisation of various acetylenic monomers. The polymerisation of 35 different mono- and di-substituted acetylenes in the presence of the complex $Ni(CO)_2.(PPh_3)_2$ has been studied in greatest detail[239,240,245]. The preferential formation of benzene derivatives or linear oligomers of the type $RC{\equiv}C-[-C(R)=CH-]_n-CH=CHR$ and $RC{\equiv}C-[-C(R)=CH-]_n-C(R)=CH_2$, where $n = 0-10$, was determined mainly by the nature of the substituent at the triple bond[239]. Whereas monosubstituted acetylenes with lower alkyl aryl, vinyl, $HOCH_2$, EtOOC, RCO, and RO substituents underwent only cyclotrimerisation, acetylenes with higher alkyl substituents yielded mainly linear oligomers. Only a linear dimer has been obtained from cyclohexylacetylene, while a number of monosubstituted (t-butylacetylene, propargyl chloride, propargyl acetate, cyanoacetylene, 5-chloropent-1-yne, and propiolic acid and its amide) and disubstituted acetylenes (with the exception of but-2-yne-1,4-diol and but-2-yn-1-ol) failed to react. With decrease of the reactivity of the monosubstituted acetylenes (ethers and esters, ketones, vinylacetylene > arylacetylenes > alcohols > higher alkynes > lower alkynes, acetylene ≫ acids), there was an increase of the yield of the linear polymerisation products.

A relation between the rate of reaction and the yield of the polymers on the one hand and the polarity and other properties of the solvents employed in the reaction on the other has not been found in the polymerisation of PA and hept-1-yne[240]. Water, dioxan, THF, acetic acid, and butan-2-one are unsuitable as solvents owing to their ability to form strong coordinate bonds or to decompose the catalyst irreversibly. The reaction is very sensitive to temperature and mixing.

The activity of the catalyst and the direction of the reaction depend also on the nature of the ligands bound to nickel. The replacement of the group R = OPh by R = C_2H_4CN in $Ni(CO)_2.(PR_3)_2$ favours linear polymerisation, while $Ni(CO)_4$ is altogether inactive in the polymerisation of monosubstituted acetylenes[240,246]. However, monomers (propargyl esters of propiolic and undec-10-ynoic acids) are capable of forming activated cyclic intermediates with $Ni(CO)_4$ polymerise in the presence of this complex[246].

In the polymerisation of PA in the presence of arene-metal tricarbonyls $ArM(CO)_3$, where Ar = toluene or mesitylene and M = Cr, Mo, or W, the reaction is fastest in the presence of molybdenum catalysts in hot aromatic solvents or in bulk at room temperature[242,243], giving a quantitative yield of a linear polyphenylacetylene with a molecular weight of 12 000 (according to gel-chromatographic data).

3. Organic Compounds of Group V-VIII Metals

Under the influence of triphenylchromium, hexafluorobut-2-yne forms only linear polymers[241]. On the other hand, when "dimesitylcobalt"[247] and "diphenylcobalt"[248], which are intermediates in the reaction of cobalt bromide with mesityl- and phenyl-magnesium bromides, are used, but-2-yne and hex-3-yne give rise to a mixture of linear polymers and cyclic trimers. The yield of the polymer and cyclic trimer is directly proportional to the initial concentration of the monomer, but the polymer : cyclic trimer ratio changes at a low temperature from 1 : 17 to 5 : 1 on passing from but-2-yne to hex-3-yne[247]. This is probably associated with the increased steric hindrance in the cyclotrimerisation of hex-3-yne. The yield of poly(hex-3-yne) increases with increase of the concentration of the monomer and falls with increase of temperature, the polymerisation involving a catalytic mechanism under any conditions[248].

Analogous active intermediates are probably formed also when the Iotsich reagents RC≡CMgX are treated with cobalt and nickel chlorides[249].

Acetylenes polymerise in the presence of dicyclopentadienylvanadium[250] and complexes of heterocyclic aromatic amines with dicyclopentadienylnickel[230]. Mainly trialkylbenzenes are formed from propyne, pent-1-yne, and hex-1-yne, PA gives a linear polymer, while disubstituted acetylenes (hept-3-yne, but-2-yne-1,4-diol, and tolane) remain unchanged under these conditions[250]. In the presence of diacrylonitrile- and diacrolein-nickel, phenylacetylene, propargyl alcohol, phenylpropiolaldehyde, and propiolate and acetylenedicarboxylate esters react vigorously to form polymeric products[251].

It has been established[234,236–238] that bistriphenylphosphine complexes of σ-organometallic derivatives of nickel and platinum $(PPh_3)_2Ni(C{\equiv}CPh)_2$,  $(PPh_3)_2Pt\left<\begin{array}{l}CH\\ \| \\ CPh\end{array}\right.$, and *cis*- and *trans*-$(PPh_3)_2Pt(C{\equiv}CPh)_2$ catalyse the polymerisation of monosubstituted acetylenes (PA and 2-methylbut-3-yn-2-ol) in bulk and in solution. The less active platinum complexes, in the presence of which the reaction occurs at a fairly high temperature (110–193°C) and is therefore complicated by the thermal polymerisation of the monomer, make it possible to obtain almost exclusively linear polymers. Vinyl-, isopropenyl-, phenyl-, divinyl-, and vinylisopropenyl- acetylenes have been recently polymerised in the presence of the diarene complexes $M(AlCl_4).2C_6H_6$ (M = Co or Ni [252,253])—the so called "alkyl-free organometallic catalysts"[254].

The polymerisation of acetylenes under the influence of catalytic systems based on π-allyl transition metal complexes is of considerable interest. Such complexes were proposed for the first time for the polymerisation of monosubstituted acetylenes by Japanese investigators[255].

In the presence of the π-allylmetal halides $[\pi\text{-(allyl)}.MX]_n$, where allyl = C_3H_5 (allyl), C_4H_7 (but-2-enyl), or C_5H_9 (pentenyl), M = Ni or Pd, X = Cl, Br, or I, and n = 1 or 2, alkylacetylenes (hex-1-yne, hept-2-yne, and oct-4-yne) cyclotrimerise and arylacetylenes (PA) oligomerise[256,257]. The activity in cyclotrimerisation falls in the above series of allyl derivatives.

Polyvinylenes have been obtained from methyl-, phenyl-, vinyl-, and vinylpropenyl-acetylenes under the influence of $(\pi\text{-}C_4H_7NiX)_2$, where X = I or Cl.[258] The reaction takes place quantitatively under mild conditions (25°C, 2 h, molar ratio monomer : catalyst = 30–50) and vinyl- and vinylpropenylacetylenes polymerise exclusively via the triple bond.

PA [259,260] and cyanoacetylene[261] in the presence of di-(π-allyl)nickel and PA in the presence of di-(π-but-2-enyl)nickel[260] form a mixture of cyclic trimers and linear polyenes. The maximum conversion of cyanoacetylene in the temperature range between −30° and 30°C occurs at 30°C. The yield of both the polyene and the cyclic trimer diminishes as the temperature is reduced[261,262].

The polymerisation of vinyl- and isopropenyl-acetylenes in the presence of di-(π-allyl)nickel gives rise to a mixture of soluble and insoluble products[263]. Above 0°C, the main reaction product from isopropenylacetylene is a soluble polymer, while below 0°C an insoluble polymer is formed. The soluble polymer loses its solubility after isolation. The polymerisation involves preferentially the isopropenyl group in the 1,2-position, together with the dissociation of the triple bonds and the formation of small blocks of conjugated double bonds. A polymer consisting mainly allenic units has been obtained from vinylacetylene via the 1,4-addition mechanism. Polymerisation via the triple bond also takes place to a slight extent.

The activity of the π-allyl complexes of nickel decreases in the sequence[257,258] $(\pi\text{-}C_4H_7NiI)_2 > (\pi\text{-}C_4H_7NiCl)_2 > (\pi\text{-}C_4H_7)_2Ni$. The influence of electron-donating (phosphines and amines) and electron-accepting (nickel trichloroacetate, $AlBr_3$, and $TiCl_4$) additives on the polymerisation reaction is extremely varied. In the presence of pyridine and DMF (in the stoichiometric amount or in excess relative to the catalysts), the overall yield of acetylene oligomerisation products in the presence of the $[\pi\text{-(allyl)}MX]_n$ catalysts falls, the cyclotrimerisation processes being retarded in the first place. Triphenylphosphine exhibits a weaker inhibiting activity than amines. Complexes containing more than three PPh_3 molecules per metal atom greatly activate the cyclisation of alkynes[257]. On passing from $(\pi\text{-}C_4H_7NiI)_2$ to its complex with one molecule of $Ni(OCOCCl_3)_2$ (the latter does not catalyse the reactions of acetylenes), triphenylbenzene is formed preferentially from PA instead of the linear polymer. On the other hand, when $(\pi\text{-}C_4H_7NiCl)_2$ is replaced by its complex with 1.5 molecules of $Ni(OCOC.Cl_3)_2$, the rate of cyclotrimerisation of hept-2-yne decreases without a change in the mode of the process[256]. A retardation of the polymerisation of vinylacetylenic hydrocarbons under the influence of Lewis acids has also been noted[258].

When di-(π-allyl)nickel is used, the influence of the additives varies depending on the nature of the monomer. The presence of phosphines does not influence the direction of the reaction of cyanoacetylene and the yield of reaction products[261,262]. On the other hand, the addition of PPh_3 and $TiCl_4$ alters the mode of polymerisation of isopropenylacetylene: the triple bond is dissociated instead of the double bond. The replacement of $(C_3H_5)_2Ni$ by $(C_3H_5NiBr)_2$ has a similar effect[263].

4. Ziegler–Natta Catalysts

The most common organometallic complex catalysts, or Ziegler–Natta catalysts, which are widely used in the polymerisation of olefins, have also found applications in the polymerisation of acetylenes. Depending on the nature of the acetylenic monomer and the reaction conditions, the process can be driven towards the preferential formation of cyclic trimers (benzene derivatives)[7,14,17,18,25] or linear polymers[7,17,18,264–271]. The available data about the influence of reaction conditions on the structural specificity of the polymerisation process are extremely contradictory. When alkynes were polymerised under the influence of catalytic systems based on organoaluminium compounds and titanium derivatives, the maximum yields of cyclic trimers were obtained in the presence of $TiCl_4$.[272–280] It was also noted[281,282] that the reaction in the presence of $TiCl_3$ leads to the formation of linear polymers only, which is inconsistent with other data (see below).

Substituents at the titanium atom have a much stronger influence on the direction of the process than changes in the aluminium component. The $Et_3Al\text{–}(C_5H_5)_2TiX_2$ catalytic systems, where X = Cl or OBu, are relatively ineffective in the linear polymerisation of PA.[283] When $TiCl_4$ in the complex with R_3Al (where R = Et or iso-Bu) is replaced by $Ti(OR')_4$ (where R′ = Et or Bu), the catalytic system becomes inactive in the cyclotrimerisation reaction[282,284–286]. On the other hand, systems of the type $R_2AlCl\text{–}Ti(OR')_4$ are active in cyclotrimerisation and polymerisation[284,286]. These data suggested that, in order to obtain benzene derivatives from acetylenes under the influence of typical Ziegler–Natta catalysts, a halogen atom combined with a transition metal[275] or in one of the catalyst components[284] is necessary. On the other hand, when Et_3Al is replaced by Et_2AlCl in the complex with $Fe(DMG)_2$ (where DMG = dimethylglyoxime), the system becomes almost inactive in the polymerisation of PA.[286] Similarly the effectiveness of the alkylaluminium component in the complex with $Fe(DMG)_2.2X$ (where X = PyH or NH_3) in the linear polymerisation of α-ethynylnaphthalene decreases in the sequence[287] $Et_3Al > (iso\text{-}Bu)_3Al > Et_2AlCl$. A change in the transition metal can affect both the proportions and the structures of the linear and cyclic polymerisation products.

The catalytic activity of the complex catalyst with Et_3Al in the polymerisation of α-ethynylnaphthalene[288] decreases in the following sequence as a function of the transition metal: $Co(Acac)_3 > Fe(Acac)_3 > Cr(Acac)_3 > Ti(OBu)_4 > VO(Acac)_2$, while in the polymerisation of PA [285] the sequence is $Co(Acac)_3 > Cr(Acac)_3 > VO(Acac)_2 > Ti(OBu)_4 > TiCl_2(C_5H_5)_2$.

Whereas the polymerisation of ethynylferrocene in the presence of the $R_3Al–Ti(OBu)_4$ catalytic system leads to the formation of polyenes with $\overline{M}_n = 1000–3500$,[285] there is no polymerisation under the influence of $Et_3Al–TiCl_4$,[289] while in the presence of $(iso\text{-}Bu)_3Al\text{-}VO(Acac)_2$ insoluble and infusible products were obtained; according to infrared spectroscopic data, such products are not formed as a result of the dissociation of the triple bond[290].

The complexes $(iso\text{-}Bu)_3Al–VOCl_3$ and $(iso\text{-}Bu)_2AlCl–VOCl_3$ are less active than $(iso\text{-}Bu)_3Al–TiCl_4$, probably in consequence of the interaction of the oxygen p electrons with the vacant orbitals of vanadium, which lowers its capacity for coordination. The coordination saturation of the vanadium atom on passing from $VOCl_3$ to $V(Acac)_3$ in the above complexes makes them inactive in the formation of linear and cyclic products[291,292]. The reduced activity of the vanadium complexes compared with the titanium complexes is also associated with the greater stability of the former[292]. The stereospecificity of the $(iso\text{-}Bu)_3Al–TiCl_4$ system demonstrated in relation to 1,3,5- and 1,2,4-tri-n-butylbenzenes formed on polymerisation of hex-1-yne, is much higher than that of $(iso\text{-}Bu)_3Al–VOCl_3$,[291] which agrees with the relative stereospecificities of the analogous systems in the polymerisation of propene[293].
