The distribution of the petroleum components with respect to molecular weight is different for different types of petroleum. Petroleums from gas-condensate deposits and petroleums which have undergone the greatest geochemical transformations under reducing conditions are enriched in the light components. Petroleums which have undergone least geometrical modification under reducing conditions or which have undergone oxidation transformations are enriched in the heavy components. The same group includes petroleums greatly enriched in tars and asphaltenes, which have undergone the stage of retrograde condensation accompanied by the elimination of the light fraction, which under suitable conditions might have formed gas-condensate deposits.

In conformity with all the foregoing factors, the distribution of petroleum heteroatomic compounds among its fractions varies just as strongly. Heavy petroleums are usually richest in the HAC. For a more correct understanding of this phenomenon, it is necessary to consider the differentiation of petroleums not only with respect to their boiling points but also with respect to their "component composition", which was introduced into practical technical analysis of petroleums as early as the beginning of this century by Richardson[6] and, independently, by Marcusson[7].

After the distillation of light-coloured petroleum products and dilution of the residue with benzene, asphaltogenic acids and then their anhydrides are extracted (by Marcusson's method) from the heavy component of petroleum. This is followed by the deposition of asphaltenes, carbenes, and carboids, heavy oils are eliminated from the residue, and petroleum tars ("silica gel" tars according to the method of their isolation) are obtained. This method of separation has been described in detail by Nametkin[8], who also indicates simplified versions of the method recommended by Sakhanov[9] and refined by Starostin and Boldyreva[10]. The essential feature of the simplification consists in the abandonment of the isolation of asphaltogenic acids and their anhydrides from asphaltenes. This version of the method has been widely adopted. Subsequently it was supplemented by the desorption of oils and tars from the silica gel by a series of solvents of increasing polarity, which made it possible to differentiate the oil fraction into saturated and aromatic fractions with increasing contents of heteroatomatic compounds. The development of component analysis is described in greater detail by Sergienko[11].

All the versions of the methods of component analysis considered involve the precipitation of asphaltenes by solvents of low polarity and the sorption of tars on silica gels, alumina, natural bentonite clays, or zeolites (for a description of the latter, see Benashvili[12]). It is then assumed that the majority of the heteroatoms detected in the tars and asphaltenes isolated are present as structural elements in molecules of high-molecular-weight compounds, being linked to them by σ bonds. However, sufficiently convincing evidence for this view has not so far been adduced. Our own observations make it necessary to assume that, together with the heteroatoms entering into the composition of asphaltenes and tars with formation of classical bonds, heteroatoms in comparatively low-molecular-weight compounds, sorbed both on silica gel and on macromolecular formations generated by tars and asphaltenes, play a significant role. The stability of the supermolecular formations formed is determined under these conditions not only by the donor–acceptor interactions with participation of the heteroatom but also by the similarity of the structures of the hydrocarbon fragments of the moieties enriched in condensed aromatic and naphthenoaromatic rings. Nor can one exclude the role of the formation of clathrate compounds by low-molecular-weight components with macromolecular components, the former being enclosed in hollow structural cells of the latter.

The characteristics of the elemental, component, and fractional compositions of the petroleums in the Soviet Union are described in a handbook[13], the majority of the data in which have been obtained by unified methods and are comparable. The same handbook quotes the structural-group characteristics of the light-coloured distillates and the compositions of the majority of petrols in terms of individual hydrocarbons.

The functional characteristics and the content of sulphur and its derivatives in petroleums from the Urals-Volga region and Siberia have been determined by Obolentsev and Baikova[14], also using unified methods. Their monograph[14] includes data concerning the presence of free, hydrogen sulphide, mercaptan, disulphide, and sulphide sulphur in fractions which begin to boil at temperatures up to 120°C, in the ranges 120–200°C, 200–250°C, and 250–300°C, and in narrow (approximately 3 K fractions) of a number of petroleums in the USSR as well as data concerning the presence of free, mercaptan, and sulphide sulphur in the initial petroleums. The monograph also contains information about the overall sulphur content, which makes it possible to deduce the presence of "residual sulphur", contained mainly in compounds belonging to the thiophen and diaryl sulphide series. Unfortunately, the authors[14] do not characterise the residues boiling above 300°C (even their yield is not quoted). The monograph lists the characteristics of a number of petroleums and fractions relating to the threshold of thermal stability, indicating the presence of thermally unstable compounds (determined using the method adopted by Coleman et al.[15]), and the analytical methods used are described.

The distribution of sulphur and nitrogen among the component fractions of the petroleums from the Urals-Volga region and Western Siberia was recently reported by Eigenson and Ivchenko[16], who established that, after the distillation of fractions boiling up to 450°C (containing about 60% of all the sulphur present in petroleum), the sulphur in the residue is present to the extent of 36–40% in oils, 42–46% in tars, and 15–20% in asphaltenes. The distribution of nitrogen is markedly different: the residue contains about 90% of the amount present in the initial raw material; the oils in the residue contain only 4–8% of the nitrogen, the tars 52–63%, and asphaltenes 37–42%. This is apparently associated with the relatively higher reactivity of the nitrogen compounds, leading to their association in the form of salts and complexes with the oxygen-containing components of petroleum—primarily acids and phenols. The overall nitrogen content is approximately an order of magnitude lower than the content of sulphur in these petroleums.

An interesting version of the component semimicro-analysis of petroleum was achieved by Pozdyshev et al.[17]: light hydrocarbons were extracted with a 1 : 4 methanol-acetone mixture; a 10% NaCl solution precipitates from the extract light oils with an admixture of surface-active comparatively low-molecular-weight heteroatomic compounds, which can be extracted with water. The residual tar ("Goudron") remaining after the extraction of the light oils was deposited on paper, from which heavy oils were extracted with isopropyl alcohol; after this, tars were extracted with boiling hexane and asphaltenes with boiling benzene. The method yielded data in satisfactory agreement with the results obtained in the usual way.

The petroleums from the deposits in the Western Siberian, Urals-Volga, and Western Kazakhstan regions (the Ust-Balyk, Pravdinsk, Megionsk, Uzen'sk, Romashkino, Arlansk [tentative transcription], Pokrovsk, and Mukhanovsk deposits) were investigated by this micromethod. The limits of variation of the compositions of these petroleums were found: 26–77% of light oils (with the average molecular weight M = 190–241); 10–49% of heavy oils (M = 311–603); 2–14% of tars (M = 577–1059); 0.2–4.4% of asphaltenes (M = 886–3298). The light transmission constants [presumably ϵ_λ values (Ed. of Translation)] of the crude petroleums and oils are similar and vary in the range 162–660; the corresponding ranges for tars and asphaltenes are 1964–3670 and 4106–15 000 respectively. The method proposed will presumably prove useful for the investigation of heteroatomic compounds in petroleum in combination with modern gas-chromatographic elemental microanalysis.

Purely chemical methods for the separation of petroleum components, based on the reactions of functional groups, are the most important for the isolation, separation, and identification of the heteroatomic components of petroleum and petroleum products. Here we shall recall the extraction from petroleum of nitrogen-containing bases by acids, the subsequent extraction of carboxylic acids with sodium carbonate, the extraction of phenols with strong alkalis, and the re-extraction of the bases liberated on hydrolysis of the salts which they have formed with petroleum acids. Since the present author and Musaev applied this method for the first time[18] in order to characterise the relation between the properties of light petroleum hydrocarbons (from deposits of different ages) and those of non-hydrocarbon components—bases, acids, tars, and asphaltenes†—it has not altered fundamentally.

It has been suggested that *o*-sulphobenzoic and sulphosalicylic acids[20] in the form of 10% aqueous solutions and in the anhydrous state be used instead of inorganic acids for the extraction of bases from fuel fractions. The extraction of bases is accompanied under these conditions by the transfer of some of the acids to the hydrocarbon phase and the elimination of acids from the extract is difficult. An important advance was the use of ion-exchange resins (anion and cation exchangers) for the selective extraction of compounds with acid and basic functions. As long as the aim of the investigations was to free the petroleum products from these components, the main task involved quantitative sorption and did not present special difficulties. Following the development of research devoted specifically to the heteroatomic components of petroleum, attention had to be concentrated on the much more difficult problem of the quantitative desorption of the test compounds in an unchanged form.

The coarsely porous sulphonic acid cation-exchange resins KU-2 and KU-23 (styrene-divinylbenzene copolymers) have been used[22–25] for the extraction of nitrogen-containing bases from crude petroleums and distillates. According to Bezinger et al.[23], the following method has been recommended for the preparation of

---

†This study was carried out in connection with the investigation of the role of surfactants in crude petroleums in the displacement of petroleum by water and in the formation of emulsions, carried out by Zinchenko in consultation with Rebinder and Kusakov. Evidently the suggestion[19] that the first studies on surfactants in crude petroleum were made in 1946[20] is erroneous.

nitrogen-containing concentrates from petroleum: a benzene solution of petroleum is treated with a cation exchanger and filtered, acetic anhydride and a portion of fresh cation exchanger being added to the filtrate in order to increase the sorbability of the nitrogen-containing bases on the cation-exchange resins. The rate and degree of extraction of the bases increase greatly under these conditions (one must bear in mind that the capacity of the cation exchanger with acetic anhydride is appreciably reduced). The role of acetic anhydride is in this case probably the same as in non-aqueous titration in differentiating solvents. However, one cannot rule out the possibility that acetic anhydride binds a proportion of the heteroatomic petroleum components, blocking the nitrogen of certain bases. Such ideas are supported by the finding that a similar effect can be obtained on replacing acetic anhydride by dimethylformamide.

The stepwise separation of chemisorbed bases into those extractable by benzene and ethanol, recommended by Bezinger et al.[23], is not obligatory. A series of solvents of increasing polarity can be used for selective desorption, particularly when one can postulate the presence in the mixture of compounds differing in their basicity. The complete extraction of all the bases by a highly polar solvent is also feasible. In experiments with distillates containing an appreciable amount of sulphides, it is best to convert them first into sulphoxides in order to facilitate their separation from nitrogen-containing bases on the cation-exchange resin.

The proposed version of the isolation of bases with the aid of acetic anhydride is naturally applicable only to petroleum and products which do not contain appreciable amounts of primary and secondary bases capable of chemical interaction with this reagent (acylation).

A procedure resembling the isolation of petroleum bases is the extraction of organic sulphides from petroleum distillates with sulphuric acid. There are no fundamental differences: both nitrogen and sulphur compounds of the above groups are freely converted into 'onium forms, which are readily hydrolysed with regeneration of the initial amines and sulphides:

$$R_3N + HA \rightleftarrows R_3NH^{\oplus}A^{\ominus} \quad ,$$

$$R_2S + HA \underset{H_2O}{\rightleftarrows} R_2SH^{\oplus}A^{\ominus} \quad .$$

The growth of interest during the last decade in the isolation of large amounts of sulphides from middle petroleum fractions stimulated vigorous research on their extraction with sulphuric acid. A version of the sulphuric acid method for the preparation of sulphide-aromatic concentrates has been proposed by Chertkov, Spirkin, and Demishev[26,27]. Subsequently, this procedure was frequently tested and refined[28,29], and has reached a stage where it can be applied on an experimental-industrial scale. The method is widely used in studies in the USSR on the sulphides of middle petroleum fractions[30].

The much lower basicity of sulphides (compared with nitrogen-containing components) and their higher concentration preclude their isolation in a pure form: sulphide-aromatic concentrates are always obtained. The same happens in sorption methods for the isolation and separation of heteroatomic petroleum compounds on silica gels, alumina, and other acid or amphoteric oxides. Certain differences between the concentrates obtained (a reduced content of light dialkylsulphides and an increased degree of extraction of thiophens into the sulphuric acid concentrate) have been examined[31].

The formation of hydrogen bonds of different types probably plays an important role in the formation of sulphide-aromatic concentrates[32]. The tendency of sulphides to form associated species with condensed aromatic compounds, recently investigated in model systems[33-35], is undoubtedly also significant[32]. It has been shown that such species are formed only by aromatic sulphides and aromatic hydrocarbons and it has been suggested that the type of association is the same as that observed in purely hydrocarbon systems. Associated species, mainly with 1:2 composition, have been observed for the latter in binary systems, while the component ratio in the associated species in sulphide-hydrocarbon systems is 1:1.

The characteristic features of the solubility of organosulphur compounds and the possibility of their isolation and separation by extraction are directly related to the characteristic features of the complex formation process. On the basis of studies of the solubilities of 30 sulphides in 24 organic solvents, Obolentsev et al.[36] divided solvents into three groups: in the first group, the solvent power depends little on the molecular weight of the sulphur compound (acetylacetone, propyl alcohol); in the second group, the solvent power varies sharply with the molecular weight; the solvents of the third group tend to dissolve selectively specific types of sulphur compounds. The study was performed by determining the consolute temperatures. In the experimental temperature ranges, the composition–temperature curves pass through a distinct maximum, with the exception of the systems formed by alkylthiophans and 2-butylthiophen with ethanol. These anomalous systems were not investigated in greater detail.

Following the development of gas-chromatographic methods for the determination of the physicochemical characteristics of organic liquids, their volatilities, activities, and extraction characteristics[37], simple and rapid methods for the estimation of the selectivities of extractants for heteroatomic compounds became possible. The relative selectivities of tens of extractants[38] have been calculated for the simplest model systems (thiophan, di-isopropyl sulphide, and hexanethiol) using literature data[39,40]. The activity coefficients (in the temperature range 60–80°C) of four alkanethiols (C_4–C_8 and six dialkyl sulphides (C_3–C_{10}), thiophan, thiophen, and 2- and 3-methylthiophens have been published[38] and the relative selectivities[41] in the separation of light sulphur compounds and hydrocarbons have been calculated. It has been shown in a report[39] covering data for 28 solvents that phenol is the best extractant for the separation of aliphatic and cyclic sulphides.

The donor–acceptor interaction of heteroaromatic compounds with metal cations and their capacity for complex formation have been known for a long time. Mercaptans and sulphides are frequently isolated from light-coloured petroleum distillates and characterised with the aid of mercury(II) salts [mercury(II) chloride and acetate]. In particular, this method has been used in Nametkin's laboratory. Nametkin always showed much interest in heteroatomic petroleum compounds, particularly in sulphur compounds. The first dissertation devoted to the sulphur compounds in petroleum from the Ishimbai deposit[42] as well as a number of reports dealing with studies on sulphur compounds in other petroleums[43-45] originated in his laboratory. Sulphur compounds were isolated and purified in these investigations via their mercury complexes. Such complexes are still being used for analytical purposes.

Systematic studies on the formation of complexes by organosulphur compounds with a number of metals were begun in 1960 in Obolentsev's laboratory. The first series of studies devoted to complexes with mercury salts was carried out by Lyapina[46]. She established that a donor–acceptor bond is formed by sulphur in complexes of dialkyl sulphides and thiacyclanes with mercury(II) bromide and found that the energies of the bonds formed by the same sulphides with mercury(II) acetate are in the narrow range 10.5–1..5 kcal mole^{-1}. It has been shown that the equilibrium yield of the complexes falls with increase of the molecular weight of the sulphides and with decrease of their symmetry. The composition of stable mercury(II) acetate complexes were found to be 1 : 2 for ten sulphides and 1 : 1 for twenty sulphides. The small differences between the heats of formation of the 1 : 1 and 1 : 2 complexes led to the hypothesis that the nature of the bond formed by the second mercury(II) acetate molecule with the sulphide differs from the donor–acceptor linkage between the sulphide and a single mercury(II) acetate molecule. The majority of saturated sulphides form stable 1 : 2 complexes with mercury(II) bromide. The electron-donating capacity of aryl and diaryl sulphides is sharply reduced.

The complexes of mercury(II) halides with dialkyl sulphides are best precipitated from alcoholic solutions and those of thiacyclanes from ethereal solutions. The methods of dielectric-constant and cryoscopic titrations, developed by Gur'yanova[47], were widely used in the above investigation in relation to a wide variety of complexes of organic compounds. The formation of complexes of sulphides having different structures with tin tetrachloride[48] and with iodine[49] had been investigated previously. A decrease of the tendency by the organic sulphides towards complex formation on passing from saturated to aromatic compounds was noted.

Using the method of cryoscopic titration, Gur'yanova et al.[50] investigated the formation of complexes by the sulphides in sulphuric acid concentrates with aluminium, gallium, tin, and titanium halides and with iodine. They found that all the sulphides extracted with 86% acid from the 150–325°C fraction of Arlansk petroleum form 1 : 1 complexes with $AlCl_3$ and $GaCl_3$; about 90% of these sulphides form 1 : 2 complexes with $SnCl_4$ and $TiCl_4$, while about 10% do not react. The heats of formation of the $SnCl_4$ complexes with dialkyl sulphides are about 12.6 kcal mole^{-1}, while those for the formation of complexes with the sulphides in the concentrate investigated are only 7.6 kcal mole^{-1}. This is probably associated with the presence in the latter of aromatic sterically hindered dialkyl sulphides and α-substituted thiacyclanes. More than 90% of the sulphides isolated from the same distillate by treatment with 91% sulphuric acid formed 1 : 1 complexes with $AlBr_3$, $GaCl_3$, and iodine and 1 : 2 complexes with $SnCl_4$. Near ultraviolet spectroscopy demonstrated the presence of aromatic compounds in these sulphides; they probably include alkyl aryl sulphides and admixtures of thiophens.

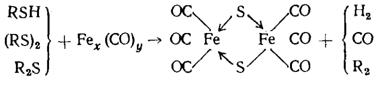
The formation of complexes by sulphides with silver nitrate[51] was investigated by Ben'kovskii and coworkers[52–55] in order to obtain pure sulphides from sulphide concentrates and for their differentiation. Complexes of 28 individual sulphides with $AgNO_3$ were investigated. Dialkyl sulphides (thia-alkanes) form 1 : 1 complexes, while thiacyclanes form both 1 : 1 and 1 : 2 complexes (mono- and di-solvates). The latter is probably due to the rigidity of the carbon–carbon bonds in thiacyclanes. The melting points of the thiacyclane complexes are much higher than those of the complexes of thia-alkanes having a similar composition. A method permitting quantitative separation of sulphides from thiophens and hydrocarbon admixtures present in sulphuric acid concentrates has been developed on model mixtures. The sulphides were regenerated from the complexes with 20% aqueous ammonia. Approximately 73% of the saturated sulphides and 24% of a mixture of thiophens and hydrocarbons were isolated from the concentrate of the 150–250°C fraction of Arlansk petroleum with the aid of silver nitrate.

The study of the solubilities of the individual complexes of sulphides with silver nitrate showed that derivatives of thia-alkanes and α-substituted thiacyclanes dissolve in aromatic hydrocarbons and alcochols much more effectively than β-substituted thiacyclanes. The possibility, in principle, of the quantitative separation of sulphides having similar properties by formation of complexes with $AgNO_3$ and subsequent extraction of the mixture of complexes with toluene has been demonstrated for binary mixtures (6-thiaundecane–3-pentylthiophan and 2-pentylthiophan–3-pentylthiophan).[53]

Saturated sulphides have been separated from aromatic sulphides present in the higher fractions of the Dzhar-Kurgan high-sulphur petroleum by the formation of complexes with silver nitrate. This made it possible to concentrate aryl sulphides and to detect for the first time the presence in the petroleum of alkyl benzyl and alkyl naphthyl sulphides[56]. The experience gained in our laboratory also demonstrated the suitability of the method employing $AgNO_3$ for the preparation of pure saturated sulphides.

The evident unsuitability of silver nitrate as a reagent for the isolation of sulphides and their elimination from petroleum products on a large preparative scale is evident.

In the search for more readily available complex-forming agents, Nametkin and coworkers made systematic studies on reactions with iron carbonyls. They considered reactions via the mechanism[57]



where $x = 1$ and $y = 5$, $x = 2$ and $y = 5$, or $x = 3$ and $y = 12$.

Table 1. The interaction of mercaptans, disulphides, and sulphides with iron carbonyls*.

Iron carbonyl	Yield of complexes, wt.% (time, h)		
	RSH	$(R'S)_2$	R''_2S
$Fe_3(CO)_{12}$	95—98 (1)	72—76 (5)	60—64 (18)
$Fe_2(CO)_9$	90—93 (11)	65—67 (19)	50—54 (24)
$Fe(CO)_5$	59—61 (22)	54—59 (34)	20—25 (36)

*R = Ethyl, n-butyl, n-hexyl, n-dodecyl, phenyl, or benzene; R′ = n-butyl, n-pentyl, n-hexyl, or n-dodecyl; R″ = methyl, ethyl, n-propyl, n-butyl, n-hexyl, n-dodecyl, cyclopentyl, or phenyl.

Data for the degrees of reaction of individual compounds were obtained and are listed in Table 1, which shows that the limits of variation of the yield of each carbonyl within groups of sulphur compounds are relatively insensitive to the structure of their hydrocarbon base. This made it possible to employ a single procedure for the estimation of relative reactivities, based on the method of the competing reactions of iron dodecacarbonyl with hexyl derivatives of sulphur, in accordance with the following scheme:

$$\left.\begin{matrix} 6\,C_6H_{13}SH \\ 3\,(C_6H_{13}S)_2 \\ 6\,(C_6H_{13})_2S \end{matrix}\right\} 2\,Fe_3(CO)_{12} \rightarrow [Fe(CO)_3SR]_2 + \left\{\begin{matrix} 3\,H_2 \\ 6\,CO \\ 3R_2 \end{matrix}\right. .$$

Having assumed that the value for the sulphide is unity, the authors[57] found that the relative reactivity decreases in the sequence $RSH > RS_2R > R_2S$ (in proportions of 13 : 9 : 1), in agreement with the data in Table 1, from which follows the following series of the reactivities of the carbonyls in the above reactions:

$$Fe_3(CO)_{12} > Fe(CO)_9 > Fe(CO)_5 .$$

In conformity with previous studies[58,59], Nametkin et al.[57] believe that the above reactivity series for iron carbonyls is correlated with the ease of formation on thermal decomposition of the coordination-unsaturated intermediate compound $[Fe(CO)_4]^*$.

In the next communication[60], it was shown that the petrol and kerosine-gas oil petroleum distillates and the products of the thermal and thermal-catalytic processing of petroleum can be completely freed from hydrogen sulphide, mercaptans, disulphides, and free sulphur and, to the extent of 20–50%, from other organic sulphur, nitrogen and oxygen compounds with the aid of iron carbonyls, dipentadienylnickel, di(ethylphenyl)chromium, and other complexes of transition metals in their lowest valence forms. Table 2 presents data illustrating the elimination of organosulphur compounds from various petroleum products.

Table 2. The desulphurisaton of petroleum products by low-valence transition metal complexes.

Petroleum products	Fraction, °C	Complexes	$[S]\cdot 10^3$, % total content initial	total content in purified fraction	content of mercaptan sulphur initial	content of mercaptan sulphur in purified fraction

The formation in these processes of cluster compounds of the heteroatomic components of petroleum and some of their reactions, leading to the regeneration of the mercaptans and the formation of some of their derivatives, have been reported[61]. The elimination of heteroatomic compounds by the complexes investigated is apparently accompanied by a significant entrainment of aromatic hydrocarbons[60], which is observed in all sorption and extraction processes leading to the formation of sulphide-aromatic concentrates, as stated above.

Plyusnin and coworkers[62-64] used complex formation with titanium tetrachloride for the isolation of tars, asphaltenes, and heteroatomic compounds from petroleum and petroleum fractions. Tars and asphaltenes were initially isolated from petroleum in a Soviet deposit (Tomsk region) by the method of Pozdyshev et al.[17] with the aid of methanol-acetone mixtures. This petroleum contained 2% of asphaltene, 6% of silica gel tars, 0.85% of total sulphur, and 0.19% total nitrogen (0.064% of basic nitrogen). Model solutions of tars in n-hexane and of asphaltenes in benzene were investigated: a fractional precipitation was carried out by the stepwise addition of $TiCl_4$. Eight fractions of tar complexes were obtained for the consumption of between 1 and 5 moles of $TiCl_4$ per mole of tars and three fractions of asphaltene complexes for the consumption of between 7 and 10 moles of $TiCl_4$ per mole of asphaltenes.

The degree of extraction of tars was about 95% and that of asphaltene about 99%. In view of this result, the authors[62] carried out experiments on petroleum without preliminary isolation of tars and asphaltenes. A change in the weight ratio of $TiCl_4$ to petroleum from 0.008 to 0.054 made it possible to observe the characteristics of the precipitation of the petroleum components. After the addition of 0.020 $TiCl_4$ (by weight), the asphaltenes are isolated completely, almost in proportion to the amount of added $TiCl_4$. For the complete extraction of tars, its weight fraction should be at least 0.050 of the petroleum taken. The curve describing the isolation of tars as a function of the amount of $TiCl_4$ is S-shaped with a linear section in the range 0.010–0.030 $TiCl_4$. Low-molecular-weight heteroatomic petroleum compounds, coprecipitated with asphaltenes and tars in amounts comparable to the latter, are isolated in an unusual manner. They are clearly distributed in two groups separated by a region where their isolation is not observed. This region coincides with the linear section of the tar isolation plot. It is interesting that the concentrates isolated in the presence of small amounts of added $TiCl_4$ (0.003) contain 62% of low-molecular-weight heteroatomic components, 25% of asphaltenes, and 13% of tars. Following the addition of 0.030 $TiCl_4$, a concentrate was obtained where the fractions of the same groups were 30%, 20%, and 50% respectively. The complexes of low-molecular-weight HAC with $TiCl_4$ are hydrolysed much more readily than the complexes of tars and asphaltenes, which permits their separation.

After the addition of 0.050 $TiCl_4$ to petroleum from a Soviet deposit in the Irkutsk region, more than 99% of the additive was bound in a complex. Together with tars and asphaltenes, $TiCl_4$ binds 80–95% of the nitrogen in petroleum (100% of basic nitrogen) and about 60% of sulphur. These results were used to isolate HAC concentrates of distillates. Their isolation from the 140–240°C fraction of Western Siberian petroleums, processed at the Omsk refinery, has been investigated[63]. The yield of the HAC isolated was 0.25% and their composition was as follows: 67.6% C, 14.0% H, 7.6% S, 0.9% N, and 9.9% O (by difference) (M = 172). The entire nitrogen and neutral oxygen were concentrated in tar-like fractions obtained on chromatography of the HAC (after the elimination of the acid components with 10% NaOH solution) on silicic acid. Sulphur is mainly contained in higher thiacyclanes (and possibly thiophens). Neutral oxygen is present in ketones and acid oxygen in phenols. Basic nitrogen can also be fully eliminated by $TiCl_4$ from higher-boiling fractions[64]. A considerable proportion of the sulphur and oxygen compounds are extracted at the same time, as can be seen from Table 3. The average composition of the concentrates from petroleum in the Tyumen deposit corresponds to 40–50% of sulphur compounds, 2% of carboxylic acids, 1% of ketones, and 5–9% of nitrogen compounds. Using $TiCl_4$, 98% of basic nitrogen was extracted from vacuum gas oil (340–500°C fraction) (6.8% of the concentrate containing 0.042% of basic nitrogen and 1.5% of total sulphur was obtained).

Table 3. Elemental composition of the concentrates isolated from fractions of Tyumen petroleums at the Omsk refinery (in wt.%).

Fraction, °C	C	H	S	N	O	–COOH	$>$CO*

*The method used to determine the carbonyl groups has been described by Maikova et al.[65]

The data considered above suggest that there are good prospects for further improvement in the methods for the differentiation of the heteroatomic components of petroleum into subgroups, particularly in relation to heavy and residual fractions, with the aid of variable-valence metal salts.

The use of complex formation and ligand exchange for the isolation and separation of the HAC is only just beginning to develop. At the present time we know much more about the extraction of metals by organosulphur compounds than about the separation of sulphur compounds by metal salts. The use of $FeCl_3$ on clay had been described previously[67].

Starting from 1973[66], groups of research workers of the American Petroleum Institute and the Bureau of Mines, investigating the composition of heavy petroleum fractions, freed the crude material from the acid and basic components with the aid of anion and cation exchangers and then extracted neutral nitrogen compounds with iron(III) chloride.

The development of ion-exchange methods (their acid–base versions were described above) led to the creation of ion-exchange resins, zeolites, and a number of amphoteric oxide sorbents in salt-forms. In these sorbents, hydrogen ions have been replaced by metals: Na, K, Mg, Ca, and, especially, the variable-valence metals Cu, Fe, Co, Ni, etc.

III. CHROMATOGRAPHIC AND MASS SPECTROMETRIC METHODS FOR CHARACTERISING THE SULPHUR COMPOUNDS IN PETROLEUM AND ITS FRACTIONS

The commercial manufacture of satisfactory and continuously improved apparatus for different types of chromatography as well as the expansion of the range of stationary and mobile phases for chromatography have led to an appreciable increase of the efficiency of separation of multicomponent systems, particularly petroleum and petroleum products containing heteroatomic compounds of different types. The number of papers, reviews, and monographs devoted to chromatographic methods is very large and we shall describe selectively only some of them.

As already stated, most of the heteroatomic petroleum compounds have been found in higher petroleum fractions. The use of anion-exchange resins, described above, has been recommended for their isolation. Versions of liquid chromatography using ion-exchange resins have been developing in recent years. Thus the study mentioned above[66] was preceded by a methodological investigation of Haynes and coworkers[68], including chromatographic procedures for the separation of the heavy part of petroleum into acids, bases, and neutral nitrogen compounds. In 1975 Vogh and Dooley[68] suggested that the copper-form of the carboxylic acid cation-exchange resin *Bio-Rex*-70 be used. Attention has been concentrated on the shrinking of the copper-saturated cation exchanger during preparation (it amounts to 10–20% along the column length). Both in model systems and in heavy petroleum fractions containing mono-, bi-, and polyaromatic components with a mixture of polar compounds, virtually complete extraction of sulphides, was achieved. Ben'kovskii and coworkers justly regard Vogh and Dooley as their predecessors[54]. However, a detailed study of the sorption of sulphur and nitrogen compounds and the static and dynamic capacities of KU-2 cation-exchange resin in metallic forms (silver, copper, mercury, lead) and AV-17-4 and AV-17-8 anion-exchange resins were not reported until later[69]. In this investigation, Ben'kovskii et al. studied the sorption of a number of mercaptans from benzene and alcoholic solutions and demonstrated the possibility of the extraction of certain individual nitrogen compounds by cation exchangers in metallic forms. Useful information concerning the separation of anion-exchange resins for the chromatography of high-boiling petroleum fractions has been published[70].

Particular attention must be concentrated on the use of liquid chromatographic methods under high and moderate pressures, whereby one can significantly reduce the diameter of the sorbent particles used, i.e. one can greatly enlarge the area of the interface and one can increase by several orders of magnitude the rate and efficiency of the separation. This method is described in greater detail by Zhukhovitskii[71] and Kirkland[72]. Bezinger succeeded in dissolving the nitrogen concentrates from petroleum in the Novo-Dmitrovsk deposit into distinct fractions in approximately 2 h using the technique developed in Chumakov's laboratory. A similar separation could not be achieved previously even after passage through a chromatographic column over a period of two months (without the application of pressure). Studies by Cook and Spangelo[73] on the separation of phenols and by Janini et al.[74] on the separation of polyaromatic hydrocarbons have shown that research on the application of liquid-crystal (nematic) phases in the gas–liquid chromatography (GLC) of heteroatomic compounds of petroleum merits attention; this has been confirmed[75]. An interesting method has been proposed by Rudenko and Ryashentseva[76] for the identification of peaks of the GLC chromatograms of multicomponent mixtures with the aid of ray diagrams; correction coefficients for a number of compounds by a procedure put forward previously were determined at the same time[77]. Postnov et al.[78] examined an internal calibration method taking into account the necessary corrections for quantitative GLC analysis. These procedures can be used successfully in the GLC analysis of heteroatomic compounds and the petroleum fractions containing them.

A GLC analytical method without a standard, using several stationary liquid phases at different temperatures, was proposed by Golovnya and Arsen'ev[79] for the homologous series of mercaptans, sulphides, and disulphides. This investigation is a continuation of previous studies[80-82]. In order to elucidate the applicability of the approach developed by the authors to more complex systems of compounds, typical for petroleum and its derivatives, much additional research is needed.

Gusinskaya and Beiko[83] investigated the catalytic microdesulphurisation of the 140–220°C fraction of the petroleum from the Kokaity deposit in Southern Uzbekistin. Using a distribution tap, the microdesulphurisation unit was included between two chromatographs. The sulphides were separated on the first chromatograph, with a katharometer, in accordance with the chromatographic peaks and passed to a microreactor, whence the sulphide conversion products formed were transferred to the second chromatograph with a flame-ionisation detector. The best catalyst for desulphurisation proved to be the industrial AP-56 catalyst. Experiments with individual sulphides showed that hydrodesulphurisation in the presence of this catalyst yields pure hydrocarbons with the appropriate composition and structure, uncontaminated by their isomerisation or decomposition products.

Gas–liquid chromatography is at present the most rapid method for the investigation of the compositions of petrols in terms of individual compounds. For each group of organosulphur compounds (mercaptans, sulphides, and thiophenes), the number of isomers boiling in the same temperature range greatly exceeds the number of isomeric hydrocarbons having the corresponding structure. This hinders analysis for two reasons: (1) the relative concentrations of the components in the sulphur-containing fraction of petrol are much lower than the concentrations of hydrocarbons in its hydrocarbon fraction; (2) the synthesis of model sulphur compounds, which are very necessary for the labelling and interpretation of the chromatograms, is very difficult and the solution of this problem is virtually impossible for the majority of laboratories. Together with Gordadze and Gollandskikh, the author of the present review[84,85] achieved the photochemical methylenation of a number of individual thiaalkanes and thiacyclanes. It was shown that the methylene group, obtained on decomposition of diazomethane, is inserted in all the C–H bonds of sulphides. The reaction is not complicated by side processes and its course is just as rigorously statistical as with hydrocarbons[86]. The observed slight deviations towards reduced reactivities of the C–H bonds at the carbon atoms adjoining the sulphur atom play hardly any role. Individual methylenated sulphides can be fully recommended as standards for the GLC analysis of sulphide-containing fractions. For a description of the application of GLC analysis in petrochemistry, see Refs. 87–89.

Drushel[90] recommended an unusual version of the reactochromatographic analysis of the sulphide–thiophen fraction of organosulphur compounds in petroleums as a more rapid method for the determination of the group composition of such compounds. The test specimen (in a stream of nitrogen or helium) is introduced into the chromatograph via a micropyrolytic cell (at 790°C in pyrolysis and at 600°C in the presence of Al_2O_3; benzothiophens are dealkylated in this cell and sulphides form hydrogen sulphide and, partly, mercaptans. The mixture of products, separated in the chromatograph, is transferred to a combustion tube, where oxygen is supplied (apart from the nitrogen or helium carrier gas) ($t \simeq 850$°C). The hydrogen sulphide formed passes to a microcoulometric (iodometric) cell connected to a pen recorder, which records the integral current–time curve. We do not know how much this method is used. It makes it possible to differentiate the sulphur in heavy petroleum products into the components present in aliphatic sulphides or "non-thiophens", benzothiophens, dibenzothiophens, benzonaphthothiophens, and unknown sulphur compounds. The duration of the experiment is approximately 1 h and the accuracy is to within 2–3%. The results agree well with those obtained previously by the mass-spectrometric method[91].

A novel "centri-chromatographic" method, combined with mass-spectrometry, has been proposed by Canadian investigators[92] for the separation of small amounts of multicomponent systems. The fundamental principle of centrifugal chromatography is similar to that of liquid chromatography under pressure. The method has apparently not found applications as yet in the study of petroleums and petroleum products. Drum thin-layer chromatography, used by Sanders and Snyder[93] is of interest. The application of thin-layer chromatography to organosulphur compounds has been examined by Karaulova[94].

Gel chromatography has been recommended as a useful subsidiary method for the separation of petroleum components[95,96]. This type of chromatography has been incorporated as the final stage in the multistage schemes for the separation of petroleums, adopted by the American Petroleum Institute and the U.S. Bureau of Mines, which were described above[66,67]. These studies were preceded by the careful investigation of Coleman et al.[99] of the use of gel permeation chromatography in relation to high-boiling petroleum components.

The characteristics of the composition of the petroleum fractions obtained by different methods and the determination of the structure of their components can be achieved on the basis of the chromatographic analysis only of the most low-boiling fractions. Higher-boiling fractions require additional chemical and physical research techniques. Among the latter, mass-spectrometry has proved to be the most informative at the present time. Some of the versions of mass-spectrometry can be combined with chromatography in integral chromato-mass-spectrometric apparatus operating particularly efficiently in combination with integrating computing devices.

There is insufficient space in the present review to consider the advances in the instrumental and computing techniques associated with the development of chromatography and mass-spectrometry. Nevertheless some of the relevant investigations must be mentioned. Robinson and Cook[100] examined in detail the application of low-resolution mass-spectrometry in the study of the group composition of the aromatic fractions of petroleum and were able to identify in the latter three main groups of compounds, each of which was in turn subdivided into seven subgroups. These consisted of dibenzofurans and benzo-, dibenzo-, and benzonaphtho-thiophens. Severin et al.[101] investigated the application of 10 eV mass-spectrometry combined with field ionisation to higher petroleum fractions. Anbar and Aberth[102] recently re-examined in detail mass-spectrometry with field ionisation in relation to vacuum distillates (176–360°). They used an apparatus with multichannel recording and automatic integration. They believe that the principal advantage of the method is a reduction of the degree of decomposition, which simplifies the spectra of the components, this being particularly important for the analysis of multicomponent systems. Problems concerning the use of mass-spectrometry with field ionisation in the study of labelled substances have been examined by many investigators; errors due to isotopic effects and fragmentation artifacts are then eliminated. The method has been recommended for the investigation of biogenic systems of complex composition. This may well prove extremely useful in the study of the heteroatomic components of the heavy part of petroleum, bitumens, and the organic material in the deposits in the existing seas and lakes.

Certain considerations favouring the use of cyclotron mass-spectrometry in the analysis of substances with ultralow vapour pressures have been described in a recent study[103]. After appropriate development, the new method will assist in the investigation of tar and asphaltene fractions of petroleum in which the majority of heteroatomic components are concentrated. Gallegos et al.[104] described in detail high-resolution chromato-mass-spectrometric analysis using as an example a study of pyrolysis products (the presence of 152 hydrocarbons, 8 cyclic and 5 acyclic dienes, and 18 unidentified compounds in such products was established).

Brodskii and coworkers[105-107] and Khmel'nitskii[108] obtained a number of new data concerning the characteristics of individual heteroatomic compounds, primarily sulphides[105-108]. Brodskii et al.[109] described the mass-spectrometric analysis of aromatic hydrocarbons and sulphur compounds present jointly in petroleum fractions; their distribution in 23 groups based on the C_nH_{2n-x} and $C_nH_{2n-y}S$ homologous series with the even values $x = 6–24$ and $y = 4–22$ is described and the relative ionisation cross-sections of the compounds are given. Khmel'nitskii et al.[110] described the mass-spectrometric analysis of nitrogen-containing bases in petroleum having the composition $C_nH_{2n-z}N$ with the odd values $z = 9$, 11, and 13.

A general examination of the principles of the mass-spectrometric investigation of heterocyclic nitrogen compounds has been made in Klyuev's dissertation[111]. The mass-spectrometric analysis of nitrogen and sulphur compounds based on fragment ions has been used[112] to investigate the petroleums from the Tajik depression (Southern Uzdekistan). An analytical method based on molecular ions was developed in that investigation for sulphur compounds whose molecular weights range from 350 to 600, involving their subdivision into seven groups differing in the degree of unsaturation with respect to hydrogen. Mal'tseva's study was devoted to an examination of the mass spectra of bicyclic heterocyclic compounds[113]. Popov developed methods for the mass-spectrometric and chromato-mass-spectrometric analysis of nitrogen-containing bases in mineral fuels[114]. Such comparative studies are of undoubted interest, since latest investigations[115] have demonstrated a similarity of the composition of the products obtained from coal by mild modern procedures to the composition of the heavy components of petroleum.

Brodskii et al.[116] emphasised that, in an investigation of the composition of complex products such as petroleum distillates, data obtained by previously developed simpler methods are useful in addition to results obtained by chromatography and mass-spectrometry. Comparison of the data derived by the two groups of methods makes it possible to improve significantly the assessment of the structural-group compositions and structures of the products investigated. The development of mass-spectrometry in combination with detailed correlations for the analysis of the heteroatomic components of petroleums, coals, shales, and the products of their processing has been described by Brodskii[117].

Polyakova et al.[118] examined the possibility of using high-resolution mass-spectrometry for the investigation and quantitative determination of thiacyclane and thiophen derivatives with different numbers of rings. Petroleum fractions have been analysed in the 400–650 mass range with the aid of the spectrometry of mass defects. The authors[118] developed a novel system for the calculation of the composition of the multiplets and compiled tables of the molecular weights of ions for a series of compounds in the residual petroleum fractions.

A number of monographs, for example that of Polyakova and Khmel'nitskii[119], have been devoted to mass-spectrometry in recent years. These methods need not therefore be considered further. Interesting information about the structure and properties of the heteroatomic components of petroleums can be obtained by the application of proton magnetic resonance. Unfortunately it has not so far been adequately developed, despite the fact that Clutter et al.[120] pointed out as early as 1972 the likelihood that a method can be devised for group NMR analysis, similar to the mass-spectrometric group analytical techniques. At the same time, NMR has been used[121] to determine the content of acids and bases in organic substances. The proton magnetic resonance method has been employed[122-124] in the study of the structural-group characteristics of the nitrogen-containing bases in Sakhalin petroleums. ^1H NMR yielded valuable information about the admixture of oxygen compounds with a furan ring in nitrogen-containing bases (the presence of diaryl ethers is not ruled out)[122] and about the ring sequence in tricyclic systems, demonstrating that angular junctions in the latter are more probable than *peri*-junctions.

Presumably ^1H NMR combined with modern computing-analytical devices will take its due place in research on petroleum products in the immediate future. The information about the homology and the number of rings present yielded by mass spectrometry will then be supplemented by the characteristics of the location and mobility of hydrogen atoms, which are directly related to the reactivity of petroleum components.

IV. PETROLEUM SULPHIDES AND THIOPHENS

In 1966 Smith[125] published a novel and elegant review of the available information concerning the qualitative and quantitative composition of crude petroleum. He recognised for the first time the quantitative equivalence of the hydrocarbon and non-hydrocarbon components of petroleum. However, the available information about the heteroatomic compounds of petroleum, particularly the high-boiling compounds, was inadequate for the determination of the correct proportions of the individual groups. A detailed survey of studies on Project 48A of the American Petroleum Institute carried out during the 20 years from 1948 to 1968 was made by a group of investigators under Thompson's supervision[126]. The group composition of the sulphur compounds in the vacuum distillates from petroleums in 17 deposits was first investigated. Determinations were made of the contents of (1) free sulphur, (2) hydrogen sulphide, (3) disulphides,

(4) mercaptans, (5) and (6) two groups of sulphides, and (7) "residual sulphur" using Ball's method[127] and it was stated that this procedure yields distorted data owing to the coprecipitation of the components when they are removed by group reagents (for further details about this, see Luk'yanitsa[128]). As a result, it was established that, for a monotonically increasing sulphur content in vacuum distillates, the qualitative compositions of sulphur compounds in the latter remain similar but the quantitative proportions of the groups vary sharply, being uncorrelated either with overall sulphur content in the petroleum or with its contents in the distillate. The distillates from the Goldsmith petroleum, where the content of free sulphur reaches 42.5% and the Deep River petroleum, where the content of mercaptans is 46%, are unique. The fraction of sulphides in the Velma petroleum is 42%. The maximum residual sulphur (80%) has been observed in the distillate from Heidelberg petroleum. The Wasson petroleum (Texas) was selected as the main object of study. The following components were identified in its fractions boiling up to 250°C as a result of the application of multistage separation schemes, chromatography, complex formation, mass spectrometry, etc: 47 mercaptans (including six alicyclic mercaptans and one aromatic mercaptan); 38 dialkyl sulphides; 5 alkyl cycloalkyl sulphides; 4 alkyl aryl sulphides; 21 thiacyclanes; 18 thiaindans; 2 disulphides; 22 benzothiophens; 2 dibenzothiophens; 160 compounds in all. However, alkylthiophens were not found (11 examples of this series were discovered in Wilmington petroleum). Quantitative estimates of the contents of 44 individual compounds were made. 58 papers were published on Project 48A during the period under consideration; some of these data are considered in Karaulova's monograph[129].

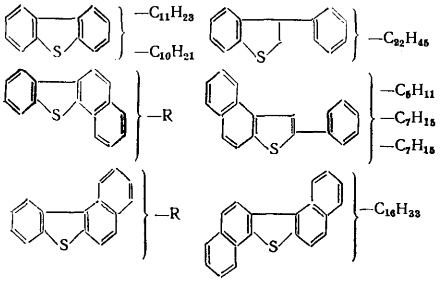
During the same period, detailed studies were made by Obolentsev and coworkers[130-133] and Vyakhirev et al.[134] on the organosulphur compounds present in the petroleums of the Urals-Volga petroleum-bearing region. The presence of mercaptans and a large number of sulphides was established in these petroleums. Among the sulphides, thia-alkanes are concentrated in the light fractions and thiacyclanes in the heavy fractions. Thiophen and methyl- and dimethyl-thiophens were identified in Romashkino petroleum[134]. These studies have been reviewed by Krivolapov[135] and Allilueva[136]. The GLC retention parameters of a number of sulphides have been calculated in the latter review.

Beiko and Gusinskaya[137] continued the investigation of the boiling points and the retention parameters of isomeric thiacyclanes. These data enabled Beiko[138] to investigate the composition of the petrol-kerosine distillates from petroleum in the Kokaity deposit. The results agree well with a series of studies devoted to the investigation of the middle fractions of petroleum from Southern Uzbekistan (the Tajik depression). A more detailed investigation of the 200–400°C fraction of combined Southern Uzbekistan petroleums (from Khaudape, Lyal'mikar, and Kokaity deposits) was made by the present author and his coworkers[139,140]‡ and in the course of this study numerous techniques were improved. The sulphides of the individual Khaudag and Kyzyl-Tumshuk petroleums were studied (simultaneously with the present author's research) at the Institute of Chemistry of the Academy of Sciences of Tajik SSR[142]. The petroleums from the Kokaity and Lyal'mikar deposits have been reinvestigated in Tashkent[143]. A mass-spectrometric investigation[112] was mentioned in the preceding Section. This was the first study to include the heavier components of the petroleums from the Tajik depression (Southern Uzbekistan). Some of the relevant data have been examined in monographs[129,144,145]. Here one must emphasise that the qualitative compositions of the petroleums from different deposits in the Tajik depression of Southern Uzbekistan are similar. This phenomenon has been known for a long time for petroleum hydrocarbons. The organosulphur compounds have been found to be similar as a result of research in recent years.

The petroleums of Southern Uzbekistan are characterised by negligible contents of light fractions and an almost complete absence of mercaptans and disulphides. The sulphides of the 200–400°C fraction consist mainly of a series of thiacyclanes[139] containing between 1 and 5 rings. Thiamonocyclanes (60%) containing between 7 and 21 carbon atoms per molecule predominate. Thiophens in this fraction also include series of compounds containing between 1 and 4 rings. The main bulk consists of benzothiophen (~33%) and condensed cycloalkyl- and dicycloalkylbenzothiophens (approximately 21% of each). The content of alkylthiophens (about 16%) is fairly high.

In terms of the order of magnitude, the values found in later studies for petroleums of Southern Uzbekistan[112,143] are close to those obtained by the present author[139]. The differences in the selection of fractions and in the details of the methods employed preclude a comparison of the quantitative data obtained in the three investigations or an estimate of the fine differences between the component compositions of the sulphur compounds in individual petroleums. The differences between the contents of thiaindans in the petroleums from different deposits in this region are significant: Kyzyl-Tumshuk—12%; Khaudag—9%; Dzhar-Kurgan—1-4%[112]; Lyal'mikar—3.3%; Kokaity—5%[143]; a mixture of Khaudag, Lyal'mikar, and Kokaity petroleums—4.5%.[139] If these data are confirmed, then the petroleum from the Kyzyl-Tumshuk deposit must be collected separately, particularly for the isolation of thiaindans, which are of special interest.

After the extraction of nitrogen compounds, it was established mass-spectrometrically in conjunction with infrared spectroscopy[112] that petroleum from the Dzhar-Kurgan deposit (150–350°C fraction) contains complex benzothiophen compounds, whose probable structure can be represented by the following formulae:



,

where R = $C_{19}H_{39}$, $C_{21}H_{43}$, and $C_{23}H_{47}$. Gal'pern et al.[146] investigated the structural-group composition of the sulphur-containing concentrate from the 350–370°C oil distillate of petroleum from the Romashkino deposit. The C_{21}–C_{24} fraction with 6.00% S_{tot}, 2.00% S_{R_2S}, and n_d^{20} = 1.4643 was isolated by chromatography on silica gel. Oxidation with hydrogen peroxide and subsequent regeneration (by reduction with lithium tetrahydroaluminate)

---

‡These data have been examined in detail in a compilation published quite recently[208].

yielded, by a procedure similar to that used in another study[139], sulphides formed from sulphoxides (obtained by oxidation with hydrogen peroxide in acetic acid and acetic anhydride and residual sulphoxides). A decrease of selectivity relative to that observed in the oxidation of lower-boiling distillates in acetic acid was observed: there is a significant increase of the fraction of thiophen compounds in the oxidation products. On reoxidation in acetic anhydride, alkyl aryl sulphides and thiaindans are fully converted to oxidation products. The total sulphides obtained by two-stage oxidation exceeds the sum of the sulphides obtained in single-stage oxidation (directly in acetic anhydride). If the oxidation is restricted to the first stage only (with acetic acid), all the saturated sulphides are fully converted into sulphoxides, but the majority of thiaindans and aryl sulphides remain in the refined products. The sulphides obtained were analysed mass-spectrometrically. Altogether 14% of sulphides and 55% of thiophens were found in the fractions; their distribution among subgroups is described by Gal'pern et al.[146]

Sulphides in the petroleum from the Arlansk [tentative transcription] deposit were isolated from the 170–310°C fraction[147]. Their purification and re-extraction by sulphuric acid was completed by a mass-spectrometric study of the composition of the concentrates[148] obtained by treatment with 86% sulphuric acid, subsequent extraction with 91% acid, and chromatographic separation into narrow fractions.

A series of fundamental studies on the compositions and structures of the sulphides in the kerosene and gas oil fractions of Arlansk petroleum have been carried out by Nikitina and coworkers[52,149–151]. The average molecular weights of dialkyl sulphides and alkyl cycloalkyl sulphides are higher than those of thiamono- and thibi-cyclanes; the average molecular weight of benzothiophens is lower than the corresponding values for alkyl- and cycloalkyl-thiophens. It has been shown[55] that an increase of the concentration of sulphuric acid in the extraction of sulphide concentrates from petroleum distillates leads to an increase of the fraction of sulphides and thiaindenes extracted and to an appreciable decrease of the average molecular weights of all the components of the extracts. This phenomenon is probably associated with the enhancement of the hydrophobic properties of the sulphides with increase of their molecular weights and with decrease of the degree of dissociation of the monosolvates of the 'onium complexes of the sulphides with sulphuric acid when the concentration of the latter increases. Comparison of the compositions of the sulphides extracted from the Arlansk petroleum fractions with those of the corresponding sulphides of Romashkino and Southern Uzbekistan petroleums demonstrates their considerable similarity. The conclusion[27] that thia-alkanes and alkyl cycloalkyl sulphides are extracted in succession by dilute sulphuric acid has been disproved[55]. In the initial investigations, the mass-spectrometric technique was apparently inadequate for the determination of low concentrations of higher thia-alkanes characterised by a uniform mass distribution[208].

The experimental industrial apparatus for the preparation of sulphide concentrates from petroleum distillates has been described[153]. The Arlansk petroleum concentrates obtained[154] were investigated by the formation of complexes with $AgNO_3$ and with thiourea, this being followed by thermal diffusion fractionation and mass-spectrometric analysis. The low efficiency of the formation of adducts with thiourea by sulphides from the middle fractions of petroleums as regards their differentiation into structurally different groups was demonstrated in this investigation. Thermal diffusion makes it possible to reduce the concentration of polycyclic sulphides and to concentrate them in the last fractions. In view of the low efficiency of the method, one can hardly hope for extensive application of the thermal diffusion of sulphides. In this sense, the employment of gas–liquid chromatography under increased pressures is much more effective. It has been shown[154] that thiamonocyclanes have on average three alkyl substituents and thiabicyclanes have two substituents, only one of these with a long chain containing between 2 and 8 carbon atoms. The distribution of the sulphide subgroups with respect to mass is largely determined by the chain length. These results are fully consistent with those obtained earlier[140,208] for the corresponding sulphides from the distillate of Southern Uzbekistan petroleum.

The latest studies on the sulphides in Western Siberian petroleums (from the Western Surgut and Samotlorsk [tentative transcription] deposits[30,31,154,155]) confirm the hypothesis that the compositions of the sulphides in mercaptan-free petroleums are similar. Data for Arlansk, Western Surgut, and Samotlorsk petroleums, obtained in the same way and investigated by the same procedures, have been compared[155]. In all the 190–360°C distillates, the fraction of thiacyclanes is 85–90% of the total sulphides. The relative contents of mono-, bi-, and poly-thiacyclanes vary in the ranges 50–58%, 20–23%, and 9–14% respectively. The concentrates contain alkyl-, cycloalkyl-, benzo-, and dibenzo-thiophens and condensed naphthenobenzothiophens. Their relative concentrations for Samotlorsk petroleum (with a lower total of sulphur content) distinguish the latter from the high-sulphur petroleums, particularly from the Southern Uzbekistan and Arlansk petroleums discussed above.

A series of studies by Thompson and coworkers have been devoted to the high-boiling fractions of five individual petroleums[157–161]. A brief description of these investigations has been published[162–166] and their overall resumé can be found in the paper by Dooley et al.[167]. Acid and basic components have been extracted from distillates by liquid chromatography under pressure with the aid of Amberlyst A-29 anion-exchange resin and Amberlyst A-15 cation-exchange resin respectively, while iron(III) chloride has been used to extract neutral nitrogen compounds (after a preliminary elimination from crude petroleum of solid paraffins which were subjected to separate mass-spectrometric analysis). Distillates freed from the above compounds were analysed and subjected to preparative liquid chromatography on silica–alumina gel for separation into four fractions: saturated and mono-, di-, and poly-aromatic compounds. The fractions of saturated compounds were transferred directly to mass-spectrometric analysis and the aromatic fractions were analysed mass-spectrometrically after an additional gel-chromatographic separation. Table 4 presents data characterising the yields and compositions of the distillates, refined products, and seven fractions. Evidently the main bulk of sulphur is concentrated together with the di- and poly-aromatic compounds. Anion-exchange resins, cation-exchange resins, and iron(III) chloride extract from 370–535°C distillates about 5% of the compounds (California petroleum yielding up to 16.5% is an exception). All three sorbents extract also neutral sulphur compounds, in most cases in amounts comparable to those of the nitrogen compounds. The comparatively high concentration of sulphur in these extraction fractions does not play a

Table 4. The yields* of 370–535°C distillates, their chromatographic fractions, and their elemental compositions (wt.%) (based on the data of Dooley et al.[167]).

* a—yield with respect to petroleum; d—yield with respect to distillates; b—nitrogen content; c—sulphur content in products a and d.

significant role in the overall sulphur balance, since their yield is low. The study of sulphur-containing components of extracts is difficult and so far is not susceptible to interpretation by mass-spectrometric methods. They probably contain a large amount of compounds, each with two and more heteroatoms per molecule (including oxygen atoms), at fairly high concentrations. This distinguishes them from the main bulk of the monofunctional organosulphur compounds transferred together with the paraffin-naphthene fractions and makes them similar to the polar polyaromatic concentrates.

The nitrogen and sulphur contents in the paraffin-naphthene fraction is low, but, despite the low concentrations of the corresponding heteroatomic compounds, one must not forget that the proportion of these saturated fractions is usually between 37 and 74% of the initial distillates. A comparatively monotonic decrease of the yields of the groups of hydrocarbons from 41 to 25% with increase of the number of rings in the latter from zero to 6 is characteristic of such distillates. In the series of petroleums considered, Wilmington petroleum is an exception, its saturated fraction containing only 13.5% of alkanes, 15.8% of monocyclanes, and 14.0% of bicyclanes; the content of tricyclanes is somewhat higher (15.8%) and there is an unusual maximum corresponding to the proportion of tetracyclanes (25.9%). The content of pentacyclanes is 9.2%, which greatly exceeds the average for remaining types of petroleum (6%). There are as yet no data concerning the nature of the sulphur compounds remaining in the saturated paraffin-naphthene part of the refined product.

The distribution of the main groups of compounds among the aromatic fractions is given in Table 5, which shows that the sulphides and thiophens in the petroleums investigated are concentrated mainly in the polyaromatic compound fractions. The contents of individual groups of organosulphur compounds are distinguished by a great variety. The differences between their overall contents are very great: from approximately 20% in Recluse petroleum to nearly 100% in Gach Saran petroleum. The aromatic fractions include the hitherto undeterminable heteroatomic oxygen and nitrogen compounds. The Gach Saran petroleum contains a relatively large amount of components with more than one sulphur atom per molecule, which reduces the accuracy of the quantitative estimate of its overall content of organosulphur compounds. The differences between the qualitative compositions of the subgroups of compounds discovered in the five distillates investigated are even greater than the differences between their overall contents.

Table 5. The distribution of sulphides (S), thiophens (T), and aromatic sulphur compounds with unknown structure (A) in 370–535°C distillates (in wt.%) among chromatographic fractions (according to the data of Dooley et al.[167]).

Further investigation of the heteroatomic compounds in petroleums, in particular sulphides and thiophens, requires the development of chemical methods for their differentiation into subgroups. The differentiation of these compounds on the basis of their reactivity is not only of theoretical but also of great practical interest.

Comparison of the data of Soviet and foreign investigators clearly demonstrates fairly significant differences not only in the overall contents of sulphides and thiophens in petroleums from different deposits but also in their distribution among subgroups corresponding to different structures. Naturally, these differences must be taken into account in the utilisation of sulphides and thiophens as the raw materials for the chemical processing of petroleum.

V. OXIDATION OF PETROLEUM SULPHIDES

In the early stages of the research into the chemistry of the sulphides in the middle fractions of petroleum[168,169], the present author and his coworkers already demonstrated significant differences between the oxidation potentials of sulphides, other groups of sulphur compounds, and hydrocarbons, which made it possible to oxidise the sulphides to sulphoxides by hydrogen peroxide under mild conditions with a high degree of selectivity. The conversion of sulphides into sulphoxides alters sharply the polarity of the functional group. Sulphoxides, which are neutral under the usual conditions, behave as distinctly basic compounds in the oxidation products from petroleum distillates, which makes it possible to separate them readily from other groups of compounds both by chromatography on coarsely porous silica gels and by acid extraction[170,171]. The influence of the differentiating solvent (acetic anhydride) was investigated[172] in solutions of individual sulphides having different structures and compared with ethers in acetic acid. This established that the degree of oxidation of aromatic sulphides in acetic anhydride is three times as high as in acetic acid. The addition of perchloric acid sharply increases the rate of homogeneous oxidation of sulphides to sulphoxides in acetic anhydride.

The heterogeneous-emulsion oxidation of sulphides to sulphoxides in the presence of perchloric acid[173] made it possible to obtain sulphoxides in a single stage from distillates of sulphur-containing petroleums in which sulphoxide perchlorates are insoluble. The selectivity of the process then increases sharply owing to the acceleration of the main reaction. The process is applicable to the formation of individual sulphoxides from sulphides and to the purification, by reprecipitation, of the sulphoxides obtained by other methods. Here one should recall that the perchlorates of lower sulphoxides are explosive. The perchlorates of C_6 and higher sulphoxides are not quite so dangerous, but it is nevertheless recommended that they should be hydrolysed with water and aqueous solutions of alkali immediately after isolation, whereupon the resulting sulphoxides may be dried in the usual way.

The principal procedure for obtaining sulphoxides was believed to be the heterogeneous-emulsion oxidation of the sulphides present in petroleum fractions without their preliminary isolation or their isolation in the form of sulphur-containing aromatic concentrates. The method was first proposed by the present author[174] and was then elaborated in significantly greater detail and improved[175-178]. In the development of the appropriate technology, we selected foam reactors and obtained the sulphoxides under novel foam-emulsion conditions[179]. The technological development was carried out by Khitrik and coworkers[180,181] on laboratory and larger scales using a continuous-operation apparatus. The results obtained by Khitrik agreed very well with earlier data obtained by Bardina[177] on small laboratory periodic-operation devices. The Vitt bell stirrer used in these experiments created conditions close to foam-emulsion conditions. A separate experiment established that, under the conditions adopted, air always behaves as an inert gas without being involved in the reaction. The final development of the technology for obtaining sulphoxides from distillates and sulphur-containing aromatic concentrates was achieved on larger-scale continuous-operation apparatus (made of metal). The fundamental laboratory data found for the oxidation of phenolic and sulphuric acid extracts of the 275–350°C fraction of Arlansk petroleum by hydrogen peroxide under foam-emulsion conditions are presented in the report of Zagryatskaya et al.[182] The results largely agreed with those obtained previously on laboratory and large laboratory apparatus. The advantage of the sulphuric acid extracts of sulphides over the phenolic extracts was demonstrated. The selectivity of the oxidation process in the presence of catalytic amounts of acetic acid is higher than in the presence of sulphuric acid. Under foam-emulsion conditions, attention must be concentrated on the number of foaming steps, maintaining the appropriate size of the average cross-sections of the bubbles, which determine the overall areas of the liquid gas and liquid 1–liquid 2 interfaces.

Data on the kinetics of the oxidation of sulphides to sulphoxides in petroleum distillates by hydrogen peroxide under foam-emulsion conditions were published recently[183]. It was shown that the rate of the process can be expressed by the equation

$$V=1.42\cdot 10^7T^{1/2}\exp\left(-\frac{16200}{RT}\right)\cdot C_{R_2S}C_{H_2O_2}\ .$$

The order of the reaction with respect to the sulphide and hydrogen peroxide is unity, the overall order is two, and $\bar{E}$ = 16.2 kcal mole^{-1}. A significant proportion of the above studies are described in Khitrik's dissertation[184]; the studies of Masagutov et al. on pilot apparatus have also been published[209].

Experiments on the replacement of hydrogen peroxide by organic hydroperoxides in the presence of organic acids in reactions designed to obtain sulphoxides are noteworthy[185,186]. The degree of oxidation by isopropylphenyl hydroperoxide is higher by a factor of 1.5–2 than the degree of oxidation by t-pentyl and t-butyl hydroperoxides. The catalytic acceleration of the oxidation of sulphides is proportional to the strength of the carboxylic acids used.

It was natural to extend the oxidation of sulphides to sulphoxides to the next stage—the oxidation to sulphones. A test of the possibility of multistage and single-stage oxidation was of particular interest. The latter has been carried out for a long time and does not yield satisfactory results, because the sulphoxide → sulphone conversion is endothermic, in contrast to the exothermic sulphide → sulphoxide conversion. In the two-stage oxidation of petroleum distillates, one removes together with sulphoxides many impurities which char on vigorous oxidation. The refined product obtained contains hardly any sulphides or sulphoxides. On reoxidation, it gives a mixture of sulphones, among which predominate benzothienyl sulphones with an admixture of tricyclic sulphones belonging to different series (most probably dibenzothiophens, naphthothiophens, and naphtheno-, benzo-, and benzonaphtheno-thiophens).[187] The oxidation of saturated sulphoxides to sulphones is of considerable interest[188]. The authors found the optimum conditions for the oxidation of petroleum sulphoxide concentrates by hydrogen peroxide in the foam-emulsion state in the presence of catalytic amounts of sulphuric acid. The sulphoxide → sulphone conversion takes place to the extent of 95–96% in 15 min.

Petroleum sulphoxides are effective and promising extractants and floatation agents for the hydrometallurgy of non-ferrous and rare elements[189,210]. Nikitin et al.[190] reported the isolation and characterisation of 32 complexes formed by sulphoxides (obtained from the sulphuric acid concentrates of the 190–360°C sulphide fraction of Arlansk petroleum) with the nitrates and certain chlorides of magnesium, calcium, zinc, aluminium, chromium, iron, cobalt, nickel, manganese, bismuth, uranyl, and gallium. The bathochromic shift of the characteristic wavenumber of the sulphoxide group (ν = 1040 cm^{-1}) has been used to characterise the donor-acceptor bond in these complexes. $\Delta\nu$(SO) is a maximum for iron and chromium chloride complexes ($\Delta\nu$ = 95 cm^{-1}) and for the copper chloride complexes ($\Delta\nu$ = 90 cm^{-1}); among the nitrates, the maximum corresponds to chromium nitrate ($\Delta\nu$ = 110 cm^{-1}), nickel, bismuth, and uranyl nitrates ($\Delta\nu$ = 95 cm^{-1}), and copper nitrate ($\Delta\nu$ = 83 cm^{-1}). It was shown that, regardless of the method of preparation of the complexes, anhydrous solvates are isolated preferentially, with displacement of water from the coordination spheres of the ions and its substitution by sulphoxides. It is suggested that in some complexes sulphoxides are present in the inner and outer spheres, for example in $FeCl_3.3PSO$ (PSO = petroleum sulphoxide). The dependence of the extracting capacity of sulphoxides on their molecular structure has been examined[191]. It was shown that the extraction of metal salts by sulphoxides from aqueous solutions of hydrochloric, nitric, and sulphuric acids and from mixed media proceeds via hydrate-solvate and solvate mechanisms. The extraction of metals by sulphoxides from hydrochloric acid solutions has been discussed in detail[192]. It was shown for the first time in the same study that cyclic sulphoxides are extracted preferentially by uranyl nitrate from their mixtures with aliphatic sulphoxides.

Sulphoxides have been used[193] for the extraction-gravimetric determination of niobium and tantalum. It was shown that the determination is not interfered with by admixtures of magnesium, aluminium, copper, titanium, chromium, manganese, iron, cobalt, nickel, zirconium, molybdenum, tin, and lead over the entire concentration range.

Rafikov and Nikitin[194] examined the possibility of using sulphoxides and their metal salt complexes as the liquid phases in gas-liquid chromatography for the separation of saturated and unsaturated hydrocarbons. The complexes with $CuCl_2$ and $FeCl_3$ (charge-transfer complexes) were the most effective. Coloured organic glasses with improved heat resistance have been obtained on the basis of sulphoxide complexes with $MnCl_2$, $CoCl_2$, etc. added to poly(methyl methacrylates) and polystyrenes.

The extraction of organic acids by sulphoxides has been investigated and certain problems of their separation by extraction have been considered[195,196].

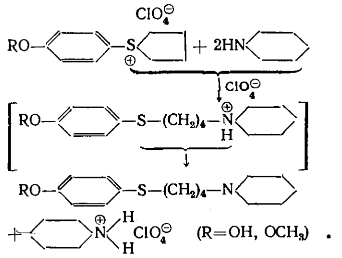
Apart from the direct utilisation of sulphides and sulphoxides in hydrometallurgy and in the chemistry of polymeric materials, it is also of interest to investigate in greater depth the chemical reactions of sulphides and sulphoxides originating from petroleum. In organic chemistry, the majority of these substances have so far been little studied or not at all. Such study required the simultaneous investigation of a number of reactions of individual compounds simulating the petroleum compounds.

The study[172] mentioned above, where sulphoxides were obtained in acetic anhydride, attracted the present author's attention to the Pummerer reaction investigated by Horner and Kaiser[197]. It has been shown[198] that the principal pathway in the reaction of C_{10}–C_{12} dialkyl sulphoxides on heating with acetic anhydride involves the formation of α-unsaturated sulphides (a mixture of *cis*- and *trans*-isomers). The reaction is accompanied by a side process, namely the sulphone-sulphide rearrangement of the sulphoxide. The α-unsaturated sulphides obtained readily combine with diethyl phosphorodithioic acid, forming stable bifunctional derivatives of saturated sulphides—di-*O*-ethyl *S*-1-pentyl phosphorodithioates.

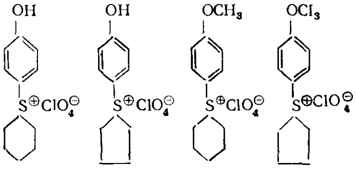
As shown above, the sulphides from the middle fractions of petroleum contain the highest concentrations of thiamonocyclanes, thiabicyclanes being next in order of abundance. When the Pummerer reaction was carried out with these sulphoxides, only the unsaturated sulphides were obtained, while the reactions with the individual substances[199] gave various results: the closest model—2-methyl-1-decalinyl sulphoxide, produced the same result—the sulphoxide was converted into the α-unsaturated 2-methyl-1-thiaoctalin; the semiaromatic 6-methyl-1-thiachromanyl sulphoxide gave 1,2-acetoxy-1-thiachromane as the main product with an admixture of the α-unsaturated 6-methyl-4*H*-benzothiapyran, which was readily converted into di-*O*-ethyl *S*-(6-methyl-1-thiachromanyl) phosphorodithioate. The reaction of thiophanyl sulphoxide with acetic anhydride gave mainly α-acetoxythiophan and, in an amount smaller by an order of magnitude, the dimer of dihydrothiophen. It has been shown[200] that thiaindan is smoothly converted into thiaindene in acetic anhydride.

Karaulova[201] showed that thiacyclanyl sulphoxides react with phenol in the presence of perchloric acid and phosphoryl chloride to form *p*-hydroxyarylthiacyclanylsulphonium salts. Sulphides can be used in this process if the condensation reaction is carried out with the same reagents in the presence of hydrogen peroxide. A Japanese study[202] served as the prototype of the first method. The present author has shown[203] that the capacity for the formation of perchlorates falls sharply in the following sequence: thiophan > thiacycloheptane > methylthiacyclohexane. 2,5-Dimethylthiophen, 2,2,6,6-tetramethylthiacyclohexane, and 2-methyl-1-thiadecalin do not form arylsulphonium perchlorates (under the conditions stated above). It has been shown that 4-hydroxyarylthiacyclanylsulphonium (aryl-4-hydroxyphenyl- or 4-hydroxynaphthyl-sulphonium) perchlorates readily undergo anion-exchange reactions, forming chlorides, phosphates, and picrates. Under the influence of potassium hydroxide in methanol, 4-hydroxyphenylthiophanylsulphonium salts yield oligomeric products, for one of which a betaine-like dimeric structure has been proposed: $(C_4H_8S.C_6H_4O)_2$.

When arylthiacyclanylsulphonium salts are treated with amines[204-206], a "transonium" reaction takes place with ring opening at the C–S bond and the simultaneous addition of the base nitrogen to the ω-position of the alkyl chain: the sulphonium sulphur is converted into sulphide sulphur and amino-nitrogen forms a complex ammonium salt derived from the aminoalkyl aryl sulphide. In reactions with stronger nitrogen-containing bases, the process proceeds further; the complex ammonium salt is converted into free aminoalkyl aryl sulphide with the simultaneous formation of the ammonium salt derived from the simple amine introduced into the reaction system. This can be illustrated schematically as follows:



The reaction in the second stage involving fairly strong secondary bases proceeds quantitatively at a high rate, i.e. a simple single-stage method for the synthesis of ω-aminoalkyl aryl sulphides has in fact been found. The reactions of arylthiacyclanylsulphonium perchlorates with nucleophilic agents have been investigated in greater detail[207]. It was established that a number of arylsulphonium perchlorates



(I) (II) (III) (IV)

react with potassium iodide and picric acid to form arylsulphonium iodides and picrates. On reaction with potassium chloride, compound (I) is quantitatively converted into the chloride; compound (II) yields about 70% of the chloride and 16% of a product incorporating a heterocycle which has undergone ring opening, i.e.  (V) only on heating with an aqueous solution of potassium chloride. The metameric effect of the *p*-methoxy-group in compounds (III) and (IV) sharply reduces the extent of the exchange reaction with potassium chloride: only about 2% of the chloride of compound (III) was obtained, while that of compound (IV) was not formed. The reactions of compounds (I) and (II) with potassium bromide yield the corresponding sulphonium bromides and compound (III) gives the corresponding sulphonium bromide hydrate with an admixture of 6% of a compound of type (V). On heating with an aqueous solution of potassium bromide, compound (IV) gives rise to 12% of compound (V) and approximately 80% of compound (VI):

$$OH^- \geqslant Cl^- > Br^- > I^- \geqslant (NO_2)_2C_6H_2O^- \ .$$

Compound (VI) readily cyclises to the initial sulphonium bromide (IV); the reactions of compounds (I) and (II) with aqueous and methanol solutions of potassium hydroxide give rise to the corresponding free bases. On heating with an aqueous potassium hydroxide solution, compounds (I) and (II) form methoxyaryl derivatives of a compound of type (V), while compounds (III) and (IV) yield the corresponding methoxyaryl, methoxybutyl, or pentyl sulphides. The reactions of compounds (III) and (IV) with aqueous potassium hydroxide solutions give only complex cleavage products. The ease of dissociation of the C–S bond in the saturated heterocycle in arylthiacyclanylsulphonium salts by nucleophilic agents varies in parallel with their electronegativity§:

(VI)

The relative stabilities of the heterocycles correspond to the sequence of compounds (I) and (IV) represented above.

The compounds obtained in the reactions enumerated above are of significant interest in the study of biological activity and complex-forming properties and as starting materials for fine organic synthesis.

The involvement in these reactions of petroleum sulphides is of dual interest: (1) some of them may be suitable for the development of chemical methods for the differentiation of these sulphides into subgroups and (2) some can give rise to a mixture of substances suitable for further use without additional separation.

It is evident from all the foregoing findings that a huge advance has been made in the accumulation of data on the compositions and properties of the heteroatomic petroleum components, particularly sulphides, in the last 5–10 years. The vigorous development of research on the heteroatomic components of petroleum is only beginning. Presumably, during the coming decade, many of these components will find applications in the national economy and the elucidation of the interactions between them will open up new pathways to the rational chemical processing of petroleum and will lead to further advances in the production, transport, and utilisation of petroleum and its derivatives.

The Gas-phase Nitration of Alkanes

A.P.Ballod and V.Ya.Shtern

The principal chemical and kinetic results obtained for this reaction are reported and discussed critically. A brief description is given of its industrial application to the manufacture of nitroalkanes. The detailed mechanism suggested during recent years for the nitration of alkanes by nitrogen dioxide is discussed in terms of the primary steps. The fundamental similarity of the mechanisms of nitration by nitrogen dioxide and by nitric acid is established on the basis of experimental data. A list of 119 references is included.

CONTENTS

I. LIQUID-PHASE NITRATION OF ALKANES

Towards the end of the nineteenth century Konovalov[1-3] discovered the subsequently famous method of introducing a nitro-group into an alkane or the side-chain of an alkylaromatic hydrocarbon by treatment with dilute nitric acid in sealed tubes (acid of specific gravity 1.075 at 120-130°C for 4-6 h). Since that time research on the nitration of the alkyl chain has become traditional for the Russian school of organic chemists.

During the first period, lasting until 1914, the most notable work was undertaken by Konovalov[1-10], Markovnikov[11-19], and Nametkin[20-27]. The attention paid by these eminent chemists to the nitration of saturated hydrocarbons is quite understandable. At the turn of the century the problem of the utilisation of petroleum became acute, not only as fuel but also as raw material for the production of intermediates in industrial organic synthesis. A serious obstacle to the latter use was the considerable chemical stability and hence low reactivity of saturated hydrocarbons, the main components of petroleum. Therefore any possibility of the chemical "revival" of these hydrocarbons was extremely important, and work leading to the discovery and study of chemical reactions of saturated hydrocarbons was fundamentally progressive.

During this first period the liquid-phase nitration of the alkyl chain (in alkanes, naphthenes, and alkylbenzenes) by nitric acid was closely examined by the above workers. They established experimental conditions for the reaction, the formation both of nitration products (nitro-compounds) and of oxidation products (aldehydes, ketones, alcohols, acids, and carbon monoxide and dioxide), and the qualitative and in several cases quantitative composition of the products. At the same time the first mechanisms were suggested in terms of valency-saturated intermediate and final compounds.

The first view on the mechanism of the newly discovered reaction was expressed by Konovalov in the principle that "nitric acid always nitrates initially, whatever its concentration, and oxidation is a secondary, subsequent step". Later, however, when the great stability of nitro-products to oxidation had become clear (for example, the oxidation of xylylnitromethane by nitric acid took place at temperatures 25 deg above those for the original pseudocumene), Konovalov concluded that the nitro-product underwent oxidation only at the instant of its formation.

Nametkin adopted a different approach to the mechanism of nitration. His attention was attracted by Konovalov's suggestion that, at the instant of formation by the double decomposition

$$RH + HNO_3 \rightarrow RNO_2 + H_2O$$

the nitro-compound is in an unstable state, and therefore immediately and readily undergoes further oxidation to aldehydes, ketones, alcohols, carbon monoxide and dioxide, etc. However, Nametkin regards this route to oxidation products as inconsistent with the "law of stepwise reaction "stages" formulated by Ostwald[28] as "no process leads immediately to the most stable state: the next or the least stable state of those possible is established initially". Indeed, the acceptance of such a law and of Konovalov's hypothesis leads to the conclusion that in the present case the formation of stable nitro-compounds is quite impossible, since, being in an unstable state at the instant of formation, the nitro-compound undergoes further oxidation.

An escape from the discrepancy was provided by Nametkin's hypothesis that *aci-* or iso-nitro-compounds are formed as an intermediate stage in the action of nitric acid on saturated hydrocarbons:

$$\rangle CH_2 + HONO_2 \rightarrow \rangle C{=}NOOH + H_2O$$

$$-CH_3 + HONO_2 \rightarrow -CH{=}NOOH + H_2O.$$

Under the influence of the acid medium or a high temperature these intermediates either isomerise into stable nitro-compounds or decompose by Nef's reaction into ketones (aldehydes) and nitrous oxide with subsequent oxidation of the ketone (aldehyde) to carboxylic acids.

Thus, whereas Konovalov suggested that the overall nitration involves two consecutive reactions—nitration of the hydrocarbon to the nitro-product followed by oxidation of the latter by nitric acid to oxygenated products—Nametkin postulated two parallel reactions—nitration itself and oxidation.

As we shall see later, Nametkin proved to be correct. In the light of modern views, the overall reaction of nitration actually involves two parallel chemical changes, yielding respectively nitro-products and oxygen-containing compounds. We now know that this is accomplished by means of free radicals, but the classical investigators of nitration—Konovalov, Markovnikov, and Nametkin—were unaware of this, and had to consider the mechanism of this reaction in terms of valency-saturated compounds. Nevertheless, Nametkin's hypothesis gave a fundamentally correct view of the mechanism of nitration.

On the whole all the vast and high-quality experimental information and the theoretical views developed during the first period of investigation on the reaction mechanism formed the foundation on which the subsequent intense study of the nitration of saturated hydrocarbons has continued. An astonishingly deep insight was obtained by these brilliant investigators, who were able to foresee the great value of nitration processes for the chemistry of petroleum.

II. GAS-PHASE NITRATION OF ALKANES

For two whole decades from the beginning of the First World War hardly any publications appeared on the nitration of saturated hydrocarbons: only in the mid-1930s was study of this chemical reaction resumed, not only in our own but also in other countries. However, considerable development and complication had occurred during 1914 to 1934 in the problems facing the renewed investigation, the experimental equipment in which it was now conducted, and finally theoretical views on the mechanism of complicated chemical reactions, which undoubtedly include nitration. And since the general characteristics of Konovalov nitration, the conditions under which it occurred, and (to a first approximation) its chemistry had already been established during the first period preceding 1914, research workers during the 1930s had two main tasks.

The first problem was to find optimum conditions for conducting nitration in order to secure maximum yields of the required products, which nitroalkanes had then become, having already found application. At the present time (the 1970s) the range of uses of nitroalkanes is quite wide: they are employed both as intermediates for the manufacture of nitro-alcohols, hydroxyalkylamines, and polynitro-compounds and also as solvents, stabilisers, explosives, and fuels for jet and piston engines[29].

The increasing emphasis on practical utilisation of the reaction had its natural consequence in the change in the experimental conditions under which study of the nitration of saturated hydrocarbons—mainly alkanes—was continued. Liquid-phase nitration by Konovalov's procedure, with its relatively low temperatures (120–140°C) and reaction velocities, was of no interest for industrial purposes. All researches after the mid-1930s, therefore, involved study of the nitration of the alkane chain almost exclusively in the gas phase at far higher temperatures (300–550°C). The number of nitrating agents also increased, with the use of nitrogen dioxide as well as nitric acid. This became possible after the appearance during 1934–1935 of papers by Shorygin and Topchiev[30,31], who were the first to nitrate alkanes by means of nitrogen dioxide. As will become clear from the later discussion, their discovery exerted a great influence on the whole subsequent development of research on the nitration of the alkane chain.

The second task was to elucidate the detailed mechanism of the nitration of saturated hydrocarbons. It must be stressed that the transition to the practically oriented study of nitration not only did not diminish but, on the contrary, increased interest in ascertaining the true mechanism of the process. This is quite understandable, since any extension of knowledge on the mechanism of a chemical reaction, in addition to its cognitive interest, at the same time advances the boundaries of the rational rather than the inventor's search for optimum conditions for the practical application of the reaction. But now the true mechanism of the high-temperature gas-phase reaction no longer implied merely the sequence of stable (valency-saturated) compounds. At this time the concepts of the chain theory, with its assertion of the important and decisive role of labile structures (free radicals) in the mechanism of a considerable number of high-temperature gas-phase and liquid-phase reactions, became increasingly widely accepted. Indeed, experimental information was fairly soon accumulated confirming unambiguously the participation of active centres (free radicals) in the nitration of saturated hydrocarbons. From this time elucidation of the mechanism of nitration of the alkane chain in terms of primary steps, i.e. involving free radicals, became the second task, initially sometimes not clearly understood but rather intuitively perceived by investigators.

It is clear from the above discussion that a comprehensive kinetic investigation using all the methods available for the study of this reaction was required in order to solve the second problem, the mechanism of nitration. This was by no means immediately understood—only at the end of the 1950s—some 20–25 years after resumption of investigation of the nitration of the alkane chain. This does not mean, of course, that aspects of the mechanism were completely excluded from the attention of research workers during the whole quarter-century. On the contrary, by the end of the 1930s (see below) Titov had already suggested a mechanism for the nitration of alkanes involving free radicals, which is still relevant at the present time.

The renewed investigation can conveniently be divided into two periods: the second period lasted from the 1930s to the 1960s (the first period had ended in 1914), and the third period began in the 1960s and continues at the present time. During the second period much experimental work was undertaken in establishing the industrial gas-phase nitration of alkanes, and the first investigations were made to determine the reaction mechanism in terms of primary steps, involving free radicals. The third period is characterised mainly by more detailed investigation of the reaction mechanism. The study of kinetic aspects of nitration has become considerably more intense, and the first radical-chain scheme has been suggested for nitration.

1. Development of the Industrial Production of Nitroalkanes

We shall begin our survey of results obtained during the second period with an examination of the most important work aimed at the industrial application of the nitration of alkanes. It involved essentially a search for optimum conditions for the production of nitroalkanes, and comprised two long series of studies undertaken in the U.S.A. The American papers resulted from a cooperative investigation by the Commercial Solvents Corporation and Purdue University. The first series of studies was made by Hass and his coworkers between 1934 and 1953[32-45], and the second by Bachman et al. from 1952 to 1961.[46-53]

Hass used C_1–C_6 alkanes, and was one of the first to change to high-temperature nitration in the gas phase. The experiments were made in glass or metal laboratory flow-type apparatus. The nitrating agent was either

50–70% nitric acid (at 400–700°C for up to 2 s) or nitrogen dioxide (at 250–600°C from a few seconds up to 14 min). In most cases the reaction was conducted under atmospheric pressure. Hass studied the influence of temperature, contact time, and composition of mixture (ratio of alkane to nitrating agent) on the total yields of nitroalkanes obtained in the nitration of methane [33, 38], ethane [33, 36], propane [37, 44], n-butane and isobutane [33], n-pentane [34], 2,2-dimethylbutane [41], and 2,3-dimethylbutane [40]. At the same time he determined the composition of the resulting mixture of nitroalkanes and analysed other reaction products. The possibility of increasing the yield of nitroalkanes by conducting the reaction under high pressures of methane (7 and 70 atm) [43] and ethane (7 atm),[36] as well as with additions of oxygen, nitrogen, and nitric oxide [44], was also examined.

Table 1. Nitration of alkanes by nitric acid and by nitrogen dioxide (from results obtained by Hass).

Some of the results obtained by Hass et al. are listed in Table 1. They show firstly that the rate of the gas-phase nitration of alkanes increases when nitrogen dioxide is replaced as nitrating agent by nitric acid. Hass made no attempt to explain this fact. Table 1 shows also that the ability to replace hydrogen atoms in an alkane by the nitro-group was retained on passing from the liquid-phase to the gas-phase reaction with nitric acid (and with nitrogen dioxide). Moreover, a considerable number of experimental results obtained by Hass (not included in Table 1) indicate increasing ease of substitution of a hydrogen atom in gas-phase nitration on passing from a primary to a secondary and then to a tertiary carbon atom. It is especially noteworthy that, as Hass proved, nitroalkanes are accompanied in both gas-phase and liquid-phase processes by oxygen-containing products (aldehydes, ketones, alcohols, oxides of carbon), i.e. the so called oxidising reaction path.

Naturally, there are also differences. Firstly, in contrast to the liquid-phase process, gas-phase nitration yields isomeric nitroalkanes, which means diminished selectivity of the reaction (Table 1). A second difference is the formation in the gas-phase reaction not only of nitroalkanes corresponding to the initial hydrocarbon but also lower nitroalkanes (Table 1). A third difference is the absence of polynitroalkanes in the gas-phase products, despite attempts by Hass to direct the process towards their formation; yet polynitroalkanes are almost always obtained when the reaction is conducted in the liquid phase. Fourthly and finally, alkenes are found among the products of gas-phase nitration but are absent from the liquid-phase process.

All these features are usually explained by the more severe temperature conditions of gas-phase nitration, with which we can agree. For example, the discovery by Hass that the 1-nitroalkane is formed in addition to the 2-nitroalkane on passing from the liquid phase to the gas phase is a consequence of the greater (by 4–5 kcal $mole^{-1}$) energy of a carbon–hydrogen bond attached to a primary than to a secondary carbon atom [54]: the activation energy of substitution by a nitro-group is therefore higher for a hydrogen atom at a primary than at a secondary carbon atom, so that the relative importance of the reaction leading to formation of the 1-nitroalkane should increase with rise in temperature. Furthermore, the high temperature of the gas-phase nitration of alkanes is probably the reason for the appearance of alkenes, since it is now known that the thermal decomposition of nitroalkanes leads to the formation not only of alkyl radicals and nitrogen dioxide but also of the corresponding alkene and nitrous acid [55,56].

Although Hass put forward several hypotheses [33,34,39,40,45], he was unable to relate the second difference—the formation of nitroalkanes having a smaller carbon skeleton than in the original alkane—with the higher temperature of gas-phase nitration. At the present time (the 1970s), however, it is generally accepted that alkoxy-radicals are present during the gas-phase process, and undergo thermal decomposition into aldehydes (or ketones) and alkyl radicals containing fewer carbon atoms than originally present. Reaction of these alkyl radicals with nitrogen dioxide leads to formation of the lower nitroalkanes.

Hass [44] investigated also the effect of added oxygen on the nitration of methane and propane by nitric acid dioxide at 395 and 410°C, varying the quantity of oxygen from zero to fivefold the molar proportion of the nitrating agent. With methane the conversion of nitric acid into nitromethane passed through a maximum of 24.2% when the molar ratio of oxygen was 2.6, falling to 1.4% when the ratio was 5. With propane, however, increasing the ratio of oxygen to nitrating agent from 0 to 3 produced a continuous increase in conversion of nitric acid from 28% to 62%, and of nitrogen dioxide from 13.7% to 24.7%. Unfortunately, no information was given on the effect of additions of oxygen either on decomposition of the alkane or on the composition of the nitroalkanes obtained.

On the basis of the series of investigations Hass formulated several empirical "rules" of nitration, mostly concerned with technical aspects of the process. His views on the mechanism of the nitration of alkanes, expressed in these rules, can be summarised as follows: (*a*) at moderate temperatures (300–500°C) nitration does not result in rearrangement of the carbon skeleton of the initial hydrocarbon; (*b*) under such conditions, however, oxygen-containing products and nitro-compounds undergo considerable decomposition with the formation of alkenes and degradation products (e.g. the pyrolysis of nitroethane and of 1-nitropropane yields alkanes, aldehydes, carbon monoxide and dioxide, and nitrogen, but no lower nitro-compounds); (*c*) nitration is accompanied by oxidation, with nitric acid oxidising both alkanes and nitroalkanes; and (*d*) he accepts McCleary and Degering's statement [57] (below) that nitric acid forms nitroalkanes by reaction with alkyl radicals

$$\dot{R} + HNO_3 \rightarrow RNO_2 + OH \ .$$

Bachman and his coworkers continued the studies of Hass by investigating the gas-phase nitration of propane and butane with nitric acid and nitrogen dioxide. Like Hass they examined the effects of temperature, ratio of hydrocarbon to nitrating agent, and contact time on the formation of nitroalkanes. Their results showed (Table 2) that optimum conditions for the nitration of butane comprised a ratio to nitric acid of 12.3 at 425°C for 1.6 s, when the yield of nitroalkane reached 50% of the butane consumed and 36% of the acid was converted into this product[47]. Propane could be nitrated by nitrogen dioxide most effectively at a ratio to the latter of 4.2 at 325°C with a time of contact of ~2 min, when the yield reached 51% of the propane consumed and the conversion 14–17% of the nitrogen dioxide consumed[48].

Table 2. Effects of composition of mixture, temperature, and time of contact on yield of nitroalkanes and conversion of nitrating agent into nitroalkanes (Bachman[48,49]).

Having determined the maximum yields of nitroalkanes, Bachman directed his further efforts at improving the results, for which purpose he studied the effect of considerable additions of oxygen on the nitration of butane and propane[46,49]. Table 3 shows that the conversion of the nitrating agent into nitroalkanes passes through a maximum with increase in the quantity of oxygen added, whether nitric acid or nitrogen dioxide is used. He attributed this to simultaneous oxidation of the initial alkane with formation of an alkyl hydroperoxide. Breakdown of this product at the peroxy-bond to give alkoxyl and hydroxyl radicals is a branching step, which was used to explain the increasing conversion of the nitrating agent by the action of oxygen on the nitration.

Bachman's hypothesis that oxidation of the alkane takes place at the same time as its nitration is obviously correct. However, the branched character of the oxidation alone is insufficient to explain the increase in conversion, especially as later additions of oxygen beyond the conversion maximum act in the opposite direction. More detailed examination of the interaction of these two reactions is undoubtedly desirable, but several of the necessary data—primarily the consumption of the initial alkanes and frequently the composition of the resulting nitroalkanes—are lacking from the publications both of Hass and of Bachman.

Bachman studied also the effect of additions of halogens on the nitration of propane by nitric acid and by nitrogen dioxide[49,50]. The quantities of halogens were considerably smaller than those of oxygen added at the same time. Degrees of conversion and nitroalkane yields depended on the halogen concentrations. Optimum additions of chlorine and bromine were found at which maximum conversions and yields were obtained.

Bachman's experiments[47] on the influence of the ratio of the surface area of the reaction vessel to its volume S/V on the nitration of butane by nitric acid are interesting. Change in the ratio from 28 to 300 cm^{-1} at 425°C had no effect on the final results: both the degrees of conversion of butane and of nitric acid and the yield of nitroalkanes remained almost constant. Only the proportion of carbonyl compounds diminished slightly, while the quantity of carbon monoxide increased. These results most probably indicate that the reaction is homogeneous under the given conditions.

In his views on the mechanism of nitration Bachman[46] adopted all the main suggestions made by Titov (below). The only modification introduced by Bachman into Titov's set of concepts concerned the path by which nitrogen dioxide is formed during nitration by nitric acid. In 1952 Bachman was probably the first to suggest that, in the high-temperature nitration of alkanes by nitric acid, nitrogen dioxide is formed by the reaction

$$HNO_3 + M \rightarrow NO_2 + OH + M$$

which by that time had become well known and thoroughly studied.

The results obtained by Hass and by Bachman and their coworkers formed the basis for the initial trial production of nitroalkanes at Sterlington (Louisiana, U.S.A.), which was followed (in 1955) by a works manufacturing many thousands of tons a year. The process involves[58] reaction between 75% nitric acid and excess of propane under 7–9 atm (gauge) at 450°C for 1 s. Nitroalkanes and dilute acid are condensed and separated, while nitric oxide is oxidised to nitric acid and returned to the reaction vessel. Varying the conditions enables the proportions of individual nitroalkanes to be varied over the ranges 10–30% of nitromethane, 20–25% of nitroethane, and 55–65% of nitropropanes.

2. Initial Ideas on the Participation of Free Radicals in the Gas-phase Nitration of Alkanes

Passing now to publications during the second period of investigation that endeavoured to establish the mechanism of nitration, we shall first give the main content of the "theory of the nitration of saturated hydrocarbons and side-chains of arylalkanes", as Titov termed his investigation in his summary paper[69]. Discussing the high-temperature nitration of saturated hydrocarbons by nitrogen dioxide, he was the first to suggest[59-69] that free hydrocarbon radicals were involved, and attributed their formation to the reaction

$$RH + NO_2 \rightarrow \dot{R} + HNO_2 \,. \qquad (1)$$

However, he regarded the nitro-products as produced by the recombination of free alkyl radicals with nitrogen dioxide, which also possesses the character of a free radical:

$$\dot{R} + NO_2 \rightarrow RNO_2 \,. \qquad (2)$$

The structure of nitrogen dioxide, which can be written

to allow for interaction between the unpaired electron and the mobile *p*-electrons, enabled Titov to predict that it would react with free alkyl radicals both through the nitrogen atom and through an oxygen atom, i.e. that it would form not only nitro-compounds but also nitrites by the recombination

$$\dot{R} + ONO \rightarrow RONO \,. \qquad (3)$$

Although by the end of the 1930s Hass had shown quite reliably that nitro-compounds containing fewer carbon atoms than in the original hydrocarbon are formed in the high-temperature nitration of alkanes, his attempts to explain this fact were unsuccessful. In 1940 Titov[61] suggested a mechanism for such puzzling degradation of nitro-compounds that was based on the assumption that, under the conditions of high-temperature nitration, an alkyl nitrite undergoes pyrolysis, which according to Rice[70] should give an alkoxy-radical, whose further thermal decomposition yields an aldehyde (or a ketone) and an alkyl radical containing a smaller number of carbon atoms than in the original hydrocarbon. Thus for isobutane as example Titov wrote down the reactions

$$(CH_3)_2CH\dot{C}H_2 + NO_2 \rightarrow (CH_3)_2CHCH_2ONO \,, \qquad (3')$$

$$(CH_3)_2CHCH_2ONO \rightarrow (CH_3)_2CHCH_2\dot{O} + NO \,, \qquad (4)$$

$$(CH_3)_2CHCH_2\dot{O} \rightarrow (CH_3)_2\dot{C}H + HCHO \,, \qquad (5)$$

$$(CH_3)_2\dot{C}H + NO_2 \rightarrow (CH_3)_2CHNO_2 \,. \qquad (2')$$

The mechanism of the gas-phase nitration of alkanes by nitrogen dioxide proposed by Titov in the 1930s comprised a set of primary steps. It must be emphasised that the choice of the actual free radicals and the sequence and nature of the elementary reactions were suggested solely on the basis of results for the chemistry of nitration in terms of stable species. No kinetic study had then been made of nitration, so that information was lacking on the formal kinetics of the reaction (e.g. the effective rate constants in Arrhenius coordinates, the order of the reaction with respect to the initial substances, the kinetics with respect to pressure, etc.) and on the kinetics with respect to stable species. Thus all those data were absent, ignorance of which makes it so difficult to establish the mechanism of chemical reactions involving free radicals. The insight exhibited by Titov in formulating his mechanism is especially surprising. Indeed, as we shall see later, the chemical framework of his scheme was largely adopted by subsequent investigators.

Titov, of course, was interested in the nitration of saturated hydrocarbons not only by nitrogen dioxide but also (perhaps still more strongly) by nitric acid. He formulated the fundamental principles of this process, too. He boldly postulated that nitric acid molecules do not exert an independent nitrating action on the alkane chain but are merely the "source of the progressive regeneration" of oxides of nitrogen. Even with nitric acid, however, the true nitrating agent is still the nitrogen dioxide molecule. Nitration thus takes place, of course, by the above set of reactions (1)-(5).

In order to prove the chemical inertness of nitric acid towards the alkane chain Titov undertook special experiments on the action of the acid on various hydrocarbons[61,62,67] both in the presence of oxides of nitrogen and in their absence (achieved by the addition of urea nitrate). At temperatures up to 150°C nitric acid (specific gravity <1.4) hardly reacted with alkanes or with the side-chain of alkylbenzenes.

This result raised the question of the route by which nitric acid became the source of nitrogen dioxide. Titov suggested that nitric acid could react readily with nitrous acid and with nitric oxide, not only at high but even at low temperatures, with formation of nitrogen dioxide in both cases:

$$HNO_3 + HNO_2 \rightleftarrows 2\,NO_2 + H_2O \,, \qquad (6)$$

$$2\,HNO_3 + NO \rightleftarrows 3NO_2 + H_2O \,. \qquad (7)$$

It was emphasised that nitrous acid already appears in the first stage as a result of reaction (1), that nitric oxide is formed by secondary oxidation processes, and that both reactions (6) and (7) lead to a progressive increase in the concentration of nitrogen dioxide, even in liquid-phase nitration at low temperatures.

Somewhat later, after the publication of Hass's results showing that replacement of nitrogen dioxide by nitric acid increased the rate of the high-temperature nitration of alkanes, Titov[69] suggested that at high temperatures the formation of nitrate radicals from nitric acid was also possible:

$$\begin{array}{c} 2\,HNO_3 \rightarrow N_2O_5 + H_2O \\ N_2O_5 \rightarrow \dot{N}O_3 + NO_2 \,. \end{array} \qquad (8)$$

By analogy with the dioxide Titov represents the very rapid reaction of the above radical with the alkane chain by the equation

$$RH + \dot{N}O_3 \rightarrow \dot{R} + HNO_3 \,. \qquad (9)$$

The great activity of the nitrate radical in this reaction is attributed by Titov to purely energetic considerations and the fact that it is more strongly electrophilic than nitrogen dioxide: the former are based on the greater heat of formation of nitric than of nitrous acid; and the electrophilicity of the two species will be proportional to a first approximation to the strengths of the corresponding acids—nitric and nitrous.

Objections to certain aspects of Titov's mechanism appeared in the literature. The first was his assertion that nitrogen dioxide is formed from nitric acid by reactions (6)-(8). Bachman et al. were probably the first to reject in 1952 [46] such reaction paths in high-temperature nitration by nitric acid, and the second were Geiseler and

Reinhardt[71] in 1957. Both papers replaced reactions (6)–(8) by the thermal decomposition of nitric acid†:

$$HNO_3 + M \rightarrow OH + NO_2 + M \quad . \qquad (10)$$

This gas-phase decomposition has now been thoroughly studied[72–74], and has the rate constant

$$k = 1.6 \cdot 10^{15} \exp(-30\,000/RT) \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1} \quad .$$

Elementary calculation shows that with this rate coefficient reaction (10) is fully able to supply the quantities of nitrogen dioxide corresponding to the quantities of nitroalkanes actually obtained at 300–400°C. Indeed, the subsequent discussion will show that the Reviewers have obtained experimental evidence of the occurrence of reaction (10) as primary stage in the high-temperature nitration of the alkane chain by nitric acid.

A different situation is found with nitration by nitric acid at low temperatures (in both liquid and gaseous phases). Calculation shows that under these conditions the necessary quantities of nitrogen dioxide cannot be formed from nitric acid by reaction (10), so that a different route must be assumed. Perhaps reactions (6) to (8) occur at low temperatures, as assumed by Titov also for high temperatures. It is noteworthy that he did not study in greater detail the conditions for and the possibility of obtaining nitrogen dioxide from nitric acid at a sufficient rate at low temperatures.

The second aspect of Titov's mechanism to be refuted was the assumption that the actual nitrating agent was nitrogen dioxide even when nitric acid was used. In opposition to this several authors suggested the reaction

$$\dot{R} + HNO_3 \rightarrow RNO_2 + \dot{O}H \quad , \qquad (11)$$

which was first considered in 1938 by McCleary and Degering[57], who detected nitroethane and ethyl nitrate among the products of the action of nitric acid on tetraethyl-lead at 150°C. They suggested the scheme

$$Pb(C_2H_5)_4 \rightarrow Pb + 4\dot{C}_2H_5$$
$$\dot{C}_2H_5 + HNO_3 \rightarrow C_2H_5NO_2 + \dot{O}H$$
$$\dot{C}_2H_5 + \dot{O}H \rightarrow C_2H_5OH$$
$$C_2H_5OH + HNO_3 \rightarrow C_2H_5ONO_2 + H_2O \quad .$$

There is no doubt that the ethyl radical is present. The thermal decomposition of tetraethyl-lead has been well studied and is widely used for the production of ethyl radicals. It can thus be accepted that one of Titov's fundamental assumptions—that free alkyl radicals are involved in the formation of nitro-compounds from alkanes—found direct experimental confirmation in the above work.

However, we cannot accept that nitroalkanes are formed by reaction (11). Since at high temperatures nitric acid undergoes thermal decomposition into nitrogen dioxide and a hydroxyl radical (Eqn. 10), the competition between reactions (2) and (11) must be considered in order to choose between them. In 1967 the Reviewers[75] found experimentally that reaction (2) has zero activation energy and the rate constant $k = 2.9 \times 10^{12}$ cm^3 mole^{-1} s^{-1}. Reaction (11) takes place with incomparably greater difficulty. The few numerical data available on reactions involving abstraction by an alkyl radical not of a hydrogen atom but of a group of atoms (e.g. $\cdot CH_3 + CH_3CHO \rightarrow CH_3COCH_3 + H\cdot$ [76]) suggest that the activation energy is greater and the pre-exponential factor smaller than for abstraction of a hydrogen atom. Therefore it can reasonably be assumed that at high temperatures (300–500°C), when decomposition of nitric acid is intense, the rate of reaction (2) will be considerably higher than that of reaction (11). Indeed, if we accept that $E_{11} = 10$ kcal mole^{-1} and $A_{11} \simeq 2 \times 10^{11}$ cm^3 mole^{-1} s^{-1}, we find that at 300°C

$$\frac{W_2}{W_{11}} = \frac{k_2[R]\cdot[NO_2]}{k_{11}[R]\cdot[HNO_3]} = \frac{2.9\cdot 10^{12}[NO_2]}{2\cdot 10^{11}\cdot e^{-10000/R\cdot 573}\cdot[HNO_3]} = 0.6\cdot 10^5\,\frac{[NO_2]}{[HNO_3]} \quad .$$

Thus even if the concentration of nitrogen dioxide is only 1% of that of nitric acid, W_2 still exceeds W_{11} almost hundredfold. We therefore regard as justified Titov's assertion that nitrogen dioxide is the immediate nitrating agent in the action of nitric acid on alkanes at high temperatures.

Almost twenty years later (in 1957) Geiseler and Reinhardt[71] studied the nitration of ethane by nitric acid under atmospheric pressure at 380–460°C. They determined the effective rate constant [$k_{\text{eff}} = 4.49 \times 10^{15} \exp(-47\,500/RT)$ s^{-1}], established optimum temperatures of formation of the nitroalkanes, and studied the thermal decomposition of nitroethane. Besides obtaining important experimental data, they concluded that both Titov's reaction (2) and McCleary and Degering's reaction (11) occurred as direct acts of nitration of ethane. No evidence, either experimental or theoretical, was given that reaction (11) occurred to an appreciable extent. Therefore the Reviewers' calculation indicating the non-competitiveness of reaction (11) with (2) is still valid. This provides no support for the direct combination[71] of the mechanisms of Titov and of McCleary and Degering‡.

The assertion that nitroalkanes are formed by reaction (11) (when alkanes are nitrated by nitric acid) again appeared in the literature in 1965. Ingold and his coworkers[77] reached this conclusion from a study of the reaction between methane and nitric acid at 349.5°C, the variation in the acid concentration being followed by the infrared spectrum. These investigators discovered several interesting features: (i) the rate of decomposition of nitric acid is increased by the presence of methane; (ii) consumption of nitric acid is of the first order with respect to the acid, but only slightly dependent on methane; (iii) although nitrogen dioxide is formed during the process, it does not inhibit decomposition of the acid; and (iv) the reaction velocity is $W = 2.8k_a[HNO_3]$, where k_a is the rate constant of the decomposition of nitric acid.

In order to ascertain a mechanism of reaction between methane and nitric acid consistent with these features the authors examined the series of known elementary reactions

$$HNO_3 \xrightarrow{a} \dot{O}H + NO_2$$
$$\dot{O}H + HNO_3 \xrightarrow{b} H_2O + \dot{N}O_3$$
$$\dot{O}H + CH_4 \xrightarrow{c} H_2O + \dot{C}H_3$$
$$\dot{C}H_3 + HNO_3 \xrightarrow{d} CH_3NO_2 + \dot{O}H$$
$$\dot{C}H_3 + NO_2 \xrightarrow{e} CH_3NO_2$$
$$\dot{C}H_3 + HNO_3 \xrightarrow{f} CH_3OH + NO_2 \quad .$$

Firstly they considered non-chain mechanisms, e.g. the set of reactions *a*, *c*, and *e* or *a*, *c*, *e*, and *f*, etc., but formulae for the reaction velocity derived from these mechanisms did not satisfy the experimental data. Closest

---

†Here and subsequently M represents any molecule of the reaction mixture.

‡We considered it necessary to emphasise this point, since Geiseler and Reinhardt's paper gained some publicity, and is widely quoted in the literature on the nitration of hydrocarbons.

agreement with the above experimental features was provided by the chain mechanism comprising the fundamental reactions

$$\begin{array}{l}
HNO_3 \xrightarrow{a} \dot{O}H + NO_2 \\
\dot{O}H + CH_4 \xrightarrow{c} H_2O + \dot{C}H_3 \\
\dot{C}H_3 + HNO_3 \begin{array}{l} \nearrow CH_3NO_2 + \dot{O}H \\ \searrow CH_3OH + NO_2 \end{array} .
\end{array}$$

It should be noted that Ingold et al. use CH_3NO_2 to represent the sum of nitromethane and methyl nitrite. They do not deny that reactions *b* and *f* may also occur to a slight extent. Thus the limiting stage in their mechanism is the breakdown of nitric acid into a hydroxyl radical and nitrogen dioxide. However, the main reaction yielding nitromethane and methyl nitrite is assumed to be interaction of the alkyl radical with the acid (*d*).

There can be no doubt about the first conclusion (concerning reaction *a*), at least at and above 350°C. The second conclusion—that nitromethane is formed by reaction *d*—has a quite different status. It is strange that these workers did not think of comparing, even to a first approximation, the quantitative kinetics of the two possible competing reactions *d* and *e* yielding nitromethane. The Reviewers have made such a comparison when discussing McCleary and Degering's work (above), and have concluded that the probability of the formation of nitroalkanes and alkyl nitrites by reaction *d* is very small.

It must be added that Ingold regards formation of the alcohol by reaction *f* as confirming the suggested mechanism. However, his mechanism is terminated, it may be said "compulsorily", at the stage of formation of nitromethane, and does not even involve either methyl nitrite or the alkoxy-radical (the latter is necessarily formed by the reaction $\cdot CH_3 + NO_2 \rightarrow CH_3O\cdot + NO$). Yet such an ordinary reaction as that of methoxyl with the initial alkane would undoubtedly have yielded the alcohol even without the inclusion of reaction *f* in the mechanism.

Titov's third principle—thermal decomposition into alkoxyl and nitric oxide of the alkyl nitrites formed—was refined by Gray[78]. On the basis of known thermochemical data he emphasised that the energy of the carbon–oxygen bond in an alkyl nitrite is ~57 kcal mole^{-1}, so that, when the molecule is formed by recombination of an alkyl radical with nitrogen dioxide, it possesses this energy of excitation. Gray assumes that in the liquid phase, although the energy of the adjacent oxygen–nitrogen bond is only ~37 kcal mole^{-1}, the excited alkyl nitrite can nevertheless be deactivated by collisions. The resulting stable alkyl nitrite, having lost the excess energy, must be regarded as of primary origin, formed by the single elementary reaction between the alkyl radical and nitrogen dioxide. A different situation obtains in gas-phase nitration. Here, according to Gray, the lifetime of the excited nitrite is so brief that decomposition into alkoxyl and nitric oxide takes place considerably sooner than the excess energy can be released in collisions. The analytically determinable alkyl nitrite is then formed by subsequent reaction between the alkoxy-radical and nitric oxide with formation of an oxygen–nitrogen bond, which is the weakest bond in the molecule. Such an alkyl nitrite must be regarded as of secondary origin, since its formation involves two successive elementary steps. Thus Gray's work gave rise to the problem of determining experimentally the primary or secondary origin of the alkyl nitrite (in the above senses of these terms) in the nitration of alkanes.

III. KINETICS AND MECHANISM OF THE GAS-PHASE NITRATION OF ALKANES. RADICAL-CHAIN MECHANISM OF THE NITRATION OF METHANE AND PROPANE

The above critiques[57,71,77,78] of certain aspects of the mechanism suggested by Titov completed the second period of investigation. The third period, beginning in the mid-1950s and continuing at the present time, has been characterised by steadily growing interest in the kinetics of the high-temperature nitration of the alkane chain. Such emphasis is not, of course, accidental. Only the most general idea of the mechanism of nitration had been formulated from all the preceding research. The scientific foundations of this chemical change, i.e. its detailed mechanism in terms of the quantitative kinetics of primary steps, had not been established. A more profound kinetic study of nitration therefore became necessary.

One of the first was Yoffe's study[79] of the action of nitrogen dioxide on alkanes (C_1–C_5) under static conditions at subatmospheric pressures. He discovered that nitration may take place either as a slow reaction without visible emission, as a slow reaction accompanied by light blue luminescence, or as an explosive reaction.

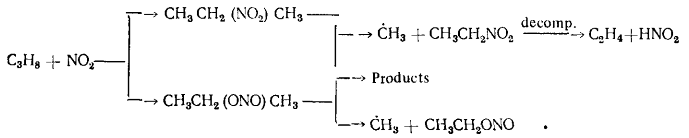
In the case of pentane the slow reaction takes place at 200–300°C. The products included primary and secondary nitroalkanes, nitric oxide, and carbon monoxide and dioxide, as well as alkyl nitrites. This worker assumed that the primary stage was detachment of a hydrogen atom from the alkane by the nitrogen dioxide. The resulting alkyl radicals react with nitrogen dioxide to yield nitroalkanes and alkyl nitrites.

With all the alkanes studied other than methane, at temperatures above 300°C and pressures above a certain limit, the reaction is accompanied by luminescence preceded by an induction period. During the latter alkyl nitrites were assumed to be formed, which decomposed into the alkoxyl and nitric oxide. The luminescence, however, may be due to reactions of the alkoxy-radical[80]. On raising the pressure (with the mixture $C_5H_{12} + 4NO_2$), Yoffe discovered a second pressure limit, above which explosion occurred accompanied by a bright white flash. This was preceded by an induction period, which could be eliminated by the addition of ethyl nitrite or shortened by acetaldehyde. With the same mixture at 400°C "composite" flames were observed, which were attributed to the dissociation $2NO_2 \rightarrow 2NO + O_2$. Analysis of the gaseous products showed in this case the presence of carbon monoxide and dioxide, nitric and nitrous oxides, and hydrogen.

Thus this work revealed several interesting features of the nitration of alkanes by nitrogen dioxide—the appearance of blue luminescence and white flames, the occurrence of an induction period, and its dependence on additions of an alkyl nitrite and of an aldehyde. The detection of an alkyl nitrite among the reaction products is significant.

Experimental results were treated differently by Myerson et al.[81], who investigated the action of nitrogen dioxide on propane at 400 and 503°C, confining their attention to the reaction accompanied by a flame. These workers observed that the colour of the flame varied from orange-red to pale blue and white depending on the pressure and the composition of the mixture. They distinguished two types of flames: (i) single-stage flames were weakly actinic; (ii) two-stage flames comprised a flame of the first type followed (after an induction period of ~9 ms) by a hot bright flame. The first flame was attributed to the formation of alkyl nitrites, but the second was regarded as due to the interaction of nitrogen dioxide with ethylene formed in the first flame. Analysis of the products showed that the first flame, when followed by the second, was accompanied by considerable reaction with the consumption of up to 20% of the propane. The main products were ethylene, methane, carbon monoxide and dioxide, nitric oxide, hydrogen cyanide, and acetylene.

The main argument used by these workers against Titov's mechanism was the absence of propene from the reaction products, which according to this mechanism they believed should have been formed in the flame by the decomposition of 2-nitropropane. The presence of a considerable quantity of ethylene instead of the expected propene and the impossibility with Titov's mechanism that it could be formed from isopropyl at subsequent stages gave these authors grounds for adopting a different mechanism of nitration, involving the formation of intermediate complexes:



Subsequent reactions of the complexes with nitrogen dioxide and (or) their decomposition yield various products, in particular nitro-compounds and alkyl nitrites having a smaller carbon skeleton than in the original alkane. Thermal decomposition of nitroethane leads to the formation of ethylene.

This mechanism with intermediate complexes is unconvincing. Immediately it was advanced Yoffe[82] made the entirely correct remark that complex formation was hardly feasible at such high temperatures (400 to 500°C). It is also hardly possible to accept the authors' statement that ethylene cannot be formed by Titov's mechanism. Actually the propoxy-radical decomposes to form the ethyl radical ($n\text{-}C_3H_7O\cdot \rightarrow C_2H_5\cdot + HCHO$), which reacts with nitrogen dioxide to give nitroethane, whose thermal decomposition yields mainly ethylene.

In spite of the doubt attaching to a mechanism involving formation of intermediate complexes, this work was important for the development of research on nitration. It continued Yoffe's study[79] of nitration accompanied by weakly actinic emission. As Myerson et al.[81] showed, such luminescence remains in the chain process, when it precedes the hot flame. We shall show below that this glow consists of slowly spreading "cool" flames, revelation of whose nature was an important turning point in establishing the kinetic mechanism of nitration.

In 1957 [sic] Gagarina and Emanuel' reported[83,84] a kinetic investigation of the reaction of methane with nitrogen dioxide under static conditions at pressures below atmospheric and at temperatures of 360–420°C. This was one of the first investigations of the gas-phase nitration of alkanes which laid stress on a kinetic study. The order of the reaction with respect to the starting materials were determined: the first order was observed with respect to methane throughout the temperature range examined; the order with respect to nitrogen dioxide varied from unity at 360 and 380 to 0.5 at 400 and 0.3 at 420°C. Determination of the order in the latter case was complicated by the fact that change in the initial pressure of nitrogen dioxide was accompanied by changes in those of nitric oxide and oxygen in conformity with the equilibrium constant (methane was introduced into the reaction vessel after the nitrogen dioxide, following establishment of the equilibrium $2NO_2 \rightleftharpoons 2NO + O_2$).

In order to ascertain whether nitric oxide and oxygen took part in the reaction, a series of experiments was made at 400°C in which the initial pressures of methane and nitrogen dioxide remained constant and only those of the test gases were varied. Increasing the concentration of nitric oxide increased the rate of reaction (measured from the increase in the total pressure), whereas addition of oxygen produced a sharp decrease. Since the effects of these gases on the reaction were not determined at all temperatures at which its order with respect to nitrogen dioxide had been determined, the authors themselves regarded their values for the order of reaction as not entirely accurate.

The effective activation energy of nitration was determined[83,84] as $E_{\text{eff}} = 42$ kcal mole^{-1}. The rate of reaction of methane with nitrogen dioxide was independent of the total pressure, and zero order was maintained during the reaction. This was attributed to the coupling of many elementary stages, involving not only intermediate species but also nitrogen dioxide and oxygen. The constant rate during the reaction is described by the empirical equation $w = k[CH_4][NO_2]/[O_2]$, where k is the effective rate constant and the square brackets indicate instantaneous concentrations of the gases.

The kinetics with respect to products showed[83,84] that the action of nitrogen dioxide on methane yields nitromethane, carbon monoxide and dioxide, nitric oxide, and small quantities of formaldehyde and hydrogen cyanide. Nitromethane was an intermediate product, but not the only one, which was confirmed by comparing its rate of consumption with the rate of increase of the total pressure at various times during the reaction. Calculation showed that around 50% of the products of intensive oxidation of methane (carbon monoxide and dioxide) is produced without intermediate formation of nitromethane.

These workers regard the step $RH + NO_2 \rightarrow R + HNO_2$ as the first stage of initiation of the reaction of alkanes with nitrogen dioxide. They consider that methane can undergo two independent reactions — nitration to nitromethane and intensive oxidation by oxygen in the nitrogen dioxide (oxidation by combined oxygen).

A study of the kinetics of the action of nitrogen dioxide on n-butane was published by Ermakova et al.[85] in 1961. Experiments were made under static conditions with subatmospheric pressures over the temperature range 250–450°C. The order of the reaction at 300°C was 0.7 and 1.4 with respect to butane and nitrogen dioxide respectively. The effective activation energy determined over the above temperature range was 30 kcal mole^{-1}. Either a slow reaction or a reaction with a hot flame was observed depending on the conditions. The temperature dependence of the explosion limit was determined for the mixture $C_5H_{10} + 6.5NO_2$ on the assumption that the explosion was thermal in nature. The primary step in the reaction was regarded as

$$n\text{-}C_4H_{10} + NO_2 \rightarrow n\text{-}\dot{C}_4H_9 + HNO_2 \text{ ,}$$

which was followed by formation either of the nitro-compound

$$\dot{C}_4H_9 + NO_2 \rightarrow C_4H_9NO_2$$

or of the alkyl nitrite

$$\dot{C}_4H_9 + NO_2 \rightarrow C_4H_9ONO \text{ .}$$

From the late 1950s to the early 1960s a comprehensive kinetic investigation of the gas-phase nitration of methane and propane was started at the Institute of Petrochemical Synthesis of the USSR Academy of Sciences[86-100]. This was directed towards establishing the mechanism of these reactions. The latter phrase applied to a gas-phase reaction involving free radicals has a quite definite and general meaning. It includes as first stage determination of the kinetic mechanism, i.e. elucidation of whether a free-radical, unbranched-chain, ordinary branched-chain, or degenerately branched-chain reaction is involved. This entails the establishment of several kinetic laws—determination of the dependence of the reaction velocity on such factors as time, pressure, temperature, diameter of reaction vessel and the ratio of its surface to its volume, addition of inert gases and intermediate products, composition of initial mixtures, etc.

The second stage is to specify the chemistry of the kinetic mechanism, i.e. to construct a set of primary chemical steps representing in totality the true course of the chemical change. Besides the above kinetic laws great importance attaches here to determining the kinetics with respect to stable species (initial compounds, intermediates, and final products).

Finally, the concluding stage is to compare the overall reaction velocity, calculated from the proposed mechanism by a quasi-stationary method, with the observed rate. During recent years this stage has often included also a comparison of the kinetics with respect to stable reaction products, determined from the suggested mechanism by calculation on an electronic computer, with experimental results for the accumulation of products.

The nitration of methane and propane by nitrogen dioxide was studied[89,91-95,99] under static conditions in glass vacuum apparatus both at 400–600°C and 10–630 mmHg and at 200–500°C and 20–500 mmHg. The variation in the concentration of nitrogen dioxide during the reaction was recorded. The reaction products were analysed polarographically, spectroscopically, and chromatographically. Three types of reaction between alkanes and nitrogen dioxide were established (Fig. 1).[86]

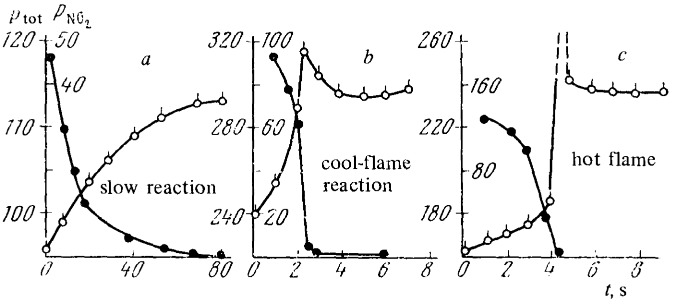


Figure 1. Kinetic curves for three types of reaction in the nitration of propane by nitrogen dioxide at 350°C: *a*) mixture of C_3H_8 + NO_2 (p_{init} = 96 mmHg); *b*) 1.5 C_3H_8 + NO_2 (237); *c*) C_3H_8 + 4NO_2 (162.5): 1) total pressure; 2) pressure of nitrogen dioxide.

1. Slow reaction. Kinetic curves based on the change in pressure Δp and the consumption of nitrogen dioxide are typical of unbranched-chain reactions. The reaction velocity is constant up to 30–50% consumption.

2. Cool-flame reaction. An autocatalytic process terminates in a jump in pressure, which is accompanied by passage through the mixture of a weakly actinic flame, termed "cool" by the authors and visible only in a darkened room. The rate of propagation of such flames is 10–20 cm s^{-1}, and the temperature in them is raised by about 100–150 deg. The nitrogen dioxide has been almost completely exhausted when the pressure peak is reached. The spectra of these cool flames indicates that their emission is due to electronically excited formaldehyde[90].

3. Reaction with a hot flame. This also begins with an autocatalytic process followed by an abrupt rise in pressure and then a rapid fall. At the instant of the jump in pressure the reaction is accompanied by a bright flame, in which it goes to completion.

Special experiments on hot flames appearing at the pressure limit and near the limit within the region of thermal ignition have confirmed that such ignition is a two-stage process[98]: the first stage involves passage of the cool flame, and is followed, in the mixture modified by the accompanying reaction, by the hot flame as the second stage. Transitions from the first to the second and then to the third type of nitration can be achieved either by increasing the pressure or by raising the temperature, and have definite limits with respect to these factors.

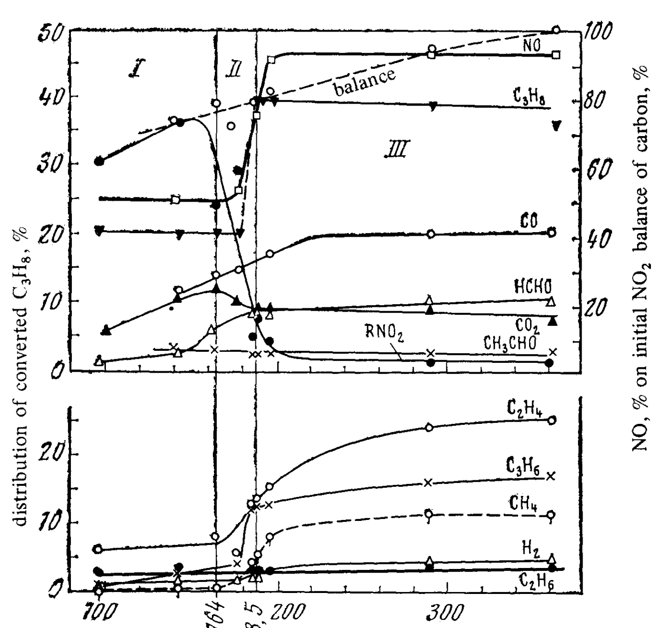

Figure 2. Composition of products at ends of slow and cool-flame reactions in the nitration of propane as function of initial pressure (C_3H_8 + NO_2 at 350°C): I) slow reaction; II) reaction "with a peak" on the pressure–time curve; III) reaction with a cool flame.

Fig. 2 shows marked differences in the composition of the products on termination of the slow and of the cool-flame reactions in the action of nitrogen dioxide on propane at 350°C. The main products of the slow reaction are nitroalkanes, carbon monoxide, and carbon dioxide, while the quantities of alkenes, carbonyl compounds, methane, and hydrogen are small. At the end of the cool-flame reaction only a minor quantity of nitroalkanes is recorded, whereas the main products are alkenes (ethylene and propene), carbon monoxide and dioxide, formaldehyde, and methane. Only carbon monoxide, carbon dioxide, and nitrogen are found at the end of the hot-flame stages[91].

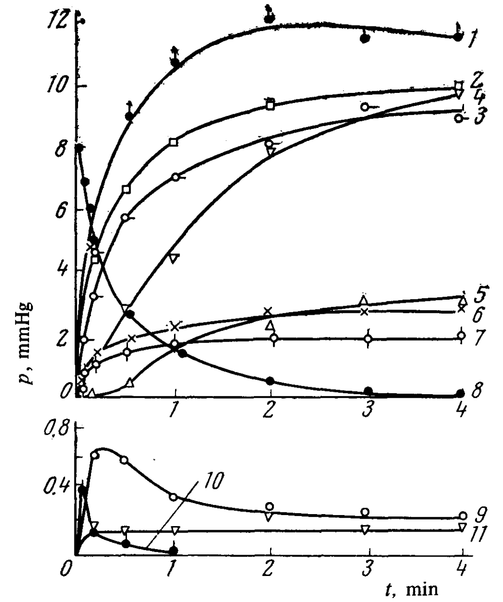

Figure 3. Rates of consumption of nitrogen dioxide and accumulation of products of the slow nitration of propane ($C_3H_8 + NO_2$ at 300°C and initially 320 mmHg): 1) $2\text{-}C_3H_7NO_2$; 2) CO_2 (×0.5); 3) CH_3NO_2; 4) CO (×0.5); 5) $(CH_3)_2CO$; 6) $1\text{-}C_3H_7NO_2$; 7) $C_2H_5NO_2$; 8) NO_2 (×0.1); 9) CH_3ONO; 10) iso-C_3H_7OH; 11) CH_3CHO.

Fig. 3 illustrates the accumulation of products throughout the slow reaction in the nitration of propane. Analysis of the products at the end of the cool-flame induction period§ gave the important result that the composition of the mixture was closely similar to that during the slow reaction. Indeed, nitroalkanes and oxides of carbon predominate at the end of this induction period, whereas methane and alkenes are almost completely absent. This suggests that the autocatalytic reaction leading to the cool flame is identical in mechanism with the slow reaction, and that the difference in composition between the products on termination of the slow and of the cool-flame reactions is due to reactions occurring in the cool flame itself as a consequence of the rise in temperature.

Determination of the order of reaction with respect to the starting materials and of the activation energy yielded formulae for the initial rates of the slow nitration of methane and propane by nitrogen dioxide[89,92]:

$$w_{CH_4+NO_2} = (7.3 \pm 0.6) \cdot 10^{14} \exp[(-33.6 \pm 0.9)/RT] \cdot [CH_4] \cdot [NO_2] \text{ mole cm}^{-3}\text{ s}^{-1}$$
(for 400—500 °C)

$$w_{C_3H_8+NO_2} = (1.0 \pm 0.1) \cdot 10^{15} \exp[(-30.0 \pm 0.5)/RT] \cdot [C_3H_8] \cdot [NO_2] \text{ mole cm}^{-3}\text{ s}^{-1}$$
(for 200—250 °C)

$$w_{C_3H_8+NO_2} = (8.5 \pm 2.5) \cdot 10^{8} \exp[(-30.0 \pm 0.5)/RT] \cdot [C_3H_8]^{0.75} \cdot [NO_2]^{1.6} \text{ mole cm}^{-3}\text{ s}^{-1}$$
(for 300—350 °C)

Studies were made[89,93] of the influence on the kinetics of nitration of varying the ratio of surface to volume *S/V* and the diameter of the reaction vessel and also of adding inert gases—nitrogen, carbon dioxide, helium—to the mixtures. Increasing the *S/V* ratio and decreasing the diameter had hardly any effect on the initial rate of the slow reaction but raised the pressure limit of cool-flame ignition. Additions of inert gases left the initial rate of the slow nitration of methane and propane almost unchanged, lowered the pressure limit for the cool-flame ignition of methane, and, rather unexpectedly, raised the pressure limit in the case of propane.

The addition of intermediate products (aldehydes and alkyl nitrites) had hardly any effect on the rate of the slow nitration of methane and propane, but shortened the induction period and lowered the pressure limit of cool-flame ignition[89,93].

The experimental results obtained made it possible to establish the kinetic mechanisms of the cool-flame and the slow nitration of methane and propane by nitrogen dioxide. With the former reaction the task was facilitated by comparison with the cool-flame oxidation of alkanes by free oxygen. Thorough investigation of this latter reaction, known for more than fifty years, indicated a chain process with degenerate branching. These two reactions were closely similar: in both cases the process began, after an induction period, with an autocatalytic reaction leading to a sharp jump in pressure accompanied by passage of a weakly actinic cool flame through the mixture; the jump was followed by a rapid drop in pressure, coinciding with extinction of the cool flame. In both cases the rate of propagation of the cool flame was 10–20 cm s^{-1}, and the temperature 100–150 deg above that of the walls of the reaction vessel. Finally, the source of the emission by the cool flame is electronically excited formaldehyde in both nitration and oxidation[90,100].

There are also differences: (*a*) only one cool flame appears in nitration, but in oxidation the number of successive cool flames may reach seven, as e.g. with propane; (*b*) all the initial reactants are consumed in the single cool flame of nitration, but only 10–20% in each of the cool flames of oxidation. However, these differences were shown[98] to be due to the negative temperature coefficient of reaction velocity characteristic of the oxidation but not of the nitration of alkanes. Therefore the differences do not disprove the similar nature of cool-flame nitration and oxidation of alkanes, and did not prevent the authors from assuming, initially by analogy, a kinetic mechanism of degenerate branching also for the cool-flame nitration of alkanes.

This conclusion is supported by several of the experimental results[89,93] for the nitration of methane and propane by nitrogen dioxide: (i) the induction period is shortened and the pressure limit of cool-flame ignition is lowered by the addition of active intermediate products (aldehydes, alkyl nitrites) to the initial mixture; (ii) increasing the *S/V* ratio and diminishing the diameter of the reaction

---

§The cool-flame induction period is the time that elapses from admission of the mixture to the reaction vessel until cool-flame ignition occurs.

vessel raise the pressure limit of cool-flame ignition; and (iii) dilution of the initial mixture with nitrogen lowers the pressure limit of cool-flame ignition in the nitration of methane. The last two effects find a reasonable explanation in the termination of chains at the walls.

A degenerate-branching mechanism of cool-flame nitration appears at first glance to be inconsistent with the above rise in the pressure limit of cool-flame ignition of propane on addition of an inert gas. An explanation for the difference from methane was obtained from a consideration of paths leading to branching during nitration. Indeed, if it were possible to show that the rate of branching in the nitration of propane diminishes on addition of an inert gas, this would explain the unexpected rise of the limit. Interaction between nitrogen dioxide and aldehydes formed by the thermal breakdown of alkoxy-radicals has been regarded[95,99,100] as the branching step in nitration. It is therefore necessary to determine possible routes by which alkoxy-radicals themselves can be formed.

The first possible path is disproportionation:

$$\dot{R} + NO_2 \rightarrow R\dot{O} + NO \ .$$

Analytically determinable alkyl nitrite is then formed in a secondary stage:

$$R\dot{O} + NO \rightarrow RONO$$

i.e. is of secondary origin. A second path is formation, from the same alkyl radical and nitrogen dioxide, of excited RONO*, which is either converted by loss of excess energy in deactivating collisions into a stable nitrite of primary origin or, because of its short lifetime, breaks down into an alkoxy-radical and nitric oxide. A stable nitrite will then be formed, as in the case of disproportionation, by the reaction RO· + NO: i.e. it will be of secondary origin.

The stable methyl nitrite obtained in a study of the primary reaction between a methyl radical and nitrogen dioxide was shown[75] to be of secondary origin. Additions of an inert gas, of course, cannot influence disproportionation but may promote deactivation of an alkyl nitrite, thereby lowering the alkoxyl concentration and hence also the concentration of aldehydes, which in turn will diminish the rate of branching.

Calculations by means of Kassel's formula yield for excited methyl and propyl nitrites the relatively long lifetimes of 10^{-6} and 10^{-2} s respectively, so that they can be stabilised even at pressures below 1 atm. In this case a primary nitrite should be formed.

During recent years, however, the view has been expressed that not all bonds in a molecule are equally involved in the redistribution of energy[101,102]. In an alkyl nitrite, for example, decomposition involves rupture of the oxygen–nitrogen bond, i.e. a bond between [relatively] heavy atoms, whose vibration frequencies are considerably lower than (33–50% of) those of a carbon–hydrogen bond. Because of the absence of resonance between the frequencies of slow vibrations of the oxygen–nitrogen bond and the rapid vibrations of the carbon–hydrogen bonds, therefore, the transfer of energy to these latter bonds can be ignored. In the Kassel formula for methyl nitrite the number of effective degrees of freedom among which the energy is distributed will then decrease to 6 from 15, and hence the lifetime will be 10^{-11} s. This implies almost instantaneous breakdown into methoxyl and nitric oxide. It is impossible to stabilise such a nitrite at pressures of ~ 1 atm. Application of this method of calculation to propyl nitrite gives a lifetime of $\sim 10^{-8}$ s. Addition of an inert gas will then increase significantly the probability of deactivation, which will naturally lead to a decrease in the rate of branching, i.e. to a raising of the limit of cool-flame ignition.

Establishment of degenerate branching for cool-flame nitration was an important factor in solving the kinetic mechanism of the slow reaction. The form of the rate curves for the latter (Fig. 1*a*), the lack of effect of additions of aldehydes, alkyl nitrites, and inert gases and of variation in the S/V ratio all appeared to suggest that the slow reaction was an unbranched-chain reaction with homogeneous chain, initiation and termination. However, the Reviewers regard such a view as incorrect.

Indeed, it is impossible to reconcile a change in kinetic mechanism from degenerately branched to unbranched (which supposedly occurs on passing from cool-flame to slow nitration) with the absence[93] of any chemical differences between the slow reaction and the autocatalytic reaction leading to cool-flame ignition. The same intermediate and final products are formed in the two cases, even in the same proportions. Thus the aldehydes responsible for branching in the cool-flame reaction are formed also in the slow reaction, and it is difficult, since transition from the first to the second reaction and *vice versa* have limits with respect to both temperature and pressure, to suppose that slight variation in these parameters at the pressure limit of cool-flame ignition would be able either completely to suppress the branching power of aldehydes or to confer on them this power. It may be recalled here that the oxidation of alkanes by free oxygen also involves a limiting transition between cool-flame and slow reactions, but they are both degenerately branched processes, and the rate curves of the slow reaction (graphs of the time dependence of Δp and the aldehyde concentration) are sigmoid.

In sum the authors accept[95,99,100] that slow nitration (just like the cool-flame process) is a degenerately branched chain reaction, since steps of degenerate branching take place during its course, but one in which the rate of chain termination exceeds the rate of branching. When the rate of chain initiation is sufficient, as in nitration¶, such a reaction will mimic kinetically an unbranched-chain process.

According to the chain theory the limit equation in a degenerately branched chain reaction can be deduced from the formula

$$M=\{w_0/[k(\nu-1)-k']\}\,[e^{[k(\nu-1)-k']t}-1],$$

where the condition $k(\nu - 1) - k' = \varphi = 0$ defines the limit. Here M is the concentration of the branching agent (in the present case an aldehyde), ν the length of the chain, given by the ratio of the rates of chain propagation and chain termination, k the rate constant of degenerate branching, and k' the rate constant for termination of the branching agent. We shall see that termination of the branching agent must be introduced in order to obtain the limit. Termination of the aldehyde on the wall is assumed in the paper.

The transition from the cool-flame reaction through the limit to the slow reaction with variation in pressure (at constant temperature) can now be explained by the fact that $\varphi > 0$ in the region of cool-flame nitration. Decrease in pressure affects only k', which with termination in the diffusion domain will increase, so that φ will decrease.

¶Table 5 gives initiation rate constants for the nitration of propane. At 350°C, for example, $k_{\text{init}} = 10^{11} \times 8.5 \times 10^{-10} = 85$, which exceeds by 10^7 the value for the oxidation of propane by free oxygen.

At a certain pressure φ will become zero, and a slight further decrease in pressure will lead to transition through the limit into the region of the slow reaction.

With fall in temperature and the accompanying transition from cool-flame to slow reaction the rate constant of homogeneous termination remains unchanged, and that of surface termination decreases only slightly. A marked decrease is observed in the rate constant of branching, which, as always, has quite a high activation energy. Overall the rate of termination may exceed the rate of branching, and in contrast to ordinary branched processes, where reaction cannot in practice be measured below the limit ($\varphi < 0$), here (in nitration) a slow reaction mimicking an unbranched process is observed owing to relatively rapid initiation.

The establishment of a chain mechanism with degenerate branching for the slow and cool-flame nitration of methane and propane gave rise to the problem of the specific chemistry of this kinetic mechanism. In other words, a radical–chain scheme must be sought, unique to each hydrocarbon, calculations based on which would lead, depending on the temperature and the pressure, either to an autocatalytic cool-flame reaction ($\varphi > 0$) or to a slow reaction, involving the branching steps but mimicking an unbranched-chain process ($\varphi < 0$) because of the preponderance of termination over branching. The schemes suggested[95,99,100] for the nitration of methane and propane have the same fundamental structure, with that for methane forming part of the scheme for propane. The latter is more complicated only in involving radicals containing two and three carbon atoms in addition to those containing a single carbon atom.

Initiation is represented by the equation

$$RH + NO_2 \rightarrow \dot{R} + HNO_2 \ . \qquad (a)$$

Calculation of the activation energy of reaction (*a*) on the basis of the Polanyi–Semenov rule gave values of 30.8, 26.2, and 23.6 kcal mole^{-1} for the formation of methyl from methane and of propyl and isopropyl from propane. An important confirmation of this step (*a*) is the discovery by Soviet workers[103-107] that additions of nitrogen dioxide accelerate the oxidation of alkanes by free oxygen.

The alkyl radicals formed in reaction (*a*) undergo parallel reactions with nitrogen dioxide:

$$\dot{R} + NO_2 \rightarrow RNO_2 \qquad (b)$$

$$\dot{R} + NO_2 \rightarrow [RONO]^* \rightarrow R\dot{O} + NO \qquad (c)$$

the first of which terminates the chain, whereas step (*c*) propagates the chain. Rate constants of these steps and of $R\cdot$ + NO → RNO were determined[94,96,97] directly for the reactions of the methyl radical with nitrogen dioxide and with nitric oxide†.

The alkoxy-radicals obtained in reaction (*c*) may undergo further change in three ways—(i) unimolecular decomposition with formation of an aldehyde and a lower alkyl radical

$$R\dot{O} \rightarrow R'CHO + R'' \qquad (d)$$

and for the methoxy-radical

$$CH_3\dot{O} \rightarrow HCHO + \dot{H} \qquad (e)$$

(ii) hydrogen abstraction with formation of the alcohol

$$RO + RH \rightarrow ROH + \dot{R} \qquad (f)$$

and (iii) recombination with nitrogen dioxide and with nitric oxide, which is significant only at relatively low temperatures because of the thermal instability of alkyl nitrates and nitrites. (iv) Disproportionation of alkoxy-radicals with nitric oxide to form aldehydes (or ketones) becomes possible in the later stages, when the concentration of nitric oxide has become considerable. In the initial stages of nitration the main reaction of alkoxy-radicals is decomposition with formation of aldehydes.

The aldehydes react with nitrogen dioxide:

$$RCHO + NO_2 \rightarrow R\dot{C}O + \dot{H}NO_2 \ . \qquad (g)$$

This is a step of degenerate branching, since it entails replacement of the relatively inactive nitro-radical by an active aldehyde radical (formyl in the nitration of methane, and acetyl in that of propane). Published experimental rate constants k_{eff} for the reactions of acetaldehyde and of formaldehyde with nitrogen dioxide are closely similar to the rate constants of the primary steps (*g*). Although the assumed branching is of degenerate type, its rate constant is closer to the value for branching in the oxidation of molecular hydrogen than to the rate constant of degenerate branching in the oxidation of alkanes.

The resulting acetyl radical reacts mainly with nitrogen dioxide according to the equation

$$CH_3\dot{C}O + NO_2 \rightarrow \dot{C}H_3 + CO_2 + NO \ .$$

Competing processes—decomposition of the acetyl radical and its reaction with nitric oxide—are considerably slower under the given conditions, and therefore were omitted from the scheme. Examination of published information on the reaction of formaldehyde with nitrogen dioxide led to the inclusion of three reactions of the formyl radical—chain termination

$$H\dot{C}O + NO_2 \rightarrow CO + HNO_2 \qquad (i)$$

and chain propagation

$$H\dot{C}O + NO_2 \rightarrow CO_2 + \dot{H} + NO \qquad (j)$$

$$H\dot{C}O + M \rightarrow \dot{H} + CO + M \ . \qquad (k)$$

The hydrogen atoms formed in reactions (*e*), (*j*), and (*k*) undergo with nitrogen dioxide the rapid chain-propagating reaction

$$\dot{H} + NO_2 \rightarrow \dot{O}H + NO \qquad (l)$$

which takes place at almost every collision. The resulting hydroxyl radical reacts with the alkane:

$$RH + \dot{O}H \rightarrow \dot{R} + H_2O \ . \qquad (m)$$

The step $HO\cdot + NO_2 \rightarrow HNO_3$ is a third-order reaction which is considerably slower than (*m*). The nitrous acid formed in several stages breaks down almost immediately: $2HNO_2 \rightarrow H_2O + NO_2 + NO$. Heterogeneous termination of aldehydes has been introduced into the scheme.

Calculations based on the schemes for the reactions of propane and methane with nitrogen dioxide were made by the method of quasi-stationary states, on the hypothesis that, since aldehydes react relatively rapidly with nitrogen dioxide, they are the active centres of the reaction. Among all active centres only aldehydes (acetaldehyde and formaldehyde) show a non-zero variation of concentration with time, since they are involved in the slow stage of degenerate branching. Calculation on the

†The reaction $R\cdot$ + NO → RNO, whose rate constant was considerably smaller than that of the reaction $R\cdot + NO_2$, is ignored in the scheme for the initial stages of reaction, when the concentration of nitric oxide is still small.

scheme for the nitration of propane was based on the assumptions that

$$k_1 = k_4 = k_7 = k_{17} = 0.45\,k_2\ ;\ \ k_2 = k_5 = k_8 = k_{18}; \qquad (1)$$

Differential equations were obtained for the time dependence of the concentration of aldehydes, whose integration (with the condition that the aldehyde concentration is zero at $t = 0$) yielded for the nitration of propane the formula

$$[HCHO] = \frac{C}{A} \cdot \frac{k_0\,[C_3H_8] \cdot [NO_2]}{1+n} \cdot \frac{1}{\varphi} \cdot (e^{\varphi t} - 1)\ ,$$

where

$$\varphi = f - g = \frac{[NO_2]}{1+n}\left\{\left[k_{11}\,\frac{C}{A} + nk_{21}\left(\frac{C}{A} + B\right)\right] - \left(k_{11} + nk_{21}\left[1 + \frac{C}{1{,}4\,A}\left(0.4 + \frac{k_9\,[NO]}{k_9\,[NO] + k_{10}}\right)\right] + \frac{C}{A} \cdot \frac{k_{11}k_{12}\,[NO_2]}{(k_{12} + k_{13})\,[NO_2] + k_{14}\,[C_3H_8 + NO_2]}\right)\right\} - \frac{k_{24} + nk_{23}}{1+n}$$

in which

$$A = k_{19}\left(0.9 + \frac{0.83\,k_9\,[NO]}{k_9\,[NO] + k_1}\right) + k_{20}\,[C_3H_8]\left(0.62 + \frac{0.13\,k_9\,[NO]}{k_9\,[NO] + k_{10}}\right);$$

$$B = \frac{0.7\,k_{10}}{k_9\,[NO] + k_{10}}\ ;$$

$$C = (1 + B)\,k_{19} + 0.25\,(k_{19} + k_{20}\,[C_3H_8])\left[1 + \frac{k_5}{k_4 + k_5}(1 + B)\right];$$

$$n = [CH_3CHO]/[CH_2O],$$

and f and g are the rate constants of chain branching and termination respectively. An analogous calculation for the nitration of methane gave

$$[HCHO] = \frac{k_{2'}k_{4'}}{k_{1'}k_{3'}\,[CH_4] + k_{4'}} \cdot k_{0'}\,[CH_4]\,[NO_2] \cdot \frac{1}{\varphi}\,(e^{\varphi t} - 1)\ ,$$

where

$$\varphi = k_{5'}\,[NO_2]\left[\frac{k_{2'}k_{4'}\,\{k_{6'}\,[CH_4 + NO_2] + k_{8'}\,[NO_2]\}}{k_{1'}\,\{k_{3'}\,[CH_4] + k_{4'}\}\,\{k_{6'}\,[CH_4 + NO_2] + k_{7'}k_{8'}\,[NO_2]\}} - 1\right] - k_{11'}\ .$$

The condition $\varphi = 0$ implies a transition from a slow steady-state reaction to the non-stationary cool-flame reaction. Calculation of φ by means of equations based on the schemes showed that with rise in temperature and increase in pressure φ passes from negative to positive values, i.e. that the slow reaction passes into the cool-flame reaction. This transition agrees satisfactorily with experiment (the bottom line in Table 4 gives the observed limits of cool-flame ignition).

Table 4. Variation of φ (s^{-1}) with temperature and pressure (for the mixtures C_3H_8 + NO_2 and $4CH_4$ + NO_2).

p_{init}, mmHg	C_3H_8+NO_2			$4CH_4$+NO_2
	300° C	350° C	400° C	450° C
50	—	—	—2.4	—
100	—1.6	—1.2	—0.04	—1.9
200	—0.7	+0.15	+2.3	+0.04
400	+0.02	+0.70	—	+1.5
500	—	—	—	+1.9
Expt. p_{lim}, mmHg	360	164	70	160

Values of φ were calculated from the rate constants listed in Table 5. Rate constants for the loss of aldehydes on the walls of the reaction vessel were calculated for termination of the aldehydes by reactions *23*, *24*, and *11′* in the diffusion range: $k_{\text{loss}} = 8D/r^2$, in which the diffusion coefficient was found by means of the formula $D = \frac{1}{3}u\lambda$, where u is the velocity of the molecules, λ the free path, and r the radius of the reaction vessel. The rate constants of the loss of formaldehyde and acetaldehyde at the walls are $k_{24} = 1.0$ s^{-1} and $k_{23} = 0.7$ s^{-1} for the nitration of propane under an initial pressure of 200 mmHg at 350°C, and $k_{11'} = 1.3$ s^{-1} for the nitration of methane under the same initial pressure at 450°C.

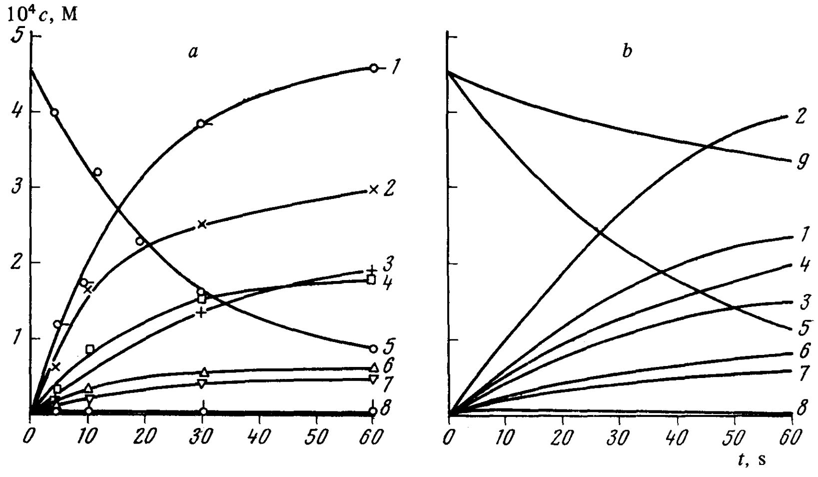

Figure 4. Comparison of (*a*) experimental and (*b*) computed curves for the accumulation of reaction products and the consumption of starting materials (C_3H_8 + NO_2 initially at 320 mmHg and 300°C): 1) CO_2; 2) 2-$C_3H_7NO_2$; 3) CO; 4) CH_3NO_2; 5) NO_2 (×0.1); 6) 1-$C_3H_7NO_2$; 7) $C_2H_5NO_2$; 8) CH_3CHO; 9) C_3H_8.

*Rate constant at 300°C and 320 mmHg.
**Rate constant at 300°C.

The mechanism suggested for the nitration of propane was tested also by numerical integration on an electronic computer of the set of differential equations describing the mechanism[108]. In view of the peculiarity of schemes comprising reactions of stable species and free radicals having rate constants differing by many orders of magnitude, use was made of a special algorithm and a programme developed in the Moscow State Pedagogic Institute[118,119]. The algorithm was based on solution of the set of differential equations by a finite-difference method with a "reverse step" procedure. Rate curves were computed for the consumption of the starting materials and the accumulation of the final products from an initial equimolecular mixture of propane and nitrogen dioxide under 320 mmHg at 300°C. The rate constants used for the calculation are given in Table 5‡. The computed curves are shown in Fig. 4*b*, and the corresponding experimental results are plotted in Fig. 4*a*. Since the reaction scheme has been set up for the initial stages and disregards secondary reactions of stable species (e.g. further reactions of the nitroalkanes), the suggested mechanism must be regarded as describing satisfactorily the nitration of propane by nitrogen dioxide.

The situation is less satisfactory with respect to the mechanism of the nitration of alkanes by nitric acid. As has been shown above, no agreement is apparent in the literature even on the nature of the direct nitrating agent, whether nitric acid itself or nitrogen dioxide formed by its decomposition. This question must be settled first of all, since if the role of nitric acid were mainly to generate nitrogen dioxide, the whole of the above mechanism should form the major part of the mechanism of nitration by nitric acid. This does not mean, of course, that changing from nitrogen dioxide to nitric acid does not introduce any changes into the reaction mechanism. In particular, the formation of hydroxyl radicals (by the decomposition of nitric acid) would increase the rate of nitration. Nor is heterogeneous decomposition of the acid excluded, which would affect the whole course of the reaction. Overall, however, the mechanism of nitration by nitric acid, with R + NO_2 → RNO_2 as the principal step, will be closely similar to the suggested mechanism of nitration by nitrogen dioxide.

These considerations led the Reviewers to undertake, at the Institute of Petrochemical Synthesis during recent years, experimental studies of the nitration of propane by nitric acid with the primary aim of ascertaining whether nitrogen dioxide is involved in formation of the nitrocompound[108]. Several facts have now been established: (i) the reaction of propane with nitric acid follows (as with nitrogen dioxide) three kinetic types—slow, cool-flame, and with a hot flame—depending on the temperature and

---

‡For computer purposes reactions *23*, *24*, and *11′* were written $CH_3CHO \rightarrow CH_4 + CO$ *23* and $HCHO \rightarrow H_2 + CO$ *24*.

the pressure; (ii) the products at the ends of slow and cool-flame reactions are closely similar in composition to the corresponding products obtained with nitrogen dioxide; (iii) in the slow reaction autocatalysis is observed both in the accumulation of nitrogen dioxide and of nitroalkane and in the increase in pressure Δp; (iv) the time variation of the concentration of nitrogen dioxide passes through a maximum; and (v) the ratio of the rates of accumulation of nitroalkanes to the rate of accumulation of nitrogen dioxide approaches zero at shorter times. These five points can be supplemented by (vi) the Reviewers' calculation (Section II, 2) of the rates of $R^{\cdot} + HNO_3 \rightarrow RNO_2 + OH^{\cdot}$ and $R^{\cdot} + NO_2 \rightarrow RNO_2$, which indicated that at 350°C the rate of the latter exceeded that of the former reaction by $\sim 10^5$. Points (i) and (ii) are evidence of the far reaching similarity in phenomenology and closely related chemistry of the actions of nitric acid and of nitrogen dioxide on propane. Point (iv) confirms that nitrogen dioxide is actually present during the reaction with nitric acid. Point (v) implies that nitroalkanes and nitrogen dioxide are formed in two consecutive reactions, with the latter formed first, i.e. that nitrogen dioxide is involved in the formation of nitroalkanes.

Together with point (vi) all this leads to adoption of $R^{\cdot} + NO_2 \rightarrow RNO_2$ as immediate step in nitralkane formation even when nitric acid is used. As noted above, the consequence of this should be a fundamental similarity in the mechanisms of nitration of alkanes by nitrogen dioxide and by nitric acid. Only slight differences can be expected, one of which is indicated by point (iii). The continuing study of the nitration of alkanes by nitric acid being conducted at the Institute of Petrochemical Synthesis has the aim of revealing also the detailed mechanism of this reaction.

The above outline reflects the evolution of views and modern ideas on the mechanism of the gas-phase nitration of alkanes, a field in which the main contribution was made by Konovalov, Markovnikov, Nametkin, Titov, ad and Topchiev. The present issue is dedicated to the memory of S. S. Nametkin, who was the first to help elucidate the mechanism of nitration by the fruitful application of contemporaneous physicochemical concepts—e.g. the influence of the relative concentrations of the initial reactants on yields of nitration and oxidation products, the dependence of the yields of nitro-products on reaction velocity and of the latter on the "mass" of the acid, and the concept of oxidation and nitration as parallel reactions—which made nitration a subject of investigation also in physical chemistry, in particular chemical kinetics. The study of nitration in relation to neighbouring branches of chemistry has been responsible for the considerable progress made in establishing its mechanism that we now witness.

Hydro-dehydropolymerisation and Isomerisation Polymerisation of Unsaturated Hydrocarbons

B.A.Krentsel'

Consideration is given to the effect of hydro-dehydropolymerisation, discovered by S.S.Nametkin and his coworkers in a study of the polymerisation of unsaturated hydrocarbons under the influence of sulphuric acid and aluminium chloride. This phenomenon is significant in the investigation of the oligomerisation and polymerisation of alkenes in the presence of various catalysts. Research on the monomer-isomerisation polymerisation of alkenes is analysed. A list of 53 references is included.

CONTENTS

I. INTRODUCTION

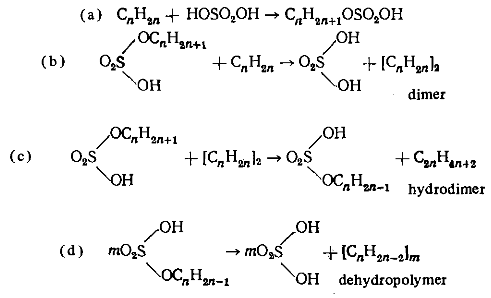
The formation of polymers by the action of sulphuric acid, aluminium chloride, and other acidic reagents on unsaturated hydrocarbons long ago attracted the attention of chemists, from Butlerov to the present time. After only a century many hundreds of papers on aspects of the polymerisation of unsaturated hydrocarbons are published annually in various chemical periodicals. Butlerov himself showed[1] that unsaturated hydrocarbons undergo polymerisation in the presence of sulphuric acid, with the formation of unsaturated compounds of higher molecular weight. The polymerisation of different types of unsaturated hydrocarbons and their derivatives has since been the subject of numerous investigations of various kinds. However, many aspects of the catalytic polymerisation of alkenes, in particular cationic polymerisation, have remained obscure.

Here we cannot consider the whole multiplicity of processes in the polymerisation of alkenes under the influence of acidic catalysts. These problems have been covered in a monograph and many review papers[2-4].

The present issure of Uspekhi Khimii is dedicated to the memory of S.S.Nametkin, whose researches on the reactions of unsaturated hydrocarbons in the presence of sulphuric acid and aluminium chloride led to the discovery of a new reaction, which he termed hydro-dehydropolymerisation. In addition, special attention is paid to monomer-isomerisation polymerisation, as an example of the variety of reactions involved in the polymerisation of alkenes. Nametkin's work on polymerisation resulted also from a non-trivial approach to the peculiarities of a well known chemical reaction.

II. HYDRO-DEHYDROPOLYMERISATION OF ALKENES WITH SULPHURIC ACID AND ALUMINIUM CHLORIDE

In his investigation of the reactions of unsaturated hydrocarbons in the presence of sulphuric acid Nametkin observed[2] the somewhat anomalous simultaneous formation of polymerisation products containing both unsaturated and saturated hydrocarbons[5]. He concluded that this was the result of the concerted occurrence of polymerisation, hydrogenation, and dehydrogenation. Polymers of saturated character, hydropolymers, were formed. The acid polymerisation of unsaturated hydrocarbons can in this case be represented by the general scheme[5]



$$\begin{aligned}
&(a)\quad C_nH_{2n} + HOSO_2OH \rightarrow C_nH_{2n+1}OSO_2OH\\
&(b)\quad O_2S\begin{matrix}OC_nH_{2n+1}\\OH\end{matrix} + C_nH_{2n} \rightarrow O_2S\begin{matrix}OH\\OH\end{matrix} + \underset{\text{dimer}}{[C_nH_{2n}]_2}\\
&(c)\quad O_2S\begin{matrix}OC_nH_{2n+1}\\OH\end{matrix} + [C_nH_{2n}]_2 \rightarrow O_2S\begin{matrix}OH\\OC_nH_{2n-1}\end{matrix} + \underset{\text{hydrodimer}}{C_{2n}H_{4n+2}}\\
&(d)\quad mO_2S\begin{matrix}OH\\OC_nH_{2n-1}\end{matrix} \rightarrow mO_2S\begin{matrix}OH\\OH\end{matrix} + \underset{\text{dehydropolymer}}{[C_nH_{2n-2}]_m}
\end{aligned}$$

which was proved correct by examining the composition of intermediate and final products.

A later study in Nametkin's laboratory of certain aspects of the preparation of isopropyl alcohol showed that hydro-dehydropolymerisation takes place in the course of the hydration of propene to propan-2-ol by means of sulphuric acid[6]. Other catalysts also effect hydro-dehydropolymerisation. Nametkin et al.[7] made a detailed study of this process when aluminium chloride acts on unsaturated hydrocarbons, in particular ethylene, pentene, etc. They pointed out that the action of aluminium chloride is complicated by partial degradation of the hydrocarbons. Subsequently Nametkin and his coworkers showed that hydro-dehydropolymerisation is observed with a wide range of unsaturated hydrocarbons of various classes. It was thus demonstrated experimentally[8] that the action of aluminium chloride on cyclohexene yields products whose formation can be explained in terms of this phenomenon. They included[8] two hydrocarbons—an unsaturated pentamer of cyclohexene (tetracyclohexylcyclohexene) and tetracyclohexylbenzene—of relatively high molecular weight. Reporting this extremely curious experimental fact, Nametkin pointed out that "the immediate mechanism of the formation of the aromatic derivative and equally of the accompanying naphthenes is still not clear, and further research is required to elucidate the routes by which they are formed". The hydropolymerisation of unsaturated hydrocarbons was later studied by Nametkin on 3-methylbut-1-ene treated with sulphuric acid monohydrate[9].

The above results suggest that the new phenomena, discovered by Nametkin and his coworkers in the polymerisation of unsaturated hydrocarbons under the influence of sulphuric acid or aluminium chloride, are general in character. They were of substantial value for the understanding of several complicated reactions involved in the production from unsaturated hydrocarbons of several technically important products (in particular, components of certain lubricating oils).

It must be borne in mind that, when aluminium chloride is used as catalyst, polymerisation is nearly always complicated by degradative effects, leading to the formation among the reaction products of compounds in which the number of carbon atoms is not a multiple of the number in the initial alkene.

A later paper by coworkers of Nametkin showed[10] that cyclopentene undergoes interesting reactions under the influence of aluminium chloride, and established for the first time the formation from cyclopentene of spirodecane. They suggested that the monomer initially dimerises, after which one ring of the dimer expands to a six-membered ring (by incorporating a carbon atom of the second ring). Trimers, tetramers, and hexamers would be formed in the same way. Unfortunately, direct evidence of the hypothetical mechanism could not be supplied at that time. In a systematic survey of several experimental investigations Rudenko[11] stated that the formation of hydropolymers from several alkenes in the presence of aluminium chloride results from a redistribution of hydrogen between the hydrocarbons forming a complex with the catalyst and the polymers. The hydrogen donors are catalytic complexes, which is confirmed experimentally by their highly unsaturated state.

In the above papers Nametkin, having examined critically results published by that time on the polymerisation of unsaturated hydrocarbons, points out that the proposed division of polymerisation processes into thermal and catalytic is incorrect. He considers that the only correct criterion for a classification of the polymerisation reactions undergone by unsaturated hydrocarbons is the composition of the products. He therefore proposes the following classification[5].

1. Polymerisation. The formation from unsaturated hydrocarbons of likewise unsaturated dimers, trimers, etc. had first been observed by Butlerov. Polymerisation may take place either at low temperatures under the influence of various catalysts (dilute sulphuric acid, zinc chloride, etc.) at high pressures and temperatures (thermally or catalytically, in particular in the presence of phosphoric acid).

2. Hydro- and dehydro-polymerisation. This process differs from polymerisation in yielding saturated hydropolymers and simultaneously highly dehydrogenated products from the unsaturated hydrocarbons. Since these products are formed at the same time, the total quantity of hydrogen involved in the reactions can be balanced.

Alkenes of iso-structure exhibit less tendency to hydropolymerisation than do the straight-chain hydrocarbons. Nevertheless, effects due to hydro-dehydropolymerisation must sometimes be reckoned with in such technically important processes as the polymerisation of isobutene. Special additives for synthetic oils are among the important products obtained from isobutene. One of the very first studies in this field, made[12] under Nametkin's direction, established that the polymerisation of isobutene in the presence of aluminium chloride (3%) at low temperatures (−78°C) yields a rubberlike polymer of molecular mass 20 000–30 000, which the authors named "superol". Several methods for obtaining polyisobutene have now found practical application, but their discussion lies outside the scope of the present Review.

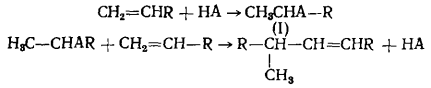
Hydro-dehydropolymerisation has since been observed on other catalysts. One of the first monographs on the catalytic polymerisation of alkenes in motor fuel[13] mentions that, in the presence of phosphoric acid at sufficiently high temperatures (up to 300°C), polymerisation is accompanied by hydro-dehydropolymerisation, so that the unsaturated compounds obtained are accompanied by saturated—including cyclic—hydrocarbons.

III. REDISTRIBUTION OF HYDROGEN IN THE REACTIONS OF UNSATURATED HYDROCARBONS ON ALUMINOSILICATE AND OTHER CATALYSTS

During the 1940–1950s the attention of investigators was especially attracted to the reactions of hydrocarbons on aluminosilicate catalysts, which acquired exceptionally important industrial value in the cracking of petroleum products. Such catalysts served and continue to serve as subjects of thousands of publications, which, of course, we do not intend even partly to survey here. The attention of the reader will be directed merely to several studies which definitely established common features in the mechanism of the action of acidic and aluminosilicate catalysts and revealed the occurence of the hydro-dehydropolymerisation of hydrocarbons on the latter.

An example is the investigation of Petrov and Frost[14], planned in some measure as a continuation of the classical studies of Lebedev and his coworkers[15], who were the first to report the redistribution of hydrogen in the transformation of unsaturated hydrocarbons on Floridin (the investigation was made on di-isobutylene and di-isopentylene [*sic*]). Petrov and Frost aimed to study the influence of the structure of the initial hydrocarbon on hydrogen redistribution on an aluminosilicate. They found that the yield of saturated products formed by hydro-dehydropolymerisation in a series of linear alkenes increases with the length of the hydrocarbon chain. This rule does not apply to cycloalkenes.

Aluminium silicate can be formulated $(HAlSiO_4)_n$ or in abbreviated form HA (i.e. it is analogous to an inorganic acid), and is able to exchange its hydrogen atoms for those of hydrocarbons reacting with it. Polymerisation (e.g. of hex-1-ene) may then occur as follows:



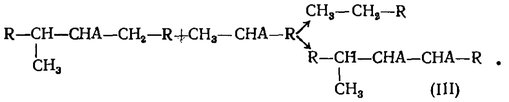
$$\mathrm{CH_2{=}CHR + HA \rightarrow \underset{(I)}{CH_3CHA{-}R}}$$

$$\mathrm{H_3C{-}CHAR + CH_2{=}CH{-}R \rightarrow R{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH{=}CHR + HA}\ ,$$

which is fully analogous to Butlerov polymerisation. The dimer then reacts again with the catalyst:

$$\mathrm{R{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH{=}CH{-}R + HA \rightarrow R{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CHA{-}CH_2{-}R}\qquad \mathrm{(II)}$$

Interaction between complexes (II) and (I) yields an alkane and the complex (III) containing less hydrogen:



$$\underset{\displaystyle CH_3}{R-\overset{|}{C}H}-CHA-CH_2-R+CH_3-CHA-R \begin{array}{l} \nearrow CH_3-CH_2-R \\ \searrow \underset{\displaystyle CH_3}{R-\overset{|}{C}H}-CHA-CHA-R \end{array} .$$

(III)

This process can be repeated. On the average every molecule may give three or four hydrogen molecules to saturate the monomer. This agrees with experimental results obtained by other workers[16].

Bashilov[17] made a detailed study of the hydropolymerisation of C_5-C_6 fractions in the presence of aluminosilicate catalysts. He showed experimentally that raising to 225–250°C the temperature of conversion of pentenes intensifies hydropolymerisation, and further rise in temperature strengthens cracking processes. The rate of redistribution of hydrogen atoms and of hydrogenation of the final reaction products is approximately the same with C_5 and C_6 alkenes.

The experimental results cited indicate the general theoretical importance of the hydro-dehydropolymerisation of alkenes on acid catalysts studied by Nametkin and his coworkers. The polymerisation of alkenes on such catalysts takes place by a cationic mechanism, in which the rate constant of chain growth is in practice usually incomparably smaller than that of termination or transfer. This extremely important fact has hitherto made it impossible to obtain products of high molecular weight by this mechanism. The cationic polymerisation of alkenes is therefore of practical interest for obtaining lower polymers, from dimers to oligomers having molecular masses of the order of a few hundreds or thousands. These oligomers are important in various branches of the chemical and petrochemical industries—the production of polymers, gasolines, lubricating oils and additives for them, the raw material for synthetic detergents, etc.—so that study of the general features and the peculiarities of the polymerisation of alkenes having various structures is not only of scientific but also of great practical interest. This governs the attention paid by research workers to the polymerisation of alkenes and several of their derivatives under the influence of various acidic catalysts. Despite the numerous papers that have appeared, many "blank spaces" still remain in our ideas on the mechanism of cationic polymerisation. However, the pioneering investigations of Lebedev and Nametkin have not lost their scientific significance even at the present time.

Experimental results confirming the hydro-dehydropolymerisation effect in several catalytic reactions of unsaturated hydrocarbons have been published even during recent years. Thus comparatively recently a study has been reported on the transformation of alkenes, cyclopropenes, alkadienes, and acetylene in the presence of $MoO_3 + Al_2O_3$.[18] The author pointed out the self-hydrogenation effects of accompanying processes of oligomerisation and isomerisation. He established that appreciable quantities of more saturated compounds than the initial hydrocarbon are formed: thus alkenes and cyclopropenes yield alkanes. The considerable quantity of hydrogen formed and of hydrogenation products found among the reaction products is regarded as indicating that the initial hydrocarbons undergo dehydrogenation on the catalyst surface followed by hydrogenation of the resulting unsaturated polymerisation products.

The experimental results are satisfactorily explained by the suggested scheme comprising—1. Dissociative adsorption of propene

$$C_3H_6\ (gas) \to C_3H_6\ (ads)\ .$$

2. Hydrogenation of propene

$$C_3H_6(ads) \xrightarrow{+H(ads)} C_3H_7(ads) \xrightarrow{+H\ (ads)} C_3H_8\ (gas)\ \cdot$$

3. Dehydrogenation of propane (transfer of hydrogen to the gas phase)

$$C_3H_7\ (ads) + H(ads) \to C_3H_6\ (ads) + H_2(gas);\ 2H(ads) \to H_2\ (gas)\ .$$

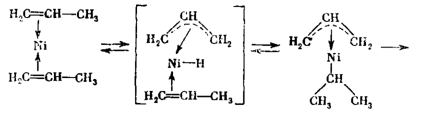
4. Formation of C_4 hydrocarbons

$$\begin{array}{ccccc} C_3H_6(ads) + CH_3\ (ads) & \to & C_4H_9(ads) & \xrightarrow{+H\ (ads)} & C_4H_{10}\ (gas) \\ +H\ (ads) \uparrow\downarrow -H\ (ads) & & -H\ (ads) \downarrow\uparrow +H\ (ads) & & \\ C_3H_5\ (ads) + CH_3(ads) & \to & C_4H_8\ (ads) & \to & C_4H_8\ (gas) \end{array}\ .$$

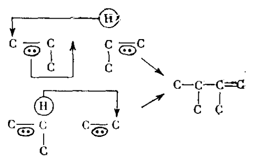
The second reaction leads to the formation of alkanes from alkenes. This may be followed by more complicated changes, in particular skeletal isomerisation. Results reported in Ref. 21 confirm and extend earlier data on the self-hydrogenation of alkenes observed in their disproportionation on $MoO_3 + Al_2O_3$ catalysts, as a consequence of which propene yields not only butene but also propane and highly unsaturated compounds.

IV. OLIGOMERISATION OF ALKENES ON TRANSITION-METAL COMPOUNDS

In all countries research workers are showing interest in the oligomerisation of alkenes on new types of catalytic systems based on compounds of transition metals. Several suggestions have been made of a reaction mechanism consisting essentially in the intramolecular transport of a hydrogen atom, i.e. with a kind of redistribution of hydrogen within the molecule. Thus in the dimerisation of propene on a complex nickel catalyst[19] the hydrocarbon undergoes oxidative addition to nickel with migration of allylic hydrogen from one propene molecule to another via an intermediate complex:



where Ni represents a coordinatively unsaturated nickel complex. Formation of a carbon–carbon σ-bond between the two coordinated alkene molecules results from activation of a carbon–hydrogen bond followed by dimerisation[18,20]:



Thus the redistribution of hydrogen atoms in polymerisation processes involving alkenes on acidic catalysts, discovered by Nametkin and his coworkers, is a common phenomenon in numerous examples of the catalytic oligomerisation and polymerisation of alkenes.

V. MONOMER-ISOMERISATION POLYMERISATION ON COMPLEX ORGANOMETALLIC CATALYSTS

The discovery and the use of complex organometallic catalytic systems containing aluminium alkyls and their halogenated derivatives helped to establish fundamentally new routes to the synthesis of macromolecules of definite structure. This line of advance was reflected also in the study of the ionic–coordination polymerisation of alkenes catalysed by alkylaluminium halides. The application of these catalysts revealed new types of transformation, among which we shall discuss monomer-isomerisation polymerisation. The essence of this process is that isomerisation of the alkene precedes monomer addition. On the one hand this permits the polymerisation of alkenes having an internal double bond, previously regarded as unreactive. On the other hand, the possibility arises of undesirable isomerisation processes in the polymerisation of α-alkenes.

One of the first studies was made by Topchiev et al.[22] on the polymerisation of isobutene in the presence of a Ziegler type of catalyst. They discovered that the resulting polyisobutene contained fragments having the unusual structure

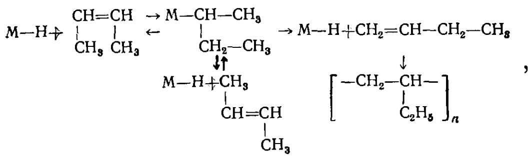
$$-\mathrm{C-C-\overset{C}{\overset{|}{C}}-C-C-\overset{C}{\overset{|}{C}}-C-C-\overset{C}{\overset{|}{C}}-}\ ,$$

which was confirmed by numerous infrared data and also by the viscosity properties of the polymers. The occurrence of isomerisation polymerisation was suggested, but this contradicted generally accepted views on the reactivity of various cations in polymerisation processes. Unfortunately, more detailed investigations on these lines were not made, and the unusual polymerisation accompanied by formation of a polyisobutene of abnormal structure remains a matter of controversy. However, study of the polydispersity of the product by a transient sedimentation equilibrium method also showed that the structure of the polyisobutene synthesised with titanium tetrachloride plus triethylaluminium as catalyst differed from the usual polymer in a smaller degree of branching[23]. Although the polymerisation of isobutene to give the above structure is so extraordinary and improbable, the Reviewer feels that the problem is worthy of attention.

Monomer-isomerisation polymerisation[24] has been and continues to be the subject of many studies. Japanese and French workers have shown[25-32] that in many cases poly-α-alkenes can be obtained by the ionic polymerisation of β-alkenes in the presence of complex organometallic catalysts. But-2-ene was among the first β-alkenes on which monomer-isomerisation polymerisation was studied, in the presence of several catalytic systems [of which the most active comprised triethylaluminium and nickel(II) chloride] in a polar solvent, in particular pyridine. The reaction converted but-2-ene into polybut-1-ene, which was explained by isomerisation of the alkene via intermediate formation of a complex with the transition-metal compound[30-32]:

The isomerisation of alkenes having internal bonds on catalytic systems comprising an aluminium alkyl and a transition-metal compound was shown independently in experiments on several β-deuterated homologues of ethylene[33-35]. The results were interpreted on the hypothesis that two types of active centres appeared on the surface of the catalytic complex: some centres effected isomerisation of the β-alkene into an α-alkene, and the already isomerised alkene underwent polymerisation on other centres.

A reaction scheme was suggested for β-butenes as example:



where M = Al, Ni. It must be noted that isomerisation is not observed with branched alkenes.

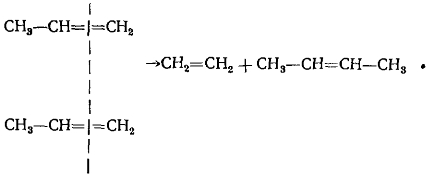
In spite of the large number of published investigations, the primary steps in a polymerisation process of this kind are still far from clear, and further detailed research is required to establish the true mechanism.

The discovery of the monomer-isomerisation polymerisation of but-2-ene is not only of theoretical interest but also of substantial practical value, since it expands considerably the raw-material base for the production of polybutene, a polyalkene possessing a valuable combination of technical properties, in particular an almost complete absence of creep.

Successful results were obtained in an investigation of the monomer-isomerisation polymerisation of pent-2-ene and hex-2-ene.[36] The plausibility of the above assumption that catalytic systems effecting monomer-isomerisation polymerisation contain two types of active centres is demonstrated by the effect of special isomerising additives on catalysts that cannot effect the process under usual conditions. Thus the monomer-isomerisation polymerisation of several higher β-alkenes can be accomplished by the use of complex organometallic catalytic systems containing acetylacetonates of certain transition metals as isomerising additives[37].

Especially noteworthy is the apparently extremely hypothetical possibility of effecting a peculiar type of isomerisation polymerisation of propene to yield from this monomer a copolymer with ethylene or (in the limiting case) polyethylene itself. Such a reaction was reported at one time by some Japanese workers in a brief communication[38], but was not subsequently confirmed.

Analogous reactions have been described in the patent literature. During recent years the disproportionation of alkenes on various types of catalytic systems has been widely used. It may be assumed that, in particular on molybdenum compounds[39,40], the disproportionation of propene yields ethylene and but-2-ene:



This may be followed by monomer-isomerisation copolymerisation of these unsaturated hydrocarbons with formation of a copolymer containing ethylene and propene units. Such a hypothesis, which has already been put forward by the Reviewer[24], undoubtedly requires experimental confirmation, especially as certain publications[41,42] quite convincingly relate the disproportionation of β-alkenes with both their homopolymerisation and their copolymerisation with other alkenes. Further research on these lines should reveal the mechanism and the characteristics of such processes.

Kennedy and his coworkers made a detailed investigation of various aspects of the cationic polymerisation and copolymerisation of alkenes, in particular of isobutene and isoprene, by means of aluminium chloride; the results have been partly summarised comparatively recently[43]. Several studies have shown[44-46] that the cationic polymerisation of isobutene and other alkenes can be accomplished by means of ethylaluminium dichloride and a hydrohalic acid. An ionic mechanism is assumed for the action of this catalyst:

$$AlR_2X + HX \rightleftarrows H^+AlR_2X_2^- \quad .$$

The resulting compound attacks the monomer:

$$H^+AlR_2X_2^- + -C{=}C- \rightarrow H-C-C^+AlR_2X_2^- \quad .$$

This is followed by the actual polymerisation:

$$H-C-C^+ + C{=}C \rightarrow H-C-C-C-C^+ \rightarrow \text{Polymer} \quad .$$

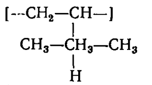
It must be noted that bimolecular protonation of the monomer is accompanied by unimolecular protonation of the gegenion. This results in formation of the saturated hydrocarbon and the corresponding aluminium dihalide:

$$H^+AlR_2X_2^- \rightarrow HR + AlRX_2 \quad .$$

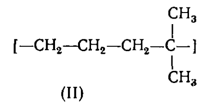
Kennedy gave[43] several experimental results on the role of such factors as the nature of the solvent in the cationic polymerisation of alkenes by means of catalytic systems based on aluminium alkyls. As was to be expected, the solvent had a significant influence both on the kinetics of polymerisation and in many cases on the structure of the polymer chain.

Saegusa et al.[47,48] made a series of interesting investigations on the cationic polymerisation of several alkenes by means of systems containing aqueous triethylalumium alone and with methoxymethyl chloride. The polymerisation was studied[49] not only of well known hydrocarbons but also of the little studied 2-methylpenta-1,3-diene, 1-isopropylindene, and 3a,4,7,7a-tetrahydroindene using catalysts of a similar type, and also paid attention to isomerisation.

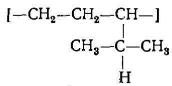
Recent work by Kennedy et al.[50] has demonstrated the monomer-isomerisation polymerisation of 4-methylpent-1-ene on ethylaluminium dichloride in chloroethane at −30 to −90°C. The presence of at least the three isomeric units



(I)



$$[-CH_2-CH_2-CH_2-\underset{CH_3}{\overset{CH_3}{C}}-]$$
(II)

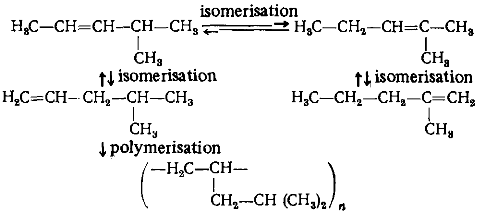


(III)

in the products was detected by ^{1}H n.m.r. (with a resolution of 300 MHz).

Still later publications[51,52] reported the monomer-isomerisation polymerisation (by means of catalysts of the Ziegler–Natta type) of several branched alkenes, in particular 4-methylpent-2-ene and 4-phenylbut-2-ene, as well as the copolymerisation of linear β-alkenes, of but-2-ene with pent-2-ene and of hex-2-ene. The maximum yield of the copolymer—a poly-α-alkene—reaches ~18% in the presence of triethylaluminium with vanadium or titanium trichloride as catalytic system at 80°C. The content of isomerised units in the polymer increased when the catalytic system contained nickel dimethylglyoxime or an acetylacetonate of another transition metal.

Subsequent studies by Japanese workers[53] have shown that the monomer-isomerisation polymerisation of 4-methylpent-2-ene catalysed by triethylaluminium with titanium trichloride gives a high yield of a macromolecular isotactic 4-methylpent-1-ene component. As in the preceding case, the presence in the reaction medium of acetylacetonates of transition metals, e.g. nickel acetylacetonate, increases the rate of isomerisation of the monomer. The monomer-isomerisation polymerisation of 4-methylpent-2-ene can be represented by the scheme



---o0o---

The Reviewer has thus attempted to show (only on two examples) that a detailed study of the polymerisation of alkenes led to the discovery of unexpected effects, forcing a re-examination of existing views on the reaction mechanism. One such effect was discovered at the beginning of research on polymerisation as a branch of organic chemistry, and another has attracted attention during recent years in connection with the discovery of new catalytic systems and the establishment of macromolecular chemistry as an independent field of chemical science.

Synthetic Plant Growth Regulators and Herbicides

N.N.Mel'nikov

The literature on the principal applications of various classes of inorganic and organic compounds as plant growth regulators and as agents for the suppression of weeds is briefly reviewed. The most important classes of chemical compounds employed for such purposes are quoted.
The bibliography includes 492 references.

CONTENTS

I. INTRODUCTION

The first studies on the synthesis of plant growth regulators in the Soviet Union were carried out by Nametkin as early as 1938.[1] He is justly regarded as a pioneer in this field, which is important for the national economy. Subsequent studies on these lines were continued in the laboratory organised by Nametkin at the Timiryazev Institute of Plant Physiology of the USSR Academy of Sciences; the results of this research led to the beginning of the manufacture in the USSR of preparations such as heteroauxin, 1-naphthylacetic acid, its potassium salt and methyl ether, magnesium chlorate (a defoliant), the butyl ether of 2,4-D, and certain others[2,3].

Plant growth regulators and herbicides have now found practical applications in the following principal fields[4]:

In the fight against weeds infesting a wide variety of agricultural crops, in meadows, pastures, and in forests and against undesirable plants on highways, in airports, on industrial sites, in water reservoirs, etc.[5]

In the removal of leaves prior to the harvest in order to mechanise the harvesting of the crop or in the transplanting of fruit and decorative plants and of the grapevine in order to enhance their frost resistance and increase the yield from the initial planting.

In the desiccation of plants to achieve partial drying and mechanisation of the harvesting of potatoes, rice, soya beans, and various other crops; desiccation by chemical preparations in many cases replaces the partial drying of feed crops prior to harvesting.

In the fight against the flattening of wheat, rice and other crops under conditions of increased humidity.

To increase the harvest of soya beans, peas, leguminous plants, and cotton seeds.

To increase the size of plums, pineapples, and other fruit.

To stimulate plant growth by the treatment of seeds of various crops prior to planting.[6]

To suppress the growth of young shoots to increase the intensity of flowering and fruiting of apples, pears, strawberries, and many other crops.

In the prevention of the shedding of apples and pears prior to harvesting and for the improvement of their commercial qualities and colour.

In the reduction of the strength of attachment of fruit to the stem (tomatoes, citrus fruit, etc.) for the purpose of mechanisation and in order to facilitate harvesting.

In the regulation of the metabolism of the cotton plant in order to enhance and accelerate the growth of its crop.

To increase the content of latex in rubber producing plants and to increase the content of sugar in sugar cane and sugar beet.

To accelerate the ripening of peaches and cherries.

To increase the harvest and to obtain parthenocarpic (seedless) tomatoes and other crops.

To retard the growth of tobacco shoots (chemical sucker control).

In the prevention of the germination of potatoes, onions, sugar beet, etc. on prolonged storage.

For the stimulation of the rooting of plants in their vegetative propagation by cuttings.

For the termination of the state of rest of potato tubers in order to employ them as seeding material during harvest[7].

In the destruction of male plant pollen in the cultivation of the hybrid seeds of various crops (mainly cereals).[8]

To accelerate the ripening of a number of crops.

To stimulate the opening of appleblossom and the blossom of certain other cultivated plants.

To retard the growth of lawns in order to reduce the expense of cutting.

To increase the number of internodal sections and to intensify the flowering and growth of decorative plants (chrysanthemums, azaleas, peonies, lilies, etc.).

To increase the life of cut flowers.

To stimulate the rooting of trees after transplanting.

To protect plants from the harmful action of certain herbicides.

Certain other practical applications of plant growth regulators have been described, but the studies in this field are at present in their early stages and their usefulness is not, as yet, entirely clear.

The scale of the practical applications of synthetic plant growth regulators and herbicides and the prospects for their further utilisation can be assessed from the data in Table 1,[9] which presents information on the sale of such products in the world and in the USA, expressed in terms of the 1974 prices.

Table 1. The sale of herbicides and plant growth regulators in 1971–1980.

Preparation	In the USA, million dollars			Worldwide, million dollars		
	1971	1974	1980	1971	1974	1980

Evidently, chemical agents for the suppression of weeds are employed on the largest scale, which is quite understandable, since their application permits a sharp increase of labour productivity in agriculture[10]. It is sufficient to point out that, solely as a result of the expanded use of herbicides in the USA, labour productivity in agriculture increased by almost 20% from 1970 to 1974.[10] The scale of the employment of herbicides for different crops can be inferred from the data in Table 2.[9]

Table 2. The consumption of herbicides in relation to various crops (in terms of 1974 prices, million dollars).

Crop	In the USA			Worldwide

Total	640	1058	1523	1131	2190	3422

Data concerning the application of different classes of herbicidal materials are presented in Table 3,[9] which shows that the increase of the consumption of different classes of chemicals as herbicides is not uniform; the greatest increase has been in the consumption of classes of compounds which satisfy most fully modern requirements as regards selectivity of action and their influence on various objects in the environment.

The increase in consumption is greatest for new preparations, which decompose fairly rapidly in the soil and in the plant and do not leave toxic residues in the crop being protected.

In connection with the necessity for the protection of the environment, there has been an increase in the stringency of the requirements which must be met by the preparations, which significantly increases the cost of their synthesis. Data on the screening and development of new pesticides by ICI,[11] which are listed in Table 4, are interesting in this respect. Whereas in 1956 one out of 1800 compounds synthesised was subsequently manufactured on an industrial scale, in 1972 not a single preparation of the 10 000 compounds tested was manufactured industrially. In connection with the large number of biological tests, the overall period from synthesis to practical introduction into an industrial manufacturing process and agriculture lasts between 7 and 9 years.[10,11]

Table 3. The consumption of individual classes of herbicides (in terms of 1974 prices, million dollars).

Despite the high cost and considerable difficulties in the utilisation and development of new preparations, intense research is being continued in this field and new interesting herbicides and plant growth regulators appear annually, which is associated not only with the possibility of a sharp increase in labour productivity in agriculture but also with the greater economic efficiency in consequence of the considerable increase in the harvest and the improvement of the quality of agricultural produce[12-14].

An enormous number of compounds of different classes with physiological activity in plants have now been described; approximately 200 substances have found practical applications as plant growth regulators and herbicides[3-5]. Without concerning ourselves with the general theoretical problems of the nature of the action of various preparations, which have been described in fair detail in the Proceedings of the 7th International Congress[15] and in reviews and monographs[16-19], we shall consider the principal classes of chemical compounds which have found applications as plant growth regulators and herbicides in different branches of agriculture.

This review does not deal with cytokinins and gibberelins, which are described in a recent monograph in Russian.[20,21]

II. INORGANIC COMPOUNDS

Among inorganic compounds, chlorates have found fairly extensive applications as herbicides and defoliants. Potassium chlorate is used in the fight against weeds[5] and sodium, magnesium, and calcium chlorates are used to defoliate and desiccate the cotton plant and other crop plants for the purpose of the mechanisation of their harvesting[22]. In order to decrease the risk of explosion, sodium borate is added to sodium chlorate and magnesium chlorate is employed as an equilibrium mixture of sodium and magnesium chlorates and chlorides, obtained on treatment of sodium chlorate with magnesium chloride. Calcium chlorate is used as the mixture produced by treating lime with chlorine.

Among other inorganic compounds, copper compounds (nitrate and sulphate)[2,3] and ammonium sulphamate have found applications as algicides. However, the amount of ammonium sulphamate consumed per hectare is about 200 kg, which sharply reduces its use[2].

III. ALCOHOLS, PHENOLS, AND ETHERS

Allyl alcohol has found application as a herbicide[3]. C_6-C_{10} saturated alcohols are employed in sucker control for the tobacco plant[23]. Their use in combination with systematic plant growth regulators is particularly effective[24]. It is then possible to reduce the labour required for the cultivation of tobacco by more than 50%.

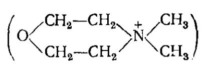
Methyl 1-naphthylmethyl ether has found application in the suppression of the germination of potato tubers on prolonged storage[3]. Derivatives of 4-nitrophenyl phenyl ether containing a wide variety of substituents in the second aromatic ring[3,5,25-34], including halogens and the trifluoromethyl and alkoxycarbonyl groups, are most widely used as herbicides in the fight against weeds infesting a wide variety of crops. These and similar compounds are obtained in high yields by the reaction of the phenoxides derived from the corresponding phenols with *p*-chloronitrobenzene and its analogues in various organic solvents and in water[35].

2-Alkyl-4,6-dinitrophenols and their esters formed with various acids, pentachlorophenol and its salts with various organic and inorganic bases[3,5], as well as 2,6-di-iodo- and 2,6-dibromo-4-cyanophenols and their salts and esters with carboxylic acids[3,5,36], known as Ioxynil and Bromoioxynil, are no less widely used as contact herbicides. These compounds are mostly employed in the fight against weeds resistant to 2,4-D preparations[3,36] in plantations of grain cereals. Ioxynil is obtained in a high yield by the iodination of 4-cyanophenol; the iodination can be also carried out electrochemically[37]. A number of other cyanophenols have been proposed as herbicides[38,39].

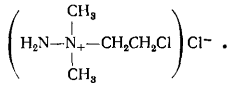
IV. AMINES AND QUATERNARY AMMONIUM SALTS

Amines and their derivatives have found fairly extensive agricultural applications in recent years and the scale of their practical utilisation is continuously increasing[3,5,9]. 2-Chloroethyltrimethylammonium chloride, known as Chlormequat, CCC, or TUR, is widely used in Europe as a plant growth regulator[40-55]. In doses ranging from 4 to 6 kg per hectare, chlormequat is used in the fight against the flattening of wheat and rice under conditions of increased humidity[40-43,45,48-51]. The application of this preparation to barley does not produce such an effect owing to the decomposition of chlormequat in the barley plants[46,47]. The application of chlormequat to wheat and rice has a major economic effect; for this reason, up to 50% of wheat plantations are treated, for example, in the German Federal Republic and in Finland. Chlormequat is used successfully on strawberries[44], vegetable cultures[46,47], in the growing of fruit[53] and cotton[54,55], and in viticulture[56]. In the growing of cotton, particularly satisfactory results have been obtained when the preparation was applied jointly with succinic acid[55].

A large number of chlormequat analogues have now been synthesised and investigated[57-76]. Some of these are highly active and may be of practical interest. In particular, trimethylalkylammonium salts containing a terpenoid structure[60,61], cyclohexyl and cyclohexenyl residues[74,75], and certain heterocyclic systems[64] in the hydrocarbon group are very active. Dimethylmorpholinium chloride (I) and 2-chloroethyldimethylhydrazinium chloride (II), and some of their analogues obtained by the reaction of alkyl halides with the corresponding amines or hydrazines[64,77,78], are of considerable interest. It is interesting to note that, when cereals are treated with 2-chloroethyldimethylhydrazinium chloride, their ripening is shortened by several days and the harvest is improved as a result of the increase of the number of sheaves. Dimethylmorpholinium chloride is active not only on wheat but also on barley, which is very significant, since in many regions barley is no less important than wheat.



(I)

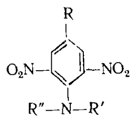


$$\left(H_2N-\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{N_+}}-CH_2CH_2Cl\right)Cl^- .$$

(II)

The study of the growth regulating activity of sulphur analogues of chlormequat has shown that 2-chloroethyldimethylsulphonium chloride is almost three times less active than chlormequat[64]. The corresponding quaternary pyridinium, piperidinium, pyrrolidinium, pyrazinium, tetrahydrothiophenium, thiophenium, tetrahydroxanthinium, dithianium, and azepinium salts have also been investigated, but they are all less active[64]. The introduction of a halogen into the heterocycle as a rule reduces the activity of the compound. The activity of five- and seven-membered heterocyclic compounds is significantly lower than that of compounds with six atoms in the ring. The replacement of the methyl group by others in most cases likewise leads to a decrease of the growth regulating activity[64]. Ethanolammonium salts with inorganic acids also exhibit growth regulating activity[79].

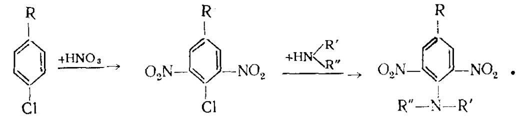
Aromatic amines have found applications as herbicides in the fight against weeds in cotton, vegetables, and many other crops[3,5,80-88]. Compounds having the general formula (III) are most widely used:



(III)

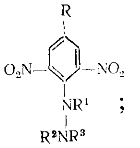
R=CH(CH$_3$)$_2$, C(CH$_3$)$_3$, CF$_3$, SO$_2$NHR, CH$_3$SO$_2$;
R′=Alk;
R″=Alk, ClCH$_2$CH$_2$.

Among the large number of compounds of this series, Treflan (2,6-dinitro-*NN*-dipropyl-4-trifluoromethylaniline) and nitraline (4-methylsulphonyl-2,6-dinitro-*NN*-dipropylaniline) are used in greatest amounts. These compounds can be obtained in high yields by the following procedure[3]:



Oryzalin (2,6-dinitro-*NN*-dipropyl-4-sulphonamidoaniline)[82,87], etafloraline [*N*-ethyl-*N*-(2-methylallyl)-2,6-dinitro-4-trifluoromethylaniline][81,88], Pregard*† (*N*-cyclo-propylmethyl-2,6-dinitro-*N*-propyl-4-trifluoromethylaniline), Dinir* (*NN*-diethyl-2,6-dinitro-*m*-phenylenediamine)[80], and certain others are being introduced into agricultural practice. The compounds of this group are not very toxic to mammals and are effective in the fight against weeds (in doses of 1–1.5 kg per hectare). However, one should note that certain compounds of this series are extremely toxic to fish[3].

One should also mention 2-hydroxyethylhydrazine, which is used in the USA to accelerate the growth of pineapples and to increase their crop[23]. It can be obtained by the reaction of oxiran and hydrazine. Among hydrazine derivatives, mention may be made of arylhydrazines having the general formula (IV)[90], which have been recommended as herbicides. These compounds are obtained similarly to the corresponding anilines:



(IV)

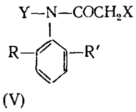
R=NH$_2$SO$_2$, CF$_3$;
R¹=H, Alk;
R², R³=Alk.

V. CARBOXYLIC ACIDS AND THEIR DERIVATIVES

One of the most important groups of compounds physiologically active in plants are carboxylic acids, among which numerous herbicides and plant growth regulators have been found. We may mention that natural plant growth regulators such as gibberellins and heteroauxins are carboxylic acid derivatives.

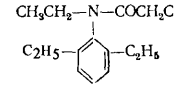
Among aliphatic compounds, derivatives of trichloroacetic, monochloroacetic, dichloropropionic, and tetrafluoropropionic acids[3] and their mixtures[89] have found extensive application as herbicides. Alkali metal trichloroacetates and dichloroprotionates are most widely used, giving satisfactory results in the fight against monocotyledonous weeds in doses of 10–50 kg per hectare[5]. Tetrafluoropropionate salts and their mixtures with dichloropropionate salts have been used successfully recently[89].

The anilides of monochloroacetic and other acids with the general formula (V)[3,91-97], which have a low toxicity for warm-blooded animals and can be used on various crops, are of considerable interest. For example, the preparation Mechet* (VI) is used successfully in the fight against weeds in rice seedlings and Anachlor* (VII) is used in plantations of maize, soya beans, groundnuts, and other crops. Propachlor (VIII), used in the fight against weeds in vegetable crops, soya beans, etc. belongs to the same group of compounds.



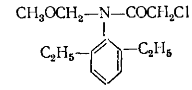
(V)

R, R′=Alk;
X=Cl,Br, OAr;
Y=Alk, CH$_2$OAlk

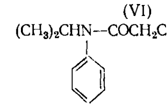


;

(VI)



(VII)



.

(VIII)

The 3,4-dichloroanilides of propionic and other acids as well as the 3-chloro-4-methylanilides of various acids have found extensive applications in the fight against weeds in various crops. A common disadvantage of this group of compounds is their relatively high toxicity to fish and also the formation of azo-compounds as a result of their metabolism in the soil[98]. The application of compounds having the general formula (V)[99], containing the furyl and tetrahydrofuryl residues at the nitrogen atom, as well as the chloralamides [1,1,1-trichloroethylideneamides] of carboxylic acids[98] has also been patented.

Among aliphatic dibasic acid derivatives, the 2,2-dimethylhydrazide of succinic acid, known as Alar, is widely used as a plant growth regulator[100-118]. Alar is used to suppress the growth of young shoots of perennial crops, which in many instances leads to a significant increase in the crop of apples and pears harvested, reduces the shedding of the fruit prior to harvesting, improves their commercial quality, facilitates the formation of the branches of young trees, and sometimes reduces the time required for the ripening of the crop. Alar is obtained in satisfactory yields by the reaction of succinic anhydride with dimethylhydrazine. The influence of Alar on the rate of ripening of fruit and the frost resistance of apple trees[100,103,104,110] on the rate of ripening of peaches[102], morello cherries[105], and plums[106], and on the harvest of pears[107-109,112], sweet cherries[111], grapes[113], alfalfa and clover[118], carrots and tomatoes[115,117], pepper[118], brussels sprouts[119], and groundnuts has been investigated. It has been noted that Alar has a favourable influence on the majority of the crops investigated, but different types of plants respond in different ways to treatment by this preparation, so that the conditions and concentrations at which the preparation gives the optimum effect should be determined for each type of plant. Alar is usually employed at a concentration of 0.5–3 g litre^{-1}.

In the USA, Alar is used to suppress the growth of young shoots of apple and pear trees, to increase the intensity of flowering, to prevent the shedding of fruit prior to harvesting and to improve their colour, to accelerate the ripening of peaches and cherries, to increase the harvest of certain types of grapes, and to improve the flowering of azaleas and chrysanthemums. The increase in the harvest of grapes when Alar is used may be very considerable.

---

†Here and henceforth the spelling of authors' names marked with an asterisk is tentative (Ed. of Translation).

Thus in some years American investigators succeeded in increasing the harvest by 25–30 centners [2500–3000 kg] per hectare[113].

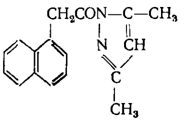
Among carboxylic acid derivatives, mention should be made of preparations which began to be used several decades ago. Such preparations include in the first place aryloxyalkanecarboxylic acids and 2-naphthylacetic acid, whose salts and amides are used to accelerate the opening of apple blossom buds and to accelerate the rooting of plants propagated by cuttings. In propagation by cuttings, the readily water-soluble salts of 2-indolylbutyric and 2-indolylacetic acids are also used[2].

TH-656 (IX), the active principle of which is 3,5-dimethyl-1-naphthylacetylpyrazole, has been proposed to accelerate the setting of mandarin fruit[120].

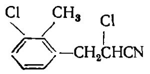
2,3,6-Trichlorobenzoic, 3,6-dichloro-2-methoxybenzoic, 3-amino-2,5-dichlorobenzoic, 2,3,6-trichlorophenylacetic, and certain other acids[3,5], which are used in mixtures with other herbicides in the form of water-soluble salts formed with inorganic and organic bases, have found extensive applications as herbicides. 2,3,5-tri-iodobenzoic acid[121-125], the application of which in doses of 125–250 g per hectare increases the harvest of soya beans[121,122], alfalfa[123], peas[124], and cotton, is a plant growth regulator. However, the effectiveness of 2,3,5-tri-iodobenzoic acid depends greatly on the type of plant[121,125].

Among carboxylic acid derivatives, mention should be made of Orthonil (X) [2-(β-chloro-β-cyanoethyl)-6-chlorotoluene], the type of action of which resembles that of abscisic acid[126-128].

Tomacone* [1-(2,4-dichlorophenoxyacetyl)-3,5-dimethylpyrazole] is used to increase the harvest of tomatoes and to obtain seedless tomatoes. The water-soluble sodium salts of α-(2,4,5-trichlorophenoxy)propionic, 4-chlorophenoxyacetic, and 2-naphthoxyacetic acids are used for the same purpose. 2-Naphthoxyacetic acid is likewise employed to improve the flowering of strawberries and pineapples. *m*-Tolylphthalamic acid, which is used in the USA to improve the harvest of cherries and Lima beans, has also been applied to obtain seedless tomatoes. α-(3-Chlorophenoxy)propionic acid is used to increase the size of plums[23].



(IX)



(X)

Despite the fact that the herbicidal and plant growth regulating properties of aryloxyalkanecarboxylic acids were discovered more than 30 years ago, the study and synthesis of new derivatives of this group are still being continued[129-146]. This is quite understandable, since the scale of the manufacture and application of this group of substances is fairly large and there is no tendency towards a decrease[9,146].

The salts and esters of 2,4-dichlorophenoxyacetic, 4-chloro-2-methylphenoxyacetic, and 2,4,5-trichlorophenoxyacetic acids, the world manufacture of which has exceeded 100 000 tonnes annually, have been most widely employed[5,9,16]. The use of 2,4,5-T has been interrupted, since the technical product has been found to contain 2,3,7,8-tetrachlorodibenzo-1,4-dioxin, which is highly toxic to warm-blooded animals and man and exhibits a powerful irritant and teratogenic activity[147]. However, after the development of methods for the elimination of the above impurity, the employment of 2,4,5-T was renewed on virtually the same scale. (In most countries the rule has been adopted that the preparation must not contain more than 0.5 mg of 2,3,7,8-tetrachlorodibenzo-1,4-dioxin per kilogram.)

It has been established that the majority of the esters of the above acids exhibit a high herbicidal activity, which is proportional to the content of the corresponding acid in the ester. Furthermore, studies have been continued on the synthesis of new esters[133,140,142]: some of them are so expensive that they can hardly have practical applications. Derivatives of aryloxyalkanehydroxamic acids[138], the sugar esters of aryloxyalkanecarboxylic acids[131], derivatives of aryloxyalkanethiocarboxylic and aryloxyalkanedithiocarboxylic acids[137,143], aryloxyalkanecarboxylic acid amides[132,145], as well as aryloxyacrylic acid[135] have also been synthesised. We may note that Nametkin and his coworkers have made a significant contribution to the field of aryloxyalkanecarboxylic acids[1].

The esters formed by 1-naphthylacetic acid with poly(ethylene glycol) continue to be used for the setting of mandarin fruit[148] and unsaturated alkoxycarboxylic acid are used in the treatment of oranges[149]. Various derivatives of fluorinecarboxylic acid (XI) have found fairly extensive applications as herbicides and plant growth regulators[3,5,150-153].

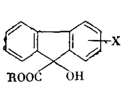
The employment of the imide of oxoglutaric acid[154] and of α-amino(hydroxyphenyl)butyric acid[155] to stimulate plant growth by treating the seeds prior to sowing has been suggested. *trans*-2-Amino-α-2-aminoethoxybutenoic acid in doses of 1–4 kg per hectare has been proposed as a herbicide to be used against beardgrass, darnel, cocklebur and other weeds.

The esters of substituted phenylpropionic acids are of interest as selective herbicides[158]; methyl α-chloro-(*p*-chlorophenyl)propionate is used in the fight against bearded oats in wheat[3,5]. It can be obtained in high yields by the following procedure[157]:

$$\mathrm{ClC_6H_4NH_2HCl} \xrightarrow{+\mathrm{HNO_2}} \mathrm{ClC_6H_4N_2Cl} \xrightarrow{+\mathrm{CH_2{=}CHCN}}$$
$$\rightarrow \mathrm{ClC_6H_4CH_2CHClCN} \xrightarrow{+\mathrm{H_2O}+\mathrm{CH_3OH}} \mathrm{ClC_6H_4CH_2CHClCOOCH_3}\ .$$

The esters of aromatic thiocarboxylic acids have also been proposed as herbicides[159].

Among carbonyl compounds, numerous aldehydes and ketones have been proposed as herbicides and plant growth regulators[160-166]. Thus C_4–C_{18} ketones have been suggested for the chemical sucker control in tobacco[160], hexahalogenoacetones have been suggested as inhibitors of the germination of potato tubers[161], and aromatic and aliphatic-aromatic ketones have been suggested as herbicides[162-165]. Both aryloxyacetophenones[166] and aminoketones[163] have been proposed as selective herbicides.



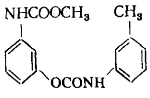
(XI)

Together with phenoxyalkanecarboxylic acids, naphthoxyalkanecarboxylic acids and their derivatives, the study of which was first began in Nametkin's laboratory[1], have been recommended in recent years for practical applications. *NN*-Diethyl-1-naphthoxy-2-propionamide, recommended as a herbicide effective against weeds in cabbage, may serve as an example of such preparations[167,168].

Among carboxylic acid derivatives, substances have been found, which are used as herbicide antidotes[169]. The anhydride of 1,8-dinaphthoic acid and the diarylamide of dichloroacetic acid may serve as examples of compounds of this kind. The latter has been fairly widely used to protect maize from damage by herbicides consisting of thiocarbamic acid derivatives. Mixtures of Eptam with diaryldichloroacetamide known as Eradicaine are nowadays used in the fight against weeds in maize plantations. Eradicaine contains 8.3% of the diallylamide of dichloroacetic acid and 91.7% of Eptam.

VI. CARBAMIC AND THIOCARBAMIC ACID DERIVATIVES

One of the fairly numerous groups of compounds with high physiological activity in plants comprises derivatives of carbamic and thiocarbamic acids[2,3]. Several decades ago, preparations such as IPC, Chloro-IPC and certain others found practical applications. During recent years, the range of arylcarbamic acid derivatives has been constantly expanding; several tens of carbamic derivatives are used at the present time[3,5,170-196]. For example, it has been found that isopropyl *N*-(3-chlorophenyl)-*N*-propoxymethylcarbamate[170], which is moderately toxic to animals, can be used as a plant growth regulator for the retardation of the growth of grasses, sucker control in tobacco, and in a number of other instances. Betanal, the active principle of which is Phenmedipham (XII)[3],



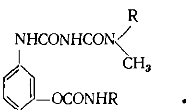
(XII)

is fairly widely used as a herbicide in the fight against weeds in sugar beet plantations. A large number of analogues of this preparation[171,182-196], including carbamic acid derivatives containing a urea residue together with the carbamoyl residue in the molecule[182,183,185,188,189,191,-192,196], have now been synthesised and proposed as herbicides. It is interesting to note that, among such derivatives, *meta*-substituted compounds exhibit the highest activity; *para*- and *ortho*-derivatives are much less physiologically active in plants.

Oxime carbamates have also been suggested as herbicides and plant growth regulators[178-181]. Thus it has been suggested that compound (XIII)[86] be used to spray orange trees in order to facilitate harvesting and that carbamoylarylenebiurets (XIV) be used as herbicides[196]:

$(C_2H_5)_2NOCONHCH_2CH_2Cl$

(XIII)



(XIV)

It is of interest that certain mixtures of carbamates act in the soil much longer than each component separately. For example, a 4 :1 mixture of Chloro-IPC and the 4-chlorophenyl ester of cyclohexylcarbamic acid are active for almost 14 weeks, whereas Chloro-IPC alone remains in the soil for not more than 4 weeks when used in the same doses[197].

Among the carbamic acid derivatives investigated, bifunctional derivatives containing various other functional groups apart from the carbamic acid residue have been found recently to occupy an important place[181,191,195]. In particular, compounds having the general formula (XV)[198] have been suggested as agents suitable in the fight against foxtail and compounds having the general formula (XVI) have been proposed as herbicides to combat other weeds[199].

$$\begin{matrix} R \\ R' \end{matrix}\!\!>NCOOCH_2C{\equiv}C{-}CH_2SCN$$

(XV)

(XVI) $X{=}NH_2, CH_3NH$.

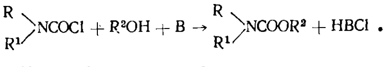
The most convenient methods for the synthesis of the alkyl and aryl esters of aryl- or alkyl-carbamic acids involve reactions of the corresponding isocyanates with alcohols or phenols[3]:

$$RNCO + R^1OH \rightarrow RNHCOOR^1$$

or of chlorocarbonates with the corresponding amines:

$$ROCOCl + NH_2R^1 \rightarrow ROCONHR^1 + HCl\ .$$

Carbamic acid esters can also be obtained by the reaction of phenols or alcohols with carbamoyl chlorides in the presence of hydrogen chloride acceptors[5]:



$$\begin{matrix} R \\ R^1 \end{matrix}\!\!>NCOCl + R^2OH + B \rightarrow \begin{matrix} R \\ R^1 \end{matrix}\!\!>NCOOR^2 + HBCl\ .$$

Together with carbamic acid derivatives, those of thio- and dithio-carbamic acids have found extensive applications in agriculture in the fight against weeds in various crops[3,5]. More than 15 derivatives of thiocarbamic acids, which include preparations such as Diallate, Triallate, Yalan, Tillam, Eptam, Vernolate, Sutan, Ro-Neet, Saturn and others, have now found practical applications[3,5]. Thiocarbamic acids are used in the fight against weeds in wheat, rice, maize, sugar beet, soya beans, certain vegetables and other crops. The majority of preparations of this class are introduced into the soil and then dug into a depth of 2–5 cm. The latter is necessary because of the relatively high volatility of this group of substances.

Thiocarbamic acid esters have found applications not only independently but also in mixtures with herbicide antidotes[169] and various other compounds[200]. A very large number of aliphatic, alicyclic, aromatic and heterocyclic derivatives of thiocarbamic acid have now been described; the search for new preparations belonging to this class is being vigorously continued[201-222].

Derivatives of thiocarbamic acid obtained from substituted cyclopropylamines[201], alkyleneimines[220,221], and alkyl- and dialkyl-amines, derivatives containing various substituents in the ester group[202,204], the benzyl and 2-chlorobenzyl esters of dialkylthiocarbamic acids[205,206], the 4-substituted benzyl esters of dialkylcarbamic acids[207-216], the thienylmethyl esters of dialkylthiocarbamic acids[217,-218], the pyridylalkyl esters of thiocarbamic acids[219], and many others have been described recently. Certain sulphenyl carbamates[219,223], which are the first products of the metabolism of thiocarbamic esters in the soil and other objects in the environment[223], also possess herbicidal properties.

Three main procedures have been described for the preparation of various types of thiocarbamic esters[3,203,204,211,212].

The interaction of mercaptans with carbamoyl chlorides:

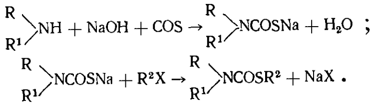
$$\begin{matrix} R \\ R^1 \end{matrix}\!\!>NCOCl + R^2SH \rightarrow \begin{matrix} R \\ R^1 \end{matrix}\!\!>NCOSR^2 + HCl\ .$$

The interaction of alkyl chlorothiocarbonates with amines:

$$\begin{matrix} R \\ R^1 \end{matrix}\!\!>NH + R^2SCOCl \rightarrow \begin{matrix} R \\ R^1 \end{matrix}\!\!>NCOSR^2 + HCl\ .$$

Both reactions take place satisfactorily in the presence of hydrogen chloride acceptors.

The reaction of salts of dialkylthiocarbamic acid with alkyl halides constitutes an interesting general method for the synthesis of thiolocarbamates. The salts required are formed in high yields when amines and strong alkalis react with carbonyl sulphide:



$$ {}^{R}_{R^1}{>}NH + NaOH + COS \rightarrow {}^{R}_{R^1}{>}NCOSNa + H_2O\ ; $$
$$ {}^{R}_{R^1}{>}NCOSNa + R^2X \rightarrow {}^{R}_{R^1}{>}NCOSR^2 + NaX\ . $$

II. UREA AND THIOUREA DERIVATIVES

Urea and thiourea derivatives constitute one of the most portant classes of chemicals which have found fairly tensive applications in the agriculture of different coun- es[3,5,224–289]. We may note that more than 40 different phatic, alicyclic, aromatic, and heterocyclic urea erivatives are used nowadays in the fight against weeds in a wide variety of agricultural crops.

Among the aliphatic urea derivatives, we may mention dichloralurea, used in the fight against grass weeds in sugar beet and certain other crops[2]. Dichloralurea can be synthesised in high yields by the reaction between urea and chloral[290]:

$$ 2\,CCl_3CHO + CO(NH_2)_2 = (CCl_3\underset{OH}{CH}NH)_2CO\ . $$

A number of asymmetric alicyclic ureas have been proposed as herbicides[3,252–257]; among these *NN*-dimethyl-*N'*-(perhydro-4,7-methylene-5-indanyl)urea, known under the commercial name of Herban (**XVII**), has found practical applications. This preparation is used in the fight against weeds in plantations of cotton plants, soya beans, peas, potatoes, and certain other crops in doses of 1.5–4 kg per hectare. *N*-Cyclo-octyl-*N'N'*-dimethylurea or cycluron (**XVIII**) has also found some applications[3]; it is used in plantations of beet and other vegetables in mixtures with other preparations. Other alicyclic ureas are also being investigated[252–257]:

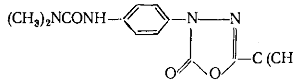
(XVII)

(XVIII) .

Ureas of this type are usually obtained by the reaction of the corresponding alicyclic isocyanates with amines[252–257]:

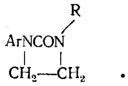
$$ RNCO + NH(CH_3)_2 \rightarrow RNHCON(CH_3)_2\ . $$

Aliphatic-aromatic derivatives of urea, some of which exhibit a highly selective action and may be used for a wide variety of crops, have found the most extensive applications. For example, 4-isopropylphenyl-*NN'*-dimethylurea has been suggested as an agent against weeds in winter wheat plantations[227,233]; 3-chloro-4-methylphenyl-*NN'*-dimethylurea[226,241] and its homologues and 3-chloro-4-methoxyphenyl-*NN*-dimethylurea and its homologues[228,234,235,239,242,245] also give satisfactory results in the fight against weeds in wheat. Cotoran [*NN*-dimethyl-*N'*-(3-trifluoromethylphenyl)urea], *N*-(3-chloro-4-trifluoromethylphenyl)-*N'N'*-dimethylurea[232], *N*-(3-chloro-4-trifluoromethoxyphenyl)-*N'N'*-dimethylurea, and certain others are widely used to combat weeds among cotton plants and other crops. Practical applications have also been suggested for *N*-(3-tetrafluoroethoxyphenyl)-*N'N'*-dimethylurea[225]. A series of urea derivatives containing various acyl groups at the nitrogen atom[236–238] as well as compounds having the general formula (**XIX**)[259–261], containing a wide variety of substituents in the aromatic group, have been proposed. Compounds having the general formulae (**XX**)[231], (**XXI**)[268], and certain others[269,270] can be classified as urea derivatives:



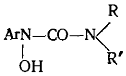
(XIX)

(XX)

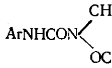


(XXI) .

Complexes of substituted ureas with acids[251] and urea derivatives of hydroxylamine[3,258] containing a hydroxy-group [compound (**XXII**)][3,181] or a methoxy-group [compound (**XXIII**)][3,258] at one of the nitrogen atoms have likewise been proposed as herbicides:

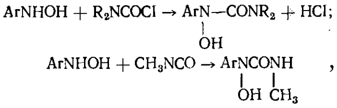


(XXII)



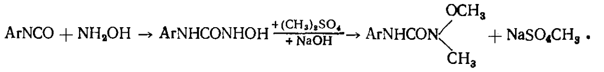
(XXIII) .

Compounds (**XXII**) are obtained in high yields by the reaction of arylhydroxylamines with dialkylcarbamoyl chlorides or alkyl isocyanates[3]:



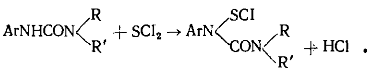
$$ ArNHOH + R_2NCOCl \rightarrow Ar\underset{OH}{N}-CONR_2 + HCl; $$
$$ ArNHOH + CH_3NCO \rightarrow Ar\underset{OH}{N}CO\underset{CH_3}{N}H\ , $$

and compounds (**XXIII**) are obtained by the following series of reactions[3]:



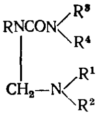
$$ ArNCO + NH_2OH \rightarrow ArNHCONHOH \xrightarrow[+NaOH]{+(CH_3)_2SO_4} ArNHCON{<}^{OCH_3}_{CH_3} + NaSO_4CH_3\ . $$

Compounds having the general formulae (**XXIV**)[244], (**XXV**), and (**XXVI**)[262–266] have been proposed recently as herbicides. Compounds (**XXV**) are obtained in high yields by the reaction of the corresponding substituted ureas with sulphur dichloride in pyridine or another similar solvent[262]:

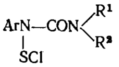


$$ ArNHCON{<}^{R}_{R'} + SCl_2 \rightarrow ArN{<}^{SCl}_{CON{<}^{R}_{R'}} + HCl\ . $$

Chlorine is readily substituted in these compounds by various other groups[263]. Compounds having the general formula (**XXVII**) have also been put forward as herbicides[246,249,253]:

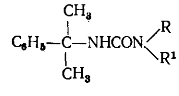


(XXIV)

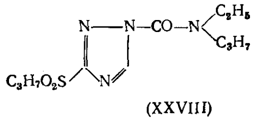


(XXV)

(XXVI)



(XXVII)



(XXVIII) .

Numerous heterocyclic ureas, including representatives of a wide variety of classes of compounds, have been suggested as agents suitable in the fight against undesirable plants. 1-(*N*-Ethyl-*N*-propylcarbamoyl)-3-propylsulphonyl-1,2,4-triazole (**XXVIII**) may serve as an example[230]. Urea herbicides include derivatives of 1,2,4-oxadiazole[287], 1,2,4-thiazole[287], furfural and pyran[275], thiazole[283,286], isothiazole[284], 1,3,4-thiadiazole[271,272,276], dichlorothiazole[278], sulphonylthiadiazole[279], pyridine[267], and certain other heterocyclic compounds[273,280-282,285,288]. Certain heterocyclic ureas have found practical applications. These include in the first place *N*-(2-benzothiazolyl)-*N'*-methylurea (Benzthiazuron), *N*-benzothiazolyl-*NN'*-dimethylurea (Metabenzthiazuron), *N*-[5-butyl-2-(1,3,4-thiadiazolyl)]-*NN'*-dimethylurea (Tebuthiuron), 1,3-dimethyl-1-[5-trifluoromethyl-2-(1,3,4-thiadiazolyl)]-urea (Thiazfluron) and others.

Despite the fact that a very large number of urea derivatives have now been described and investigated as herbicides and plant growth regulators, the research in this field is being vigorously continued and new preparations, promising for practical applications, are being systematically produced.

Certain conclusions concerning the dependence of herbicidal activity on the structure of the urea derivatives can be reached on the basis of the available data. Since this problem cannot be dealt with in detail here, we shall merely mention certain general postulates concerning substituted dialkylarylureas. Dialkylarylureas containing not more than two substituents in the benzene residue and with at least one of the *ortho*-positions relative to the amide group containing hydrogen are the most active herbicides. The total number of hydrogen atoms in the two alkyl residues at the nitrogen atom must not be more than five; in the presence of a larger number of carbon atoms in these groups, the activity of the compound falls. However, this does not apply to arylcycloalkylureas. For example, *N*-(2-methylcyclohexyl)-*N'*-phenylurea is an active herbicide. With increase of the number of carbon atoms in the alkyl or cycloalkyl residues, the overall herbicidal activity falls, but the selectivity of the action of the preparation rises.

Among *NN*-dialkyl-*N'*-arylureas, the chloro- and iodo-derivatives are the most and least active respectively. Ureas containing substituents in the 3,4-positions of the phenyl group show the most selective activity. *NN*-Dialkyl-*N'*-naphthylureas exhibit a weaker herbicidal activity. The derivatives of thiourea among which only *NN*-dimethyl-*N'*-(3-methylphenyl)thiourea has found a practical application are of lesser interest as herbicides. Other thiourea derivatives are more interesting as fungicides[3].

VIII. ORGANOPHOSPHORUS AND ORGANOARSENIC COMPOUNDS

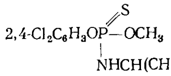
Among arsenic compounds, arsenic acid has found a practical application for the defoliation and desiccation of the cotton plant[3,22]; in the USA considerable areas of cotton plantations are treated with this substance. Salts of methylarsenic and cacodylic acids are also used in the fight against weeds. However, one should note that the wide-scale employment of arsenic in agriculture leads to its accumulation in the soil and in the plants[291]. Salts of methylarsenic and cacodylic acids have been used on a particularly large scale in mixtures with various other herbicides[289] and also in the fight against certain weeds in meadows[293].

The herbicidal and growth regulating properties of organophosphorus compounds have been investigated on a large scale during recent years and considerable advances have been achieved in this field[293-371]. Among the organophosphorus compounds investigated, there are representatives of a wide variety of phosphorus derivatives with different biological activities. The interest in organophosphorus compounds is quite understandable, since the majority of these compounds readily decompose in the soil with formation of phosphoric acid and other simple compounds, leaving practically no toxic residues in the environment[291,372]. The accumulation of organophosphorus compounds in the environment has not so far been observed[372].

Some of the first organophosphorus herbicides were the preparations Falone (**XXIX**), Zytron (**XXX**), and Prefar (**XXXI**), which have found comparatively limited applications. Butifos (**XXXII**) and Merphos (**XXXIII**) are used on a much larger scale as defoliants for the removal of leaves from the cotton plant prior to harvesting[22].

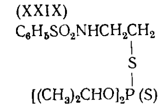
$(2,4\text{-}Cl_2C_6H_3OCH_2CH_2O)_3P$

(XXIX)



$2,4\text{-}Cl_2C_6H_3OP(=S)(-OCH_3)NHCH(CH_3)_2$

(XXX)



$C_6H_5SO_2NHCH_2CH_2\text{-}S\text{-}P(S)[OCH(CH_3)_2]_2$

(XXXI)

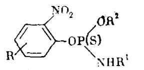
$(C_4H_9S)_3PO$

(XXXII)

$(C_4H_9S)_3P$

(XXXIII)

A large number of Zytron analogues containing the nitro-group in the 2-position of the phenyl substituent have been synthesised recently[333,340,344,352,367,368,370,374]; compounds of this type, having the general formula (**XXXIV**), are at present being investigated in Japan under experimental industrial conditions.



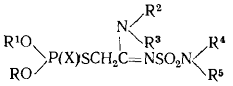
(XXXIV)

$ArSO_2NHCH_2CH_2SP(=S)(OR)OR^1$

(XXXV)

Together with the synthesis and study of a large number of Prefar analogues having the general formula (**XXXV**)[347], numerous compounds having the general formula (**XXXVI**)[332,335,345,351] and containing aliphatic[357], aromatic[351] and heterocyclic[345] residues at the nitrogen atom, have been synthesised. In most instances, these compounds exhibit selective herbicidal activity; among them, there are derivatives of both phosphorothioic and phosphorodithioic acids[332].

(XXXVI)



(XXXVII)

Prefar and its analogues can be synthesised by the following procedure[347]:

$$ArSO_2NHCH_2CH_2Cl + NaSP(S)(OR)_2 \rightarrow (RO)_2P(S)SCH_2CH_2NHSO_2Ar + NaCl.$$

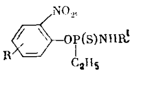
A number of other phosphates[326], phosphorothioates[349,350,359,360], phosphoramidates, and phosphoramidothioates[327,328] have been synthesised and their herbicidal and growth regulating properties investigated. For example, *SS*-dialkyl phosphorochloridodithioates, obtained by the reaction of dialkyl disulphides with phosphorus trichloride in the presence of anhydrous aluminium chloride, have been proposed as defoliants[348], while phosphorus-containing derivatives of *s*-triazine[346] and 2,3,6-trichlorobenzoylphosphazo-*N*-aryliminotrichloroacyl[338] have been proposed as herbicides.

The use of phosphonate analogues of compounds (XXXIV), having the general formula (XXXVIII)[375], which are safe for the cotton plant, carrots, potatoes, and certain other crops, has been patented.

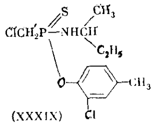
Systematic studies on the ester-amides of methylphosphonic and methylphosphonothioic acids and their derivatives, containing various substituents in the methyl group attached to the phosphorus atom, have shown that derivatives of chloromethylphosphonothioic acid exhibit the highest activity[376-379] and the ester-amides of alkylphosphonothioic acids can be arranged in the following sequence in terms of their decreasing herbicidal activity[376-379]:

$$ClCH_2{-}P > CH_3{-}P = ROCH_2{-}P > ClCH_2CH_2{-}P > C_2H_5{-}P > C_3H_7{-}P > RSCH_2{-}P > C_6H_5{-}P$$

The study of the conformational transitions of the ester-amides of chloromethylphosphonothioic acid has shown that compounds with the smallest difference between the free energies of the rotational isomers have the highest herbicidal activity[377,379]. This observation can also explain the lower herbicidal activity of phosphonates compared with phosphonothioates[377]. In this group of substances, the preparation known as Isophos-3 (XXXIX) is of considerable interest[379]:



(XXXVIII)



(XXXIX)

The use of Isophos-3 gives good results in the fight against weeds in rice, wheat, maize, soya beans, tomatoes, and a number of other crops. This preparation is particularly effective in the fight against millet-like weeds[379]. A large number of Isophos analogues with herbicidal activity have now been synthesised[380,381]. It is interesting to note that the ester-amides of chloromethylphosphonothioic acid containing secondary amine residues are the most active. The structure of the ester residue also has a considerable influence[379].

Phosphonomethylglycine (XL), which exhibits powerful herbicidal properties in the form of its salts with aliphatic amines, being effective against monocotyledonons perennial weeds, including witchgrass, is of great interest. This preparation, known as glyphosate, is obtained by the reaction of chloromethylphosphonic acid or its derivatives with glycine[371]. A large number of derivatives and mixtures of glyphosate with various other herbicides have been described[342,353,358,362,363].

Various carbamoylphosphonates have been proposed as growth regulators and herbicides[329,336,341,343,382], among which the ammonium salt of *O*-ethyl carbamoylphosphonic acid (XLI)[382] has found practical applications in the fight against certain perennial plants.

$(HO)_2P(=O)CH_2NHCH_2COOH$

(XL)

$C_2H_5OP(=O)(ONH_4)CONH_2$

(XLI)

2-Chloroethylphosphonic acid and some of its derivatives[292-324] (the acid is known as Ethrel, Ethephon, etc.) have found extensive applications as plant growth regulators. The action of 2-chloroethylphosphonic acid is based on the fact that, at pH > 4.5, ethylene, which possesses a high growth activating activity, is evolved. 2-Chloroethylphosphonic acid is obtained by the hydrolysis of its 2-chloroethyl ester with hydrochloric acid or hydrogen chloride[325,373,383]. Satisfactory yields are obtained when the most concentrated hydrochloric acid is employed. The 2-chloroethyl 2-chloroethylphosphonate required for synthesis is obtained in high yields by Kabachnik's method[383] from tri-(2-chloroethyl) phosphite. Together with 2-chloroethylphosphonic acid, its various derivatives[331,337,361], homologues[355,375], and many other phosphonic acid derivatives[354,366,384] have been proposed as plant growth regulators.

Depending on the concentration of the preparation and the stage of development and species of the plant, 2-chloroethylphosphonic acid can have various physiological effects: stimulation or inhibition of growth, the awakening of dormant buds, the acceleration of the ripening of fruit and vegetables, the acceleration of axillary branching of plants, the induction of flowering, the increase of frost resistance of buds, and the acceleration of the shedding of leaves, flowers, and fruit[300,301]. When Ethrel was used to vernalise wheat, an increase of the earing of the seedlings by a factor of 8–53 compared with the control seeds was noted[302]. The use of 2-chloroethylphosphonic acid on tomatoes[303-309], mandarin oranges[310,311], lemons, oranges, and grapefruits[311], peaches[312], cucumbers[313-315], cherries, onions[316], strawberries[317], hazelnuts[318], groundnuts[319], walnuts[320,321], sunflowers[322,323], tobacco[323], and the cotton plant[298] has yielded satisfactory results in the acceleration of ripening and the facilitation of the mechanisation of harvesting.

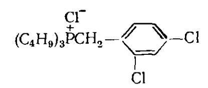
Ethrel is particularly promising for the mechanisation of the harvesting of fruit including citrus fruit. When the preparation is used, the facilitation of the removal of fruit from the plant is accompanied by the acceleration of their ripening, which promotes an increase in the harvest and an improvement in its quality. Thus peaches ripen 5 days earlier than usual[312] and the crop of tomatoes increases by 20–30%[307] and that of strawberries by 36–44%.[317] Ethrel is also an effective agent for the termination of the dormant state of groundnuts[319]. Depending on its purpose, Ethrel is used at concentrations ranging from 0.25 to 10 g litre^{-1}. It is used as a concentration of 0.5–1 g litre^{-1} as a plant growth regulator and at higher concentrations as a defoliant. Depending on the plant to be treated, its dose is 250–3000 g per hectare and the employment of even the highest concentrations of the preparation is economically justified. Ethrel leaves no toxic residues on the plants, since it decomposes almost completely with formation of phosphoric acid, which is assimilated by the plants.

It is interesting to note that certain derivatives of 2-chloroethylsilicon[369,385] and the esters of 2-chloroethylphosphinic acid[386] have properties resembling those of Ethrel.

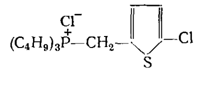
We may note that Ethrel is of interest also as a gametocide[387], since at concentrations of 2–3 g litre^{-1} it completely sterilises the male pollen of plants, which is of interest for the preparation of hybrid seeds.

Among phosphonic acid derivatives, mention must be made of *NN*-di(phosphonomethyl)glycine, which has been proposed for the acceleration of the ripening of sugar cane and for the increase of its sugar content[388].

Together with phosphorus acid derivatives, quaternary phosphonium salts have found practical applications in plant cultivation[293-297,365], the preparation Phosfon-D (XLII) being the best known representative of these. Phosfon-D is used as a broad-spectrum retarding agent mainly in soil under cover in relation to flowering plants. The CHE-8728 preparation [tributyl-2-chlorothienylmethylphosphonium chloride (XLIII)], recommended for increasing the crop of cotton, soya beans, kidney beans, and sugar cane, has been widely investigated recently[293–297,365]. When the above plants were sprayed with aqueous solutions of the preparation (25–30 mg litre^{-1}), the crop increased by 7–15%.



(XLII)



(XLIII)

Tributyl-2-chlorothienylmethylphosphonium chloride is obtained in high yields by the reaction of tributylphosphine with 2-chloro-5-chloromethylthiophen[365]. The tributylphosphine required for the synthesis can be obtained from tributylaluminium and phosphorus trichloride. According to patent data, trialkyl-2-chlorothienylammonium salts also possess plant growth regulating properties[334]. It is seen from the above by no means complete survey that organophosphorus compounds occupy a firm position in agriculture both as herbicides and as plant growth regulators.

IX. HETEROCYCLIC COMPOUNDS OF DIFFERENT SERIES

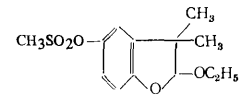
Heterocyclic compounds of different series include the greatest number of substances physiologically active in plants, which have found practical applications in agriculture[3]. Indolylacetic acid (heteroauxin) and indolylbutyric acid, which are still widely used to accelerate the rooting of plants in their vegetative propagation by cuttings[3], as well as maleic acid hydrazide, used to inhibit plant growth[391], a rational method for the manufacture of which had been developed in Nametkin's laboratory[2], have been known for the longest time.

A large number of modern herbicides are pyridine derivatives, among which the quaternary salts of 4,4'-bipyridyl and 2,2'-bipyridyl occupy the first place as regards the scale of manufacture and applications[389]; the former are obtained by the alkylation of 4,4'-bipyridyl using various alkylating agents and the latter by the reaction of dibromoethane with 2,2'-bipyridyl[389,390].

4-Amino-3,5,6-trichloropicolinic acid, which is exceptionally long acting, is a broad-spectrum herbicide[3,4].

Among pyridine derivatives, we may also mention tetrachloropyridinol, dichlorodifluoropyridinol[3], the esters and other derivatives of 4-amino-3,5,6-trichloropicolinic acid[392], 3,5,6-trichloropyridylacetic acid[393], sulpho- and nitro-derivatives of chloropyridine[394–396], polychlorocyano- and dicyano-pyridines[396,397], 3,5-dichloroalkoxyethoxypyridines[398], 3,5-difluoro-2,4,6-trimethoxypyridine[399], 2-amino-6-chloro-4-trichloromethylpyridine[400], 2,3,5,6-tetrahalogeno-4-mercaptopyridines[401], polyhalogenopyridines[402–404], perchlorovinylcyanopyridine[405], halogenoalkylpyridines[406], polysubstituted dipyridylamines[407], and sulphonium derivatives of polychloropyridines[408,409], which have been proposed as plant growth regulators and herbicides. We may also note that substituted pyrrolidines[410] and maleimides[411] have been suggested as plant growth regulators.

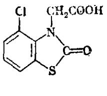
Among oxygen-containing heterocyclic compounds, 6,8-dichlorochromone[412] and various ethers of substituted hydroxytetrahydrobenzofuran[413–415] have been proposed as herbicides. In this group of preparations, 2-ethoxy-2,3-dihydro-3,3-dimethyl-5-benzofurylmethanesulphonate (XLIV), known under the commercial name Nortron, is of considerable practical interest. This preparation is used in the fight against weeds in sugar beet plantations[415]. It can be obtained in high yield by the reaction of 1-ethoxy-2,3-dihydro-5-hydroxy-3,3-dimethylbenzofuran with methanesulphonyl chloride in the presence of hydrogen chloride acceptors[414]. A number of other derivatives of dihydrobenzofuran[413,414], some of which also exhibit herbicidal activity but have not so far found practical applications, can be synthesised by a similar procedure.



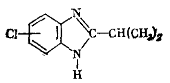
(XLIV)

Numerous studies have been devoted to the herbicidal and plant growth regulating properties of five- and six-membered heterocyclic compounds with two heteroatoms in the ring, including derivatives of imidazoline[416,417], benzimidazoline and benzimidazole[418–420], indazole[421], pyrazole[422–425], oxazole and oxazolidine[426], thiazolidine and thiazole[427–429], isothiazole[430], hydantoin[431–434], and certain others.

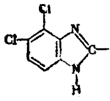
Among the classes of heterocyclic compounds enumerated above, the following have found practical applications: Benazolin (XLV), BKh-584 (XLVI), Chlorofluorazole (XLVII), RP-17623 (XLVIII), Diphensoquat* (XLIX), *NN*-dimethyl-2-(3,4,5-tribromo-1-pyrazolyl)propionamide (L), and certain others have found practical applications. Benzglycerite* (LI)[435] is a heterocyclic compound with two oxygen atoms in the ring, which has found practical applications.



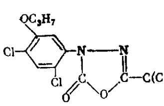
(XLV)



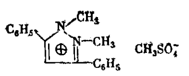
(XLVI)



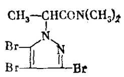
(XLVII)



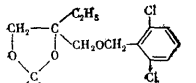
(XLVIII)



(IL)



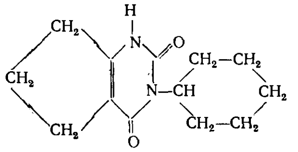
(L)



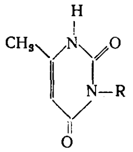
(LI)

Heterocyclic compounds with two heteroatoms in the ring have found even wider practical applications. Substituted uracils[3,4,436,437], pyrimidines[438–443], and pyrazines and pyridazinones[444–453] are used on the largest scale. The most frequently used compounds of this group are Lenacil (LII) (in the fight against weeds affecting various useful plants), uracil derivatives having the general formula (LIII), Pyramin (LIV) (in the fight against weeds in sugar beet plantations), 3-phenoxypyridazine (LV), and certain others.

Cyclopropyl-(4-methoxyphenyl)-5-pyrimidinylmethanol (LVI) has found some applications as a plant growth regulator for the improvement of the flowering of chrysanthemums, lilies, and peonies[454]; it is employed as a spray in the form of a 0.026% solution on plants or in the treatment of soil.

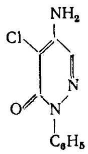


(LII)

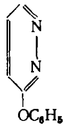


X=Cl, Br; R=C$(CH_3)_3$, iso-C_3H_7, s-C_4H_9

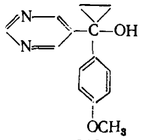
(LIII)



(LIV)



(LV)

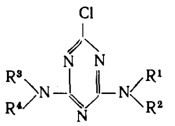


(LVI)

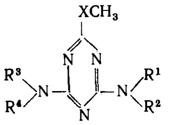
A large number of analogues of the above compounds have been synthesised and some of them may be of significant practical interest. However, their investigation has not yet been completed. There is no doubt that many interesting compounds physiologically active in plants will be found among them.

Heterocyclic compounds with three and more heteroatoms in the ring, including triazole[3], s-triazine[3,455-476] tetrahydro-s-triazine[479-482], asymmetric triazine[477,478,482], 2,2-dioxybenzo-2,1,3-thiadiazine[3,483], thiadiazole[485], oxadiazole[486], and others[484,487-491] have been investigated in detail.

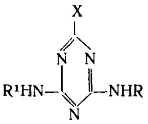
Derivatives of s-triazine, having the general formulae (LVII), (LVIII) and (LIX), which are readily obtained by the substitution of chlorine in cyanuryl chloride by the appropriate groups, have been most widely used as herbicides.



(LVII)

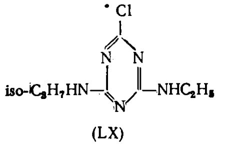


(LVIII)

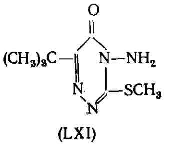


(LIX)

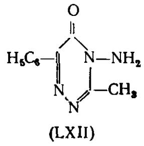
Derivatives of s-triazine occupy one of the leading places[9] among other preparations in terms of the scale of manufacture and their applications in the fight against weeds in various plantations. It is sufficient to point out that Atrazine (LX) alone is used in amounts up to 40 000 tonnes annually in the fight against weeds in maize plantations[492].



(LX)

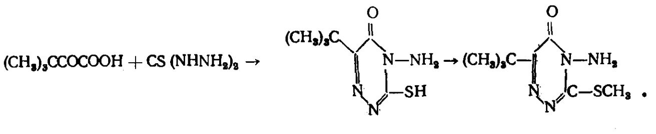


(LXI)



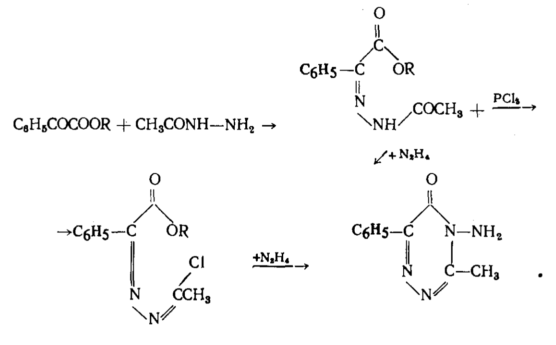
(LXII)

The first herbicide among derivatives of asymmetric thiazine is Metribuzin (Sencor) (LXI), obtained by the following procedure[477];



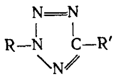
This preparation is used in the fight against weeds in soya bean, tomato, potato, and alfalfa plantations.

Another interesting preparation of this series is Metametron*[477] (LXII), obtained by the following reactions:



Metametron* has been proposed as an agent against weeds in sugar beet plantations. Particularly satisfactory results have been obtained when it was used together with certain chloroacetanilide derivatives.

Tetrazoles having the general formula (LXIII) have been proposed as plant growth regulators, inhibiting the growth of shoots and stems of various plants[489,491]:



(LXIII)

---o0o---

It has not been possible to characterise fully in this review the research designed to discover and develop new chemical weed killers and plant growth regulators, but the examples quoted are sufficient to give a general idea about the scale of such studies and about the importance which chemical preparations have assumed in plant cultivation.

Heterogeneous Catalytic Oxidation of Aromatic Hydrocarbons in the Gas Phase

Yu.I.Pyatnitskii

A systematic account is given of experimental results. Kinetic data are considered from general principles based on the model of Mars and Van Krevelen supplemented by the concept of successive surface oxidation of the initial organic molecule. Certain general laws of the occurrence of reactions of this class are formulated. A list of 137 references is included.

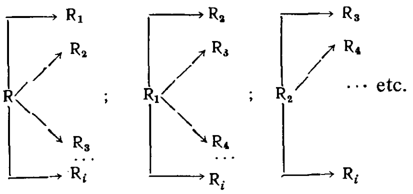
CONTENTS

I. INTRODUCTION

The heterogeneous catalytic oxidation of aromatic hydrocarbons in the gas phase includes a large number of reactions, many of practical interest. The most widely used at the present time are those yielding organic acid anhydrides (maleic, phthalic, naphthalic, trimellitic, and pyromellitic), as well as anthraquinone. The oxidation products often include other compounds of practical value—benzoquinone, naphthaquinone, aromatic aldehydes and acids, etc. In spite of the considerable variety of such reactions, their occurrence exhibits several common features, the elucidation of which should help to lay scientific foundations for the selection of catalysts.

The present Review will cover mainly work during recent years, since earlier research was the subject of a detailed discussion by Dixon and Longfield[1]. During the past fifteen years considerable improvements have been made in the experimental technique, which have permitted considerable broadening and deepening of our ideas on the kinetics and the mechanism of the oxidation of aromatic hydrocarbons. At the same time original concepts have been developed on the interrelationship between catalytic and physicochemical properties.

The oxidation of aromatic hydrocarbons usually proceeds by a consecutive–parallel mechanism. This means in general that, if a starting material R forms oxidation products R_1, R_2, ..., R_i (in order of increasing degree of oxidation), parallel processes of the type



occur, when each reaction takes place without the formation of gaseous intermediates, as well as the consecutive reactions

$$R \rightarrow R_1 \rightarrow R_2 \rightarrow R_3 \rightarrow \cdots \rightarrow R_i.$$

The complicated character of the processes creates certain difficulties in the analysis of their kinetics and mechanism, and compels recourse to various simplifications. In particular, pseudounimolecular equations are sometimes used for individual reactions in constructing a formal kinetic model, although the true kinetic relations are usually much more complex. Some authors select power formulae describing more or less satisfactorily the rates of accumulation of individual reaction products. This is in general a too crude approximation to the true kinetic equations, since the directly measurable rates of accumulation of products of mild oxidation depend on their rates of formation not only from the initial oxidisable substance but also from products of intermediate degrees of oxidation, as well as on the rate of conversion of the given reaction product into higher oxidation products. Hence such an approach is inconsistent with the consecutive–parallel character of mild oxidation established in many studies.

Definite advances in the rational interpretation of kinetic data on the basis of largely similar reaction schemes have been achieved in several recent publications. Before considering specific published information, therefore, a general discussion of such schemes and their consequences is advisable.

II. GENERALISED KINETIC MODEL OF THE CATALYTIC OXIDATION OF AROMATIC HYDROCARBONS

Mars and Van Krevelen[2,3] interpreted the kinetics of the oxidation of many substances in terms of a redox scheme involving two irreversible stages:

$$\text{Hydrocarbon R} + \text{Oxidised catalyst} \xrightarrow{r_R} \text{Oxidation products } R_1, R_2, \ldots + \text{Reduced catalyst} \quad (1)$$

$$\text{Reduced catalyst} + O_2 \xrightarrow{r_{O_2}} \text{Oxidised catalyst} . \quad (2)$$

Several workers have shown[4-8] that kinetic equations of the Langmuir–Hinshelwood type do not satisfy experimental results for the catalytic oxidation of aromatic hydrocarbons. For reactions (1) and (2) we can adopt the rate equations

$$r_R = k_R P_R \theta^a, \quad (3)$$

$$r_{O_2} = k_{O_2} P_{O_2} (1-\theta)^b, \quad (4)$$

where k_R and k_{O_2} are rate constants, θ is the coverage of the surface by oxygen, P_R and P_{O_2} are the partial pressures of the reactants, and a and b are the orders with respect to adsorbed oxygen and to oxygen vacancies on the catalyst surface respectively. In a steady state we should have

$$r_R = r_{O_2}/\nu, \tag{5}$$

where the stoichiometric coefficient ν, the number of oxygen molecules required to oxidise one R molecule to the products R_1, R_2, ..., R_i, is given by

$$\nu = \nu_1 S_1 + \nu_2 S_2 + \nu_3 S_3 + \ldots + \nu_i S_i, \tag{6}$$

in which S_i is the selectivity for R_i, and ν_i is the number of oxygen molecules involved in oxidising one R molecule to R_i. Substituting (3) and (4) in (5) yields

$$\frac{\theta^a}{(1-\theta)^b} = \frac{k_{O_2}}{k_R} \cdot \frac{1}{\nu} \cdot \frac{P_{O_2}}{P_R}, \tag{7}$$

from which it follows that the surface concentration of oxygen is a function of the ratio P_{O_2}/P_R.

For the simplest case $a = b = 1$, and from (3) and (7) we obtain for the surface coverage and the total rate of oxidation of R the formulae

$$\theta = \frac{1}{\nu} \cdot \frac{k_{O_2}}{k_R} \cdot \frac{P_{O_2}}{P_R} \Big/ \left(1 + \frac{1}{\nu} \frac{k_{O_2} P_{O_2}}{k_R P_R}\right), \tag{8}$$

$$r_R = k_{O_2} k_R P_{O_2} P_R / (k_{O_2} P_{O_2} + \nu k_R P_R). \tag{9}$$

The coefficient ν is variable, but its relative variations are often small, and for convenience a mean value $\bar{\nu}$ is used. Equation (9) can be written in a different form. For example, if the process comprises the consecutive reactions

$$R \xrightarrow[(O)]{r_R} R_1 \xrightarrow[(O)]{r_1} R_2 \xrightarrow[(O)]{r_2} R_3 \xrightarrow[(O)]{r_3} \ldots \xrightarrow[(O)]{r_{i-1}} R_i,$$

and the kinetics of each is expressed by the equation $r_i = k_i P_i \theta$, it is readily found that the overall rate of conversion of the initial substance is given by

$$r_R = \frac{k_{O_2} k_R P_{O_2} P_R}{k_{O_2} P_{O_2} + \nu_1 k_R P_R + (\nu_3 - \nu_1) k_1 P_1 + (\nu_3 - \nu_2) k_2 P_2 + \ldots + (\nu_i - \nu_{i-1}) k_{i-1} P_{i-1}}. \tag{10}$$

Since

$$S_i = (k_{i-1} P_{i-1} - k_i P_i) / k_R P_R,$$

it can be shown from (6) that

$$\nu k_R P_R = \nu_1 k_R P_R + (\nu_2 - \nu_1) k_1 P_1 + (\nu_3 - \nu_2) k_2 P_2 + \ldots + (\nu_i - \nu_{i-1}) k_{i-1} P_{i-1},$$

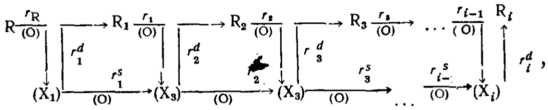
i.e. the kinetic equations (9) and (10) are equivalent.

In order to analyse the overall kinetics it is necessary to examine the detailed mechanism of the reduction stage (1). Two general schemes can be envisaged for such a mechanism. According to the first, all the observed reactions take place independently, via surface complexes specific to each reaction, e.g. on different types of active centres[9,10]. The second scheme, in contrast, is based on a close interrelationship between individual reactions. Oxidation on the surface takes place consecutively[11-16]:

$$R \xrightarrow[(O)]{} (X_1) \xrightarrow[(O)]{} (X_2) \xrightarrow[(O)]{} (X_3) \xrightarrow[(O)]{} \ldots \xrightarrow[(O)]{} (X_i)$$

(here and below parentheses denote the adsorbed state). The surface intermediates Xi yield on desorption the reaction products R_i, which may then partly undergo further oxidation. It is assumed that formation of a given product R_i involves the same final intermediate complex, independently of whether the complex has been formed from the initial compound R or by further oxidation of a product in an intermediate state of oxidation.

One variant of such a mechanism[15,16] can be represented as†



, (11)

where the r with the various affixes are the rates of the individual stages. It is evident that this scheme corresponds to a consecutive–parallel (in the generally accepted sense) reaction mechanism: the consecutive reactions are denoted by the stages

$$R \xrightarrow[(O)]{} (X_1) \rightarrow R_1 \xrightarrow[(O)]{} (X_2) \rightarrow R_2 \ldots,$$

and the parallel reactions by

$$R \xrightarrow[(O)]{} (X_1) \rightarrow R_1,\ R \xrightarrow[(O)]{} (X_1) \xrightarrow[(O)]{} (X_2) \rightarrow R_2$$

etc. Adopting for the individual stages in scheme (11) the expressions

$$r_R = k_R P_R \theta,\ r_i = k_i P_i \theta,\ r_i^d = k_i^d \theta_i,\ r_i^s = k_i^s \theta_i \theta$$

(in which the θ_i are the concentrations of the intermediate compounds X_i), we obtain for the selectivity with respect to the individual reaction products the equations[16]

$$S_1 = \frac{1}{(1 + n_1\theta)(1 + k_1\theta\tau)}, \tag{12}$$

$$S_2 = \frac{1 - S_1}{(1 + n_2\theta)(1 + k_2\theta\tau)}, \tag{13}$$

$$S_3 = \frac{1 - S_1 - S_2}{(1 + n_3\theta)(1 + k_3\theta\tau)}, \tag{14}$$

$$S_4 = \frac{1 - S_1 - S_2 - S_3}{(1 + n_4\theta)(1 + k_4\theta\tau)} \tag{15}$$

etc., where the $n_i = k_i^s/k_i^d$ are the ratios of the oxidation rate constants for the surface compounds X_i to their desorption rate constants, and τ is proportional to the contact time. In the particular case in which further oxidation of the products can be neglected and the process has a parallel mechanism (e.g. at low degrees of conversion of R), Eqns. (1)–(15) simplify to[14,15]

$$S_1 = \frac{1}{1 + n_1\theta}, \tag{16}$$

$$S_2 = \frac{1 - S_1}{1 + n_2\theta}, \tag{17}$$

$$S_3 = \frac{1 - S_1 - S_2}{1 + n_3\theta}, \tag{18}$$

$$S_4 = \frac{1 - S_1 - S_2 - S_3}{1 + n_4\theta}. \tag{19}$$

The set of equations (8), (9), and (12)–(19) describes the kinetics of all partial reactions within the framework of the given kinetic model. We can formulate certain consequences of the above ideas for the mechanism, which will then be compared with experimental results.

(1) A close analogy should exist between the catalytic reaction under steady-state conditions and the surface

---

† Such a scheme is a kinetic model of a process in which the structure of intermediate complexes, their charges, etc. can be disregarded. Certain chemical aspects of the oxidation of aromatic hydrocarbons have been discussed in a review (in terms of the model of Mars and Van Krevelen)[17].

reduction of the catalyst by the initial hydrocarbon. As reduction proceeds, the surface concentration of oxygen decreases, while the selectivity for products of milder oxidation increases in conformity with Eqns. (12)–(19) with simultaneous decrease in the rate of reduction. At the same surface coverage during catalysis and reduction their rates and selectivities will also be closely similar.

(2) Selectivity during catalysis is determined by the ratio P_{O_2}/P_R of oxidant to reductant in the reaction mixture under otherwise similar conditions, since this ratio determines the surface coverage (formulae 7 and 8).

(3) Addition to the initial mixture of a product may inhibit the process, the more strongly the greater the reactivity of the compound (e.g. Eqn. 10). The Reviewer has already discussed this question in greater detail[18].

(4) In a series of catalysts of the same type a correlation should be observed between the activity and the oxygen–catalyst bonding energy q_S, analogous to that observed for complete oxidation, the mechanism of which also involves stages of alternating reduction and oxidation of the catalyst[19–21].

(5) If the variation in the rate constants of all stages in a series of catalysts is due mainly to the variation in q_S, a correlation will be observed between the selectivities S_i and q_S. Absence of such correlation may indicate that the progress of the reaction is influenced significantly by other physicochemical properties of catalysts and reactants (other than the energy of bonding of oxygen to the catalyst).

III. EXPERIMENTAL RESULTS ON THE OXIDATION OF INDIVIDUAL AROMATIC HYDROCARBONS AND THEIR OXYGEN-CONTAINING DERIVATIVES

1. Oxidation of Benzene

The catalytic oxidation of benzene to maleic anhydride (MA) is an industrial process. Low yields of phenol and *p*-benzoquinone (BQ) are also produced. The kinetics of the oxidation of benzene on the catalysts V_2O_5–K_2SO_4–SiO_2 [2,3,22] and V_2O_5–MoO_3 [23] are described by Eqn. (9).

The mechanism of the interaction of benzene with an oxide catalyst was represented[12] by the scheme

$$\begin{array}{ccccccccc} \text{Benzene} & & \text{Phenol} & & \text{BQ} & & \text{MA} & & \text{CO}_2,\text{CO} \\ \downarrow\uparrow & & \uparrow\downarrow & & \downarrow\uparrow & & \downarrow\uparrow & & \downarrow\uparrow \\ (C_6H_6) & \rightarrow & (C_6H_5OH) & \rightarrow & (C_6H_4O_2) & \rightarrow & (C_4H_3O_2) & \rightarrow & (CO_2, CO) \end{array} \quad . \qquad (20)$$

Such a scheme is consistent with experimental results showing that on separate oxidation phenol is converted into *p*-benzoquinone, maleic anhydride, and carbon dioxide[24], *p*-benzoquinone into maleic anhydride and carbon dioxide[25], and maleic anhydride into carbon dioxide[9,26]. Consecutive surface oxidation of the initial hydrocarbon forms the basis both of (20) and of scheme (11) discussed in Section II. However, the Reviewer prefers (11), since the reversible adsorption stages in (20) are inconsistent with the observed kinetics: equations like that of Mars and Van Krevelen[2,3,22,23] were deduced on the hypothesis of irreversible interaction between reactants and catalyst. The same equations, as will be shown below, agree with experimental results for other aromatic hydrocarbons and their oxygen-containing derivatives.

Several studies have been made on the effect of the chemical composition of a catalyst on its catalytic properties in the oxidation of benzene. Schaefer[27] used a microcatalytic pulse method to obtain information on the activities and selectivities of several vanadium oxides. On the assumption that unchanged activity of a specimen during an experiment indicates constancy of its chemical composition, he obtained the sequence of specific activities

$$VO_{1,99} > VO_{2,03} > VO_{2,17} > VO_{2,33} > VO_{2,50} \quad .$$

Experiments on the interaction of benzene with vanadium oxides in the absence of molecular oxygen showed[27] that the rate of catalysis exceeded the rate of reduction by factors of 1.5–7, but the sequence of the catalysts with respect to their rate of reduction by benzene was identical with the above sequence of catalytic activity.

The initial specific activities of various oxides (for degrees of conversion of benzene approaching zero) decrease in the sequence[13]

$$Co_3O_4 > Mn_2O_3 > Cr_2O_3 > NiO > CuO > Fe_2O_3 > SnO_2,\ U_3O_8 > TiO_2 > V_2O_5 > ThO_2 > ZnO > Bi_2O_3 >$$
$$> Nb_2O_5 > WO_3 > ZrO_2 > MoO_3 > Ta_2O_5 > Sb_2O_4.$$

On plotting $\lg r_{sp}$[13] against q_S (for oxides for which values of the latter were known[20]), the Reviewer obtained a characteristic curve passing through a maximum (Fig. 1*a*), which indicates that the energy of bonding of oxygen to the catalyst has a significant influence on the relative variation in the activity of individual oxides[19–21].

Among the catalysts investigated[13] only three exhibit sufficiently high selectivity with respect to products of mild oxidation (among which maleic anhydride predominates), forming the sequence $V_2O_5 > MoO_3 > WO_3$. The mixed V_2O_5–MoO_3 systems used in industry are more active and more highly selective than is vanadium pentoxide. Maximum activity corresponds to specimens containing 25–30 mole % MoO_3.[12,28] The initial selectivity for maleic anhydride[12] also passes through a maximum, reaching 62% and 25 mole % MoO_3 (the corresponding selectivities on the individual vanadium and molybdenum oxides are respectively 35% and 10%).

In a series of V_2O_5–MoO_3 catalysts an antiparallel relation is observed[30] between the specific activity and the strength of bonding of oxygen to the catalyst estimated from the initial rate of reduction by hydrogen[29] and the equilibrium partial pressure of oxygen[30] by infrared spectroscopy[31]. The opposite result is obtained when the strength of bonding is estimated from the activation energy of isotopic exchange of oxygen: addition of molybdenum(VI) oxide to vanadium(V) oxide increases the strength of bonding of oxygen to the catalyst until the composition reaches ~ 25 mole % MoO_3.[32,33] The cause of this discrepancy is obscure and requires further investigation.

The mixed vanadium–molybdenum oxide catalyst surpasses in specific catalytic activity and selectivity other binary oxide systems containing molybdenum trioxide and oxides of tin, titanium, uranium, antimony, iron, and bismuth[34]. The selectivity of V_2O_5–MoO_3 catalysts is improved by additions of thallium(III), cadmium(II), silver(I),[35] and phosphorus(V)[36] oxides. This is evident from the patent literature, where V_2O_5–MoO_3–P_2O_5 catalysts are proposed alone[37–39] and with additions of bismuth(III),[40] silver(I),[41] nickel(II), and cobalt(II + III)[42] oxides.

Phosphorus pentoxide has been regarded[43] as a structure promoter, and has been reported[44] as increasing the life of a catalyst. It may also modify chemically the catalyst surface, increasing the acidity and thereby facilitating desorption of an acidic substance—maleic anhydride—in conformity with the views of Golodets[45] on the role of acid–base properties in catalytic oxidations.

2. Oxidation of Toluene

The kinetics of the oxidation of toluene on a V_2O_5–K_2SO_4–SiO_2 catalyst can be described[2,3,46] by Eqn. (9). At low degrees of conversion the oxidation products contain[46] 86% of benzaldehyde, 4% of benzoic acid, 7% of *p*-benzoquinone, and 3% of maleic anhydride, the yield of carbon dioxide being insignificant.

Trimm and Irshad[47] established a first order with respect to toluene and zero order with respect to molecular oxygen in the oxidation of toluene on a catalyst comprising molybdenum trioxide and pumice, which may be regarded as a particular case of Eqn. (9). The slow stage involves[47] interaction of toluene with surface O^{2-} ions. The main reaction product at low degrees of conversion of toluene is benzaldehyde, with conversion into carbon dioxide not exceeding 3%.

The rate of oxidation of toluene on copper(II) oxide with additions of molybdenum and tungsten oxides (on a Silit carrier) at 350–450°C is proportional to the concentration of molecular oxygen and independent of the concentration of toluene[48]. The reaction products are benzaldehyde (selectivity up to 85% with 0.6–6% conversion of toluene) and carbon dioxide.

The sequence of oxides with respect to initial specific catalytic activity in the oxidation of toluene is[49]

$$Co_3O_4>CuO>Mn_2O_3>Fe_2O_3>Cr_2O_3>U_3O_8>NiO>V_2O_5>TiO_2>ThO_2>WO_3>ZnO>SnO_2>$$
$$>MoO_3>Bi_2O_3>Ta_2O_5>Nb_2O_5>ZrO_2>Sb_2O_4.$$

The initial selectivity of these oxides for benzaldehyde decreases in the sequence[49]

$$V_2O_5>MoO_3>WO_3>U_3O_8>NiO>Sb_2O_4>Cr_2O_3>TiO_2>Fe_2O_3>Nb_2O_5>$$
$$>Mn_2O_3>CuO>Ta_2O_5>Co_3O_4>SnO_2,\ ZnO,\ ThO_2,\ ZrO_2,\ Bi_2O_3.$$

On vanadium, molybdenum, and tungsten oxides benzaldehyde is accompanied by benzoic acid. The first two of these oxides are more selective[50] than those of copper, manganese, cobalt, lead, and iron in the oxidation of toluene to benzaldehyde. The specific catalytic activity of the oxides correlates approximately with the energy of bonding of oxygen to the catalyst (Fig. 1*b*).

It was of interest to analyse the relation between the selectivity for benzaldehyde and the energy of bonding of oxygen to the catalyst surface. If the reaction mechanism is represented by scheme (II), where R denotes toluene, R_1 benzaldehyde, R_2 benzoic acid, etc., formula (16) can be used for the selectivity for benzaldehyde (initial selectivities correspond to conditions under which complete oxidation of the products can be neglected). Applying the Brønsted–Temkin relation to individual stages in (11) on the assumption that the variation in their activation energies is determined mainly by the bonding energy q_s, we obtain

$$\begin{aligned} E_R &= E_R^0 + m_R q_s, \\ E_{O_2} &= E_{O_2}^0 - m_{O_2} q_s, \\ E_i &= E_i^0 + m_i q_s, \\ E_i^s &= (E_i^s)^0 + m_i^s q_s, \\ E_i^d &= (E_i^d)^0 + m_i^d q_s, \end{aligned} \qquad (21)$$

where $m = \alpha\gamma$ (in which α is the transport coefficient and γ a coefficient proportional to the number of oxygen–catalyst bonds ruptured or formed in the given stage). The validity of formulae (21) for E_R and E_{O_2} is confirmed by the correlation found between specific activity and bonding energy.

Differentiation of S_1 (Eqn. 16) with respect to q_s yields the expression

$$\frac{dS_1}{dq_s} = \frac{1}{RT}\left[(m_1^s - m_1^d) + (m_R + m_{O_2})(1-\theta)\right]\frac{n_1\theta}{(1+n_1\theta)^2}\ . \qquad (22)$$

Il'chenko and Golodets[51,52] have shown that the formation of highly oxidised products involves cleavage of a larger number of oxygen–catalyst bonds than does the formation of products of mild oxidation, so that $m_1^s > m_1^d$. It then follows from Eqn. (22) that the dependence of S_1 on q_s should pass through a minimum. Fig. 2*a* indicates that such a relation holds approximately for oxides of transition metals. Most oxides of non-transition metals are non-selective and depart from the correlation. It will be shown below that this is observed also for the similar oxidation of *o*-xylene to *o*-tolualdehyde.

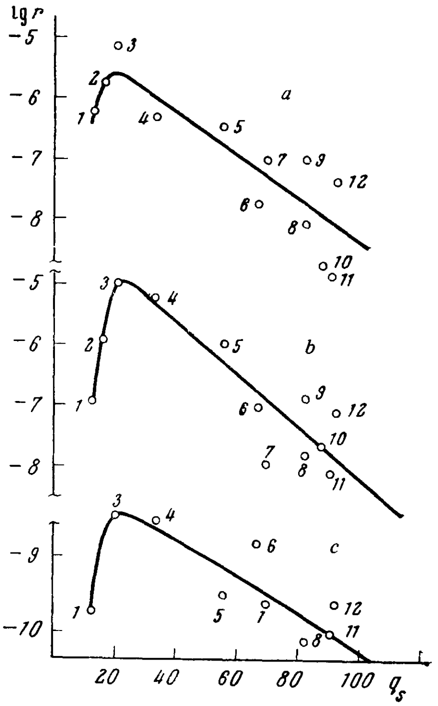


Figure 1. Dependence of lg *r* (where *r* is the reaction velocity, mole m^{-2} s^{-1}) on the oxygen–catalyst bond energy q_s (kcal g-atom^{-1} O)[20] in the oxidation of: *a*) benzene (400°C);[13] *b*) toluene (400°C);[49] *c*) *o*-xylene (300°C)[89] on the oxides: 1) NiO; 2) MnO_2 (or Mn_2O_3); 3) Co_3O_4; 4) CuO; 5) Fe_2O_3; 6) V_2O_5; 7) SnO_2; 8) ZnO; 9) U_3O_8; 10) WO_3; 11) MoO_3; 12) TiO_2.

As in the oxidation of benzene, a mixed V_2O_5–MoO_3 catalyst is more active and selective towards the oxidation of toluene than are the vanadium and molybdenum oxides separately[53]. The specific activity of binary oxide systems falls in the sequence[54]

V–Mo–O>Fe–Mo–O>Ti–Mo–O>Sb–Mo–O>U–Mo–O>Bi–Mo–O.

Among these the iron–molybdenum oxide catalyst is the most selective for benzaldehyde[54].

The poor selectivity of bismuth molybdate is explained by its great ability to accelerate not only the oxidation of methyl groups but also secondary dealkylation and degradative oxidation of toluene[55]. A selective catalyst for the oxidation of toluene to benzaldehyde is copper oxide to which tungsten and molybdenum oxides have been added, in contrast to copper oxide alone[48]. Addition of phosphorus pentoxide to molybdenum trioxide increases the activity and the selectivity for benzaldehyde, as well as the stability of the catalyst[56]. The activity of this mixed catalyst is increased by promotion with oxides of vanadium, chromium, titanium, tin, aluminium, bismuth, nickel, cobalt, and iron, while the oxidation of benzaldehyde to benzoic acid is accelerated[56]. Highly selective oxidation of toluene to benzaldehyde is achieved on a molybdenum–tungsten–aluminium oxide catalyst[57], and on molybdenum(VI) oxide with additions of vanadium(V), zirconium(IV), and copper(II) oxides on ferrochrome[58].

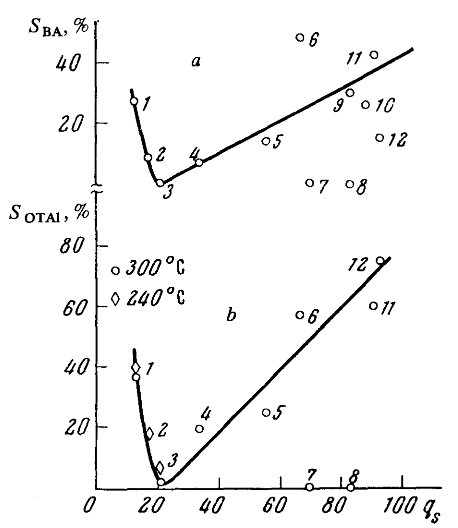

Figure 2. Dependence on q_s of the selectivity for: *a*) benzaldehyde in the oxidation of toluene (400°C)[49]; *b*) *o*-tolualdehyde in the oxidation of *o*-xylene[89]. Numbering as in Fig. 1.

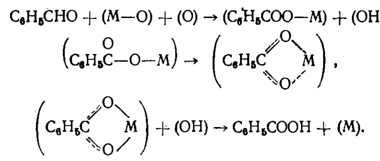
The vanadium(V)–tin(IV) oxide system is evidently highly selective, in comparison with the other catalysts studied, for the oxidation of toluene to benzoic acid[59,60]. The same system exhibits high selectivity in the oxidation of benzaldehyde to benzoic acid[61]. Results of fundamental importance for an understanding of the nature of the selective action of catalysts were also obtained[61]. The relative catalytic activity *a* and the selectivity for benzoic acid *S* of manganese dioxide, vanadium pentoxide, and the mixed catalysts were compared[61] with their thermodynamic functions—the enthalpy and the free energy ΔH and ΔF (in kcal mole^{-1}) of removal of oxygen from the oxide—Table 1, in which x is the degree of reduction of the catalyst. The antiparallel relation between catalytic activity and free energy of removal of oxygen is attributed[61] to a redox mechanism. Such a mechanism is confirmed by the close parallel between catalytic oxidation and the reduction of catalysts by benzaldehyde: at a given temperature the two processes exhibit almost the same selectivity for benzoic acid.

The suggested[61] interpretation of selective oxidation was based on certain qualitative considerations. After the adsorbed organic radical has reacted with a surface oxygen atom of the catalyst, its subsequent fate depends on the probability of (i) desorption or (ii) further chemical interaction with a neighbouring oxygen atom. Decrease in the latter probability leads to increased selectivity. This explains the increase in selectivity with the steepness of the gradient $\partial\Delta H(x)/\partial x$, since subsequent removal of a second or a third oxygen atom from the same cell requires more energy than does removal of the first atom.

Table 1.

Catalyst	$\Delta F_{x=0,02}$	$\partial\Delta H(x)/\partial x$	*a*	*S*, %
MnO_2	10	8	≫10	0
V_2–O_5–SnO_2	24	200	5	90–100
V_2O_5	38	80	1	70–80

The results obtained[61] by the kinetic method combined with infrared and electron spin resonance spectroscopy indicate for the formation of benzoic acid the detailed mechanism



$$C_6H_5CHO + (M{-}O) + (O) \rightarrow (C_6H_5COO{-}M) + (OH),$$

$$\left(C_6H_5\overset{O}{\overset{\|}{C}}{-}O{-}M\right) \rightarrow \left(C_6H_5C\langle{}^{O}_{O}\rangle M\right),$$

$$\left(C_6H_5C\langle{}^{O}_{O}\rangle M\right) + (OH) \rightarrow C_6H_5COOH + (M).$$

The reduced surface centres formed (M) are oxidised by interaction with molecular oxygen to the original oxidised state (M–O). The suggested mechanism and the hypothesis to explain selectivity evidently agree in large measure with the general mechanism expressed by scheme (11). However, energetic non-uniformity is not the only factor determining selectivity. Indeed, a diminished probability of further oxidation of the adsorbed organic complex (which is equivalent to decrease in k_i^S and hence n_i in the selectivity equations 12–19) may result from increase in the oxygen–catalyst bond energy in a series of catalysts, even if their surface oxygen is energetically equivalent.

3. Oxidation of *p*- and *m*-Xylenes

The orientation of methyl groups in *p*- and *m*-xylenes, in contrast to that in the *ortho*-isomer, does not permit formation of the very stable phthalic anhydride, so that their oxidation is considerably less selective than that of *o*-xylene. At low degrees of conversion the main products of the catalytic oxidation of the *para*- and *meta*-isomers on vanadium catalysts are *p*- and *m*-tolualdehydes and carbon dioxide (small quantities of acids are also formed)[62,63]. The formation of aldehydes and carbon dioxide proceeds by a parallel scheme[64,65].

The kinetics of the oxidation of *p*-xylene on tin vanadate[62] and on vanadium pentoxide on silica gel[64,65] is described by Eqn. (9). Increasing the reactant concentrations in the oxidation of *m*-xylene on a V_2O_5–K_2SO_4–SiO_2 catalyst[63] results in a gradual slowing down in the growth of the reaction velocity, which tends to approach a constant value; this is a characteristic feature of Mars–Van Krevelen kinetics. The main oxidation products at high degrees of conversion of *p*- and *m*-xylenes on vanadium catalysts[66] are maleic anhydride and carbon dioxide, with slight formation of aldehydes and acids.

At low degrees of conversion the oxidation of these isomers on a catalyst comprising molybdenum trioxide and pumice yields monoaldehydes and carbon dioxide[47]. The formal kinetic orders are 0.71 and 0.75 with respect to *m*- and *p*-xylenes, the corresponding values with respect to molecular oxygen being 0.40 and 0.49. The power relation is interpreted[47] as an approximation to a Langmuir–Hinshelwood type of equation.

4. Oxidation of *o*-Xylene

The oxidation of *o*-xylene to phthalic anhydride (PhA) is a promising industrial process, competing successfully with manufacture from naphthalene. This was responsible for the great interest taken by research workers in the reaction. Furthermore, many other oxidation products are obtained—*o*-tolualdehyde (oTAl), *o*-toluic acid (oTAc), phthalide (Ph), etc.—which makes the process an interesting model reaction.

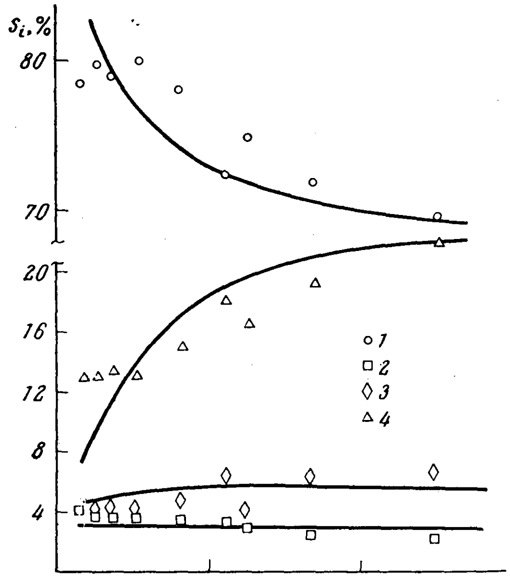


Figure 3. Dependence on the ratio P_{O_2}/P_R at 330°C of the selectivity for: 1) *o*-tolualdehyde; 2) *o*-toluic acid; 3) phthalide; 4) phthalic anhydride. The full curves have been calculated by means of Eqns. (8) and (16)–(19) with $n = 36$, $n_1 = 0.5$, $n_2 = 11$, and $n_3 = 4.5$.[15]

The mean composition of the oxidation products for low degrees of conversion (< 5 mole %) on a V_2O_5–K_2SO_4–SiO_2 catalyst at 290–310°C was 80% of *o*-tolualdehyde, 12% of *p*-benzoquinone, and 8% of carbon dioxide. The kinetics of the process was described satisfactorily by Eqn. (9), which held also for the oxidation of *o*-xylene at low degrees of conversion on fused vanadium pentoxide at 310–330°C.[6,15,67] The Mars–Van Krevelen model was used to interpret the kinetics of oxidation at high degrees of conversion on vanadium catalysts[5,68,69]. The use of other common kinetic models (the Rideal and Langmuir–Hinshelwood models) to analyse the experimental data gave negative results[4-6].

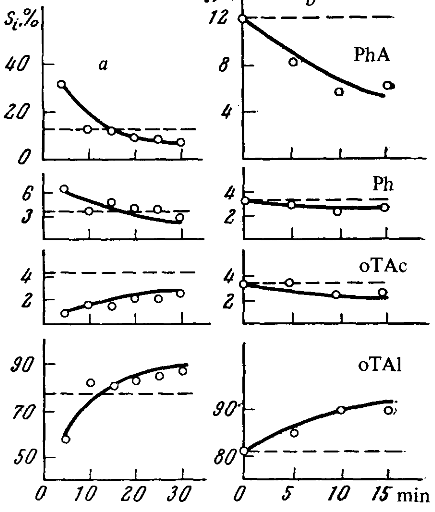

Figure 4. Dependence of selectivity on time of reduction of fused vanadium pentoxide by *o*-xylene at 330°C: *a*) catalyst specimen previously oxidised with oxygen; *b*) catalyst specimen after the catalytic oxidation of *o*-xylene under steady-state conditions[72].

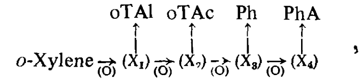
Over a restricted range of conditions the kinetics of the oxidation of *o*-xylene can be described by empirical power equations[5,70,71], but such relations do not agree with experiment as well[5] as the theoretical relations based on the mechanism of Mars and Van Krevelen.

The Reviewer has used[14,15] scheme (11) to interpret the kinetics of partial reactions in the formation of individual products. In the present case this can be written



$$o\text{-Xylene} \xrightarrow[(O)]{} \overset{\substack{\text{oTAl}\\ \uparrow}}{(X_1)} \xrightarrow[(O)]{} \overset{\substack{\text{oTAc}\\ \uparrow}}{(X_2)} \xrightarrow[(O)]{} \overset{\substack{\text{Ph}\\ \uparrow}}{(X_3)} \xrightarrow[(O)]{} \overset{\substack{\text{PhA}\\ \uparrow}}{(X_4)}, \tag{23}$$

where separate experiments have demonstrated[6] that complete oxidation of the products can be neglected under the given range of conditions. Fig. 3 shows that experimental results for the selectivity with respect to all the products satisfy the theoretical relations expressed by formulae (8) and (16)–(19).

The above mechanism is supported by experimental results on the surface reduction of vanadium pentoxide by *o*-xylene[72], which takes place at about the same rate as does catalysis. The variation in selectivity on reduction agrees qualitatively with Eqns. (16)–(19) relating selectivities to surface coverage by oxygen (reduction is accompanied by decrease in θ). These results are plotted in Fig. 4 (the difference in the initial selectivities for an oxidised specimen and a specimen on which catalysis has taken place is due to a difference in the initial surface coverage, which is higher for the oxidised specimen, on which the original selectivity for more highly oxidised products is greater, in conformity with Eqns. 16–19).

The kinetics of the oxidation of *o*-xylene has been investigated[9] on a high-temperature vanadium catalyst under gradient-free conditions. The principal reactions involved were conversion of *o*-xylene into *o*-tolualdehyde, phthalic anhydride, maleic anhydride, carbon monoxide, and carbon dioxide, and of *o*-tolualdehyde into phthalic anhydride. The rates of all these reactions are represented by formulae of the same type:

$$r_{ij}=\frac{k_{ij}c_{ij}}{1+b_ic_{\mathrm{X}}+a_i(c_{\mathrm{oTAl}}+c_{\mathrm{PhA}}+c_{\mathrm{MA}})},$$

where j denotes the oxidisable compound and i the type of active centre in the catalyst, k_i, a_i, and b_i are constants, the c are concentrations, and X denotes *o*-xylene. These equations were deduced from the postulates that each reaction takes place on a separate type of active centre differing in energy of bonding of oxygen with the catalyst; the mechanism, regarded as the same for all the reactions, involved reversible adsorption of the oxidisable compound on the oxidised surface, interaction of the adsorbed molecule with surface oxygen, and desorption of the product. Reaction is inhibited by all organic components of the gas phase owing to their reversible adsorption. Oxygen vacancies are rapidly filled by oxygen from the gas phase, so that zero order with respect to molecular oxygen is observed.

Although the rate equations in Ref. 9 describe the experimental results, the physical premises underlying them are open to doubt. Thus it is not clear how the oxygen–catalyst bond energy determines unambiguously the direction in which the oxidisable substance changes.

Experimental rates of oxidation of *o*-xylene under gradient-free conditions on a vanadium catalyst have been interpreted[5] by means of a scheme according to which the hydrocarbon is converted into *o*-tolualdehyde, phthalic anhydride, and carbon dioxide, *o*-tolualdehyde into phthalic anhydride and carbon dioxide, and phthalic anhydride into carbon dioxide. The kinetic equations

$$r_i=\frac{k_iP_jk_{\mathrm{O_2}}P_{\mathrm{O_2}}}{k_{\mathrm{O_2}}P_{\mathrm{O_2}}+(k_1+k_2+k_3)P_{\mathrm{X}}+(k_4+k_5)P_{\mathrm{oTAl}}+k_6P_{\mathrm{PhA}}}$$

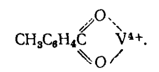
were suggested for each of these reactions, where i denotes the number of the reaction and j the oxidisable compound, k_1, k_2, and k_3 are oxidation rate constants for conversion of *o*-xylene into *o*-tolualdehyde, phthalic anhydride, and carbon dioxide respectively, k_4 and k_5 are rate constants for oxidation of *o*-tolualdehyde into phthalic anhydride and carbon dioxide, and k_6 is the rate constant of oxidation of phthalic anhydride to carbon dioxide. These equations were deduced on the hypothesis that each individual reaction occurs by irreversible interaction of the organic reactant with adsorbed oxygen at rates $k_iP_j\theta$, and that oxygen is adsorbed irreversibly at the rate $k_{\mathrm{O_2}}P_{\mathrm{O_2}}(1-\theta)$.

The agreement between the kinetic results and the above equations, together with the Arrhenius dependence of the resulting rate constants, indicates that the main features of the mechanism assumed in Ref. 5 are correct. Nevertheless, the view that individual reactions take place in isolation on the catalyst surface is in some degree artificial. A more reasonable mechanism is that represented by scheme (11), according to which the final intermediates leading to formation of a given product are the same independently of the oxidisable compound from which they had been formed. Furthermore, the above equations indicate that at low degrees of conversion the selectivity should not depend on reactant concentrations, which contradicts experiment (Fig. 3).

The close analogy between catalysis and reduction noted above suggests that the catalytic process involves surface oxygen ions O^{2-}, since it is difficult to expect other forms of oxygen, e.g. the radical-anions O^- and O_2^-, to be present on the surface during the reduction experiments. Moreover, these species are less reactive towards aromatic hydrocarbons than are other reductants (hydrogen, carbon monoxide, etc.).[73]

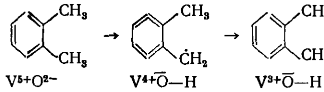
Interaction of *o*-xylene with the surface of vanadium pentoxide is accompanied by electron transfer from the hydrocarbon to the oxide[74]. Addition of small quantities of metallic palladium to the oxide accelerates significantly its reduction by *o*-xylene[75], probably because activation of carbon–hydrogen bonds is facilitated on the metal surface. The part played by additions of metals to oxides in the catalytic oxidation and reduction of the latter has been examined in detail in a review by Il'chenko[76].

With regard to the nature of the compounds X_i postulated in scheme (23) it may be suggested[72] that there is probably no significant difference in the mechanisms of formation of benzoic acid from toluene and of benzaldehyde and *o*-tolualdehyde from *o*-xylene. The structure of compound X_2 responsible for the formation of *o*-toluic acid can then be written[61]



Another acidic substance is phthalic anhydride, formed from X_4, which is most probably also saltlike in character. According to infrared-spectroscopic data[77] surface phthalates on vanadium pentoxide are readily decomposed, and can therefore be assumed to take part in the catalytic process.

We have not yet considered the mechanism of the formation of products of degradative oxidation—maleic anhydride and carbon dioxide—which may also be formed from the surface compound X_4, so that a single chain of consecutive surface reactions takes place. However, it is also possible that products of degradative oxidation are formed at least partly by a different path, when the primary attack on the hydrocarbon affects the aromatic ring. This view is held by Vanhove and Blanchard[78], who suggest that the initial interaction of *o*-xylene with a vanadium–titanium oxide catalyst in the formation of products of mild oxidation—*o*-tolualdehyde, phthalide, phthalic anhydride—follows the scheme



(reduction of the catalyst surface may involve[78] several metal ions because of the rapidity of electron transfer in the oxide lattice, so that V^{4+} ions will be formed preferentially, in agreement with experimental results). The resulting carbonium ion interacts with oxygen O^{2-} of the catalyst to give an adsorbed alkoxide ion. The latter does not undergo desorption: when a mixture of *o*-tolylmethanol and ^{14}C-labelled *o*-xylene is oxidised, the unchanged alcohol is non-radioactive. On the other hand, the alkoxide ion may serve as an intermediate species in the oxidation of *o*-xylene, since the oxidation products of *o*-tolylmethanol are also *o*-tolualdehyde, phthalide, and phthalic anhydride.

Repetition of the processes of detachment of hydrogen from the adsorbed species, electron transfer to the catalyst, and interaction with a surface oxygen ion may ultimately yield phthalic anhydride. Such is the suggested[78] mechanism of the formation of products of mild oxidation.

The degradative oxidation of *o*-xylene to maleic anhydride and oxides of carbon is attributed[78] to a competing reaction between an oxygen ion of the catalyst and the unsaturated portion of the aromatic molecule. This is consistent with results obtained by the same workers[79] on the oxidation of *o*-xylene in which a methyl group is labelled with carbon-14: the maleic anhydride detected among the reaction products is non-radioactive, so that the carboxy-groups have been formed from carbon atoms of the aromatic ring. A mechanism of formation of maleic anhydride was suggested[79] involving surface compounds of quinonoid type, which is supported by the detection of quinones among the oxidation products from *o*-xylene[4,71].

It is suggested[78] that the unsaturated part of the oxidisable molecule interacts with an oxygen ion after preliminary bonding to the catalyst as a π-complex. It is assumed also that oxidation on a series of catalysts will be more selective the weaker the bond between the π-complex and the catalyst surface.

Several studies have been made on the effect of the chemical nature of a catalyst on its activity and its selectivity in the oxidation of *o*-xylene. Investigation of the catalytic properties of individual oxides of vanadium by a pulse method showed[80] that their chemical composition changed significantly even during a short period in an atmosphere of the reaction mixture, although formation of new phases was not observed. The oxides V_2O_4, V_6O_{13}, and V_3O_7 had closely similar initial specific activities lower than that of V_2O_5 and even lower than that of V_2O_3. With increase in the number of pulses the activity and the selectivity change, abruptly with V_2O_5: after the catalytic properties of the pentoxide have been constant during the first ten pulses, the activity increases rapidly to a new constant value.

Investigation of the phase constitution of a vanadium oxide catalyst corresponding to steady-state oxidation showed[81] that, in air containing 1.1% of *o*-xylene, the catalyst comprised V_2O_5, $V_2O_{4.34}$, and V_2O_4 phases. Electron diffraction established that the $V_2O_{4.34}$ layer was located above the V_2O_4 layer. The appearance of the latter is explained in macrokinetic terms: conditions for reduction of the initial vanadium pentoxide are more severe inside the catalyst grains. With increase in the *o*-xylene concentration to 3.3 mole % the catalyst rapidly loses its activity, being converted almost completely into V_2O_4 (at the edge of the layer V_2O_3 is also detected).

The vanadium catalysts used according to the patent literature in the manufacture of phthalic anhydride from *o*-xylene can be divided into three main groups: vanadium pentoxide alone or with small quantities of additives is applied on relatively non-porous carriers (high-temperature catalysts); vanadium–potassium sulphate catalysts on carriers (silicon and titanium dioxides) resemble those employed for the oxidation of naphthalene (low-temperature catalysts); and mixed vanadium–titanium oxide catalysts (usually on an inert support) have recently found widespread application. High-temperature catalysts are not very selective, but the high temperatures permit large outputs because of the use of very short contact times[9,71,79]. The V_2O_5–K_2SO_4–SiO_2 catalysts possess enhanced selectivity, especially at low degrees of conversion, when the main product is *o*-tolualdehyde[4,63,69,71]. This applies also to vanadium–titanium oxide catalysts[82].

Investigation by Vanhove and Blanchard[82,83] of the effect of composition in the third group of catalysts indicated that specimens containing 12.5 and 89.5 mole % of titanium dioxide are initially the most selective for C_8 products. The latter specimen also possesses the maximum activity per unit mass of the catalyst. The initial selectivities correlate with the activation energies of the isotopic exchange of oxygen[83]. Increasing the degree of conversion of *o*-xylene even up to ~ 100% has little effect on the selectivity for products of degradative oxidation, mainly shifting the distribution of C_8 products towards formation of phthalic anhydride[82]. On the whole this applies also to other types of vanadium oxide catalysts[4,63,69,71,79].

Conversion of *o*-xylene into phthalic anhydride is relatively slight on tin, silver, and copper vanadates, as well as on molybdenum oxide catalysts[66]. Several studies have been made of the individual oxidation of products of the mild oxidation of *o*-xylene on vanadium catalysts[9,71,84–86]. Oxidation of *o*-tolualdehyde on the fused pentoxide[84] yields *o*-toluic acid, phthalide, phthalic anhydride, maleic anhydride, carbon monoxide, and carbon dioxide, with kinetics conforming to Eqn. (9). Power equations have been suggested[71] for the oxidation of *o*-tolualdehyde on a high-temperature vanadium catalyst and on a vanadium–potassium sulphate–silica gel catalyst. On the latter, as in the oxidation of *o*-xylene, methylbenzoquinone was formed. The oxidation of *o*-toluic acid on vanadium pentoxide at 450°C gives[85] phthalic anhydride in 85 mole % yield; the corresponding yield from *o*-xylene under analogous conditions was 67 mole %. The oxidation products from phthalide on a V_2O_5–K_2SO_4–SiO_2 catalyst are phthalic anhydride (92–95% selectivity) and carbon dioxide[71,86].

The properties of non-vanadium catalysts in the oxidation of *o*-xylene have not been adequately investigated. Popova and Kabakova[87] used copper(II) oxide with additions of molybdenum and tungsten oxides at 370–450°C. The rates of overall conversion of *o*-xylene and of formation of *o*-tolualdehyde (with ~ 15% selectivity at 380°C) and carbon dioxide are independent of the concentration of the hydrocarbon but proportional to that of molecular oxygen.

The Reviewer has obtained[88,89] initial specific activities and selectivities for the oxidation of *o*-xylene on titanium, vanadium, molybdenum, manganese, iron, cobalt, nickel, copper, zinc, tin, and chromium oxides, as well as on metallic platinum. An approximate correlation has been established between the specific activity of an oxide and the energy of bonding of oxygen (Fig. 1*c*). The specific activity of metallic platinum exceeded about thousandfold that of oxides with similar energy of bonding of oxygen, which results from the different natures of oxides and metals[19,20].

The initial selectivity for products of mild oxidation is quite high not only on typical catalysts for this process (vanadium pentoxide, molybdenum trioxide) but also on those which under normal conditions catalyse complete oxidation (Co_3O_4, MnO_2, NiO). On the cobalt oxide at 240°C, for example, the initial selectivity for phthalic anhydride is 64% (and for C_8 products 74%).

The reduction of catalysts by *o*-xylene (in experiments on cobalt and iron oxides) takes place at rates closely similar to the rate of catalysis. The gradual decrease in the rate of reduction with time is accompanied by an increase in selectivity for products of mild oxidation. Thu the rules of reduction are qualitatively the same as for vanadium pentoxide (Fig. 4).

If the oxidation of *o*-xylene takes place by mechanism (11), the dependence of the selectivity for *o*-tolualdehyde on the bonding energy for oxygen should obviously be analogous to that already discussed for the selectivity for benzaldehyde in the oxidation of toluene (Eqn. 22). This is indeed the case: an approximate correlation is observed between S_{OTAl} and q_{S} for oxides of transition metals[88,89] (Fig. 2*b*). In contrast to this, no regular relation is found between the selectivity for phthalic anhydride and the bonding energy[88,89]. One reason may be that the intermediate yielding this product may be saltlike, with its heat of desorption (also the activation energy) depending not only on q_{S} but also on the acid–base properties of the surface[45].

Results for the properties of catalysts at low degrees of oxidation both of *o*-xylene[88,89] and also of toluene[50] indicate that no sharp boundary exists under these conditions between catalysts of "complete" oxidation (cobalt, manganese, and nickel oxides) and those of "mild" oxidation (vanadium and molybdenum oxides). Differences between them are apparent with increase in the degree of conversion of the initial hydrocarbon, when further oxidation of the reaction products begins to play an appreciable part. This is accompanied on catalysts of the former type by a sharp increase in the proportion of combustion products, whereas on vanadium pentoxide further oxidation leads to a redistribution of C_8 products (with predominant formation of phthalic anhydride) and in lesser degree to an increase in the yield of products of degradative oxidation[4,63,69,71,79,82]. The resistance of phthalic anhydride to further oxidation on vanadium oxide catalysts largely determines their effectiveness.

Another factor may be that the rate of further oxidation decreases with increase in the oxygen–catalyst bond energy. However, the question then arises why the rate of oxidation of the initial hydrocarbon undergoes a greater change than do the rates of conversion of products of mild oxidation. Indeed, on the assumption that a process takes place by a consecutive scheme

$$R \xrightarrow[O_2]{r_{\mathrm{R}}} \mathrm{RO} \xrightarrow{r_{\mathrm{RO}}} \mathrm{RO_2}$$

and that

$$r_{\mathrm{R}} = k_{\mathrm{R}} P_{\mathrm{R}} \theta, \quad r_{\mathrm{RO}} = k_{\mathrm{RO}} P_{\mathrm{RO}} \theta,$$

it is easy to show that the selectivity for **RO** is

$$S_{\mathrm{RO}} = \left(1 + \frac{k_{\mathrm{RO}}}{k_{\mathrm{R}}} \frac{x}{1-x}\right)^{-1},$$

where x is the degree of conversion of the initial hydrocarbon. With different catalysts at the same degree of conversion the selectivity is evidently governed by the ratio of the reactivities of **R** and **RO**, which are measured by the rate constants k_{R} and k_{RO}. If, for example, the ratio $k_{\mathrm{RO}}/k_{\mathrm{R}}$ is independent of q_{S}, oxides having low bonding energies are more effective catalysts, since the reaction velocity on them will be higher for the same selectivity. However, experience shows that in most cases the selectivity for products of mild oxidation increases with q_{S}, including processes occurring predominantly by a consecutive scheme[90].

5. Oxidation of Acenaphthene, Pseudocumene, and Durene

As with *o*-xylene the structure of these hydrocarbons permits the formation of acid anhydrides by oxidation of methyl groups without degradation of the aromatic ring.

The oxidation of acenaphthene was investigated on vanadium pentoxide alone and with potassium sulphate, on the latter with iron and copper vanadates respectively, and on manganese dioxide (with pumice as carrier) over the range 320–450°C.[91] The chief products of mild oxidation on vanadium catalysts were acenaphthylene and naphthalic anhydride, but on manganese dioxide only acenaphthylene was formed. Increasing the ratio of air to acenaphthene tended to increase the yield of naphthalaldehyde relative to acenaphthylene (on manganese dioxide the proportion of combustion products increased). These results are qualitatively consistent with scheme (11). Oxidation of acenaphthene begins at lower temperatures on manganese dioxide than on vanadium catalysts, but the maximum yield of acenaphthylene—the product of mild oxidation—was lower on the dioxide. The yield of naphthalic anhydride reached 75–80% on the most effective of the catalysts studied[91] (iron vanadate with potassium sulphate). An active catalyst giving an 87% yield of naphthalic anhydride from acenaphthene at 355°C comprised 6% of vanadium pentoxide with 94% of titanium dioxide[92].

The oxidation of pseudocumene on vanadium pentoxide with added silver(I) and tungsten(VI) oxides at 410–420°C produces trimellitic (yield 40%), phthalic (28%), and maleic (11%) anhydrides[93]. A comparative examination of the oxidation of benzene, toluene, *o*-xylene, pseudocumene, and durene on a vanadium–molybdenum–phosphorus oxide catalyst with added sodium and nickel on synthetic corundum shows[93] that the rates of overall conversion of the alkylbenzenes are closely similar, and that the presence of isolated methyl groups in the acid anhydrides formed tends to increase the rate of production of carbon dioxide (the maximum yield of products of mild oxidation is observed with *o*-xylene). A molybdenum–tungsten oxide catalyst (1 : 9) on alundum can be used for the highly selective oxidation of pseudocumene to triformylbenzene[94].

The oxidation of durene was investigated[95-97] on fused vanadium pentoxide, the latter with additives on a carrier, V_2O_5–MoO_3–Al_2O_3, V_2O_5–SnO_2, V_2O_5–P_2O_5–kieselguhr, V_2O_5–K_2SO_4–SiO_2, V_2O_5–SnO_2–P_2O_5, V_2O_5–MnO_2–pumice, and vanadium–potassium catalysts. The best results were obtained on finely crystalline fused vanadium pentoxide: at 430–450°C with 100% conversion the yield of pyromellitic anhydride was 52–55 mole %. The fused pentoxide has been recommended also by other workers[98-100]. The yield of the anhydride is increased[101] by a considerable excess of molecular oxygen above the stoichiometric quantity. Investigation of the individual oxidation on fused vanadium pentoxide of certain products of the incomplete oxidation of durene—pyromellitic and maleic anhydrides, mono- and di-methylmaleic anhydrides, and 3-methyl-, 4-methyl-, and 4,5-dimethyl-phthalic anhydrides—showed[100,102] that the unsubstituted cyclic anhydrides were the most resistant to oxidation. The main reaction products other than oxides of carbon from the oxidation of duroquinone on fused vanadium pentoxide are dimethylmaleic anhydride and acetic acid[103]. Catalysts recommended in the patent literature for the oxidation of durene are V_2O_5–Cr_2O_3,[102] V_2O_5–MoO_3–P_2O_5 on SiC or Al_2O_3,[103] V_2O_5–WO_3–P_2O_5–Na_2O on Al_2O_3,[104] and V_2O_5–Cr_2O_3–Sb_2O_3–SnO_2 on Al_2O_3.[105] On the last catalyst the yield of pyromellitic anhydride at 360°C is 80 mole % (the temperature rises to 590°C during the process).

6. Oxidation of Naphthalene and Methylnaphthalenes

The oxidation of naphthalene on a vanadium oxide catalyst is the first industrial process for the gas-phase production of phthalic anhydride. Other products are naphthaquinone (NQ), maleic anhydride, and oxides of carbon.

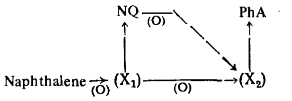
Equation (9) was suggested[2,3] to describe the kinetics of the oxidation of naphthalene on a fluidised bed of a V_2O_5–K_2SO_4–SiO_2 catalyst at 337°C. This was confirmed[106] for low degrees of conversion on the same catalyst at 300–335°C. The chief oxidation products were[106] naphtha-1,4-quinone and phthalic anhydride, with insignificant yields of maleic anhydride and carbon dioxide; naphtha-1,2-quinone was also formed (at most 5% on the content of the 1,4-quinone).

Roiter et al.[10] investigated the kinetics of the oxidation of naphthalene at 330–360°C on a V_2O_5–K_2SO_4–SiO_2 catalyst deposited on glass for degrees of conversion of naphthalene over the range 15–80% in a gradientfree reaction vessel. The equations

$$r_{PhA} = k_{PhA} P_N^0 P_{O_2},$$
$$r_{NQ} = k P_N P_{O_2} / P_{NQ}^{0.6} (1 + b P_N)$$

were suggested for the rates of formation of phthalic anhydride and naphthaquinone. The two reactions were assumed to take place in parallel, on different types of active centres[10].

The Reviewer[16] has attempted to interpret these results[10] by means of a redox model in which the reduction stage is represented by scheme (11). In the present case it can be written



(24)

The intermediate compound X_1 most probably has a quinonoid structure. The formation of such structures is indicated by electron spin resonance results obtained for the interaction of naphthalene with vanadium pentoxide[107]. The structure of X_2 can be regarded as a surface phthalate[77], as mentioned above for the mechanism of the oxidation of *o*-xylene.

The results in Ref.10 are satisfactorily described by Eqn. (9) for the total rate of the process and by Eqn. (12) for the selectivity for naphthaquinone[16]. Closely similar rate constants and activation energies of oxygen adsorption are obtained for catalysts of the same chemical composition, independently of the initial oxidisable hydrocarbon (Table 2), which supports a mechanism based on a two-stage redox model[4].

The above ideas on the mechanism are confirmed by results obtained by Andreikov et al.[108] using a pulse method for the oxidation of naphthalene on a V_2O_5–K_2SO_4–SiO_2 catalyst at 360–380°C. Under these conditions the reaction products were naphthaquinone and phthalic anhydride; irreversible adsorption of naphthalene and its oxidation products was not observed. The composition of the initial catalyst subjected to preliminary oxidation in a stream of air at 400°C (84% V^{5+} + 16% V^{4+}) differed considerably from the steady-state composition (6% V^{5+} + 94% V^{4+}). The latter composition was independent of its mode of attainment: it was the same for preoxidised and prereduced specimens. The high degree of reduction corresponds in terms of the redox model to low surface coverage θ and hence approximately zero order with respect to naphthalene and the first order with respect to molecular oxygen, which is indeed observed experimentally[108].

Comparison of the rates of catalytic oxidation and the reduction of the V_2O_5–K_2SO_4–SiO_2 catalyst by naphthalene, as well as the selectivities of both processes[108], confirms the redox mechanism (Table 3). With increasing reduction of an oxidised catalyst specimen by naphthalene the reaction velocity gradually diminished, with a simultaneous decrease in the selectivity for phthalic anhydride from 85% to 40%. These results are consistent with scheme (24).

Table 2. Rate constants and activation energies of the adsorption of oxygen (corresponding to Eqn. 9) in the oxidation of aromatic hydrocarbons on V_2O_5–K_2SO_4–SiO_2 catalysts.

* Calculated from data in Ref. 16.

A similar comparison of rates of catalysis and reduction on vanadium pentoxide alone and deposited on silica revealed[109] that catalysis was rather more rapid. This was attributed[109] to partial occurrence of the reaction by an associative mechanism. The difference between the rates of catalysis and reduction diminished with rise in temperature (for 18% of the pentoxide on silica at 400°C the rates were almost identical). A similar transition to a stepwise mechanism with rise in temperature was observed[110] for other oxidations, showing that the associative mechanism involves direct participation of surface O^{2-} ions in forming the reaction products, while desorption of the products is facilitated by the presence of O_2^- radical-anions on the surface (these are absent under the conditions of the reduction experiments).

Investigation of the kinetics of the oxidation of naphthalene on vanadium pentoxide alone is complicated by changes in the chemical composition and the phase constitution of the catalyst under the influence of the reaction conditions[111]

Power rate equations were obtained[112] over a narrow range of conditions for the kinetics of the oxidation of naphthalene to individual products. The same workers[113], having taken special measures to diminish the influence of composition changes in the catalyst on the kinetics, found that the rate of formation of phthalic anhydride on coarsely crystalline vanadium pentoxide below 385°C is independent of the naphthalene concentration and proportional to the molecular oxygen concentration, but above 390°C it is proportional to the naphthalene concentration (the dependence of the rate on the oxygen concentration above 390°C was not investigated).

Equation (9) applies to the kinetics of the oxidation of 1- and 2-methylnaphthalenes on several types of vanadium–potassium sulphate–silica gel catalysts[114,115]. The mutual inhibition of the oxidation of naphthalene and methylnaphthalenes in their mixtures was explained[114,115] in terms of a redox mechanism: in the simultaneous oxidation of hydrocarbons the steady-state surface concentration of oxygen is lower than when they are oxidised separately. The rate constants of catalyst oxidation k_{O_2} are the same for different oxidisable hydrocarbons. Decrease in the degree of conversion of methylnaphthalenes[115] is accompanied by increased selectivity for the naphthaldehydes, whose yield at degrees of conversion of 35% and below exceeds the aggregate yield of the remaining products. Such "mildness" of the action of V_2O_5–K_2SO_4–SiO_2 catalysts is evident also, as noted above, in the oxidation of *o*-xylene to *o*-tolualdehyde.

An attempt was made[116,117] to examine the catalytic properties of certain individual oxides of vanadium towards the oxidation of naphthalene under pulse and continuous régimes. The composition of the specimens changed significantly even during the initial pulses (except in the case of vanadium pentoxide, on which the first pulse had hardly any influence). The specific activity sequence obtained $V_2O_{4.34} > V_2O_3 > V_2O_4 > V_2O_5$ (380–415°C) therefore relates to partly modified catalyst compositions. The extreme members of the sequence differ ninefold in specific activity, and by a factor of 13.5 in rate of formation of phthalic anhydride. Below 370°C the oxides V_2O_4 and V_2O_3 change places in the sequence. The activity and the selectivity of the pentoxide remain unchanged for ~ 1 h, in spite of the appreciable change in chemical composition, after which sharp increases are observed in the activity and in the selectivity for phthalic anhydride. Those of the other oxides remained almost unchanged for several hours' operation.

The chemical composition of the catalyst changes initially probably in its surface layers. Thus grains of fused vanadium pentoxide that had functioned in industrial plants for 2½ years were considerably reduced near the surface, whereas in the centre they remained almost unchanged[111]. The average chemical composition of separate fractions of a catalyst that had operated for a long time showed[118] a regular dependence on grain size: the content of V_2O_4 decreased from 90% to 30% between the 0.05-mm and the 0.5-mm fractions.

Vanadium–potassium sulphate systems and fused vanadium pentoxide are used in the manufacture of phthalic anhydride from naphthalene. The composite catalyst is more common though less efficient, since the selectivity for phthalic anhydride is greater thereon[119]. The properties of the mixed catalyst are improved by the continuous or periodic addition of sulphur compounds—sulphur dioxide[120–123], thionaphthen[123,124]—to the reaction mixture.

The role of potassium sulphate has not been adequately elucidated. The view has been expressed that this component diminishes the activity of vanadium pentoxide, while tending to enhance selectivity[119]. Investigation of the phase constitution and the chemical composition of vanadium–potassium sulphate systems indicates the formation of a number of chemical compounds between the pentoxide and potassium sulphate[125–127]. Study of the activity of vanadium–potassium catalysts as a function of the proportions of the components has established[128] the activity sequence

$$K_2O\cdot 4V_2O_5 > K_2O\cdot V_2O_4\cdot 8V_2O_5 > K_2O\cdot 3V_2O_5 \gg 3K_2O\cdot 5V_2O_5 > KVO_3.$$

Tin vanadate is highly active towards the oxidation of naphthalene[129]. A correlation was found[130] in the series of catalysts V_2O_5, V_2O_5–TiO_2, and V_2O_5–SnO_2 between the rate of oxidation of naphthalene and the rate of reduction of the oxides by naphthalene.

7. Oxidation of Anthracene

Anthraquinone is the main product of the oxidation of anthracene on a vanadium catalyst; phthalic anhydride is also formed. The kinetic equation (9) is applicable to oxidation on vanadium(V) oxide–potassium sulphate with iron(III) oxide[131] and with silicon dioxide[7], and on cobalt molybdate on silica gel[8]. Rate equations based on the Langmuir–Hinshelwood model were inconsistent with experimental results[8].

During operation a vanadium–potassium sulphate catalyst undergoes abrupt deactivation[132]. At 370°C this ensues after 10 h, when the degree of conversion falls from 80% to 40%, and the selectivity for anthraquinone from 90% to 40%. The deactivation was attributed[132] to the highly reduced state of the catalyst due to the great reactivity of anthracene. Additions of iron and manganese oxides to the catalytic system improve the stability of the catalyst towards reduction[133].

The chief products of the oxidation of anthraquinone on a vanadium catalyst[134] at 330–410°C are phthalic and maleic anhydrides (proportion of the latter ~ 5%) with hardly any oxides of carbon. On the same catalyst at 350°C anthraquinone is oxidised more slowly than is anthracene by factors of 30–40 and than naphtha-1,4-quinone by factors of 10–15.[134] Since anthracene is far more reactive than naphthalene, it becomes clear why selectivity for anthraquinone can be maintained at a high level far more easily than in the oxidation of naphthalene to naphthaquinone.

8. Oxidation of Phenanthrene

Kinetic investigation of the oxidation of phenanthrene on a V_2O_5–K_2SO_4–SiO_2 catalyst at 330–370°C gave empirical power equations[132,135] for the formation of phenanthra-9,10-quinone, 9-fluorene, the lactone of 2′-hydroxybiphenyl-2-carboxylic acid, 1,2-naphthalic, phthalic, and maleic anhydrides, and carbon dioxide. The rate of oxidation of phenanthrene is less than that of anthracene on the same catalyst; deactivation of the catalyst was not observed[132].

Addition to the reaction mixture of sulphur dioxide (0.04%) improves the yield of phenanthra-9,10-quinone from 3.5% to 25% (44.7% on the phenanthrene that has reacted) in the oxidation of phenanthrene on a V_2O_5–K_2SO_4–SiO_2 catalyst at 383°C.[136]

The oxidation of phenanthrene on fused vanadium pentoxide is accompanied by significant activation of the catalyst after a few hours' operation[137].

IV. CONCLUSION

The published information surveyed, covering a large range of diverse reactions, reveals much in common in the oxidation of aromatic hydrocarbons. The consequences of the generalised kinetic model listed at the end of Section II have found confirmation in many studies. Thus the reactivity of different aromatic hydrocarbons on the same catalyst depends regularly on the energy characteristics of the oxidisable molecules (ionisation potentials[72,132], carbon–hydrogen bond energies[72]). As an example Fig. 5 illustrates the relation[72] between rate constants k_R found[4,22,46,106] by means of Eqn. (9) and the corresponding energy parameters.

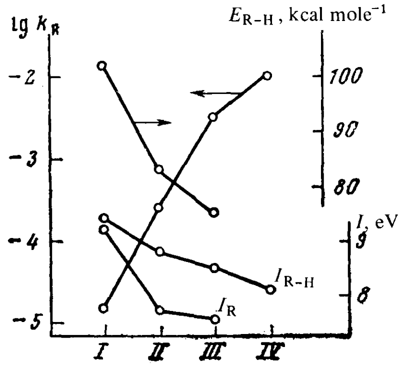

Figure 5. Variation of logarithm of rate constant k_R (with V_2O_5–K_2SO_4–SiO_2 catalyst[4,22,46,106]), R–H bond energy E_{R-H}, ionisation potential of initial molecule I_{R-H}, and ionisation potential of R· radical I_R. in a series of aromatic hydrocarbons: I) benzene; II) toluene; III) *o*-xylene; IV) naphthalene.

The above kinetic model obviously contains several simplifications. A more rigorous approach would take into account the non-uniformity of the catalyst surface. It is also possible that more than one oxygen atom is involved in individual primary stages (Eqns. (12)–(19) were deduced on the assumption that a single surface oxygen atom was involved in the oxidation stages). A further possibility is that, owing to an appreciable contribution by an associative mechanism[90,109,110], the view that the stages of reduction and oxidation of the catalyst take place independently may in individual cases (especially at low temperatures) be inadequate for interpreting the kinetic data.

Little experimental investigation has been undertaken on the reasons for the inhibiting effect sometimes exhibited by reaction products. A possible cause may be competition between oxidisable substances for available oxygen[18]. Inhibition may be due also to blocking of the surface by organic reactants. It is difficult to distinguish these two effects without detailed kinetic investigation. In many studies inhibition has been deduced from the dependence of the rates of formation of individual products on the concentration of the oxidisable substance, which is varied by changing the time of contact. Under these conditions the formal order with respect to the oxidisable substance is abnormally high, which is regarded as indicating inhibition. However, the latter may be apparent, since with increase in the period of contact not only the concentration of reaction products but also the probability of their further oxidation increases, so that the observed order may exceed the true value. In this connection it is noteworthy that, with the above experimental procedure, the formal reaction orders are always higher for products that are less oxidised and hence capable of further oxidation (independently of the nature of the initial oxidisable compound)[71,86,-111,115,132].

Vanadium catalysts—the most widely used for the oxidation of aromatic hydrocarbons—are highly active towards their degradative oxidation. Many of the products detected under mild conditions therefore undergo further transformation. However, the chain of such conversions is terminated or strongly retarded if organic acid anhydrides are formed. High yields of the latter can always be obtained if the initial oxidisable molecule contains a chain of at least four carbon atoms that includes an unsaturated bond (aromatic hydrocarbons, butenes, pentenes, heterocycles, etc.).

Anthraquinone is also comparatively resistant to oxidation on vanadium catalysts, which is responsible for its high yield from the oxidation of anthracene. Naphthaquinone and especially benzoquinone are less stable. The decrease in the yield of quinones in the sequence—anthracene, naphthalene, benzene—is intensified also by the fall in reactivity of the initial hydrocarbon in the same sequence. Formation of quinonoid structures probably precedes oxidative degradation of the aromatic ring. In the case of alkylated hydrocarbons this process competes with oxidation of the alkyl groups. This may be why, in the oxidation of *o*-xylene on vanadium catalysts, a considerable yield of oxides of carbon is observed (as noted above, benzoquinone is unstable). Intermediate formation of quinonoid structures takes place also in the oxidation of naphthalene, but, in contrast to the oxidation of *o*-xylene, they may be precursors of phthalic anhydride, which is stable towards further oxidation; and smaller quantities of carbon dioxide are obtained from naphthalene than from *o*-xylene on the same catalysts[119].

Catalysts having the same chemical composition show largely similar behaviour in the oxidation of different aromatic compounds. Thus vanadium pentoxide undergoes partial reduction during the reaction, with the formation of lower vanadium oxides as separate phases. The resulting catalyst is more active and more selective than the initial system, independently of the nature of the oxidisable aromatic hydrocarbon (benzene[27], *o*-xylene[80], naphthalene[116,-117], phenanthrene[137]). The great activity of vanadium pentoxide alone is often used to obtain a high output of a desired product of mild oxidation, despite a considerable loss of the initial hydrocarbon by combustion.

Vanadium–potassium sulphate systems are characterised by low outputs, but possess enhanced selectivity. The mildness of the action of such catalysts is especially clearly shown at not too high degrees of conversion of the oxidisable substance, when products of the mildest oxidation predominate—aldehydes from *o*-xylene[4] and methylnaphthalenes[114,115], quinones from naphthalene[10,106] and anthracene[132].

The Reviewer has enumerated certain general features of the selective catalytic oxidation of aromatic hydrocarbons in order to emphasise the interrelationship of mechanism, kinetics of various reactions, and selective action of various catalytic systems. This should facilitate future discussion of new experimental results concerning specific reactions.

Methods for the Synthesis of Complexones—Aminopolyacetic Acids

V.G.Yashunskii and O.I.Samoilova

Methods for the synthesis of "true" complex-forming agents containing one or several iminodiacetic acid groups are examined and discussed.
The bibliography includes 203 references.

CONTENTS

I. INTRODUCTION

Among organic complex-forming agents, one of the most important places is occupied by polyaminopolyacetic acids—the so called complexones derived from iminodiacetic acid. Compounds of this series are capable of interacting with almost all metal cations, forming chelate complexes readily soluble in water. By virtue of these properties, complexones have found applications in various branches of science and engineering, agriculture, biology, and medicine.

Complexones are widely used as water softening agents[1], for example, in the leather, textile, and food industries and in photography. Complexometry[2], an analytical procedure based on the use of complexones whereby almost all metals can be determined quantitatively, has been developed extensively and is widely used in analytical chemistry. The employment of complexones for the separation of cations of elements having similar properties (particularly lanthanides) and for obtaining them in a pure form has become very important under laboratory and industrial conditions[3]. Complexones have proved to be extremely valuable in power engineering, primarily in nuclear power engineering as agents for the washing and passivation of the equipment, where they are used as such or in the form of compositions[4,5].

The ability of complexones to bind strongly heavy metal ions is used to inhibit the oxidation processes catalysed by these cations, which has served as a basis for the application of complexones as stabilisers and antioxidants, particularly in the chemical and pharmacological industries[6,7], biology, and preparative organic chemistry. The ability of complexones to form stable water-soluble complexes with metals (particularly those important for plants) led to their use as agents in the fight against chlorosis in certain agricultural crops[8]. Some complexones, for example ethylenediaminetetra-acetic and diethylenetriaminepenta-acetic acids, have found application as medicinal agents accelerating the elimination from the organism of toxic metals, including radioactive metals[9,10].

More than 30 years have elapsed since the first, parent substances of the class of complexones—nitrilotriacetic and ethylenediaminetetra-acetic acids—were obtained. During this period, a large number of similar compounds have been synthesised and investigated, as can be seen from the extensive monograph, review, periodical, and patent literature. Particular attention has been devoted to the study of the complex-forming capacity and practical applications of complexones. The problems of the synthesis and methods for the preparation of polyaminopolyacetic acids are dealt with in a number of reviews[11–14], which are clearly obsolete, and there is a short section in a recently published monograph by Dyatlova et al.[15]

The present review deals with methods for the preparation of only the "true" complexones, i.e. compounds containing one or several iminodiacetic acid groups in the molecule.

There are several ways of synthesising complexones, which can be divided into three groups. The methods of the first group are based on the reactions of various mono- or poly-amines with halogenoacetic acids or formaldehyde and cyanides, which may be combined by the term "carboxymethylation reaction". The second group embraces methods for the preparation of complexones in which the starting material is iminodiacetic acid or its esters. The third group comprises procedures for the preparation of complexones by the modification of the structural analogues or derivatives of iminodiacetic acid as well as other less common procedures.

II. THE CARBOXYMETHYLATION REACTION

This method is most widely used in the synthesis of complexones, since it is based on the employment of fairly readily available amines as the starting materials. The method for the synthesis of complexones by treating amines with halogenoacetate esters followed by hydrolysis of the esters [formed] is closely related.

The "indirect" carboxymethylation reaction—cyanomethylation with simultaneous or subsequent hydrolysis of the nitrile groups—has found fairly extensive applications in the synthesis of complexones.

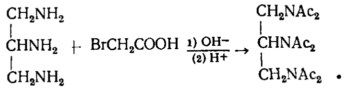
1. Alkylation of Amines by Monohalogenoacetic Acids

The "direct" carboxymethylation reaction is frequently used to prepare complexones under laboratory and industrial conditions. It takes place in accordance with the following mechanism:

$$\mathrm{R{-}NH_2 + HalCH_2COOH \xrightarrow{OH^-} RN(CH_2COO^-)_2 \xrightarrow{H^+} RNAc_2}, \qquad (\mathrm{Ac = CH_2COOH})$$

The reaction consists in the treatment of the amine by a halogenoacetic acid in an alkaline medium. At the end of the reaction, the salt formed is converted into the complexone by acidification.

The carboxymethylating agent most frequently employed is the readily available monochloroacetic acid, which reacts with aliphatic and aromatic mono-, di-, and poly-amines, forming complexones in fairly high yields. In some cases, when the reaction with chloroacetic acid does not proceed, or does not proceed satisfactorily, monobromoacetic acid is used. Thus, when 1,2,3-triaminopropane was treated with chloroacetic acid, the corresponding hexa-acetic acid could not be obtained; the complexone (I) was obtained in a low yield by the reaction of the triamine with bromoacetic acid[16]:

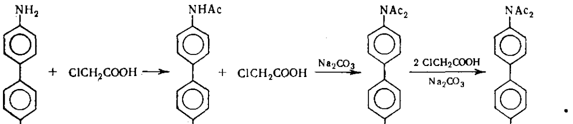


$$\begin{matrix}\mathrm{CH_2NH_2}\\ |\\ \mathrm{CHNH_2}\\ |\\ \mathrm{CH_2NH_2}\end{matrix} + \mathrm{BrCH_2COOH} \xrightarrow[(2)\ \mathrm{H^+}]{1)\ \mathrm{OH^-}} \begin{matrix}\mathrm{CH_2NAc_2}\\ |\\ \mathrm{CHNAc_2}\\ |\\ \mathrm{CH_2NAc_2}\end{matrix}\ .$$

(I)

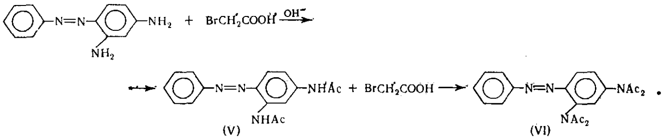
Much higher yields were obtained in the alkylation of 1-phenylethylenediamine and racemic 1,2-diphenylethylenediamine with bromoacetic acid than in the reaction with chloroacetic acid[17]. It follows from the literature data that bromoacetic acid is most frequently used for the carboxymethylation of aromatic amines[18–20]. The use of iodoacetic acid has also been reported[21]. The employment of iodide salts as additives in conjunction with chloroacetic acid, which leads to a more complete and rapid carboxymethylation reaction, has also been described[16,22]. For example, it has been shown[22] that the rate of reaction of aniline with chloroacetic acid increases by approximately 30% in the presence of potassium iodide.

For more complete substitution of the hydrogen atoms of the amino-groups, an excess of halogenoacetic acid, varying in the range 20–100% relative to the stoichiometric amount, is always used. The excess alkylating agent accelerates the reaction, ensures exhaustive carboxymethylation, and "meets the requirement" of the obligatory accompanying side reaction—the hydrolysis of the halogen in the halogenoacetic acid. When a deficiency of halogenoacetic acid is employed, it is possible to isolate products of the incomplete substitution of the amino-groups. Thus when benzidine is heated with one mole of chloroacetic acid in the absence of a condensing agent, benzidinemonoacetic acid (II) is formed[23]. When the reaction is carried out with two moles of the acid in the presence of sodium carbonate, the *NN*-diacetic acid (III) is obtained. On further treatment with chloroacetic acid and Na_2CO_3, the latter yields the tetra-acetic acid (IV):



(II) (III) (IV)

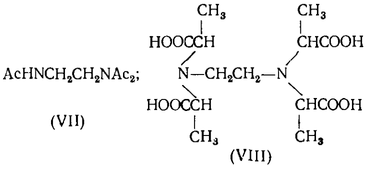
Crysoidinediacetic acid (V) was isolated as an intermediate when crysoidine was treated with bromoacetic acid in molar proportions of 1:6. The corresponding tetra-acetic acid (VI) was obtained by its reaction with bromoacetic acid[25]:



(V) (VI)

On carrying out the reaction of ethylenediamine with chloroacetic acid in molar proportions of 1:3 at a low temperature, Blackmer and Hamm[24] isolated ethylenediaminetriacetic acid (VII) from the reaction mixture in 36% yield and identified it in the form of the cobalt complex. The attempts to isolate this triacetic acid by other procedures proved unsuccessful[25,26]. When a large excess of the halogenoacetic acid is introduced into the carboxymethylation reaction, the isolation and purification of the final product may be hindered.

Apart from halogenoacetic acids, α-halogenopropionic acids may be used to synthesise complexones. Thus ethylenediaminetetra-(α-propionic) acid (VIII) was isolated in 15% yield after the reduction of ethylenediamine and α-chloropropionic acid[27]:



$AcHNCH_2CH_2NAc_2$; (VII)

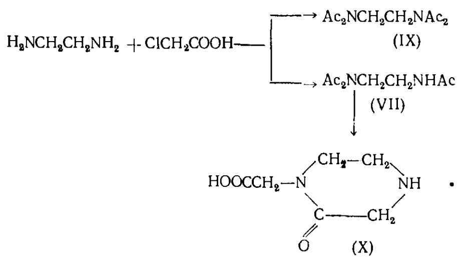
$(HOOCCH(CH_3))_2N-CH_2CH_2-N(CH(CH_3)COOH)_2$ (VIII)

Together with the tetra-acetic acid (VII), di- and tri-substitution products were isolated from the reaction mixture, which indicates steric hindrance to exhaustive alkylation.

The carboxymethylation reaction is always carried out in the presence of bases in order to neutralise the initial halogenoacetic acid, capable of protonating the amine, and to prevent the protonation of the amino-groups during the reaction as a result of the liberation of the proton during alkylation. The protonated amino-group is incapable of reacting with the electrophilic alkylating agent. The use of a neutralising and condensing agent is particularly important in the carboxymethylation of aliphatic amines, since aromatic amines are protonated with much greater difficulty, being much weaker bases. Solutions of sodium hydroxide are frequently used as the condensing agent in the carboxymethylation of aliphatic and aliphatic-aromatic amines. The reaction is carried out at a constant pH (10–11) maintained by the gradual addition of alkali. The employment of sodium carbonates in the carboxymethylation of ethylenediamine has been described[28].

Since the reactions of aromatic and heteroaromatic amines with halogenoacetic acids are carried out at lower pH values (8–10), alkali metal carbonates[28-30] and even magnesium oxide[31] are frequently used together with the alkali. In a few instances, for example in the carboxymethylation of *p*-phenylenediamine[32], the reaction is carried out in the absence of a condensing agent.

As a rule, the alkylation with a halogenoacetic acid is performed in an aqueous medium, but, when amines readily soluble in water are to be alkylated, a solvent miscible with water is sometimes added, mainly acetone[33] and alcohol[34-36]. Several examples of the carboxymethylation reaction using aqueous suspensions of amines have been described[37,38]. The temperature and duration of the reaction are as a rule related. The carboxymethylation of aliphatic and aliphatic-aromatic amines proceeds fairly rapidly (3–10 h) at 40–95°C. An increase of temperature promotes a more complete substitution of the nitrogen atoms, but side reactions are intensified at the same time. A decrease of temperature requires an appreciable increase of the reaction time and incomplete substitution products are then detected in the reaction mixture together with the fully carboxymethylated amines. Genik-Sas-Berezowsky and Spinner[39] investigated in detail the reaction of ethylenediamine with chloroacetic acid at room temperature. After allowing the reaction system to stand for 8 days, they isolated a complex mixture of products consisting largely of ethylenediaminetetra-acetic acid (IX) and ethylenediaminetriacetic acid (VII); the latter cyclised during the reaction to the lactam (X):



$H_2NCH_2CH_2NH_2 + ClCH_2COOH \rightarrow Ac_2NCH_2CH_2NAc_2$ (IX)

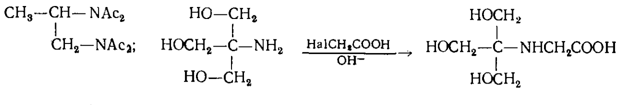
$\rightarrow Ac_2NCH_2CH_2NHAc$ (VII) $\rightarrow$ (X)

On the other hand, it has been shown[40] that, when racemic propylenediamine is heated with chloroacetic acid, the expected tetra-acetic acid (XI) is formed in an insignificant yield, while the reaction carried out in the course of 6 days at 20°C gives an 82% yield of the complexone (XI).

The carboxymethylation of aromatic amines is usually carried out at a higher temperature (of the order of 80–110°C) in order to increase the reaction rate. The duration of the process does not then exceed 4–10 h.

The main reaction, the alkylation of the amines to synthesise complexones by direct carboxymethylation, is to a greater or lesser extent accompanied by side processes, which may have a significant influence on the yield and purity of the final products. The main secondary and competing reaction is the hydrolysis of the halogenoacetic acid in an alkali medium, which reduces the concentrtion of the alkylating agent. This reaction, occurring simultaneously with the main process, is promoted by an increase of temperature and of alkalinity. Together with the hydrolysis of the halogenoacetic acid, the carboxymethylation reaction may involve other side processes, for example the formation of incomplete carboxymethylation products. Apart from temperature and the insufficiency of the alkylating agent, the degree of formation of these side products may be influenced by the structural characteristics of the amines, preventing their exhaustive methylation at the amino-group.

In the carboxymethylation of tri(hydroxymethyl)aminomethane (XII) with chloro- and bromo-acetic acids, it was not possible to introduce two acetic acid residues into the amino-group[41] despite the modification of the reaction conditions; only the monocarboxymethylation product, namely tri(hydroxymethyl)sarcosine (XIII), was always isolated from the reaction mixture:

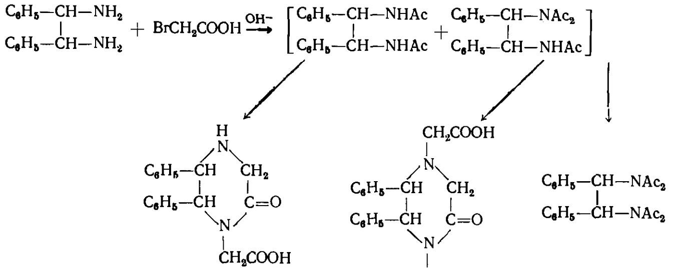


$CH_3-CH(NAc_2)-CH_2-NAc_2$; (XI)

$(HOCH_2)_3C-NH_2 \xrightarrow[OH^-]{HalCH_2COOH} (HOCH_2)_3C-NHCH_2COOH$

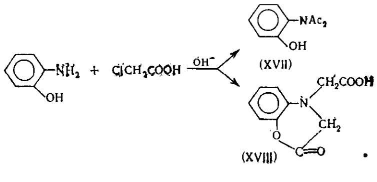
(XII) (XIII)

It has been observed[17] that, in contrast to racemic 1,2-diphenylethylenediamine, the meso-analogue reacts with bromoacetic acid with much difficulty, forming only traces of the tetra-acetic acid (XIV). In this case the main reaction products were the lactams (XV) and (XVI), formed by the cyclisation of the products of the incomplete carboxymethylation of the diamine:



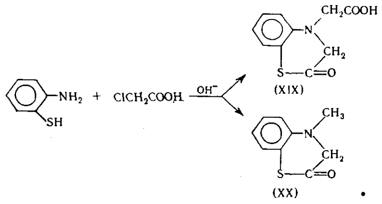
(XV) (XVI) (XIV)

The carboxymethylation reaction may be in many instances complicated by the presence in the molecule of the initial amine of other functional groups or groupings. Thus, when *o*-aminophenol is treated with chloroacetic acid at pH 8–10, the δ-lactone (**XVIII**) is formed together with *o*-hydroxyphenyliminodiacetic acid (**XVII**):[42]



The extent of the latter reaction may be reduced by adding potassium iodide to the reaction mixture[22], which makes it possible to perform the process at a lower pH and reduce thereby the reactivity of the phenolic hydroxyl.

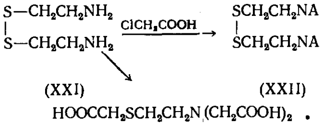
The carboxymethylation of *o*-aminothiophenol proceeds in a more complex manner. On treatment with chloroacetic acid (60°C, pH 8–10), the thiolactone (**XIX**) was isolated from the reaction mixture together with its decarboxylation product (**XX**):[42]



In the amino-β-naphthol series, it was impossible to obtain the corresponding complexone, since naphthoxy-acids are formed under the conditions of "direct" carboxymethylation.

In order to prevent the possible alkylation of the glycolic hydroxyls in 2,3-dihydroxypropylamine, the latter was carboxymethylated at pH < 9 at room temperature[41].

When di(aminoethyl) disulphide (XXI) was carboxymethylated under the conditions leading to the formation of complexones from aliphatic diamines, the expected tetra-acetic acids (XXII) were not isolated[44]. The only reaction product was the triacetic acid (XXIII), the formation of which takes place, according to the authors, as a result of the cleavage of the disulphide linkage in the alkaline medium and alkylation of the nitrogen and sulphur atoms:



(XXI) (XXII)

$HOOCCH_2SCH_2CH_2N(CH_2COOH)_2$.

(XXIII)

This process could not be prevented even by employing oxidising agents. Only when the reaction was carried out in a neutral medium was the previously described[45] tetra-acetic acid (XXII) obtained, but its yield was low.

The mechanism and kinetics of the carboxymethylation reaction have been studied in relation to the interaction of aqueous ammonia with chloro- and bromo-acetic acids[46]. In the first place, it was observed that the rate of reaction of bromoacetic acid with ammonia at 60°C is 26–40 times faster than with the chloroacetic acid. It was found[46] that the reaction proceeds consecutively via an S_N2 mechanism and its maximum rate is reached at pH 10–11. It has been shown that glycine reacts approximately ten times more vigorously with chloroacetic acid than does ammonia:

$$NH_3 \xrightarrow{HalCH_2COOH} H_2NCH_2COOH \xrightarrow{HalCH_2COOH} HN(CH_2COOH)_2 \xrightarrow{HalCH_2COOH} N(CH_2COOH)_3 .$$

Continuing the investigation of the mechanism of the carboxymethylation reaction, Temkina[22] confirmed the consecutive mechanism of the process in relation to methylamine and aniline. She found that the rate-limiting stage of the reaction is the addition of the first carboxymethyl group.

The "direct" carboxymethylation reaction is applicable to a wide variety of amino-compounds. The reaction of chloroacetic acid with ammonia proceeds smoothly and leads to the formation of nitrilotriacetic acid (NAc_3). Under the same conditions, hydrazine leads to hydrazine-*NN*-diacetic acid[30]; semicarbazide-*NN*-diacetic acid ($NH_2CONHNAc_2$) is obtained similarly[30].

A series of *N*-alkyl-derivatives of iminodiacetic acid, from the methyl derivatives to the $C_{15}H_{31}$ analogue, have been synthesised by the "direct" carboxymethylation reaction[35,47].

The preparation of certain derivatives of alkyliminodiacetic acid (XXIV, a – f), containing functional groups in the alkyl chain, by the reaction of the corresponding substituted alkylamines with chloro- or bromo-acetic acid, has been described[48–52].

The "direct" carboxymethylation method has been used successfully to synthesise cyclohexyl derivatives (XXV, a and b) [42,53], benzyl derivatives (XXVI, a –g) [50,54–57], and phenylethyl derivatives (XXVII) [50,58,59] of iminodiacetic acid and also to synthesise heterocyclic complexones (XXVIII, a – i) [33,37,60–63] with a single iminodiacetic acid group. These complexones are listed below (together with the appropriate references):

$HOCH_2CH_2NAc_2$

(XXIV a)[48,49]

$HOOCCH_2CH_2NAc_2$

(XXIV b)[50,51]

$$\underset{NAc_2}{HOOC—CHR}$$

(XXIV) c—R=CH_3
d—R=iso-C_4H_9[50]

$HO_3SCH_2NAc_2$

(XXIV e)[51,52]

$HO_3SCH_2CH_2NAc_2$

(XXIV f)[51]

(XXV) a—$n=0$[53]

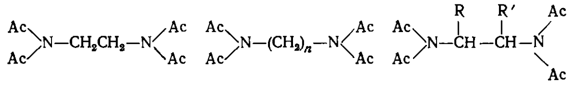
(XXVIII i)[37,63]

A large number of examples of the synthesis of complexones by the direct carboxymethylation of aliphatic amines have been described in the periodical and patent literature. Ethylenediaminetetra-acetic acid (EDTA)[64,65], its homologues with hydrocarbon chain lengths ranging from 3 to 10 (XXIX) [54,66,67], as well as derivatives with methyl [(XI) [40] and (XXX) [68]] and aryl [(XIV) [17] and (XXXI) [69]] substituents in the ethylene chain:



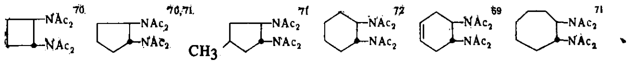
EDTA

(XXIX) $n=3\text{—}10$

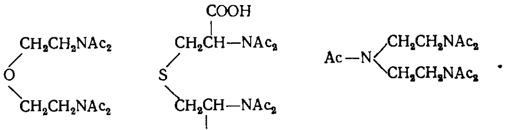
(XXX) $R=R'=CH_3$;

(XXXI) $R=Ph$, $R'=H$.

A series of cyclic analogues of EDTA have been obtained by the condensation of alicyclic 1,2-diamines with chloro- and bromo-acetic acids[69-72]:



The direct carboxymethylation method has found extensive applications in the synthesis of analogues of ethylenediaminetetra-acetic acid containing heteroatoms or functional groups in the hydrocarbon chain. In contrast to di(aminoethyl) disulphide (see above), the carboxymethylation of the corresponding ether to (XXXI) [72] and the sulphide with carboxy-groups to (XXXIII)[74] proceeds normally:

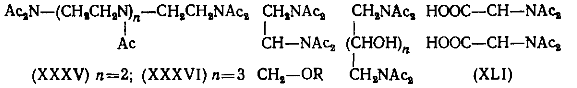


(XXXII)

(XXXIII)

(XXXIV)

The EDTA analogues with amino-groups in the hydrocarbon chain have attracted much attention in view of their high complex-formation capacity. The direct carboxymethylation method has proved extremely convenient for the synthesis of diethylenetriaminepenta-acetic acid (XXXIV) [74]—one of the most effective complexones, which has found applications in engineering, medicine, and agriculture[5]. Its higher homologues triethylenetetraaminehexa-acetic acid (XXXV) and tetraethylenepentaaminehepta-acetic acid (XXXVI) have been synthesised by the same method[75]. *N*-Substituted diethylenetriaminetetra-acetic acids (XXXVII) have been obtained in fairly high yields from the corresponding diamines and chloroacetic acid[76-79]:

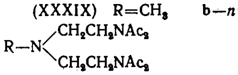


(XXXV) $n=2$; (XXXVI) $n=3$

(XXXVIII) $R=H$
(XXXIX) $R=CH_3$

(XL) a—$n=2$
b—$n=4$

(XLI)



(XXXVII)

$R=C_4H_9$; $C_6H_5CH_2$; C_8H_{17}
$HOCH_2CH_2$; $HOOCCH_2CH_2$

The carboxymethylation of di- and tri-amines containing hydroxy-groups in the hydrocarbon chain takes place smoothly. 2,3-Diamino-1-hydroxypropanetetra-acetic acid (XXXVIII) and 2,3-diamino-1-methoxypropanetetra-acetic acid (XXXIX)[80], racemic 1,4-diamino-2,3-dihydroxybutanetetra-acetic acid and its *meso*-form (XLa) [81-83], D-*manno*-1,6-diamino-1,6-dideoxy-2,3,4,5-tetrahydroxyhexanetetra-acetic acid (XLb) [84,85], and *N*-hydroxyethyldiethylenetriaminetetra-acetic acid (XXXVII, $R = HOCH_2CH_2$) [86] have been obtained by the same method. Side reactions involving the hydroxy-groups were never observed under these conditions. The formation of the EDTA analogue (XLI) containing carboxy-groups at the carbon atoms in the chain has been described[87] and 1,2,3-triaminopropanehexa-acetic acid, mentioned above, has been synthesised by the same method.

A large number of examples of the preparation of aryliminodiacetic acids with various substituents in the benzene ring [compounds (XLII) and (XLIII)] have been described[18,20,42,88-90]. The complexones with the appropriate references are indicated below:

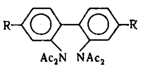
(XLII)

(XLIII)

a—$R=H$; *o, m, p*-CH_3; *o, m, p*-CH_3O; *p*-C_2H_5O; *o, p*-Cl[89]
b—$R=$*o, m, p*-OH[88,90]
c—$R=$*o*-$COOH$[88]
d—$R=$*o*-AsO_3H_2[18].

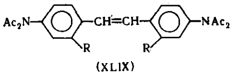
a—$R=COOH$; $R'=OH$[90]
b—$R=CH_3$; $R'=CH_3O$[20]

o-, *m*-, and *p*-Phenylenediaminetetra-acetic acids (XLIV) [91]; (XLV, a and b) [23,92,93], and (XLVI, a and b) [21,22,94], a series of diaminobiphenyltetra-acetic acids (XLVII) [34] and (XLVIII) [25,95] and diaminostilbenetetra-acetic acids (XLIX) [38,96], as well as a complexone of the triphenylmethane series (L) [97] have been synthesised by the same method:

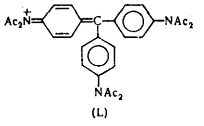


(XLVII)
R = H, CH$_3$, OH, CH$_3$O, NH$_2$

(XLVIII)
R = H, 2-OH, 2-COOH, 2-COOCH$_3$:
2-SO$_3$H, 3-CH$_3$, 3-CH$_3$O, 3-C$_2$H$_5$O

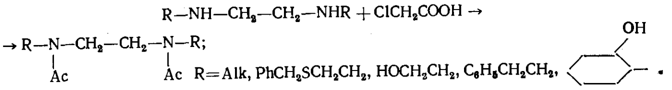


(XLIX)
R = H, SO$_3$H



(L)

The carboxymethylation reaction has been used to prepare analogues of ethylenediamine-*NN′*-diacetic acid with various substituents at the nitrogen atom[58,98-100]:



The simultaneous carboxymethylation and arylalkylation or arylation of ethylenediamine, resulting in the formation of EDTA analogues of type (LI), has been described[101]:

$$\underset{\mathrm{Ac}}{\mathrm{R{-}N}}\mathrm{CH_2CH_2NAc_2} \qquad \underset{\mathrm{Ac}}{\mathrm{R{-}N}}\mathrm{CH_2CH_2}\underset{\mathrm{Ac}}{\mathrm{N}}\mathrm{CH_2CH_2NAc_2}$$

(LI) (LII)

$R{=}XC_6H_4$; $XC_6H_4CH_2$; $X{=}H, Cl, CH_3$ $R{=}C_8H_{17}$; $C_{15}H_{21}$; $C_{12}H_{25}$; $C_{14}H_{29}$; $C_{16}H_{33}$. p-ClC_6H_4

Similar compounds have been synthesised also from diethylenetriamine, for example (LII)[102,103].

In many cases halogenocarboxylate esters are used instead of the acids themselves. This makes it possible to carry out the reaction in a non-aqueous medium in the absence of alkalis. The iminodiacetate esters thus obtained are converted into the corresponding complexones by hydrolysis:

$$R{-}NH_2 + XCH_2COOAlk \rightarrow RN(CH_2COOAlk)_2 \rightarrow RNAc_2.$$

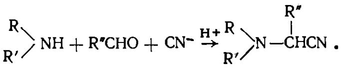
The reaction is carried out as a rule with ethyl monobromoacetate in the absence of a solvent or in alcohol in the presence of potassium carbonate[48]. The esters formed can be purified by distillation. This fact and also the mild reaction conditions make this method very convenient for the synthesis of aliphatic complexones in those cases where an aqueous alkaline medium must be avoided.

2. The Cyanomethylation Reaction

Another method for the carboxymethylation of amines is based on the cyanomethylation reaction. Several versions of this method are used in the synthesis of complexones.

1. Cyanomethylation in an acid medium with formation of the corresponding iminodiacetonitriles and their subsequent conversion into the acids.
2. Cyanomethylation in an alkaline medium with simultaneous hydrolysis of the nitrile groups.
3. Cyanomethylation with the aid of glycolonitrile followed by hydrolysis of the nitrile formed.

Cyanomethylation in an acid medium. This reaction has been known for a long time as the "Strecker reaction"[104] and is widely used in the synthesis of a large variety of aminoacetonitriles[105]. It is based on the reaction of primary or secondary aliphatic amines with aldehydes and hydrocyanic acid. The latter may be replaced by alkali metal cyanides with added acid:

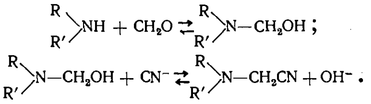


Complexones are synthesised by a specific example of this reaction—the reaction of primary mono-, di-, and poly-amines with formaldehyde and hydrocyanic acid (or its salts in an acid medium) with substitution of both hydrogen atoms in the amino-group by cyanomethyl residues:

The reaction is usually carried out in an aqueous medium at 0–20°C for several hours at pH 1–6.5. Since the use of liquid hydrocyanic acid is relatively inconvenient, sodium or potassium cyanides are usually employed and the added acids are hydrochloric, sulphuric, phosphoric, acetic, or formic acids[106].

The aminonitriles formed in the reaction may be isolated from the reaction mixture and hydrolysed. When water-soluble nitriles are obtained, they are converted into acids without isolation. The hydrolysis of iminodiacetonitriles proceeds most smoothly on heating with alkali or barium hydroxides. Inorganic acids are used for this purpose less frequently.

According to current ideas, the cyanomethylation of amines proceeds via a stage involving the formation of hydroxymethyl derivatives:

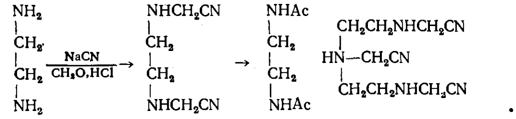


Di(cyanomethyl) derivatives are probably formed in a similar manner.

The introduction of a single cyanomethyl residue into both aliphatic and aromatic primary amines proceeds readily and smoothly. However, the substitution of a second hydrogen atom by the cyanomethyl group is much more difficult, owing to the sharp reduction of the basicity of the monocyanomethylated amino-group[107].

The cyanomethylation reaction is therefore most widely used in the synthesis of aliphatic complexones. However, in this case too the reaction may be stopped at the first substitution stage. The resulting monocyanomethylamines are converted after hydrolysis into complexone analogues—glycine derivatives. In this respect the cyanomethylation reaction has an advantage over direct carboxymethylation, which cannot as a rule yield amine monosubstitution products.

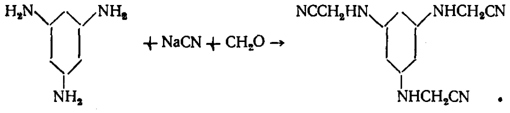
When ethylenediamine is treated with two moles of sodium cyanide and formaldehyde in hydrochloric acid, ethylenediamine-*NN′*-di(acetonitrile) (LIII) is obtained in a high yield and after hydrolysis gives rise to ethylenediamine-*NN′*-diacetic acid (LIV), which is the starting material for the synthesis of complexones[39,108-110]:



(LIII) (LIV) (LV)

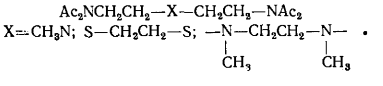
The *NN′N″*-tricyanomethyl derivative (LV) has been synthesised by treating diethylenetriamine with three moles of hydrocyanic acid and formaldehyde[110].

Having treated *cis*, *cis*-1,3,5-triaminocyclohexylamine with sodium cyanide in alcoholic hydrochloric acid, Zompa and Shindler[111] obtained the corresponding tri(aminoacetonitrile) (LVI):



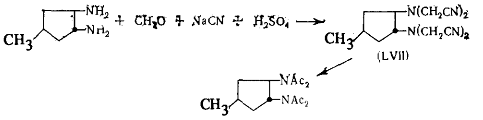
(LVI)

A series of iminodi(acetonitrile) derivatives with aliphatic[45,48] and aliphatic-aromatic[111] substituents have been obtained by the cyanomethylation reaction in an acid medium. Several examples of the synthesis by this method of cyanomethylated di-, and poly-amines, which were converted by hydrolysis into complexones of the type of ethylenediaminetetra-acetic and diethylenetriaminepenta-acetic acids[112-114], including tetra-acetic acids containing a hydroxy-group [compound (XXXVIII)][80] or heteroatoms [(compound (LVII)] in the chain joining the two imino-diacetic acid groups have been described[45]:



$$Ac_2NCH_2CH_2—X—CH_2CH_2—NAc_2$$
$$X{=}CH_3N;\ S—CH_2CH_2—S;\ —\underset{\displaystyle CH_3}{N}—CH_2CH_2—\underset{\displaystyle CH_3}{N}— \ .$$

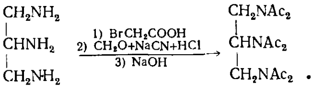
"Acid" cyanomethylation is used in those cases where the synthesis of aliphatic complexones by "direct" carboxymethylation involves difficulties. Thus, when *trans*-1,2-diamino-3-methylcyclopentane was treated with chloroacetic acid, the corresponding tetra-acetic acid could not be isolated[71]. The cyanomethylation of this diamine gave a 32% yield of the tetranitrile (LVII), which was then hydrolysed to *trans*-1,2-diamino-3-methylcyclopentanetetra-acetic acid (LVIII):



(LVII)

(LVIII)

It was already mentioned above that, when 1,2,3-triaminopropane is treated with bromoacetic acid, the corresponding hexa-acetic acid (LIX) is formed in a low yield[16]; the authors succeeded in synthesising this complexone in 84% yield by treating the reaction mixture (after carboxymethylation) with formaldehyde and sodium cyanide in an acid medium and subsequent hydrolysis:



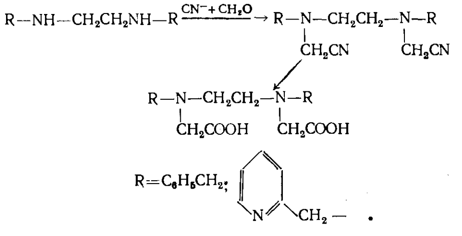
$$\begin{array}{l} CH_2NH_2 \\ | \\ CHNH_2 \\ | \\ CH_2NH_2 \end{array} \xrightarrow[3)\ NaOH]{1)\ BrCH_2COOH \quad 2)\ CH_2O+NaCN+HCl} \begin{array}{l} CH_2NAc_2 \\ | \\ CHNAc_2 \\ | \\ CH_2NAc_2 \end{array} .$$

(LIX)

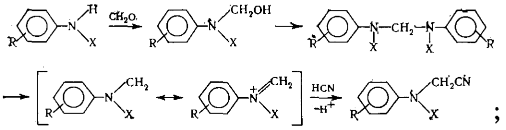
The cyanomethylation reaction in an acid medium has been used to synthesise complexones and their analogues from aliphatic secondary amines. Schwarzenbach et al.[48] synthesised cyanomethyliminodiacetic acid by treating iminodiacetic acid with formaldehyde and sodium hydroxide in hydrochloric acid:

$$HN(CH_2COOH)_2 + NaCN + CH_2O + HCl \rightarrow NCCH_2NAc_2.$$

The synthesis of *NN'*-di(carboxymethyl) derivatives of ethylenediamine by cyanomethylation in an acid medium has been described[115]:



Satisfactory results were obtained in the cyanomethylation of ammonia in an acid medium; this results in the formation of a high yield of tri(cyanomethyl)amine, which is converted into nitrilotriacetic acid by hydrolysis with alkali[116-120]. Being weaker bases, aromatic amines enter into the cyanomethylation reaction with greater difficulty than aliphatic and aliphatic-aromatic amines. The introduction of the second cyanomethyl residue requires the use of glacial acetic acid as the solvent and formaldehyde must be replaced by paraformaldehyde[121,122]. However, this method is suitable only for aniline derivatives without electronegative substituents. Derivatives containing such substituents must be di(cyanomethylated) in the presence of a catalyst—zinc chloride[121]. It is suggested[122] that the cyanomethylation of aromatic amines proceeds in accordance with the following mechanism:



X = H, or CH₂CN .

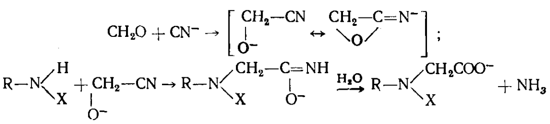
Under the above conditions, arylaminodiacetonitriles can be obtained in 60–90% yield.

Cyanomethylation in an alkaline medium. The cyanomethylation of amines can be carried out by heating in an alkaline medium[123-130]. Under these conditions, the acetonitriles formed are hydrolysed to the corresponding acids with evolution of ammonia:

$$R—N\begin{smallmatrix} X \\ H \end{smallmatrix} \xrightarrow[NaOH]{NaCN,CH_2O} \left[R—N\begin{smallmatrix} X \\ CH_2CN \end{smallmatrix}\right] \rightarrow R—N\begin{smallmatrix} X \\ CH_2COONa \end{smallmatrix} + NH_3\ ;$$

$X{=}H;$ or $CH_2CN.$

If the ammonia is not removed from the reaction mixture, it is cyanomethylated with formation of nitrilotriacetonitrile and then nitrilotriacetic acid[126,131]. In order to avoid this side reaction, a method was developed in which the cyanomethylating components are introduced periodically with subsequent repeated distillation of ammonia at a reduced pressure during the reaction[124,130,132]. It has been suggested that the cyanomethyl derivatives are not formed in an alkalkine medium, the initial products of the reaction of the cyanide and formaldehyde being glycolonitrile or its salts, the subsequent interaction of which with the amine immediately leads to the formation of the iminodiacetate salt[124-126]:

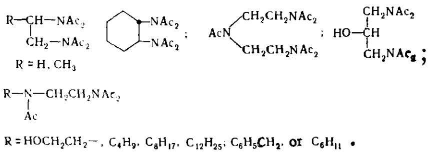


$X{=}H,$ or CH_2CN $\quad X{=}H;$ or CH_2COO^- .

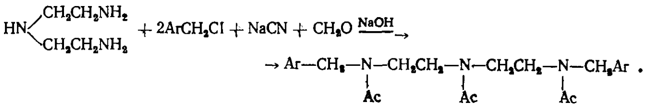
It is suggested that the alkalinity of the medium is necessary for the formation of the glycolonitrile alkoxide ion, which catalyses the cyanomethylation reaction[133].

The yield of polyaminopolycarboxylic acids obtained by this procedure is nearly quantitative when ammonia is rapidly eliminated and the cyanomethylating agents are introduced slowly[134]. As in acid cyanomethylation, in this case it is also possible to carry out the process in a single stage, i.e. one carboxymethyl group may be introduced at each nitrogen atom. It has been found[108,109] that the optimum conditions for this process obtain when the pH of the reaction medium is maintained at approximately 9. Cyanomethylation in an alkaline medium proved to be a convenient procedure for the synthesis of ethylenediamine-*NN*-diacetic acid (LIV), mentioned above[108,109,135]. Its analogues and derivatives can be synthesised similarly[101,108,109,124].

Although the synthesis by the alkaline cyanomethylation method of complexones with a single iminodiacetic acid group, for example nitrilotriacetic acid[131], butyl- and cyclohexyl-iminodiacetic acids[130], and ethyl- and hydroxyethyl-iminodiacetic acids[127], has been described, in the main this method is used to synthesise polyaminopolycarboxylic acids[109,124,130,132,136]. Complexones obtained by this method are indicated below:



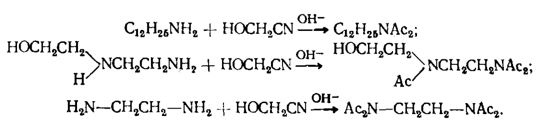
As for direct carboxymethylation, the use of alkaline cyanomethylation simultaneously with arylalkylation of polyamines for the synthesis of complexones with aryl substituents has been described[102,137], for example:



$$HN\begin{matrix}\diagup CH_2CH_2NH_2\\ \diagdown CH_2CH_2NH_2\end{matrix} + 2ArCH_2Cl + NaCN + CH_2O \xrightarrow{NaOH} \to Ar{-}CH_2{-}\underset{\underset{Ac}{|}}{N}{-}CH_2CH_2{-}\underset{\underset{Ac}{|}}{N}{-}CH_2CH_2{-}\underset{\underset{Ac}{|}}{N}{-}CH_2Ar\ .$$

Satisfactory results were obtained when alkaline cyanomethylation was used in the synthesis of aryliminodiacetic acids: *o*-carboxyphenyliminodiacetic acid[127] and certain naphthalene complexones[22,43,76,90,138] have been synthesised in fairly high yields.

A very interesting modification of the cyanomethylation reaction involves treating amines with glycolonitrile[139,140]. The reaction is carried out at pH 11–12 in an aqueous medium heated to 90°C. It has been shown for dodecylamine, ethylenediamine, and hydroxyethylethylenediamine as examples that the corresponding complexones are obtained in nearly quantitative yields under these conditions[139]:



$$C_{12}H_{25}NH_2 + HOCH_2CN \xrightarrow{OH^-} C_{12}H_{25}NAc_2;$$
$$\begin{matrix}HOCH_2CH_2\diagdown\\ H\diagup\end{matrix}NCH_2CH_2NH_2 + HOCH_2CN \xrightarrow{OH^-} \begin{matrix}HOCH_2CH_2\diagdown\\ Ac\diagup\end{matrix}NCH_2CH_2NAc_2;$$
$$H_2N{-}CH_2CH_2{-}NH_2 + HOCH_2CN \xrightarrow{OH^-} Ac_2N{-}CH_2CH_2{-}NAc_2.$$

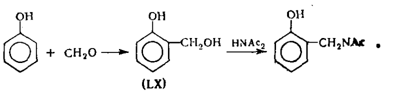
III. THE SYNTHESIS OF COMPLEXONES FROM IMINODIACETIC ACID AND ITS ESTERS

This group of methods combines two procedures for the synthesis of complexones: 1. The reaction of iminodiacetic acid with phenols and formaldehyde (the Mannich reaction). 2. The condensation of iminodiacetic acid and its esters with halogeno-derivatives.

The Mannich Reaction

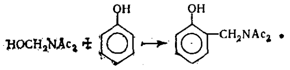
The reaction of iminodiacetic acid with phenols and formaldehyde is a special case of the Mannich reaction[141]. It is usually carried out in acetic acid (pH 2–3) at 5–10°C [87,142,143], but it can also be performed in an alkaline medium at pH ⩽ 10.[87,144] The reactants are usually introduced into the reaction in equimolar amounts[87].

It has been suggested[22] that the first stage of this reaction, carried out in an aqueous medium, is the formation of the phenolic alcohol (LX), which then interacts with iminodiacetic acid, the process being accompanied by the elimination of water:



However, there is no direct evidence for this mechanism and one cannot therefore rule out the possibility that the process can also proceed via a different mechanism:

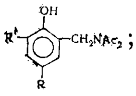
$$CH_2O + HNAc_2 \longrightarrow HOCH_2NAc_2\ ;$$



The problem of the mechanism of the Mannich reaction still continues to be controversial; views have been expressed in the literature concerning the above two mechanisms of this reaction[145,146].

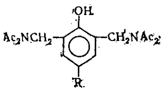
The formation of complexones in both acid and alkaline media is accompanied by side reactions leading to the formation of various admixtures and side products, caused mainly by the oxidation of phenols and the interaction of the latter with formaldehyde, leading to the formation of phenol-formaldehyde oligomers and polymers, methylenebisphenol compounds, phenolic poly(hydroxymethyl) derivatives, etc.

Not only phenol itself[145], but also its methyl and other derivatives[87,142,144,147-149] react with iminodiacetic acid, the methyleneiminodiacetic acid group always entering the *ortho*-position with respect to the hydroxy-group:



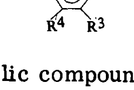
; R = R' = H ;
R = CH₃; R' = H ;
R = NO₂; R' = H ;
R = R' = CH₃ .

Interesting studies on the application of the Mannich reaction in the synthesis of complexones have been carried out by Temkina and coworkers[76,140,142,143,150-152]. They showed that phenol and *p*-cresol can form di(methyliminodiacetic) acid derivatives (LXI) and (LXII)[142,148]. The analogous compound (LXIII) has been obtained from *p*-hydroxybenzenesulphonic acid[153-156]:

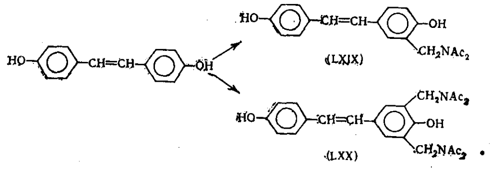


; (LXI) R = H ;
(LXII) R = CH₃ ;
(LXIII) R = SO₃H .

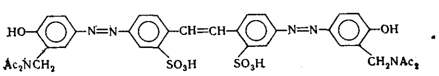
The same workers succeeded in introducing dihydric phenols and even phloroglucinol into the Mannich reaction with iminodiacetic acid[150-152]. It has been shown (Table 1) that the complexones formed under these conditions have the following structure [compounds (LXIV)–(LXVIII)]:



More complex phenolic compounds also undergo the Mannich reaction. Interesting results have been obtained for the reaction of iminodiacetic acid and formaldehyde with dihydroxystilbene[157]. For equimolar reactant ratios, the product is the monosubstituted derivative (LXIX); a second methyleneiminodiacetic acid group enters the same ring compounds (LXX):



The substitution in stilbenediazo-derivatives involves both benzene rings, containing a phenolic hydroxyl, with formation of a symmetric product (LXXI)[158]:



(LXXI)

Table 1.

Compound	R	R1	R2	R3	R4
(LXIV)	$CH_2N(CH_2COOH)_2$	H	OH	H	H
(LXV)	$CH_2N(CH_2COOH)_2$	H	OH	$CH_2N(CH_2COOH)_2$	H
(LXVI)	OH	$CH_2N\begin{matrix}CH_2COONa\\CH_2COOH\end{matrix}$	H	H	H
(LXVII)	$CH_2N(CH_2COOH)_2$	OH	H	H	H
(LXVIII)	OH	$CH_2N(CH_2COOH)_2$	OH	H	H

Complexones have been synthesised by the Mannich reaction from indophenol and its derivatives (LXXII) and (LXXXIII)[159-166] (Table 2):

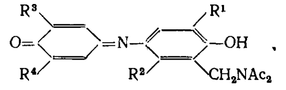


Table 2.

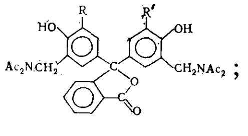
Compound	R^1	R^2	R^3	R^4	Compound	R^1	R^2	R^3	R^4
(LXXII)	H	H	Cl	Cl	(LXXVIII)	C_2H_5	CH_3	Cl	Cl
(LXXIII)	H	H	Br	Br	(LXXIX)	C_2H_5	CH_3	Br	Br
(LXXIV)	CH_3	H	Cl	Cl	(LXXX)	OCH_3	H	Cl	Cl
(LXXV)	CH_3	H	Br	Br	(LXXXI)	OCH_3	H	Br	Br
(LXXVI)	CH_3	CH_3	Cl	Cl	(LXXXII)	H	CH_3	Cl	Cl
(LXXVII)	CH_3	CH_3	Br	Br	(LXXXIII)	H	CH_3	Br	Br

The methods for the introduction of methyleneiminodiacetic acid groups in the synthesis of complexones from phthalein indicators have acquired particular importance. More than 50 compounds of this kind, forming coloured complexes with different metals, have been synthesised by this procedure. Because of this, some of them are used as metalloindicators[1, 167].

The first complexone of this type was 3,3-di-(*NN*-dicarboxymethylaminomethyl)-*o*-cresolphthalein (LXXXIV), synthesised by Schwarzenbach and coworkers, which has been called "phthalein complexone"[144]:

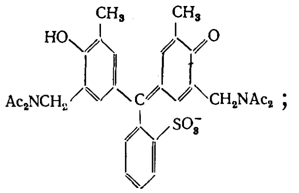


(LXXXIV) $R=CH_3$; $R'=H$;

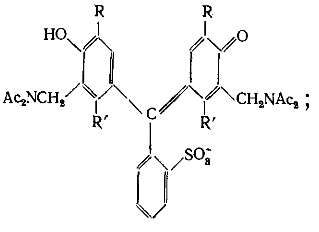
(LXXXV) $R=R'=H$;

(LXXXVI) $R=(CH_3)_2CH$; $R'=CH_3$.

The method for the synthesis of metalloindicators was developed further by Korbl and coworkers[159,160,162,165,168]. They synthesised the phthalein complexone analogues (LXXXV) and (LXXXVI)[168] as well as methyleneiminodiacetic acid derivatives of sulphophthalein (LXXXVII)[169], (LXXXVIII), and (LXXXIX)[159,160,162,165]:



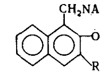
(LXXXVII)



(LXXXVIII) $R=CH_3$; $R'=H$;

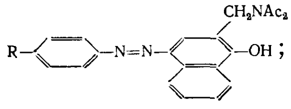
(LXXXIX) $R=(CH_3)_2CH$; $R'=CH_3$.

The aminomethylation reaction can also be used to obtain complexones from condensed phenols. *β*-Naphthol reacts smoothly with iminodiacetic acid and formaldehyde, forming an *α*-substituted derivative of methyleneiminodiacetic acid (XCa)[147, 152]. (3-Carboxy-2-hydroxy-1-naphthyl)methylenediacetic acid (XCb) has been synthesised in a high yield[170]:



(XC) a - R = H; b - R = COOH.

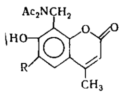
Complexones based on napthalene analogues [compounds (XCI) and (XCII)] have been synthesised similarly to indophenol derivatives[171]:



(XCI) $R=NO_2$;

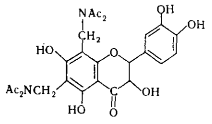
(XCII) $R=SO_3H$.

More complex condensed phenols containing a hydrogen atom in the *o*-position also react with iminodiacetic acid and formaldehyde. The synthesis by this method of fluorescent indicators—iminodiacetic acid derivatives of coumarone [compounds (XCIII) and (XCIV)][172-174], flavone (XCV)[175], and xanthone (XCVI)[172] has been described:

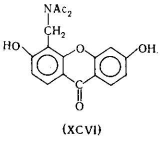


(XCIII) R = H

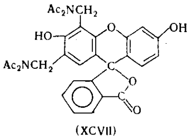
(XCIV) R = OH



(XCV)



(XCVI)



(XCVII)

The complexone (XCVII) has been synthesised from fluorescein[176]. Initially a symmetrical structure was attributed to this compound[176-178], but subsequently it was established that both methyleneiminodiacetic acid groups are in the same benzene ring[153,155].

NN-Di(carboxymethylaminomethyl)anthraquinone derivatives (XCVIII)–(CII)[179] have also been obtained with the aid of the Mannich reaction (Table 3):

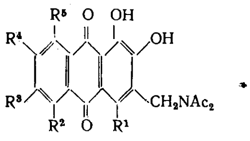


Table 3.

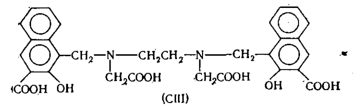
Compound	R^1	R^2	R^3	R^4	R^5
(XCVIII)	H	H	H	H	H
(XCIX)	H	OH	H	H	H
(C)	H	H	OH	H	H
(CI)	H	H	H	OH	H
(CII)	H	OH	H	H	OH

An attempt has been made, with 2-hydroxy-3-naphthoic acid as an example, to use ethylenediamine-*NN'*-diacetic acid as the amino-component in the Mannich reaction[170], but the expected complexone (CIII) was obtained in a yield not exceeding 20%, despite the employment of copper salts as the catalyst:



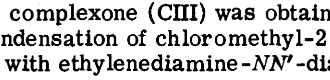
(CIII)

The main reaction product was the corresponding diarylmethane. The complexone (CIII) was obtained in a higher yield by the condensation of chloromethyl-2-hydroxy-3-naphthoic acid with ethylenediamine-*NN'*-diacetic acid[170].

The Reaction of Iminodiacetic Acid and Its Esters with Halogeno-Derivatives

The reaction of iminodiacetic acid with halogeno-derivatives is carried out in an aqueous medium at pH 8.5–9 and a temperature of 40–100°C. Alkali or carbonates may be used as condensing agents. There are potent data[180] concerning the use of this reaction for the synthesis of ethylenediaminetetra-acetic acid.

Satisfactory results were obtained in the condensation of 1,3-dichloro-2-hydroxypropane with iminodiacetic acid (80°C, 5 h) in the presence of alkali; this resulted in the isolation of 1,3-diamino-2-hydroxypropanetetra-acetic acid (CIV) in 52% yield.[181] It was not possible to obtain the tetra-acetic acid by this procedure from *d*- and 1,6-dichloro-1,6-dideoxymannitol[85]:



(CIV)

The synthesis of the tetra-acetic acid (CIV) by treating 2-chloromethyloxiran with iminodiacetic acid has been described recently[182]. Certain analogues of compound (CIV) have been synthesised by this method[182,183].

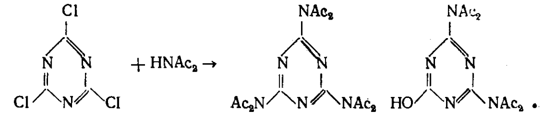
When iminodiacetic acid was treated with chloromethylphosphonic acid (20°C, pH 10–11, 8 days), the complexone (CV) was synthesised[184]:

$$H_2O_3PCH_2NAc_2 \ .$$

(CV)

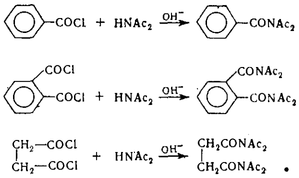
The application of this method to the synthesis of iminodiacetic acid derivatives of triazine proved successful. Thus the corresponding hexa-acetic acid (CVIa) was synthesised by the reaction of cyanuryl chloride with iminodiacetic acid in the presence of an aqueous solution of sodium hydroxide[185].

The tetra-acetic acid (CVIb) was synthesised similarly from 4,6-dichloro-2-hydroxytriazine[185]:



(CVIa) (CVIb)

The condensation of the chlorides of benzoic, succinic, and phthalic acids with iminodiacetic acid in an alkaline medium, resulting in the formation of the corresponding complexones, has been described[186]:



Alkyl sulphates have been used frequently in place of halogeno-derivatives for the alkylation of iminodiacetic acid[187]:

$$(RO)_2SO_2 + HNAc_2 \rightarrow RNAc_2 ;$$
$$R{=}CH_3,\ C_2H_5.$$

The methylation of iminodiacetic acid by the Hess method has also been described[45]:

$$HNAc_2 + CH_2O + HOOCH \rightarrow CH_3NAc_2.$$

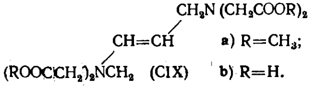
When halogeno-compounds are allowed to react with iminodiacetic acid, there is a difficulty involving the elimination of the initial iminodiacetic acid from the final product. To avoid this, the halogeno-derivatives may be condensed with iminodiacetate esters with subsequent hydrolysis of the ester group in an alkaline medium.

The conditions governing the synthesis of *N*-alkyliminodiacetate esters have been investigated in detail in relation to the reactions of propyl, isopropyl, and allyl bromides with dimethyl iminodiacetate[188]. It has been found that best results are obtained when alcohols isopropyl alcohol and ethylene glycol) are used as solvents and the condensing agent is the iminodiacetate ester itself. Iminodiacetate esters (CVII) are obtained most readily by this method and with a high yield from alkyl or arylalkyl derivatives with a mobile (allyl or benzyl) halogen: dimethyl allyliminodiacetate (CVIIc) was obtained in a yield of about 80%; the yield of tetramethyl *trans*-1,4-diaminobut-2-enetetra-acetate (CIXa) was somewhat lower:

$$R{-}Br + HN(CH_2COOCH_3)_2 \rightarrow RN(CH_2COOCH_3)_2 \rightarrow RNAc_2 ;$$

a) $R{=}n\text{-}C_3H_7$; b) $R{=}iso\text{-}C_3H_7$; (CVII) (CVIII)

c) $R{=}CH_2{=}CH{-}CH_2$



$$(ROOCCH_2)_2NCH_2{-}CH{=}CH{-}CH_2N(CH_2COOR)_2$$

(CIX) a) $R{=}CH_3$; b) $R{=}H$.

The acids (CVIII) and (CIXb) were obtained smoothly from the esters.

Shtacher and Taub[189] described the synthesis by this method of a whole series of aliphatic-aromatic derivatives of iminodiacetic acid (CX). The authors hydrolysed the resulting diesters with sodium hydroxide or lithium hydroxide (in the case of readily soluble acids):

$$R{-}NAc_2$$

(CX)

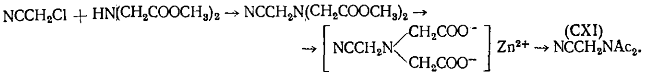
$R = C_6H_5CH_2$; p-$FC_6H_4CH_2$; p-$IC_6H_4CH_2$; 3-OH-4-$BrC_6H_3CH_2$;

$C_6H_5CH_2CH_2$; p-$FC_6H_4COCH_2$; p-$BrC_6H_4COCH_2$; m-$BrC_6H_4COCH_2$;

$C_6H_5OCH_2CH_2$; p-$FC_6H_4OCH_2CH_2$ p-$BrC_6H_4OCH_2CH_2$;

p-$BrC_6H_4NHCOCH_2$; p-$FC_6H_4NHCOCH_2$.

Several alkyl derivatives of iminodiacetic acid with substituents in the hydrocarbon chain have been synthesised by the condensation of halogeno-derivatives with iminodiacetates[48]. Thus dimethyl cyanomethyliminodiacetate (CXI) was obtained in a high yield by the reaction of chloroacetonitrile with dimethyl iminodiacetate without solvent at room temperature. By hydrolysis with zinc perchlorate, it was converted via the zinc salt into cyanomethyliminodiacetic acid (LIX)[48]:



$$NCCH_2Cl + HN(CH_2COOCH_3)_2 \rightarrow NCCH_2N(CH_2COOCH_3)_2 \rightarrow \left[NCCH_2N\begin{smallmatrix} CH_2COO^- \\ CH_2COO^- \end{smallmatrix} \right] Zn^{2+} \rightarrow \underset{}{\overset{(CXI)}{NCCH_2NAc_2}}.$$

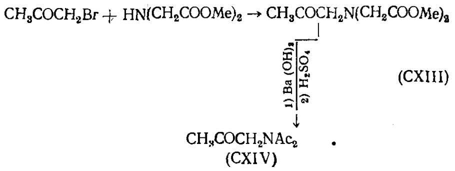
The reaction with chloroacetamide was carried out under the same conditions but with heating to 100°C.

Diethyl 2-nitroethyliminodiacetate (CXII) was synthesised in a quantitative yield by the reaction of 2-chloronitroethane with diethyl iminodiacetate in ethyl acetate at 0°C. However, it could not be hydrolysed, since it proved to be extremely unstable:

$$O_2NCH_2CH_2N(CH_2COOC_2H_5)_2\ .$$

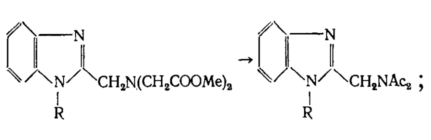
(CXII)

Dimethyl acetonyliminodiacetate (CXIII) was synthesised under the same conditions, but with heating (60–70°C, 4 h), from monobromoacetone and dimethyl iminodiacetate. Without isolation, it was converted into the corresponding iminodiacetic acid (CXVI) in 70% yield[190]:



$$CH_3COCH_2Br + HN(CH_2COOMe)_2 \rightarrow CH_3COCH_2N(CH_2COOMe)_2 \quad (CXIII)$$
$$\xrightarrow{1)\ Ba(OH)_2;\ 2)\ H_2SO_4} \underset{(CXIV)}{CH_3COCH_2NAc_2}\ .$$

The application of this method to the synthesis of heterocyclic derivatives of iminodiacetic acid has been described: 2-chloromethylbenzimidazole and its 1-methyl derivative react with methyl iminodiacetate to give the corresponding diesters (CXV), which are converted by hydrolysis into the complexones (CXVI); the overall yield is about 50%[191]:



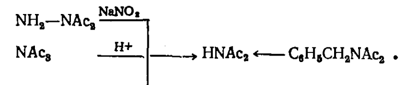
(CXV) (CXVI)

R=H, CH_3.

IV. OTHER METHODS FOR SYNTHESISING COMPLEXONES

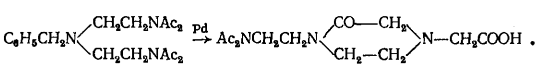
There exist several specific methods for the synthesis of complexones. They include, for example, reactions whereby the molecules of iminodiacetic acid derivatives are modified. Thus the most convenient method for the synthesis of iminodiacetic acid, which is used in industry, involves the cleavage of hydrazine-*NN*-diacetic acid under the influence of sodium nitrite[30, 192].

The synthesis of iminodiacetic acid by the acid cleavage of nitrilotriacetic[193, 194] and semicarbazide-*NN*-diacetic[30] acids and by the catalytic debenzylation of benzyliminodiacetic acid[55] has been described:



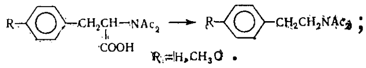
$$NH_2{-}NAc_2 \xrightarrow{NaNO_2};\quad NAc_3 \xrightarrow{H+};\quad NH_2CONHNAc_2 \xrightarrow{H+} \longrightarrow HNAc_2 \longleftarrow C_6H_5CH_2NAc_2\ .$$

Debenzylation has also been used to synthesise diethylenetriaminetetra-acetic acid, which was isolated as the lactam[137]:

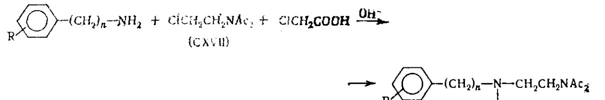


$$C_6H_5CH_2N\begin{smallmatrix} CH_2CH_2NAc_2 \\ CH_2CH_2NAc_2 \end{smallmatrix} \xrightarrow{Pd} Ac_2NCH_2CH_2N\begin{smallmatrix} CO{-}CH_2 \\ CH_2{-}CH_2 \end{smallmatrix}N{-}CH_2COOH\ .$$

The use of the decarboxylation reaction for the modification of complexones has been described. Thus phenylethyliminodiacetic acid was obtained from phenylalanine[50] and its *p*-methoxy-derivative was synthesised[195]:

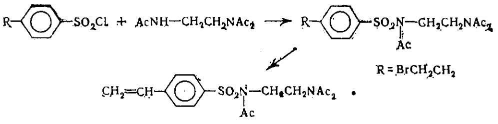


There are several examples of the synthesis of complexones using β-substituted ethyliminodiacetic acids. Thus the interaction of β-chloroethyliminodiacetic acid (CXVII) with arylalkylamines and with chloroacetic acid led to the synthesis of complexones of type (CXVIII).[101] β-Mercaptoethylaminodiacetic acid was synthesised by treating the diacetic acid (CXVII) with sodium hydrogen sulphide[196]:

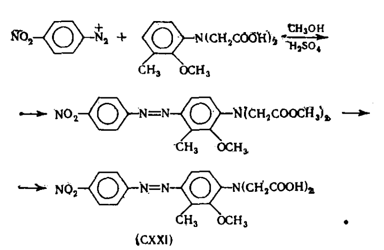


β-Aminoethyliminodiacetic acid (CXIX) was obtained from *N*-acetamidoethyl-*NN*-iminodiacetic acid[197] and was used to synthesise complexones with the sulphonamide group [compounds (CXX)][39]:

Similar reactions have been carried out with ethylenediaminetriacetic acid[39]; the compounds with a bromoethyl substituent thus obtained were converted into vinyl derivatives:

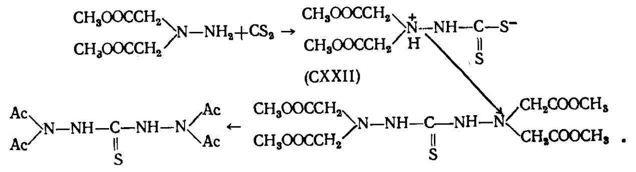


The complexone (CXXI) was synthesised by coupling the *p*-nitrophenyldiazonium cation to 2-methoxy-3-methylphenyliminodiacetic acid[23] in methanol in the presence of sulphuric acid with subsequent hydrolysis of the resulting ester:



(CXXI)

By treating dimethyl hydrazine-*NN*-diacetate with carbon disulphide, Podgornaya[198] obtained a dithiocarbazic acid derivative (CXXII), which yielded thiocarbohydrazide-tetra-acetic acid (CXXIII) after dimerisation in alcohol and hydrolysis:



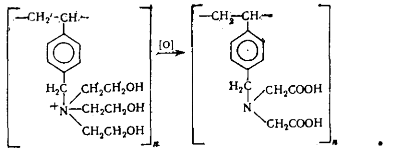
CXXIII

In addition, several examples of the synthesis of complexones by the conversion of *N*-di(hydroxyethyl) groups into aminodiacetic acid groups have been described. The oxidation is carried out in the presence of catalysts (for example, cadmium or its oxide)[199] or under the influence of alkali at 200–260°C.[200] Nitrilotriacetic acid, ethylenediaminetetra-acetic acid, and its analogues have been obtained by this method[200,201]:

$$N(CH_2CH_2OH)_3 \xrightarrow{[O]} N(CH_2COOH)_3;$$

$$(HOCH_2CH_2)_2NCH_2CH_2N(CH_2CH_2OH)_2 \xrightarrow{[O]} Ac_2NCH_2CH_2NAc_2 \ .$$

The method has been used to synthesise polymeric complexones of the type of benzyliminodiacetic acid[202]:



Finally, a method has been described for the synthesis of complexones on the basis of the reaction of amines with aminoacids, particularly with glycine[203]:

$$H_2NCH_2CH_2NH_2 + NH_2CH_2COOH \rightarrow Ac_2NCH_2CH_2NAc_2 + NH_3 \ .$$

The reaction is carried out in an aqueous alkaline medium in the absence of air with elimination of the ammonia formed. However, this interesting reaction has only limited applicability.

Consideration of the existing methods for the synthesis of aminopolycarboxylic acids permits the conclusion that the simplest and universal procedure is the carboxymethylation reaction with mono- and poly-amines as the starting materials. Under laboratory conditions, the direct carboxymethylation method is mainly used, i.e. condensation with halogenoacetic acids. In industry, the procedure based on the cyanomethylation of amines in an alkaline medium competes with the above method, being more economical.

However, the carboxymethylation reaction is in many cases unsuitable for the synthesis of complexones with functional groups, since the latter may undergo transformations under the conditions of these processes, which involve heating with aqueous solutions of alkalis or inorganic acids. Furthermore, the method may suffer from limitations due to the low availability of the initial amines. Other methods of synthesis, based on the employment of halogeno-, hydroxy-, and other derivatives as starting materials instead of amines, may be more successful under these conditions.

The Polarity and Strength of the Intermolecular Hydrogen Bond

E.N.Gur'yanova, I.P.Gol'dshtein, and T.I.Perepelkova

The results of studies on the dipole moments and the thermodynamics of the formation of complexes with an intermolecular hydrogen bond are reviewed and the nature of the relation between the energies and lengths of intermolecular hydrogen bonds is examined. The enthalpy-entropy relations for the formation of hydrogen-bonded complexes and the linear correlation between the energy of charge transfer and the hydrogen bond energy are analysed and validated. The theoretical and experimental results of the study of hydrogen-bonded complexes are examined from the standpoint of the donor-acceptor nature of hydrogen bonds.

The bibliography includes 240 references.

CONTENTS

I. INTRODUCTION

Numerous studies have been made on hydrogen bonds. The interest in this common type of coordination interaction can be accounted for by its exceptionally important role in many physical, chemical, and biological processes. A number of books[1-6], general reviews[7,8], as well as reviews on specific aspects of the hydrogen bond (theory[9-16], infrared and ultraviolet spectroscopy[17,18], NMR[19-25], and reactivity[26]) have been written. There exists an appreciable gap in the survey of results of studies on the polar properties of hydrogen bonds and in this field there exists only a short and extremely limited review[27].

Nevertheless the dipole moment is one of the most important characteristics of the molecular complex, since it carries information about the nature of the redistribution of electron density and complex formation. This parameter assumes particular importance when hydrogen-bonded complexes are examined from the standpoint of the donor-acceptor interaction, since it makes it possible to assess the role of charge-transfer forces in the stabilisation of hydrogen-bonded complexes.

In the present review, an attempt is made to survey the results of studies on the polar properties of intermolecular hydrogen-bonds, to examine the question of the type of correlation between the polarity and energy of hydrogen bonds, and to discover the common features and differences in the properties of hydrogen-bonded complexes and the usual complexes of the donor-acceptor type (EDA complexes). Mainly studies concerned with hydrogen-bonded complexes formed by neutral molecules A-H and B are dealt with in the review. Furthermore, the results which make it possible to determine fairly reliably the parameters characterising intermolecular hydrogen bonds are given preferential consideration.

It is usual to refer to the components of the (A-H)-B system as acid-base, or proton donor-proton acceptor, or electron acceptor-electron donor respectively. In the main, we shall use the terminology electron donor (B) and electron acceptor (A-H).

II. THE NATURE OF THE HYDROGEN BOND

The theoretical aspect of the hydrogen bond has been examined in detail in the monographs and reviews mentioned above and will not be discussed here. We shall only point out that a characteristic feature of research in this field is a consistent increase in the number and sophistication of studies devoted to both semi-empirical and, particularly, non-empirical (*ab initio*) quantum-mechanical calculations on systems with hydrogen bonds. The latter is to a large extent due to the development of methods for calculations on multielectron systems and to the improvement of computational techniques.

The results of calculations of electron density redistribution and molecular orbital populations on formation of hydrogen bonds are the most important from the standpoint of the understanding of the nature of the hydrogen bond. Despite the wide variety of systems for which calculations have been made, general trends can be recognised[10-12]. When a hydrogen bond is formed, electron density shifts from the donor molecule B to the acceptor molecule A-H. This type of electron density redistribution has been observed also on formation of the usual donor-acceptor bond[28]. This factor justifies the consideration of hydrogen-bonded complexes as complexes of the donor-acceptor type. The magnitude of the transferred charge differs in different systems. For example, it amounts to only 0.0064*e* for the water dimer[29] and to 0.04*e* and 0.07*e* for the more stable complexes[30] $HOH.NH_3$ and $FOH.NH_3$. Here the decrease of electron density at the electron donor atom causes a charge redistribution in the entire molecule B. The greatest increase of electron density is observed in the region of the atom X of the electron acceptor molecule A-X-H.[31-36]

In the solution of the problem of intermolecular interaction, the question of the forces leading to the formation of complexes is extremely important. There have been numerous studies designed to obtain quantitative estimates of the contributions of Coulombic attraction, exchange repulsion, inductive and dispersion interactions, and the stabilisation energy of relatively weak hydrogen bonds[9,11]. Using perturbation theory, Murrell and coworkers[37,38] developed a method which can take into account not only the electrostatic interactions but also the effects of the overlapping of the interacting orbitals of the donor and acceptor molecules. This procedure makes it possible to trace the trend in the changes of individual contributions with increasing strength of the interaction. It has been shown that the role of the inductive and exchange system energies is not great: the main contribution to the energy of hydrogen bonds comes from the Coulombic interaction. The charge-transfer energy is low when the overlap integral S of the interacting orbitals is less than 0.1, but increases rapidly with increase of S.[38] Consequently the contribution of the charge-transfer energy is low for weak hydrogen bonds, becoming more important for moderately strong and strong hydrogen bonds. This hypothesis is consistent with the results from the analysis of the contribution of different forces to the stabilisation energy of the usual complexes of the donor–acceptor type.

The contributions of the polarisation interaction to the dipole moment (μ_C, D) and to the energy of formation (ΔH, kcal mole^{-1}) of a number of charge-transfer complexes are given below:

Complex	μ_C	$-\Delta H$ (calc.)	μ_C	$-\Delta H$ (expt.)
HMB*-chloranil (Ref.39)	0.5—0.9	2.2—2.4	1.0	5.4
HMB*-trinitrobenzene (Ref.39)	1.1—1.5	2.6—3.0	0.87	4.7
$I_2.NH_3$ (Ref.40)	0.91—1.96	0.34—1.68	6.4	4.8
$I_2.N(CH_3)_3$ (Ref.40)	0.30—0.57	0.04—0.13	6.0	10.2

† Hexamethylbenzene.

Comparison of the calculated and experimental values shows that the role of polarisation interaction is considerable in comparatively weakly bonded complexes, the contribution of electrostatic forces being comparable to the contribution of charge-transfer forces. In stronger complexes, the charge-transfer forces predominate over the classical intermolecular interaction forces.

A similar situation probably obtains also for hydrogen-bonded complexes. The hypothesis of a large contribution of charge-transfer forces to the stabilisation energy of hydrogen bonds and of the possibility of considering hydrogen-bonded complexes from the common standpoints of the donor–acceptor interaction and of Mulliken's theory of charge-transfer complexes[41,42] has been frequently put forward[43-48]. In recent years this concept has been increasingly accepted and confirmed experimentally[47,48].

Whereas Mulliken did not classify hydrogen-bonded complexes as electron–donor–acceptor complexes at the time of the creation of his theory[41], in his later studies it is concluded that these two types of interaction are similar and that hydrogen-bonded complexes can be included in the general classification of charge-transfer complexes[42]. The classification is based on the type of interacting orbitals—the highest occupied molecular orbital of the electron donor and the lowest vacant orbital of the acceptor. From this standpoint, compounds of the type A–X–H can be regarded as σ acceptors; charge is transferred from the electron donor to the antibonding orbital of the X–Hσ bond. Hence it follows that the complexes A–H...B can be logically regarded as part of the series of other **EDA** complexes.

The main success of Mulliken's theory is that it explained the appearance in the electronic spectrum after complex formation of a new absorption band, the so called charge-transfer band. The fact that charge-transfer bands have not so far been reliably observed in the spectra of hydrogen-bonded complexes to some extent inhibits the extension of this theory to such complexes[11,12]. Nevertheless, the spectra of the most stable **EDA** complexes of Group **III** metals with different n donors also failed to exhibit charge-transfer bands. Calculations have shown[49,50] that these bands should occur in the region of ultraviolet spectrum which is difficult to investigate experimentally (below 200 nm). Some investigators[46,47,51] suggest with justification that the charge-transfer bands for hydrogen-bonded complexes also occur in the far ultraviolet.

The observed discrepancy between the enthalpies of formation or stability constants of the complexes of a given acceptor A–H with a series of donors B and the ionisation potentials on the latter is sometimes quoted as evidence against the possibility of treating hydrogen-bonded complexes as charge-transfer complexes[11]. It is noteworthy that such a discrepancy is frequently observed also for typical **EDA** complexes[28]. Although the ionisation potential is an important characteristic of the donor molecule, it is not the only quantity which determines the relative stabilities of the complexes. The conditions governing the overlapping of the interacting donor and acceptor molecule orbitals are very important in the formation of an intermolecular bond. This can be seen, for example, from a comparison of the corresponding parameters of the hydrogen-bonded complexes and iodine complexes. The ionisation potentials I (eV) of the analogous amines, phosphines, sulphides, and ethers, the overlap integrals S between the orbital of the corresponding heteroatom (indicated in brackets) and the 5p orbital of iodine or the 1s orbital of the hydrogen atom, and the enthalpies of formation ΔH (kcal mole^{-1}) of the corresponding complexes of iodine (**I₂**) and p-chloro-phenol (**OH**) are listed below:

	$(C_2H_5)_3N$	$(C_2H_5)_3P$	$(C_2H_5)_2S$	$(C_2H_5)_2O$
I[52]	7.58	7.86	8.43	9.55
S (I_2)[28]	0.29 ($2sp^3$)	—	0.23 ($3p$)	0.14 ($2sp^2$)
$-\Delta H$ (I_2)[28]	11.4	—	8.5	4.2
S (O—H)[28]	0.48 ($2sp^3$)	0.37	0.36 ($3p$)	0.43 ($2sp^2$)
$-\Delta H$ (O—H)[53,56]	9.9	8.0*	5.0	6.3

* Data for $(C_4H_9)_3P$.

The overlap integrals of the orbitals involved in the formation of the intermolecular bonds in iodine complexes decrease in the sequence amine > sulphide > ether. The ionisation potentials of these compounds increase in the same sequence. Consequently both parameters, the ionisation potential of the donor and the overlap integral of the interacting orbitals, are responsible for the observed sequence of decreasing enthalpies of formation of the corresponding iodine complexes: amines > sulphides > ethers. Similar relations between I, S, and ΔH have been observed also for hydrogen-bonded complexes in the amine–phosphine–sulphide series. Differences have been observed in oxygen compounds. The ionisation potentials of ethers are much higher than those of sulphides and yet the former give rise to much more stable complexes. This discrepancy can be accounted for by the more effective conditions for the overlapping of the interacting orbitals in the O–H...O (S = 0.42–0.43) linkages[28] than in the O–H...O (S = 0.36)[28] linkages.

From the theoretical standpoint, the increment in the dipole moment $\Delta\mu$ on complex formation is the most interesting property of donor–acceptor complexes. In terms of the approximation of the vector additivity method, $\Delta\mu$ is determined as the vector difference between the dipole moment of the complex μ_C and the dipole moments of the components $\mu_{A\text{-}H}$ and μ_B. $\Delta\mu$ is directly related to the charge transferred from the electron donor molecule to the electron acceptor molecule. The determination of the nature of the relation between the magnitude of the transferred charge and the energy of the donor–acceptor bond is of fundamental importance. Comparison of the theoretical and experimental relations may serve as a criterion of the validity of the hypothesis concerning the significant role of charge transfer in the stabilisation of intermolecular bonds.

A linear relation between the degrees of charge transfer and the enthalpies of formation of the complexes has been established on the basis of extensive experimental data embracing a wide variety of complexes of the donor–acceptor type, the enthalpies of formation of which varied from zero to 20 kcal mole^{-1}.[49] The equation of the straight line is

$$-\Delta H = 35.3\,\frac{\Delta\mu}{e\,r_{\mathrm{DA}}}\,, \tag{1}$$

where ΔH, $\Delta\mu$, and r_{DA} are respectively the heat of formation, the dipole moment increment, and the length of the donor–acceptor bond and e is the electronic charge. A similar linear relation between ΔH and $\Delta\mu$ has been established also for various hydrogen-bonded complexes, the energies of which were between 4 and 26 kcal mole^{-1}.[47,48]

Using the relation between the intensity of the stretching vibration band of A–H in the infrared spectrum of the hydrogen-bonded complex, the energy of formation of the hydrogen bond, and the dipole moment increment on complex formation, Iogansen[57] also concluded that there is a linear relation between ΔH and $\Delta\mu$.

The linear relation between ΔH^0 and $\Delta\mu/er_{\mathrm{DA}}$ follows from Mulliken's theory of charge-transfer complexes, which has been described in fair detail in a number of monographs[28,42,58–61]. Here we shall only quote the fundamental equations necessary for the determination of the nature of the relation between the most important parameters of the complexes. According to Mulliken[40,41], the wave function of the ground state of a molecular complex DA can be formulated to a first approximation as the sum of two terms:

$$\psi_N = a\psi_0\,(\mathrm{D},\mathrm{A}) + b\psi_1\,(\mathrm{D}^+ - \mathrm{A}^-). \tag{2}$$

The wave function ψ_0 refers to the state of the system without bonding. The interaction between the donor D and the acceptor A takes place via the classical electrostatic forces. The function ψ_1 refers to the state in which the electron has been transferred from the donor to the acceptor. The coefficients a and b characterise the contribution of the structure with charge transfer to the ground state of the complex.

The wave function of the complex in the excited state is

$$\psi_E = a^*\psi_1\,(\mathrm{D}^+ - \mathrm{A}^-) - b^*\psi_0\,(\mathrm{D},\mathrm{A}). \tag{3}$$

An approximate solution of the Schrödinger equation yields the following expressions for the energies of the ground and excited states of the complex (E_{N} and E_{E}) respectively and for the coefficient ratios b/a and b^*/a^*:

$$E_N = E_0 - \frac{(H_{01} - E_0S_{01})^2}{E_1 - E_0}\,; \tag{4}$$

$$E_E = E_1 - \frac{(H_{01} - E_1S_{01})^2}{E_1 - E_0}\,; \tag{5}$$

$$\frac{b}{a} = -\frac{H_{01} - E_0S_{01}}{E_1 - E_0}\,; \tag{6}$$

$$\frac{b^*}{a^*} = -\frac{H_{01} - E_1S_{01}}{E_1 - E_0}\,, \tag{7}$$

where

$$E_0 = \int \psi_0 H\psi_0 \mathrm{d}\tau;\ H_{01} = \int \psi_0\hat{H}\psi_1\,\mathrm{d}\tau;\ E_1 = \int \psi_1\hat{H}\psi_1\mathrm{d}\tau;\ S_{01} = \int \psi_0\psi_1\mathrm{d}\tau = \\ = 2S/(1+S^2)^{1/2}$$

are the overlap integrals of the wave functions ψ_0 and ψ_1 and their expression in terms of the overlap integral S of the corresponding interacting orbitals.

The equation for the energy of the charge-transfer band $h\nu_{\mathrm{ct}}$ can be obtained from Eqns. (4) and (5):

$$h\nu_{\mathrm{ct}} = E_E - E_N = (E_1 - E_0)\left[1 + \left(\frac{b^*}{a^*}\right)^2 + \left(\frac{b}{a}\right)^2\right]. \tag{8}$$

The dipole moment increment $\Delta\mu$ due to the charge transfer on formation of the donor–acceptor bond can be expressed as follows according to Mulliken's theory:

$$\Delta\mu = \mu_1(b^2 + abS_{01}), \tag{9}$$

where μ_1 is the dipole moment of the structure with complete charge transfer. It is assumed that approximately

$$\mu_1 = e\,r_{\mathrm{DA}}, \tag{10}$$

where r_{DA} is the distance over which the charge is transferred. If the degree of charge-transfer is defined as $\Delta\mu/er_{\mathrm{DA}}$, then, after substituting Eqn. (10) in Eqn. (9), we obtain

$$\frac{\Delta\mu}{er_{\mathrm{DA}}} = b^2 + abS_{01}. \tag{11}$$

The enthalpy of formation of the complex ΔH can be assumed equal to the difference between the energies of the ground state of the complex and the sum of the energies of the initial components ($E_{\mathrm{A}} + E_{\mathrm{D}}$):

$$\Delta H = E_N - (E_{\mathrm{A}} + E_{\mathrm{D}}). \tag{12}$$

This quantity may serve as a measure of the energy of the donor–acceptor bond.

Simultaneous solution of Eqns. (4), (6), (8), (11), and (12) yields Eqn. (13), which relates the fundamental parameters of the complex—the enthalpy of formation ΔH, the dipole moment of the donor–acceptor bond $\Delta\mu$, and the energy of the charge-transfer band $h\nu_{\mathrm{ct}}$:

$$-\Delta H = \frac{h\nu_{\mathrm{ct}}}{\mathrm{A}} \cdot \frac{\Delta\mu}{er_{\mathrm{DA}}} - [E_0 - (E_{\mathrm{A}} + E_{\mathrm{D}})], \tag{13}$$

where

$$A = a^2\left(1 + \frac{a}{b}S_{01}\right)\cdot\left[1 + \left(\frac{b^*}{a^*}\right)^2 + \left(\frac{b}{a}\right)^2\right].$$

For fairly stable complexes, the term $E_0 - (E_{\mathrm{A}} + E_{\mathrm{D}})$, which is a measure of the energy of the interaction between the donor and acceptor molecules via the classical electrostatic forces, may be regarded as small compared with the first term of Eqn. (13). In this case, Eqn. (13) can be written in the form[28,49,61]

$$-\Delta H^0 = \frac{h\nu_{\mathrm{ct}}}{A} \cdot \frac{\Delta\mu}{er_{\mathrm{DA}}}\,. \tag{14}$$

According to Eqns. (13) or (14), the necessary and sufficient condition for a linear relation between the enthalpy of formation of the complex ΔH^0 and the degree of charge transfer $\Delta\mu/er_{\mathrm{DA}}$ is the constancy of the term $h\nu_{\mathrm{ct}}/A$ for different complexes. Calculations have shown[49] that, within the limits of the accuracy of the estimates, this quantity is indeed constant and equal to 1–2 eV, in agreement with the coefficient (1.5 eV) in the experimental Eqn. (1).

We may note that the attempts to establish the nature of the correlation between the strength and polarity of hydrogen bonds have been made frequently. Thus Sutton and coworkers[62,63] compared the dipole moments of hydrogen-bonded complexes with the equilibrium constants K of the complex-formation reactions. However, owing to the linearity of the relation between ΔH and ΔS (as will be demonstrated below), the values of K cannot serve as a sufficiently reliable measure of the energy of the hydrogen bonds. Toyoda[46] attempted to obtain a theoretical description of the relation between ΔH and $\Delta\mu$ on the basis of Mulliken's theory. The following fairly rough approximations were adopted: $a \simeq 1$, $S_{01} = 0$, $\Delta\mu \simeq b^2\mu_1$, $E_0 =$ const., and $H_{01} =$ const.

Assuming that the entropy of complex formation ΔS is constant for different complexes and using the equilibrium constants as a measure of the strength of the hydrogen bonds, Toyoda obtained the relation

$$\lg K \propto \sqrt{\Delta\mu}.$$

However, he correctly remarks in his paper that there are no theoretical grounds for the constancy of H_{01}.

In a recently published series of investigations[64-67], Ratajczak and Orville–Thomas obtained the following expression using the relations from Mulliken's theory and the same approximations as in Toyoda's work:

$$-\Delta H = \frac{H_{01}}{\mu_1^{1/2}}(\Delta\mu)^{1/2} + E_0. \tag{15}$$

On the basis of Eqn. (15), they concluded that there is a linear relation between ΔH and $(\Delta\mu)^{1/2}$. This correlation was tested using extremely limited experimental data[65].

It must be emphasised that Eqns. (13) and (14), indicating a linear relation between $-\Delta H$ and $\Delta\mu/er_{\text{DA}}$, were obtained[49,61] without introducing any approximations additional to those adopted in the derivation of the fundamental equation of Mulliken's theory.

III. HYDROGEN-BONDED COMPLEXES AND PROTON TRANSFER

The hypothesis that the hydrogen-bonded complex is an intermediate in protonation reactions has been gaining increasing recognition at the present time[12]. Proton transfer between the neutral molecules A–H and B via the mechanism

$$\underset{\text{I}}{\text{A—H} + \text{B}} \rightleftarrows \underset{\text{II}}{\text{A—H}\cdots\text{B}} \rightleftarrows \underset{\text{III}}{\text{A}^-\cdots\text{H—B}^+}$$

is believed to be one of the fastest chemical reactions[68].

Not so much the dynamics of the proton transfer process as the question of the positions of the equilibria indicated above is important for the problem discussed in this review. The position of the equilibrium (I) ⇌ (II) determines in many respects the feasibility and accuracy of the estimation of the parameters of the hydrogen-bonded complexes (see below). The equilibrium (II) ⇌ (III) determines the state to which the measured parameters refer. The thermodynamic parameters of the formation of hydrogen-bonded complexes are relatively insensitive to the position of the equilibrium (II) ⇌ (III), since the energetics of the formation of the complex A–H...B and the ion pair A^+...H–B^- in inert solvents are similar[69].

The problem of the origin of the dipole moment of the hydrogen-bonded complex is most controversial. There are two views. According to one, the dipole moment increment on complex formation is caused mainly by the presence in the system of the highly polar protonated form of the complex A^-...H–B^+. The tautomeric equilibrium (II) ⇌ (III) occurs in solution and the experimental dipole moment includes contributions from the dipole moments of the weakly polar hydrogen-bonded complex and the highly polar ion pair. Hence, $\Delta\mu$ reflects either the tautomeric (II) ⇌ (III) equilibrium constant[27,70-72] or the mole fraction of species with proton transfer[73-75].

The dipole moment increment is interpreted in a different way from the standpoint of the electron donor-electron acceptor interaction in systems with hydrogen bonds. According to this concept, the differences between the values of $\Delta\mu$ for different hydrogen-bonded complexes are not caused by the different contents of the protonated form of the complex in solution but are determined by the different degrees of charge transfer from the molecule B to the molecule A–H in the hydrogen-bonded complexes. Consequently, the experimental dipole moment refers to the given hydrogen-bonded complex and the dipole moment increment on complex formation is determined to a first approximation by the magnitude of the transferred charge. The ion pair (III) is regarded as the limiting state of the hydrogen-bonded complex.

The non-linearity of the relation between $\Delta\mu$ and $\Delta\text{p}K_\text{a}$,[27] where $\Delta\text{p}K_\text{a}$ is the difference between the $\text{p}K_\text{a}$ values of the base and acid, is frequently quoted as one of the pieces of evidence in support of the first view. The S shape of the curves relating $\Delta\mu$ to $\Delta\text{p}K_\text{a}$ is then interpreted from the standpoint of the existence of two forms of the complex, (II) and (III), having different polarities[27,72,74,76]. Furthermore, starting from the investigations of Barrow and coworkers[77,78], who detected by infrared spectroscopy two tautomeric forms of the complex in systems formed by mono- and di-chloroacetic acids with pyridine in chloroform, there have been numerous publications in which the observed changes in the infrared spectra on interaction between acids and bases are treated from the standpoint of the formation of either hydrogen-bonded complexes, or protonated forms of the complex, or of both types of species in equilibrium[79-91]. The latter to some extent justified also the treatment of $\Delta\mu$ from the standpoint of the presence of a tautomeric equilibrium in the system. However, these two types of evidence cannot be regarded as sufficiently reliable.

There exist extensive experimental data showing that the $\text{p}K_\text{a}$ values cannot serve as a reliable measure of the electron-donating and electron-accepting properties of molecules and of the strength of hydrogen bonds. The nature of these parameters is very complex and they characterise not only the proton affinity of the molecule but include also the energy and entropy of hydration of the components[92]. Arnett et al.[93-95] failed to observe a general correlation between the enthalpies of formation of hydrogen-bonded complexes of a number of bases with *p*-fluorophenol in carbon tetrachloride, on the one hand, and the heats of protonation of these compounds in strong acids (sulphuric and fluorosulphonic), on the other, having shown thereby that the concepts of basicity in these processes are not identical. At the same time, an excellent correlation between the heats of protonation of bases in chlorosulphonic acid and the $\text{p}K_\text{a}$ values has been demonstrated on the basis of extensive experimental data[95]. The latter is quite natural, since both parameters characterise the formation of solvated ions in the acid–base interaction.

In a study of the interaction of a number of bases with *p*-fluorophenol in carbon tetrachloride and with *p*-fluorobenzenesulphonic acid in methylene chloride by ^{19}F NMR, Taft and coworkers[96,97] showed that the relative basicity scale obtained relative to *p*-fluorophenol (hydrogen-bonded complexes) differs from the basicity scale obtained for *p*-fluorobenzenesulphonic acid (ion pairs). As in the previous case, the chemical shifts and ΔH values for the systems with *p*-fluorobenzenesulphonic acid are satisfactorily correlated with the pK_a values measured in water. The dependence of the basicity scales on the acid properties of the proton donor has been demonstrated by Hadzi et al.[98]

In a chromatographic study of the complexes of HCl and HBr with different bases, Iogansen et al.[99] concluded that the capacity for the formation of a hydrogen bond in terms of energy is completely inconsistent with the strength of the acid as defined by the dissociation constant. A similar conclusion, namely that the strength of the hydrogen bond is not determined by the tendency of the proton to pass from the acid to the base (which is measured by the pK_a value), was reached on the basis of the infrared spectroscopic measurements of $\Delta\nu$ and ΔH for the complexes of HX (X = F, Cl, Br, or I) with different bases[100,101]. A similar situation has been observed for compounds containing SH and OH groups. Mercaptans are stronger acids than alcohols, but, other conditions being equal, the compounds RSH form weaker hydrogen-bonded complexes than the analogous compounds ROH.[102]

Thus it is clear from the foregoing that the correlations of particular parameters of hydrogen-bonded complexes with pK_a and ΔpK_a should be treated with much caution. The linearity of the relations between pK_a and some parameter of hydrogen-bonded complexes may be expected only in those cases where the acid–base interaction leads to the formation of solvated ions. The parameters of hydrogen-bonded complexes measured in inert solvents should not be correlated, in principle, with pK_a. This applies, in particular, to the $\Delta\mu$–ΔpK_a correlation, as stated above. The linearity of the relations between ΔH, $\Delta\nu$, and other parameters of hydrogen-bonded complexes, on the one hand, and ΔpK_a, on the other, which is sometimes observed, refers as a rule to a narrow range of similar complexes. The position of the equilibrium (II) $\rightleftharpoons$ (III), which is sometimes observed, depends to a large extent on the medium.

In a study of the complexes of nitrophenols with aliphatic amines in benzene and in a benzene–cyclohexane mixture by ultraviolet spectroscopy, Vinogradov and coworkers[69,103,104] demonstrated the possibility of converting the hydrogen-bonded complex into a protonated form when a relatively small excess of the amine is added to the solutions. The influence of the solvent on the degree of conversion of the hydrogen-bonded complexes into a protonated form has been observed in systems comprising *p*-nitrophenol and various bases in chlorobenzene[105] and in the *p*-nitrophenol–ethylenediamine system in methanol, ethanol, dioxan, and their mixtures with water[106]. Analogous observations concerning the influence of the solvent on the state of the equilibrium (II) $\rightleftharpoons$ (III) were reached also for carboxylic acid–base systems[107-110]. Benzoic acid reacts with triethylamine in inert solvents (cyclohexane, carbon tetrachloride, and carbon disulphide) to form hydrogen-bonded complexes, while in acetonitrile and chloroform ionisation takes place[107]. The conversion of the protonated form of the complex of trifluoroacetic acid with dimethylaniline into a molecular hydrogen-bonded complex has been observed by ^{1}H NMR when the system was diluted with an inert solvent[109].

The results of studies of the infrared spectra of the H_2O–HCl and NH_3–HCl systems in a nitrogen matrix are instructive[111,112]. In an isolated matrix, the complexes $H_2O.HCl$ and $NH_3.HCl$ are not ion pairs but consist of molecular complexes with strong hydrogen bonds. On the other hand, the presence of ionic forms is characteristic of these systems in a number of solvents. The presence of only the molecular complex in solution without an appreciable contribution of the protonated form has been demonstrated by ^{19}F NMR for complexes of *p*-fluorophenol with a wide variety of bases in carbon tetrachloride[113] and other inert solvents[114]. The conclusion that hydrogen-bonded complexes are formed in binary systems of carboxylic acids and phenols with pyridine was reached on the basis of infrared spectroscopic data[115].

Hydrogen-bonded complexes without the formation of the protonated form have been observed also for the hexafluoropropanol–triethylamine[116] and acetic acid–pyridine[117] systems in benzene and for systems comprising HF and different bases[118]. The study of the infrared spectra of the binary and ternary systems formed by a number of carboxylic acids, including strong acids such as trifluoro- and trichloro-acetic acids, with different bases led to the conclusion that only hydrogen-bonded complexes are formed; proton transfer was not observed[119]. The study of the dielectric relaxation times of the complexes formed by picric acid with tributylamine in benzene[120,121] showed that species of only one type exist in solution. The conductivities of the solutions were low.

Thus one can evidently assume with adequate certainty that, in the studies on systems with hydrogen bonds in inert solvents, we are dealing in the vast majority of cases with only one type of hydrogen-bonded complex, namely complex (II), and not with a mixture of the two forms (II) and (III). The measured parameters ($\Delta\mu_c$, ΔH, ΔS, etc.) then refer to the complex A–H...B and are not the overall characteristics of the hydrogen-bonded complex–ion pair equilibrium system.

IV. THE COMPOSITION AND THERMODYNAMICS OF THE FORMATION OF HYDROGEN-BONDED COMPLEXES

We shall now examine the problem of obtaining the most reliable data characterising the properties of the complex A–H...B. Apart from the X–H bond, which behaves as an electron acceptor on formation of the hydrogen-bonded complex, the A–H molecule frequently contains electron-donating atoms or groups. These are oxygen, sulphur, and nitrogen atoms in alcohols, mercaptans, and primary and secondary amines respectively and the CO, PO, and SO groups in carboxylic, phosphoric, and sulphonic acids and the π-electron systems in aromatic and unsaturated compounds. Such polyfunctionality leads in the majority of cases to the self-association of the A–H molecules. The structure of the associated species $(AH)_n$ and the degree of association n depend on the composition and structure of the A–H molecules and on the conditions under which they exist (the state of aggregation, the concentrations in solutions, and temperature)[122-152].

Carboxylic acids tend to form in solution preferentially cyclic dimers[125-132,150]. The association of alcohols and phenols is more complex. Dimers, trimers, and higher polymers, to which both linear and cyclic structures have been attributed, are observed in solutions of these compounds[23,123,133-146]. The problem of the structure of the associated species formed by alcohols and phenols has been extensively discussed in the literature for a long time, but, nevertheless, it still cannot be regarded as finally solved[23,123,138].

The capacity for self association depends both on the electron-donating and the electron-accepting properties of the A–H molecules. However, in series of compounds A–H with identical structures the introduction of electronegative substituents into the group A leads to a decrease of the capacity of the A–H molecules for self association simultaneously with increase of their electron-accepting capacity. Such a tendency has been observed for alcohols[23], phenols[23,123,139,143], and carboxylic acids[124,128–131]. For example, the enthalpies of formation ΔH_{dim} (kcal mole^{-1}), and the stability constants K_{dim} (litre mole^{-1}) of chloro-substituted acetic acid dimers in carbon tetrachloride decrease with the increase in the number of chlorine atoms in the acid molecule[129]:

	$-\Delta H_{\text{dim}}$	K_{dim}
CH_3COOH	8.4	1400
$CH_2ClCOOH$	7.8	701
$CHCl_2COOH$	6.7	600
CCl_3COOH	5.6	150

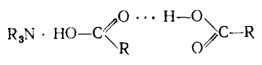
A similar decreased stability of the dimers with increasing degree of halogenation has been observed in a series of substituted fluorophenols[139]:

	$-\Delta H_{\text{dim}}$
2-F—C_6H_4OH	5.2
2,3,5,6-F_4—C_6HOH	3.7
C_6F_5OH	2.9

The decreased stability of the associated species leads to a decrease in the tendency of the A–H molecules towards the formation of higher n-mers $(AH)_n$ with $n > 2$. For example, it has been noted that the self-association of polyfluorophenols proceeds via the monomer ⇌ dimer mechanism, while in solutions of phenols and monofluorophenols, cyclic trimers and tetramers and linear n-mers have been detected[135].

Steric factors also have a significant influence on the capacity of the compounds A–H for self association[132,146]. For example, *ortho*-substituted phenols show less tendency towards self association than their *para-* and *meta*-substituted analogues. The reason for this may be either the formation of intramolecular hydrogen bonds (for example in *o*-nitro and *o*-halogeno-phenols[123,146]) or steric hindrance (for example, the absence of association in 2,6-di-t-butylphenol[146]).

The capacity of the A–H molecules for self-association can lead to the formation, together with the AH...B complexes, also of more complicated complex species having the composition $(AH)_n.B$. The addition of further A–H molecules to AH.B takes place via the same coordination centres as in the self-association of A–H. However, charge transfer from the B molecule to the A–H molecule increases the electron-donating capacity of the latter and the AH...AH linkage is stronger than in the self-associated species[48,53]. For example, the energy of the C=O...H–O hydrogen bond in 2 : 1 complexes of carboxylic acids and amines,



is greater than in the initial acid dimers, the strengthening of this bond being greater the higher the enthalpy of formation of the corresponding complex[48]. The latter is probably associated with the increase of the electron-donating properties of the carbonyl oxygen as a result of charge transfer on formation of the O–H...N linkage.

In view of the self-association of A–H molecules and the possibility of the formation of the complexes $(AH)_n...B$, the interaction in systems with intermolecular hydrogen bonds can be treated as a multistage process:

$$\begin{array}{ll}
AH + AH \rightleftarrows (AH)_2\,; & AH + B \rightleftarrows AH \cdot B\,; \\
(AH)_2 + AH \rightleftarrows (AH)_3\,; & AH \cdot B + AH \rightleftarrows (AH)_2 \cdot B\,; \\
\cdots\cdots\cdots & \cdots\cdots\cdots \\
(AH)_{n-1} + AH \rightleftarrows (AH)_n\,; & (AH)_{n-1} \cdot B + AH \rightleftarrows (AH)_n \cdot B.
\end{array}$$

In solution or in the gas phase, where there is a possibility of the dissociation of the complexes into their components, systems of this kind consist of a complicated equilibrium mixture of complexes having different compositions and of the initial components. In a physicochemical study of such systems, it is necessary to determine simultaneously the parameters of all the complexes present in the mixture, together with their stability constants, which requires the use of special methods for the interpretation of the experimental results[28,153]. If only one comparatively stable complex is formed in the system, the graphical and analytical methods for the interpretation of the measurements[28] used in the study of EDA complexes, which are as a rule approximate, can be applied to the determination of parameters of this complex. For weak interactions or multistage processes, these methods are relatively unsuitable and a rigorous solution of the problem becomes possible only with the aid of a computer[28,53,153].

In order to diminish the degree of self-association of A–H and to avoid the formation of the complexes $(AH)_n.B$, one usually carries out experiments in dilute solutions or a large excess of B is employed. However, the superposition of secondary processes by the appropriate formulation of the experiment is virtually never possible. Thus, if the A–H compounds form fairly stable associated species, self-association can be eliminated only at very low concentrations[53,123] (for example, 0.005 M for phenol[123]). Under these conditions, the comparatively weak complexes AH.B can be fully dissociated into their components or can be present in such low amounts that they cannot be detected because of the limited sensitivity of the given physical method. On the other hand, when a large excess of B is used, there is a possibility of complicating effects associated with the solvating action of the medium[53,94].

The experimental results are frequently treated by approximate computational methods, which are suitable only for single-stage complex-formation processes. At the same time, these methods do not involve criteria which would confirm the occurrence in the system of only one postulated equilibrium and do not allow a choice of the concentration conditions in which the superposition of the side process might be neglected[28,53].

The majority of the methods proposed in the literature for the calculation of equilibrium constants and the physical parameters of complexes from physicochemical data obtained in studies on solutions are based on the hypothesis that the solutions are ideal (the activity coefficients of all the components of the complex-formation reaction are unity). However, under real experimental conditions one is not always dealing with ideal solutions[53,94,154–159]. The thermodynamic non-ideality of solutions results, in particular, from the use of solvents with high dielectric constants (nitrobenzene, dichloroethane, etc.) or from the employment of solutions at high concentrations in the experiments. Furthermore, solvents with electron-donating or electron-accepting properties, such as aromatic hydrocarbons, chloroform, methylene chloride, etc. can enter into specific interactions with the components of the test system. The equilibrium constants determined under such conditions are apparent and do not represent the true values[28].

An enormous amount of data has now accumulated on the thermodynamics of the formation of complexes with intermolecular hydrogen bonds. Most of the literature results have been obtained from the temperature variation of the equilibrium constants using a spectroscopic method (ultraviolet, infrared, Raman, and NMR). The standard free energies ΔG^0, enthalpies ΔH^0, and entropies ΔS^0 are determined from the relations

$$\Delta G^0 = -RT \ln K = \Delta H^0 - T\Delta S^0, \qquad (16)$$

$$T = 298\ ^\circ\mathrm{K};$$

$$\ln K = \frac{-\Delta H^0}{RT} + \frac{\Delta S^0}{R}. \qquad (17)$$

ΔH^0 and ΔS^0 are usually found by a graphical procedure based on Eqn. (17) from the slope of the linear plot of $\ln K$ against $1/T$ and from the intercept on the ordinate axis. The possible errors in the determination of K, which were discussed above, can lead to a very significant distortion of the values of ΔH^0, ΔS^0, and ΔG^0 determined from the equilibrium constants[28].

Iogansen and coworkers[57] proposed a spectroscopic method for the determination of the enthalpies of formation of hydrogen-bonded complexes from the intensities of the stretching vibration bands of the groups X–H in the complex and in the free molecule A–H and not on the basis of the equilibrium constants.

It is noteworthy that an additional source of errors in the determination of thermodynamic parameters by spectroscopic methods may be the overlapping of the absorption bands of the initial components and the complexes and also the possible temperature variation of the molar extinction coefficients[8].

Methods for the estimation of the thermodynamic parameters of hydrogen-bonded complexes on the basis of parametric equations have been proposed in a number of studies[6,56,160–163]. For example, Drago et al.[56] proposed a four-parameter equation:

$$-\Delta H^0 = E_\mathrm{D}E_\mathrm{A} + C_\mathrm{D}C_\mathrm{A}. \qquad (18)$$

The parameters E_D, E_A, C_D, and C_A characterise the electrostatic and covalent properties of the donor and acceptor respectively. The reliability of such parametric methods depends on the accuracy of the estimation of the parameters in the corresponding equations.

The most reliable thermodynamic data for complex-formation reactions can be obtained from direct calorimetric measurements[8,28]. However, here too the accuracy of the determination of the parameters depends to a large extent on the method of mathematical treatment of the results and on the inertness of the medium[28,53]. The Table presents what we believe to be the most reliable thermodynamic parameters (ΔH^0 and ΔS^0) for the complex-formation reactions AH + B $\rightleftharpoons$ AH.B. It includes data obtained in the most inert solvents: hexane, cyclohexane, octane, and carbon tetrachloride, and only in a few instances in benzene, toluene, etc. Preference has been given to calorimetric data. Complexes with enthalpies of formation below 4–5 kcal mole^{-1} have been excluded from consideration because the errors associated with the influence of the medium in such cases are comparable to the parameters being determined. Systems where it is virtually impossible to prevent the superposition of side reactions owing to the strong association of the compounds A–H or owing to the presence of additional coordination centres in the donors B are not considered either.

One of the characteristic features of the thermodynamics of the formation of donor–acceptor complexes of

Thermodynamic parameters and dipole moments of hydrogen-bonded complexes.

* Abbreviations: B = benzene, H = hexane, HP = heptane, O = octane, ODCB = *o*-dichlorobenzene, T = toluene, CH = cyclohexane, CT = carbon tetrachloride.

** These data have been refined in relation to those quoted in the relevant literature (more accurate calculations, replacement of benzene by a more inert solvent—octane).

type *nv* and *nσ* is the so called compensation effect, i.e. a linear relation between ΔH^0 and ΔS^0. As shown previously[164], this relation is general for the complex-formation reactions A + B $\rightleftharpoons$ A.B and is described by the equation

$$-\Delta H^0 = -0.337\Delta S^0 + 3.1. \qquad (19)$$

A linear relation between ΔH^0 and ΔS^0 was also observed in series of hydrogen-bonded complexes having similar compositions[8,154].

The tabulated data, which cover a wide range of various hydrogen-bonded complexes, are illustrated in Fig. 1, in the form of a plot of ΔH^0 against ΔS^0. Evidently these results fit fairly satisfactorily on a single straight line, whose equation, found by the method of least squares, is

$$-\Delta H^0 = -(0.346 \pm 0.013)\Delta S^0 + (2.77 \pm 0.38). \qquad (20)$$

The correlation coefficient is r = 0.970.

Within the limits of the confidence intervals, the coefficients of Eqn. (20) agree with those of Eqn. (19). Consequently the values of ΔH^0 and ΔS^0 for hydrogen-bonded complexes obey the relation characteristic of typical EDA complexes, which demonstrates the identity of the mechanisms of the formation of both types of complexes. A theoretical justification of the linearity of the relation between ΔH^0 and ΔS^0 for the formation of donor-acceptor complexes has been obtained[164] and it has been shown that it is caused mainly by the changes in the intramolecular degrees of freedom on complex formation. The entropy of complex formation can be represented by a sum of two terms:

$$\Delta S = \Delta S_{\text{transl + rot}} + \Delta S_{\text{int}}. \qquad (21)$$

The first term of Eqn. (21) reflects the change in the degrees of freedom associated with the motion of molecules as rigid bodies and the second reflects the change in the intramolecular degrees of freedom. The contribution of $\Delta S_{\text{transl. + rot.}}$ is always negative, since the binding of two molecules, and in particular A–H and B molecules, in a complex leads to the loss of three translational and three rotational degrees of freedom. This contribution (50–55 e.s.u.) is almost independent of the stability and structure of the complex[164]. The appearance of six new vibrational degrees of freedom, accompanying the formation of the intermolecular bond, makes the dominant contribution to ΔS_{int}. This contribution is always positive and is greater the lower the energy of the donor–acceptor bond[164]. For this reason, the absolute negative entropy of formation of complexes increases with increase of their enthalpy of formation.

The equilibrium constants for the formation of hydrogen-bonded complexes are frequently used as a measure of their relative stability. Such estimates must be treated with caution. The existence of the so called "isoequilibrium temperature" which is equal to the slope of the ΔH^0–ΔS^0 linear plot, follows from the linear relation between the enthalpy ΔH and entropy ΔS.[164,165] At this temperature (346 ± 13°K or 73° ± 13°C), the equilibrium constants for all complexes obeying Eqn. (21) are similar. At temperatures below the isoequilibrium value, the equilibrium constants increase with the enthalpy of formation of the complexes. Above the isoequilibrium temperature, the opposite relation should hold. Hence it follows that only those values of K which have been obtained below the isoequilibrium temperature may be used for the estimation of the relative energies of the hydrogen bonds.

V. THE STRUCTURE OF HYDROGEN-BONDED COMPLEXES AND ESTIMATION OF THE POLARITY OF HYDROGEN BONDS

Extensive experimental data have accumulated on the dipole moments (DM) of molecular hydrogen-bonded complexes. The Debye method, in which the concentration dependence of the dielectric constants and densities or refractive indices of fairly dilute solutions of the test substances is measured in inert solvents, is the commonest method for the determination of dipole moments. The measurement of the dipole moments of complexes by the Debye method makes it necessary to take into account the equilibrium constants[28], which are either determined by an independent procedure or from dielectric constant measurements simultaneously with μ_c, requiring the use of special methods for the interpretation of the results[28,166-170]. The difficulties arising in the measurements of the dipole moments of hydrogen-bonded complexes in solution and the methods for their determination are similar to

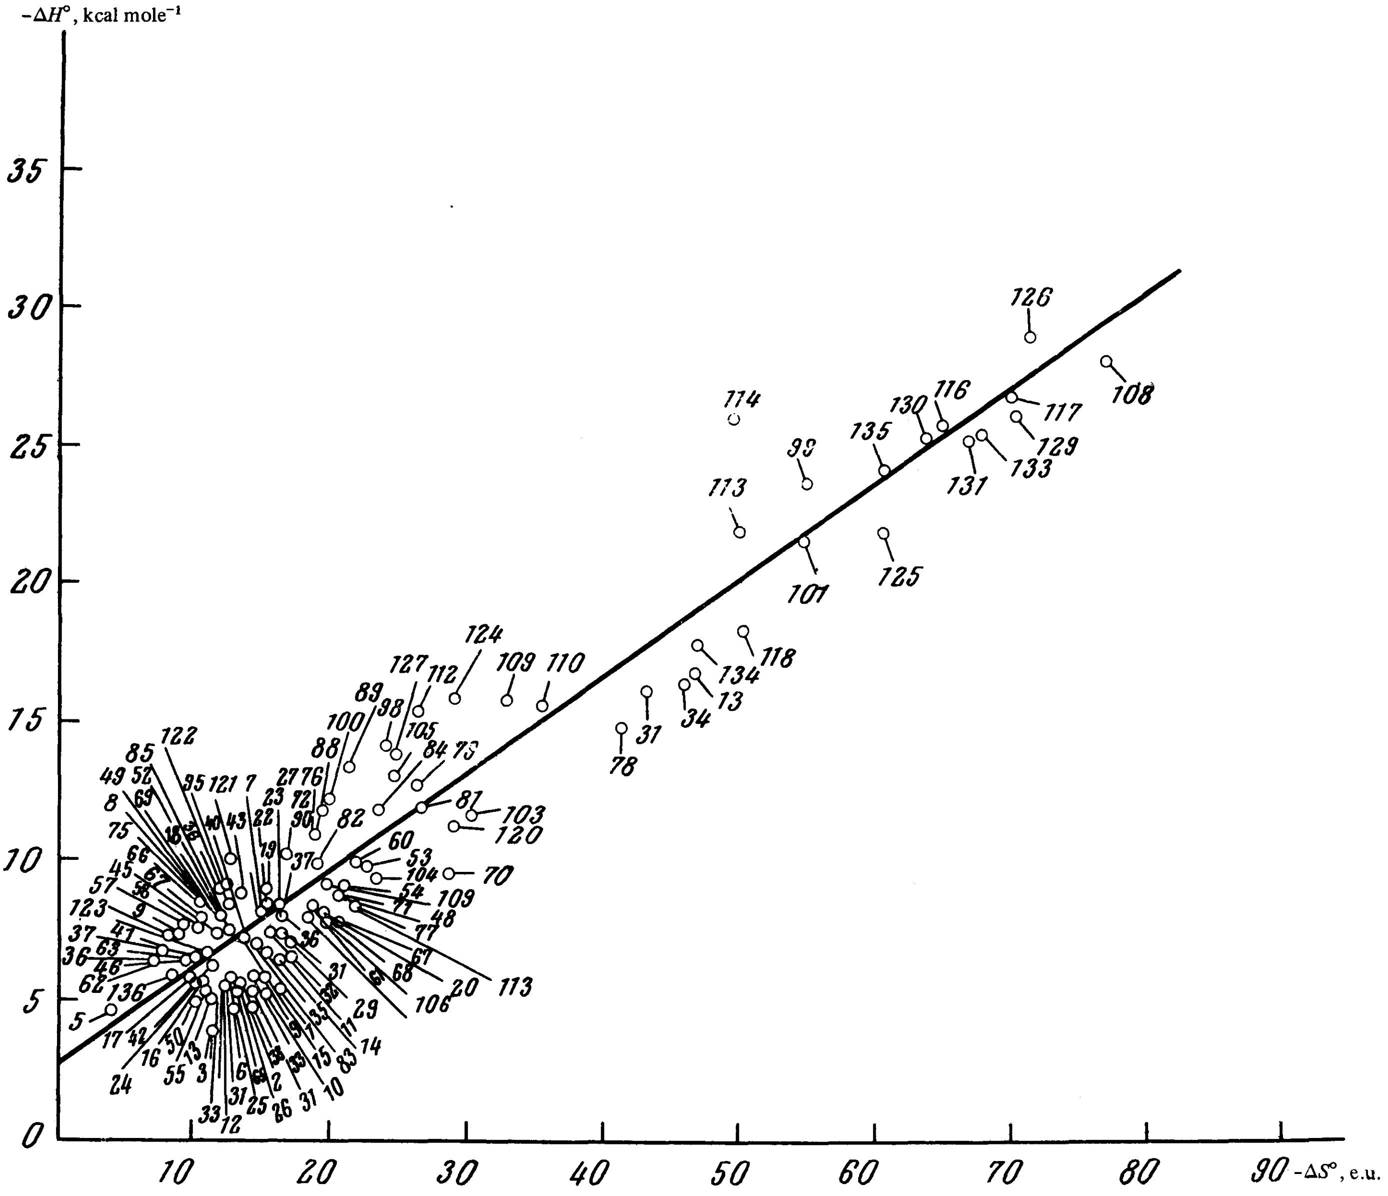

Figure 1. Relation between $-\Delta H^0$ and $-\Delta S^0$ for hydrogen-bonded complexes (the numbers of the points correspond to the numbers in the Table).

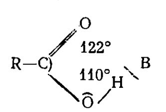
those described above for the determination of the thermodynamic parameters. The differences probably consist in the fact that, other conditions being equal, the values of μ_C are less sensitive to the influence of the solvent (naturally, comparatively inert solvents are considered) than the thermodynamic parameters. This is clearly shown, for example, by a comparison of the values of μ_C and ΔH^0 measured by the present authors[47,53] in benzene and octane for the complexes of 4-bromo- and 3,4-dimethyl-phenols with pyridine:

	Benzene		Octane	
	μ_C	$-\Delta H^0$	μ_K	$-\Delta H^0$
$4\text{-BrC}_6H_4OH \cdot NC_5H_5$	5.24	6.9	5.30	8.0
$3,4\text{-}(CH_3)_2C_6H_3OH \cdot NC_5H_5$	4.40	5.9	4.40	7.2

Within the limits of the present review, we are unable to give a compilation of all the measurements of the dipole moments of hydrogen-bonded complexes. We believe that the Table lists the most reliable dipole moments of such complexes. We may note that, in order to obtain information about the polarity of the intermolecular hydrogen bonds, one mainly considers the simplest systems in which the formation of the intermolecular hydrogen bond is not complicated by an additional interaction. Furthermore, compounds where the enthalpies of formation have been measured as well as their dipole moments are given preference.

Within the framework of the approximation of the vector additivity method for the determination of $\Delta\mu$ (the increment in the dipole moment of a hydrogen-bonded complex relative to the vector sum of the dipole moments of the components), it is necessary to know not only the values of μ_C, μ_{AH}, and μ_B, but also the angles between these vectors. The available literature data on the structures of hydrogen-bonded complexes are considered below in this connection.

Structure (I) is most probable for the 1 : 1 complexes of carboxylic acids with bases[46,171,172]:

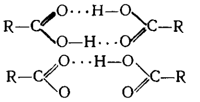


. (I)

The planar conformation of the carboxy-group with the *cis*-disposition of the proton of the O–H group relative to C=O has been established by gas-phase electron-diffraction for the formic acid[173] and propionic acid[174] monomers. X-Ray diffraction studies on the 1 : 1 complexes of trichloroacetic acid with pyridine *N*-oxide[172] and of *p*-bromo- and *p*-chloro-benzoic acids with piperidine[175] have shown that the *cis*-conformation of the carboxy-group persists also in the hydrogen-bonded complexes. It was established that complex formation does not cause any significant changes in the structures of the electron donor and electron acceptor molecules, with the exception of the groups directly involved in the formation of the hydrogen bond[175]. This behaviour is characteristic of *nσ* complexes, particularly the complexes of halogens with *n* donors[28].

The orientation of the B molecules relative to the X–H...Y bond depends on a number of factors. For sterically unhindered compounds, it is determined primarily by the state of the orbital occupied by the free electron pair of the corresponding heteroatom. As in the formation of intermolecular bonds in donor–acceptor complexes, in the hydrogen-bonded complexes the principle of maximum overlap probably holds[28]. From this standpoint, the most probable structure of the complexes of carboxylic acids with amines and phosphines is one where the X–H...Y bond axis coincides with the symmetry axis of the R_3N or R_3P molecule (the sp^3 orbital of the lone electron pair of the heteroatom). In complexes with sulphides and selenides, the planes of the R_2S and R_2Se molecules are almost perpendicular to the X–H...Y axis (*p* orbital). In complexes with oxygen compounds, the angle between the plane of the donor molecule and the X–H...O axis is approximately 120°, which corresponds to the sp^3 hybridisation of the atomic orbitals of oxygen. However, this angle is not constant in different complexes, appreciable variations being observed[6,28,176].

The problem of the structure of the 2 : 1 complexes of carboxylic acids is still obscure. It has been shown that the hydrogen-bonded ring of the carboxylic acid dimer is planar and has a centre of symmetry[177–184] [structure (II)]. The dissociation of one of the hydrogen bonds in the dimer and the formation of a 3 : 1 complex are associated with significant changes in the conformation of the dimer. Analysis of the dipole moments of such carboxylic acid complexes with amines[48] leads to the conclusion that they most probably have conformation (III):



, (II)

. (III)

The changes in the structure of phenol molecules on complex formation are insignificant, as for carboxylic acids[192,193]. The orientation of the B molecules relative to the X–H...Y linkages in the complexes of phenols and alcohols was assumed to be the same as in the complexes of carboxylic acids. In the calculations of $\Delta\mu$, the same group dipole moments and valence angles were used as in earlier studies[47,48,171]. The calculated values of $\Delta\mu$ for the corresponding complexes are listed in the sixth column of the Table.

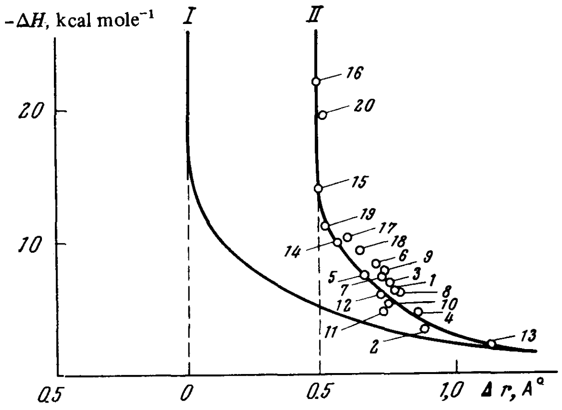


Figure 2. Relation between $-\Delta H^0$ and Δr: I) for typical EDA complexes; II) for hydrogen-bonded complexes; 1) $(CH_3OH)_2$;[226,231] 2) $[2,6\text{-}(CH_3)_2C_6H_3OH]_2$;[143,187] 3) $[3,4\text{-}(CH_3)_2C_6H_3OH]_2$;[142,191] 4) $(4\text{-}ClC_6H_4OH)_2$;[142,191] 5) $(HCOOH)_2$;[184,232] 6) $(CH_3COOH)_2$;[152,233] 7) $[(CH_3)_3.CCOOH]_2$;[184,234] 8) $(C_2H_5COOH)_2$;[151,235] 9) $(C_3H_7COOH)_2$;[184,236] 10) $(CCl_3COOH)_2$;[129,181] 11) $(H_3C\text{–}C{\equiv}C\text{–}COOH)_2$;[126,237] 12) $(C_6H_5COOH)_2$;[149,238] 13) 2,6-$(t\text{-}C_4H_9)C_6H_4.O(CH_2)_4$;[198] 14) 4-$ClC_6H_4OH.N(C_2H_5)_3$;[47,66] 15) $C_6H_5COOH.N(C_2H_5)_3$;[47,66] 16) $C_6H_5COOH.N(C_2H_5)_3$.[232,172]

The energies of the intermolecular hydrogen bonds vary over a wide range: from a few to several tens of kcal mole^{-1} (see the values of ΔH^0 in the Table). Appreciable differences in the X–H...Y bond lengths are observed at the same time. It was of interest to elucidate the relation between these most important parameters of hydrogen-bonded complexes. A relation between ΔH^0 and Δr (Fig. 2, curve I), where $\Delta r = r_{exp} - \Sigma r_{cr}$ is the difference between the experimental length of the donor–acceptor bond and the sum of the covalent radii r_{cr} of the atoms forming this bond, was obtained previously[194] for donor–acceptor complexes of type *nv* and *nσ*. For comparatively weak complexes, with enthalpies of formation up to 8–10 kcal mole^{-1}, there is a definite parallelism in the variation of ΔH^0 and Δr: the higher the intermolecular interaction energy the shorter the coordinate bond. The maximum approach of the molecules ($\Delta r = 0$) is reached for $-\Delta H^0$ = 14–16 kcal mole^{-1}. Consequently, when the enthalpy of formation of a particular complex of type *nv* or *nσ* reaches this value, one can assume with a fair degree of certainty that the length of the donor–acceptor bond in this complex is equal to the length of the corresponding covalent bond in conformity with Fig. 2 (curve I).

Naturally, owing to their mutual repulsion, the X, H, and Y atoms in systems with a hydrogen bond cannot form an X–H...Y linkage whose length is equal to the sum of the covalent radii r_X, $2r_H$, and r_Y. However, as in the EDA complexes, here too one may expect a limit to the approach of the molecules for a specific interaction energy. Fig. 2 (curve II) presents a plot of ΔH^0 against Δr for hydrogen-bonded complexes. Here $\Delta r = r_{exp} - \Sigma r_{cr}$, r_{exp} being the experimental X...Y distance in the A–H...B complex and $\Sigma r_{cr} = r_X + 2r_H + r_Y$. In order to plot ΔH^0 against Δr, the most reliable enthalpies of formation and interatomic distances in hydrogen-bonded complexes were used. Owing to the lack of experimental data, the results of quantum-chemical calculations were employed for systems 17–20; for systems 13–15, the bond lengths were obtained from the $\Delta\nu - r_{XY}$ correlation[66].

The fact that the nature of the relation between ΔH^0 and Δr for hydrogen-bonded complexes and EDA complexes is the same is most striking. In systems with comparatively weak hydrogen bonds (up to 10 kcal mole^{-1}), the values of Δr increase appreciably with increase of ΔH^0, but for stronger interactions Δr changes little. It is extremely remarkable that the limiting approach of the A–H and B molecules in hydrogen-bonded complexes is reached for approximately the same intermolecular interaction energy as in the usual EDA complexes.

It follows from the analysis of curve (II) in Fig. 2 that Δr is constant and approximately equal to 0.5 Å for complexes with an intermolecular hydrogen bond the enthalpy of formation of which exceeds 12–14 kcal mole^{-1}. Hence one may conclude that, in comparatively stable A–H...B complexes, the minimum X–H...Y distance within the limits of the approximations introduced, may be close to the sum $r_X + 2r_H + r_Y + 0.5$ Å.

The correlation between ΔH^0 and Δr proved extremely useful for the estimation of the intermolecular hydrogen bond lengths $r_{X...Y}$ from the ΔH^0 for the corresponding complexes. We have used it widely for the estimation of the degrees of charge transfer $\Delta\mu/er_{DA}$.

VI. RELATION BETWEEN THE DEGREE OF CHARGE TRANSFER AND THE ENERGY OF HYDROGEN BONDS

The most important evidence in support of the hypothesis that the intermolecular hydrogen bonds are of the donor–acceptor type is provided by the analysis of the relation between the degree of charge transfer and the energy of formation of hydrogen bonds. A linear relation between $-\Delta H^0$ and $\Delta\mu/er_{DA}$ has been established[47,48] for a number of hydrogen-bonded complexes, mainly those of carboxylic acids and phenols. In the present review, we attempted to survey results referring to a wider range of systems, including the results of studies in recent years.

According to theoretical quantum-chemical calculations, the maximum fraction of the transferred charge is localised near the atom X in the X–H bond. One can assume to a first approximation that the charge is localised at the X atom. In this case, the distance r_{DA} over which the charge has been transferred and which is necessary for the calculation of $\Delta\mu/er_{DA}$ is equal to r_{XY}. We obtained the values of r_{XY} with the aid of a plot of ΔH^0 against Δr (Fig. 2, curve II) using the values of ΔH^0 for the corresponding complexes.

Fig. 3 shows a plot of the relation between the values of $\Delta\mu/er_{DA}$, calculated in terms of the $r_{DA} = r_{XY}$ approximation and the enthalpies of formation of the complexes listed in the Table. Evidently all the results fit fairly satisfactorily on a single straight line. Its equation is found by the method of least squares to be

$$-\Delta H^0 = (38.0 \pm 5.1)\frac{\Delta\mu}{er_{DA}} + (3.9 \pm 1.4). \qquad (22)$$

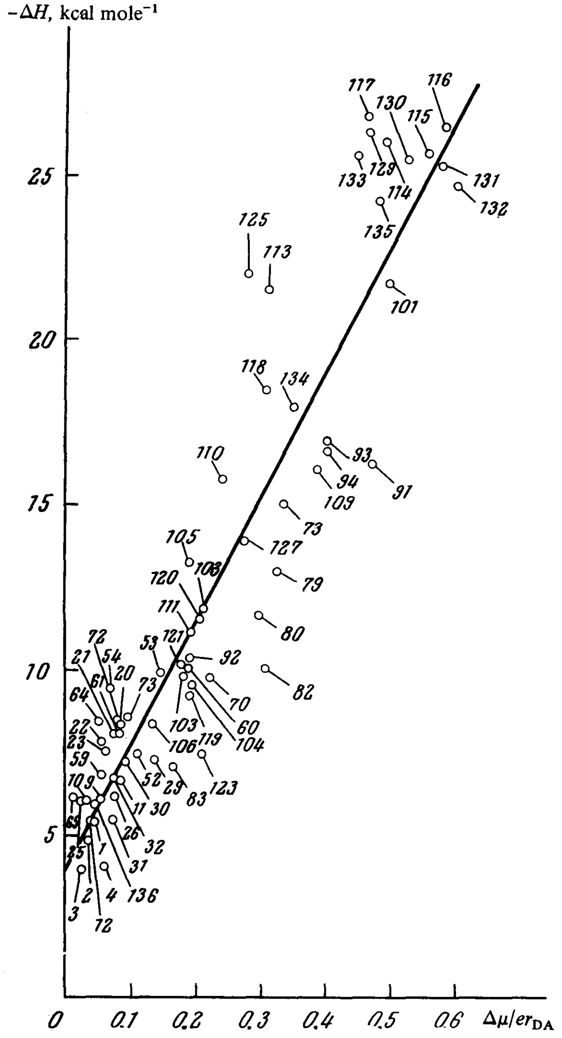

Figure 3. Relation between $-\Delta H^0$ and $\Delta\mu/er_{DA}$ for hydrogen-bonded complexes (the numbers of the points correspond to the numbers in the Table).

The fairly high correlation coefficient (0.946) shows that, within the limit of the approximations adopted in the calculation of the degrees of charge transfer, one can postulate with a definite degree of certainty a linear relation between $-\Delta H^0$ and $\Delta\mu/er_{DA}$ for hydrogen-bonded complexes.

The linear correlation between the degree of charge transfer and the energy of intermolecular hydrogen bonds established on the basis of experimental data is consistent with Eqn. (13) derived from the equations of Mulliken's theory of charge-transfer complexes. According to Eqn. (13), the intercept which the linear plot of $-\Delta H^0$ against $\Delta\mu/er_{\text{DA}}$ makes on the ordinate axis is a measure of the energy of the intermolecular interaction via classical electrostatic forces. The value of 3–4 kcal mole^{-1} obtained in Eqn. (22) agrees fully with this hypothesis. The slope of the linear plot of $-\Delta H^0$ against $\Delta\mu/er_{\text{DA}}$ is equal, according to Eqn. (13), to the ratio of the energy of the charge-transfer band $h\nu_{\text{ct}}$ and the parameter A. The latter can be found from the dipole moment of the complex and the overlap integral for the interacting orbitals[49,61]. According to Eqn. (22), $h\nu_{\text{ct}}/A \simeq 1.6$ eV for hydrogen-bonded complexes. On the basis of this quantity and knowing the parameter A for the given complex, it is possible to estimate the position of the charge-transfer band in the electronic spectrum of this complex. The calculations showed that such bands for hydrogen-bonded complexes should occur in the far ultraviolet (below 200 nm).

It is remarkable that the slopes of the linear plots corresponding to Eqns. (1) and (22), which have a fully definite physical significance, agree within their confidence limits. Hence it follows that the relations between $-\Delta H^0$ and $\Delta\mu/er_{\text{DA}}$ for hydrogen-bonded complexes and typical EDA complexes are similar. This constitutes an experimental confirmation of the validity of the hypothesis, but there is no fundamental difference between the natures of the forces leading to the formation of both types of complexes.

The linear relation between the degree of charge transfer and the energy of intermolecular hydrogen bonds may be regarded as the most fundamental evidence for the donor–acceptor nature of the hydrogen bond, since this relation actually reflects the main features of the mechanism of the donor–acceptor interaction.

Investigation of the ESR Spectra of Adsorbed Radical-ions as a Method for the Study of the Oxidation-reduction Properties of Zeolites

M.I.Loktev and A.A.Slinkin

The influence of the conditions in the preliminary heat treatment of zeolites, of the degree of elimination of metal cations and aluminium, and of the nature of the cation introduced and the adsorbed molecule on the oxidation-reduction properties of zeolites is examined. It is shown that the available experimental data support the model postulating the formation in zeolites of centres of different strengths, the activity of which in the formation of radical-ions is determined by the type of zeolite and the conditions in its preliminary treatment.
The bibliography includes 33 references.

CONTENTS

I. INTRODUCTION

The study of the nature of the acid–base centres in zeolites is a fundamental problem the solution of which is necessary for understanding the mechanism of the action of this most important group of catalysts. Studies on amorphous aluminosilicates have already shown[1] that, apart from the usual Lewis and Brønsted centres, the surfaces of these catalysts contain the so called oxidation and reduction centres, the adsorption on which of condensed aromatic systems involves a one-electron transfer, and not the transfer of an electron pair, with formation of the corresponding adsorbed radical-ions (Fig. 1). However, the nature of these centres is not yet clearly understood. Nevertheless studies in recent years have shown that the oxidation-reduction centres can play a significant role in acid–base reactions catalysed by aluminosilicates.

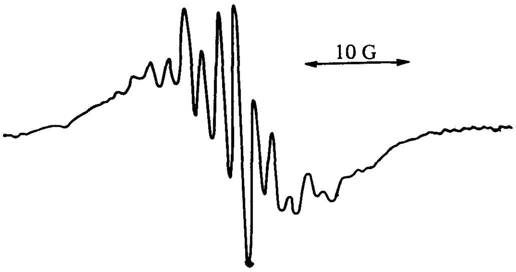

Figure 1. The ESR spectrum of anthracene adsorbed on an aluminosilicate from benzene solution[1].

The crystal structures of zeolites and the centres in these structures where cations may be located have now been quite thoroughly investigated. In recent years this situation stimulated detailed research on the oxidation-reduction centres in zeolites, which has led to new important generalisations in this field. The aim of the present review is to examine data obtained in studies, mainly by ESR, of the oxidation-reduction properties of different types of zeolites towards a wide variety of electron-donating and electron-accepting molecules.

It is not yet possible to classify the oxidation-reduction properties of zeolites according to any single characteristic of the adsorbent (the Si : Al ratio, the degree of elimination of cations or aluminium from the given type of zeolite) or according to the conditions in its preliminary treatment (heat treatment temperature, the amount of O_2 or H_2O determined). We shall therefore consider initially the oxidation-reduction properties of zeolites of types X and Y from which metal cations have been partly or completely eliminated. The review does not deal with studies in which the formation of radical-ions following the adsorption of hydrocarbons on zeolites has been observed under the conditions of external influences on the system, for example ultraviolet light or γ-radiation.

II. THE OXIDISING AND REDUCING PROPERTIES OF FAUJASITES

1. The Influence of the Degree of Elimination of Metal Cations, the Conditions in the Heat Treatment of Zeolites, and the Nature of the Adsorbed Molecule on the Oxidation-Reduction Properties of Faujasites

The adsorption of diphenylethylene, triphenylamine, quinoline, perylene, *p*-phenylenediamine, and aniline from 1 : 1 or 1 : 2 solutions in n-heptane or chloroform on type Y zeolites from which metal cations have been eliminated to different extents has been investigated[2]. The preliminary dehydration of the zeolite was carried out *in vacuo* at temperatures up to 500°C for 24 h. The substances were adsorbed in an atmosphere of pure N_2 at room temperature and the amount of adsorbed hydrocarbons was determined spectrophotometrically by measuring the concentration in the solution before and after the adsorption. Equilibrium in the adsorbate–zeolite system was attained after approximately 24 h. It was shown that the maximum degree of adsorption of triphenylamine on the NH_4Y zeolite activated at 500°C corresponds to 3.4×10^{20} molecules per gram of zeolite (one molecule per large cavity or approximately eight molecules per unit cell). The maximum number of triphenylamine radical-cations formed in the adsorption process is 1.2×10^{19} spins g^{-1}.

The authors[2] suggested that there exists definite steric hindrance to the approach of the $(C_6H_5)_2N$ molecule to the electron-accepting centre.

It is noteworthy that the concentration of neutral perylene molecules in the charge-transfer complexes formed in the perylene–iodine system[3] is also approximately 30 times higher than the concentration of the free perylene radicals produced. The alternative explanation is that the stabilisation of a single radical-cation formed may require several neutral molecules.

The influence of the temperature of activation of the zeolite towards adsorption and the formation of radical-ions has been studied for diphenylethylene[2]. It was observed that the equilibrium degree of adsorption of diphenylethylene, corresponding to ten molecules per unit cell of the zeolite, is already reached on the specimen activated at temperatures $\geqslant 200°C$. However, appreciable formation of radical-ions following adsorption was observed only on specimens heat-treated at approximately 400°C and the maximum concentration of radicals was noted on zeolites activated at temperatures $\geqslant 500°C$. In other words, for the adsorption of diphenylethylene it is sufficient to eliminate water molecules from the zeolite cavities, which occurs at 200°C, while the formation of electron-accepting centres requires higher activation temperatures (~400°C).

A similar dependence of the degree of adsorption and radical-cation concentration on the dehydration temperature of the NH_4Y zeolite was also observed for $(C_6H_5)_3N$. The degree of adsorption of $(C_6H_5)_3N$ is independent of the degree of elimination of metal cations from the type Y zeolite and corresponds to 3.4×10^{20} mol. g^{-1} or eight molecules per unit cell, which is characteristic of a specimen from which metal cations have been fully removed. However, the concentration of the triphenylamine radical-cations formed for low degrees of elimination of metal cations (up to 16 Na^+ ions from the unit cell) increases linearly with the degree of elimination of metal cations and the remains constant and equal to approximately 1.5×10^{19} spins g^{-1}.

It is known[4] that in the NaY zeolite unit cell 32 Na^+ ions are located in the plane of the six-membered oxygen rings (SII), 16 ions are in the hexahedral prisms (SI), and eight ions are in the large cavities (SIII). It has been suggested[2] that the exchange of only the first 16 Na^+ ions leads to the formation of electron-accepting centres. The centres formed in the course of the elimination of Na^+ ions from the S_{III} sites and partial removal from the S_{II} site, which are readily accessible to triphenylamine molecules, participate in the formation of radical-cations. However, it should be noted that a number of studies have now been published where a different distribution of Na^+ cations in NaY zeolites is suggested on the basis of X-ray diffraction data. In particular, some authors believe that 2–4 Na^+ cations remain non-localised (SIII) or that in general all the Na^+ cations in the unit cell are located at the S_I and S_{II} sites.

Assuming that the removal of only eight of the 56 Na^+ cations from the zeolite unit cell leads to the formation of active centres, Stamires and Turkevich[2] obtained 2.8×10^{20} centres g^{-1}, which is approximately 20 times more than the maximum number of the triphenylamine radical-cations formed (approximately 1.5×10^{19} spins g^{-1}). The possible causes of this discrepancy were discussed above. The determination of the spin–spin and spin–lattice relaxation times of the $(C_6H_5)_3N^+$ radical–cations adsorbed on the HY zeolite and measurements of the temperature dependence of the spin susceptibility for different concentrations of these radical-cations led to the hypothesis that associated species comprising neutral $(C_6H_5)_3N$ molecules, solvent molecules, and the radical-cations $(C_6H_5)_3N^+$ are formed and that there is equilibrium between the paramagnetic and diamagnetic molecules:

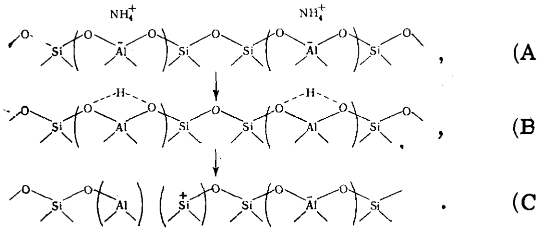
$$\underset{\text{2 radical-cations}}{2\,(C_6H_5)_3N^+} \rightleftarrows \underset{\substack{\text{diamagnetic}\\ \text{ion}}}{(C_6H_5)_3N^{2+}} + \underset{\text{neutral molecule}}{(C_6H_5)_3N + Q} \,.$$

The resolution of the hyperfine structure (HFS) spectrum of the triphenylamine radical-cation (triplet due to the ^{14}N nucleus with $I = 1$) depends on the number of $(C_6H_5)_3N$ molecules present in the zeolite pores which have reacted. It may be that this is associated with the interaction between $(C_6H_5)_3N^+$ and $(C_6H_5)_3N$ already mentioned, leading to the delocalisation of the unpaired electron and the disappearance of the HFS, or with the hindrance of the rotation of the radical by an excess of neutral molecules in the zeolite pores.

The influence of the solvent on the HFS of the $(C_6H_5)_3N^+$ ESR spectrum has been demonstrated by the following experiment. Triphenylamine was adsorbed from the gas phase at 200°C on a type Y zeolite from which metal cations had been eliminated and the ESR spectrum at room temperature was recorded at different time intervals (as the colour of the specimen changed). In all cases, a singlet line with slight asymmetry and a g-factor close to 2.00 was observed. The addition of n-heptane to zeolites at room temperature in a nitrogen atmosphere led to the immediate appearance of the HFS due to the nitrogen nuclei. On the other hand, the well resolved spectrum of the $(C_6H_5)_3N^+$ radical-cation adsorbed on the HY zeolite from solution in n-heptane is broadened and becomes anisotropic as a result of removal of the solvent or the reduction of the temperature at which the spectrum is recorded.

Stamires and Turkevich[2] noted that, in all cases where they observed a well resolved HFS of the spectrum of the adsorbed radical-cation, the subsequent adsorption of O_2 caused a reversible broadening of the ESR line. The fact that in the adsorption of the radical-cation the ESR method does not reveal the unpaired electron captured by the zeolite is probably due to the short relaxation time or the complete delocalisation of the electron in the zeolite lattice, where the varying crystal fields broaden the ESR line so much that it becomes impossible to observe.

It was shown[2] that iodine, one of the best acceptors in charge-transfer complexes, does not form these complexes at room temperature with donors such as aniline, naphthalene diphenylamine, and diphenylethylene, systems of this kind giving rise to an ESR signal only at elevated temperatures. Since the adsorption of the above substances on a zeolite freed from metal cations leads to the appearance of radical-cations already at room temperature, one may conclude that the electron-accepting centres of such an adsorbent exhibit at least the same activity as iodine. The following scheme for the formation of electron-accepting centres during the heat treatment of the NH_4Y zeolite was put forward on the basis of the results[2]:



Heat treatment of the ammonium-form of the zeolite leads to the formation of NH_3 and H^+ ions. The latter, interacting with the lattice oxygen, form the intermediate structure (B). With increase of heat-treatment temperature (~400°C), the elimination of OH groups begins, the latter giving rise to H_2O by reacting with H^+, and defects appear in the zeolite [structure (C)]. A complex involving charge transfer from an adsorbed molecule to a tricoordinate aluminium atoms is formed in the adsorption of triphenylamine. The stabilisation of the radical-cation produced is due to the rigid arrangement of the electron-accepting centres in the zeolite lattice. The formation of such centres probably does not disrupt the zeolite structure, since the degree of adsorption of triphenylamine is independent of the degree of elimination of metal cations and is equal to 3×10^{20} mol. g^{-1}, which is characteristic of the specimen freed from metal cations. The active centre with the tricoordinate aluminium atom possesses properties analogous to those of $SbCl_5$,[5] acting similarly to iodine, and is an electron trap. Such $(AlO)_{3/2}$ traps are distributed uniformly throughout the zeolite structure.

In the communication by the same workers, dealing with an ESR study of γ-irradiated zeolites of types X and Y, it is shown that such combined $(AlO)_{3/2}$ centres and traps capture the electrons liberated on γ-irradiation of the zeolite and a six-component HFS, due to the splitting of the levels of the captured electron in the field of the ^{27}Al nucleus ($I = 5/2$), is observed in the spectrum. The adsorption of $(C_6H_5)_3N$ from solution after γ-irradiation of a type Y zeolite freed from metal cations does not lead to the formation of triphenylamine radical-cations, since the electron-accepting centres have already been occupied by the electrons liberated by the γ-irradiation. However, annealing of the γ-irradiated preparations regenerates the active centres: the six-component spectrum of the captured electron vanishes and the spectrum characteristic of the $(C_6H_5)_3N^+$ radical-cation appears immediately after the adsorption of triphenylamine.

As will be shown below (subsection 2 of this Section), these results conflict with the data of Dollish and Hall[7], who observed the formation of the radical-cations of perylene when it was adsorbed on an irradiated HNaY zeolite (45% exchange).

It has been shown[8] that the hydrogen-form of a type Y zeolite (HY) possesses, after appropriate activation oxidation-reduction properties similar to those of Al_2O_3 or amorphous aluminosilicates. The authors investigated the formation of the radical-ions of tetracyanoethylene (TCE), 1,3,5-trinitrobenzene (TNB), *m*-dinitrobenzene (DNB), and perylene in the adsorption of these compounds from solutions in benzene on NaY, HNaY, and HY zeolites, Al_2O_3, and an industrial 13% $Al_2O_3-SiO_2$ catalyst. The specimens were subjected to preliminary activation in a stream of O_2 for 1 h at temperatures in the range 100° to 1000°C and, after cooling *in vacuo* and reheating in O_2 at a pressure of 20 cm, were conditioned for 16 h *in vacuo* (10^{-5} mmHg) at the given temperature.

Preliminary tests showed that the concentration of the TCE, TNB, and DNB radicals formed depends on the concentration in the solution and on the time of contact between the adsorbate and the catalyst. The dependence of the number of radicals on the concentration in the solution implies that an adsorption equilibrium is established between the adsorbate molecules in the solution and the corresponding radicals on the adsorbent surface. The slow increase of the concentration of radical-ions with time shows that the radicals are formed not only on the outer surface but also within the channels and cavities of the zeolite. The maximum concentration of the radicals was observed in adsorption from 0.1 M solution after contact for 48 h. Additional ultraviolet irradiation of the adsorbate solution—zeolite system for 1 h led to an increase of the concentration of radical-ions by a factor of 1.5 for TCE and by factors of 2 and 3 for TNB and DNB respectively. Ultraviolet irradiation probably increases the electron-donating activity of weak centres. Presumably the fraction of such centres increases with the electron-affinity of the adsorbed molecule. The effect of irradiation in the case of TCE, a fairly strong electron-acceptor, is therefore significantly smaller than for the relatively weak acceptors such as TNB and DNB. These results indicate a fairly wide range of energies of the electron-donating (reduction) zeolite centres. In all subsequent experiments, the concentration of the radical-ions formed was determined after keeping a 0.1 M adsorbate solution in contact with the zeolite for 48 h and after additional ultraviolet irradiation of the system for 1 h.

It has been shown[8] that the adsorption of TCE by the HY zeolite dehydrated at 150—400°C is accompanied by the appearance of a nine-line ESR spectrum with $g = 2.0027$ and an HFS constant of approximately 4.9 G, which is characteristic of the TCE radical-anion. At dehydration temperatures above 400°C, the HFS disappears and the observed singlet is analogous to the ESR signal of the TCE polymer[9]. The singlet is observed also in the adsorption of TCE on the NaY zeolite over the entire range of dehydration temperatures. The dependence of the concentration of the TCE radical-anions on the heat-treatment temperature of HY and NaY is characterised by two maxima in the region of temperatures of approximately 250° and 650°C.

Table 1. The concentration of TCE radical-anions (spins g^{-1}) on various adsorbents[8].

Activation temperature	Adsorbent			
	HY	NaY	Al_2O_3	13% $Al_2O_3-SiO_2$
250°	$3 \cdot 10^{17}$	$3.5 \cdot 10^{17}$	$4.5 \cdot 10^{18}$	$6.5 \cdot 10^{17}$
660°	$4.2 \cdot 10^{18}$	$3.1 \cdot 10^{17}$	$9.0 \cdot 10^{18}$	$9.8 \cdot 10^{17}$

Table 1 presents data characterising the reducing properties of the adsorbents investigated in the formation of TCE radical-anions.

It has been shown[8] that the concentration of TCE radical-anions is independent of the degree of exchange of Na^+ for NH_4^+ and amounts to approximately 3×10^{17} spins g^{-1} when the preliminary dehydration of the zeolite has been carried out at 250°C. However, a sharp non-linear increase of the concentrations of TCE, TNB, and DNB radical-anions, starting from 35% exchange, was observed on specimens activated at 650°C. It is interesting to note that the oxidising activity of the type Y zeolite in the formation of triphenylamine radical-cations[2] reaches a maximum for approximately the same degree of elimination of metal cations (approximately 30%), remaining constant on further increase of the degree of exchange. One cannot rule out the possibility that the removal of the first Na^+ ions leads mainly to the formation of oxidation centres and further elimination of metal cations (after approximately 30% exchange) is accompanied by a sharp increase of the number of reduction centres.

The oxidising properties of type Y zeolites have been studied[8] in relation to the adsorption of perylene from a saturated benzene solution (approximately 6.5×10^{-3} M) at room temperature. The maximum concentration of the perylene radical-cations was reached after the solution has been in contact with zeolite for 5 days and did not change after additional ultraviolet irradiation. In the presence of O_2, the adsorption of perylene on the HY zeolite at room temperature gives rise to an ESR spectrum characteristic of the perylene radical-cation. It was noted that the HFS of the spectrum and its relatively slight time variation are analogous to the changes observed in the adsorption of perylene on amorphous aluminosilicate.

The concentration of the perylene radical-cations depends almost linearly on the activation temperature of the HY zeolite over the temperature range 150–660^{c}C. The maximum concentration observed on the specimen activated at 660°C corresponds to approximately 1.7×10^{19} spins g^{-1} or approximately 3.1×10^{16} spins m^{-2}. The adsorption of anthracene under the same conditions involves the formation of a number of radical-cations smaller by a factor of approximately 4. This finding shows that the yield of radical-cations is determined mainly by the ionisation potential of the adsorbate molecule and not by its size (at least for perylene and anthracene). When the activation temperature exceeds 700°C, a sharp decrease of the concentration of perylene radical-cations is observed, being due to the disruption of the zeolite structure, which is revealed by X-ray diffraction.

Table 2.

Adsorbent	Concentration of TCE radical-anions, 10^{-15} spins m^{-2}	Concentration of perylene radical-cations, 10-15 spins m^{-2}
HY	8	31
Al_2O_3	45	7
13% Al_2O_3—SiO_2	3	2

Table 2 presents the oxidising and reducing activities of the HY zeolite, an amorphous aluminosilicate (13% Al_2O_3–SiO_2), and Al_2O_3 expressed in terms of the number of perylene radical-cations and TCE radical-anions referred to 1 m^2 of the adsorbent surface for an activation temperature of 660°C.

It is suggested that two types of reduction (electron-donating) centres exist on the HY surface. The relatively weak centres correspond to the activity maximum for an activation temperature of 250°C. These centres reduce the TCE molecules to the radical-cations, but are too weak to reduce the TNB and DNB molecules. It is significant that the activity of the weak centres is independent of the degree of exchange of Na^+ ions for NH_4^+. It is suggested[8] that such centres may be hydroxy-groups as happens in Al_2O_3 activated at low temperatures.

An increase of activation temperature to 660°C is accompanied by the dehydroxylation of the HY zeolite and leads to the formation of strong electron-accepting and electron-donating centres responsible for the oxidation-reduction properties of the zeolite, i.e. the mechanism is the same as that proposed by Stamires and Turkevich[2] (see above).

The fact that the maximum concentration of the radical-ions formed is significantly smaller than the possible number of oxidation-reduction centres is due, according to the authors[8], to the inaccessibility of some of these centres to the adsorbed organic molecules. It is postulated that, for low degrees of exchange (<35%), mainly Na^+ cations at the $S_{I'}$ sites, inaccessible to TCE molecules, are substituted and the activity of the HNaY zeolite in the formation of radical-anions does not therefore change. For degrees of exchange >35%, Na^+ ions at the S_{II} sites, accessible to TCE molecules, begin to exchange, which leads to a sharp increase of the reducing activity of the zeolite. However, subsequent investigations showed that this explanation is not the only one possible. It was shown previously[10] that the oxidising and reducing properties of activated Al_2O_3 are to some extent interrelated. It was of interest to discover whether this relation between the oxidising and reducing properties holds for zeolites.

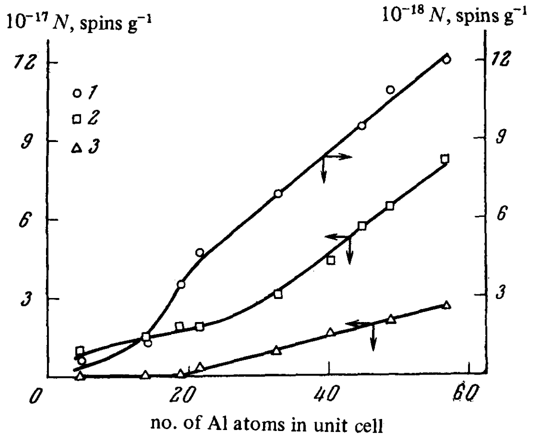


Figure 2. Variation of the concentration (N) of anthracene (curve *1*), TCE (curve *2*), and TNB (curve *3*) radical-ions with the number of aluminium atoms in the unit cell of a type Y zeolite[10].

A detailed study has been made[11] of the dependence of the oxidising and reducing properties of the HY zeolite on the Al : Si ratio. The adsorbates employed were 0.1 M benzene solutions of TCE, TNB, and DNB and 0.005 M benzene solutions of naphthalene, anthracene, and perylene. Fig. 2 illustrates the dependence of the concentration of the radical-ions of anthracene, TCE, and TNB on the number of aluminium atoms per unit cell of the type Y zeolite activated at 600°C. The decrease of the redox activity of the zeolite with decreased aluminium content is consistent, according to the authors, with the mechanism of the formation of electron-donating and electron-accepting centres already examined. The linearity of the plots in Fig. 2 shows that the activity of the zeolite is due to highly localised centres and not to the collective effect of several centres incorporating Al^{3+}.

We may note that this treatment of the experimental data is by no means self-evident. The point is that, even for maximum degrees of elimination of aluminium, the residual aluminium in the zeolite is quite sufficient for the formation of the same number of oxidation-reduction centres as in the specimens from which aluminium has not been removed. However, since the yield of radical-cations nevertheless falls with decrease of the aluminium content in the zeolite, one must suppose that not all the aluminium atoms in the crystal lattice are equivalent in relation to the formation of the oxidation-reduction centres. However, the aluminium elimination process is probably not homogeneous, i.e. some aluminium atoms are removed first. The linearity of the plots in Fig. 2 in such a case is rather unexpected.

It has been shown[11] that preliminary adsorption of anthracene and perylene on the HY zeolite causes a tenfold increase of the concentration of TNB radical-anions compared with the yield of these species in adsorption on a clean zeolite surface.

Almost the same increase of the yield of TNB radical-anions after the preliminary adsorption of electron-donating molecules (anthracene and perylene) was observed on the HY zeolite activated *in vacuo* and on the dealuminated HY zeolite. However, the effect is not observed when naphthalene is the first substance to be adsorbed. The preliminary adsorption of TNB likewise does not increase the yield of the anthracene radical-cations. Table 3 presents data illustrating the influence of the preliminary adsorption of various aromatic hydrocarbons on the yield of TNB radical-anions.

Table 3.

Adsorbate	Ionisation potential, eV	Maximum concn. of radical-cations per gram of zeolite	Average number of radical-cations required for the formation of one TNB radical-anion
Perylene	6.83	$5 \cdot 10^{19}$	2.7
Anthracene	7.23	$1{,}2 \cdot 10^{19}$	2.7
Naphthalene	8.1	$6 \cdot 10^{17}$	—
Benzene	9.25	$1 \cdot 10^{17}$	—

Evidently approximately one TNB radical-anion is formed additionally for each three anthracene or perylene radical-cations. This implies that only one of the three oxidation-reduction centres is involved in the increase of the yield of TNB radical-anions by virtue of its structure and energy relations. One can also suppose that the increased yield is due to the cooperative interaction of three neighbouring oxidation centres with one reduction centre. The latter hypothesis is supported by the finding that the increased yield is almost independent of the degree of elimination of aluminium from the zeolite.

Flockhart et al.[11] believe that such a large increase (by an order of magnitude) in the concentration of radical-anions as a result of the formation on the zeolite surface of radical-ions of opposite sign cannot be accounted for solely on the basis of the model proposed previously, which assumes that some of the active centres are inaccessible to the adsorbate molecules. A more likely hypothesis is that centres having different strengths exist. Possibly the observed tenfold increase in the concentration of radical-anions characterises the number of electron-donating centres whose strength is insufficient to reduce the TNB molecule to the radical-anion. The electron-donating capacity of such centres increases following the adsorption of anthracene or perylene on neighbouring oxidation centres. The independence of the increase in the yield on the degree of elimination of aluminium apparently shows that it is mainly aluminium atoms responsible for the strong electron-donating centres which are removed during the aluminium elimination process.

Naphthalene, which has a higher ionisation potential than anthracene and perylene, is adsorbed on energetically stronger oxidation centres, which do not interact with the nearest reduction centres. Preliminary adsorption of naphthalene does not therefore lead to an increase of the yield of TNB radical-anions.

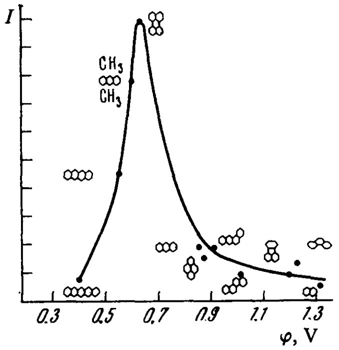

Figure 3. Variation of the integral ESR signal intensity (*I*) with the half-wave potentials (φ) of various aromatic hydrocarbons adsorbed on 22% Al_2O_3–SiO_2 (the potentials have been measured relative to Ag–0.1 *N* Ag^+ in acetonitrile)[11].

It is noteworthy that the conclusion concerning the formation of oxidation-reduction centres of different strengths had been made earlier[12], but in relation to amorphous aluminosilicates. The author obtained an experimental relation between the concentration of the radical-cations of different aromatic hydrocarbons formed in the experiment and the half-wave potential of the adsorbate (Fig. 3). He attempted to describe this relation theoretically and showed that the best agreement between the theoretical and experimental curves is observed when account is taken of the distribution of the oxidation centres of the aluminosilicate with respect to strength. Since such distribution is unknown *a priori*, the author postulated a Boltzmann distribution in the calculation of the theoretical curve. Furthermore, the possibility of the formation of doubly charged cations was postulated for adsorbates with low ionisation potentials (tetracene and pentacene).

2. The Nature of the Influence of Molecular Oxygen on the Formation of Radical-Ions

In the investigations discussed above[2,8,10], the problem of the influence of O_2 on the oxidising and reducing properties of zeolites was not specially studied. Flockhart and coworkers[8,10] carried out the preliminary heat treatment and the adsorption of hydrocarbons in the presence of O_2. Although Stamires and Turkevich[2] carried out the preliminary dehydration *in vacuo*, their method for the impregnation of the adsorbent with the adsorbate solution (in an atmosphere of dry nitrogen) did not rule out the access of traces of O_2 into the system.

Dollish and Hall[7] studied the influence of the preliminary heat treatment of the NH_4Y, NH_4X, NaY, and CaY zeolites and of O_2 on the yield of radical-anions in the adsorption of perylene and triphenylamine from benzene solutions. They investigated zeolite specimens activated in four different ways: (*a*) by evacuation at 550°C; (*b*) by heat treatment in a stream of O_2 for 17 h at 550°C with subsequent evacuation at the same temperature for 17 h; (*c*) by heat treatment in a stream of O_2 at 550°C with subsequent slow cooling in O_2 to room temperature and evacuation at room temperature; (*d*) by heat treatment in a stream of O_2, evacuation for 6 h, treatment in a stream of H_2 for 24 h, and evacuation for 6 h, all the treatments being carried out at 550°C. Table 4 presents the experimental data for the influence of the preliminary treatment of the zeolites on the yield of radical-ions. In all cases, the surface coverage by the adsorbate was 7×10^{20} mol. g^{-1} (4×10^{20} mol. g^{-1} for triphenylamine).

Table 4. The influence of the preliminary treatment of zeolites on the concentration of radical-ions (10^{17} spins g^{-1}).

Adsorbent, % exchange, adsorbate	NH_4Y			CaY		NH_4X*	NaY
	45%	79%	79%	36%	79%	48%	
Type of treatment	perylene	perylene	tri-phenyl-amine	perylene	perylene	perylene	perylene
a	1.3	6.2	1.0	0.3	0.6	0.3	not detected**
b	9.5	32.3	8.1	0.3	9.1	1.0	not detected
c	36***	58****	20****	0.4***	15***	2.6***	—
d	1.0	1.8	0.7	—	0.3	—	—

*Heat-treated at 500°C owing to its lower thermal stability.

**Exposure to dry air for 24 h leads to the appearance of a signal equivalent to 0.9×10^{17} spins g^{-1}.

***Exposure to air for 24 h does not alter the concentration of the radical-ions or alters it only slightly (≤15%).

****Exposure to air for 24 h increases the concentration to 1.2×10^{19} spins g^{-1}.

The influence of O_2 on the yield of perylene radical-cations was studied in detail on an NH_4Y specimen with 45% exchange, treated by method *a*. The results show that the adsorption of a single O_2 molecule induces the formation of a single perylene radical-cation. The same stoichiometry was obtained also from the determination of the amount of H_2O formed after the reduction with hydrogen (method *d*). In order to elucidate the nature of the chemisorbed oxygen, the NH_4Y specimen with 45% exchange, treated by method *a*, was irradiated by X-rays *in vacuo*. The ESR spectrum of this specimen consisted of the sextet characteristic of the electron captured by an aluminium-27 ion[6] and of the spectrum of the O_2^- radical-ion. The concentration of these species was 1×10^{16} and 4×10^{16} spins g^{-1} respectively. Contact between the irradiated specimen and the perylene solution led to the disappearance of both signals and the appearance of the spectrum of theperylene radical-cation equivalent to 1.3×10^{18} spins g^{-1}. Table 4 shows that the yield of the perylene radical-cations on a non-irradiated NH_4Y specimen with 45% exchange is 1.3×10^{17} spins g^{-1}. These data demonstrate the important role of the oxygen chemisorbed irreversibly at 550°C in the formation of radical-ions. Since ESR signals due to O_2^- are not observed on the non-irradiated specimens, the authors assume that oxygen is chemisorbed in the form of some other species. However, such oxygen must react with perylene to form the ion pair $Pn^{\cdot+}O_2^-$. Nevertheless, the formation of the radical-cations is not accompanied by the appearance of an ESR signal due to O_2^-, which is perhaps a common feature of all donor–acceptor systems.

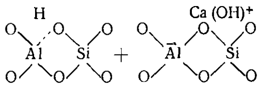
Dollish and Hall[7] discuss in detail the possible reasons why the maximum observed concentration of radical-cations is smaller by approximately two orders of magnitude than the number of anionic vacancies  in the 79% NH_4Y zeolite (approximately 1×10^{21} centres g^{-1}). Comparison of the sizes of the large cavities (approximately 13 Å), the diameters of the large channels (8–9 Å for NaY), and the sizes of the triphenylamine (approximately 10 Å) and perylene (6.5 × 9.1 Å) molecules led the authors to the conclusion that steric hindrance lowers the yield of radical-ions in the adsorption of such comparatively large molecules.

The influence of air and water vapour on the concentration of benzene, anthracene, naphthalene and diphenylamine radical-ions adsorbed *in vacuo* on a type Y zeolite from which cations have been removed has been investigated[13]. The preliminary treatment of the zeolite involved heat treatment for 4 h in air at 600°C followed by evacuation at 470–500°C. Benzene and naphthalene were adsorbed at room temperature and diphenylamine and anthracene at 85–90°C. It was shown that the ESR signal of the benzene radical-cation appears only after irradiation of the benzene molecules adsorbed on the zeolite with ultraviolet light for 20 h.

Naphthalene, anthracene, and diphenylamine radical-ions are formed without additional ultraviolet irradiation. It is suggested that the radical-ions are apparently formed via charge transfer to the electron-accepting centre formed when cations are eliminated from the zeolite, since adsorption on the metal cation-containing specimen does not lead to the formation of radical-ions. The formation of radical-ions from adsorbates with a high ionisation potential (benzene) requires an additional activation of the adsorbed molecule by ultraviolet radiation. The admission of water vapour gradually decreases the intensity of the ESR signals from anthracene and diphenylamine by a factor of 1.5–2. However, prolonged exposure of the specimen to water vapour does not lead to the complete disappearance of the signal. The influence of water has been explained by the reverse reaction involving the conversion of the radical-ion into a neutral molecule under the conditions of strong specific adsorption of water molecules by the zeolite. The admission of air increases the intensity of the ESR signals of the adsorbed anthracene and diphenylamine radical-ions which is probably due to the effect of oxygen.

3. The Influence of the Nature of the Cations and Their Location in the Zeolite Structure on the Oxidising and Reducing Properties of Faujasites

In the studies already mentioned[7-11], the formation of radical-ions was also observed on different cationic forms of zeolites of types X and Y. The appearance of an ESR signal (singlet) in the adsorption of TNB on CoY, NiY, and LaY has been noted[11]. The adsorption of TNB on CaY leads to the appearance of an ESR signal with a HFS. Dollish and Hall[7] investigated the influence of the degree of exchange of Na$^+$ for Ca^{2+} on the yield of perylene radical-cations. They found (Table 4) that, for low degrees of exchange ($\leqslant 36\%$), the activity of the CaY zeolite in the formation of radicals is very low even in the presence of O_2. However, for high degrees of exchange ($\geqslant 79\%$), the activity of CaY becomes comparable to that of the NH_4Y zeolite. For low degrees of exchange, Ca^{2+} ions occupy S_I sites in the hexagonal prisms connecting neighbouring cubo-octahedra and capable of accommodating 50% of the ions. Centres of another type are located in the plane (or close to it) of the six-membered rings in the large zeolite cavities. In the initial zeolite, there is on average one Na$^+$ ion for each ring of this kind. The complete exchange of the singly-charged Na$^+$ ions for the doubly-charged Ca^{2+} ions should lead to the formation of a positively charged centre and a centre with a partial negative charge (a cationic vacancy). In the presence of small amounts of water, the structure of the CaY zeolite can be represented schematically as follows:



.

Dehydation results in the formation of centres in CaO analogous to those postulated for a type Y zeolite from which cations have been removed [see structure (C) in the scheme presented in Subsection 1 of the present Section].

A wider assortment of cationic forms of type Y zeolites was studied by Hirschler et al.[14] In order to elucidate the possibility of the formation of radical-ions on adsorption of molecules with a high ionisation potential (>9.0 eV), the authors studied the adsorption of olefins (oct-1-ene, pent-1-ene, etc.), benzene, and methylbenzenes on cationic forms of a type Y zeolite containing lanthanides as well as CaY and CeX. The zeolites were dehydrated in air at 500°C and the hydrocarbons were adsorbed from solutions in carbon tetrachloride. The authors concluded that the ESR spectra of the radical-cations observed in the adsorption of olefins cannot be accounted for solely by electron transfer from the adsorbed molecule to the adsorbent. On the basis of the gas-chromatographic analysis of the products of the reaction of pent-1-ene with the zeolite, the authors suggested that the radical-cations are formed from polymerisation products.

The influence of the amount and nature of the added cations on the ability of type X and Y zeolites to form radical-cations in the adsorption of anthracene and naphthalene has been investigated[15]. In addition to the sodium-form of the zeolites and the form freed from metal cations, a study was made of the magnesium, lanthanum, and yttrium cationic forms with different degrees of exchange. The zeolites were heat-treated for 6 h in a stream of dry air and then for 1 h in a stream of helium at 550°C. Naphthalene and anthracene were adsorbed from benzene solutions at room temperature. The formation of radical-cations in the adsorption on the NaY zeolite was not observed. In contrast to the results obtained by Hirschler et al.[14], Zhavoronkov[15] did not observe ESR signals in the adsorption of benzene on zeolites containing triply-charged cations. The adsorption of anthracene on cationic forms of a type X zeolite (with degrees of substitution of sodium by magnesium and lanthanum of 44 and 22% respectively) also did not lead to the appearance of an ESR signal. The latter result is, incidentally, not surprising, since the degree of substitution of cations was too low. The formation of radical-cations was observed in the adsorption of naphthalene and anthracene on type Y zeolites containing doubly- and triply-charged cations, the anthracene signal being more intense.

With increase of the degree of exchange of sodium for magnesium, lanthanum, and yttrium cations, the concentration of the radical-cations arising on adsorption of anthracene greatly increases, particularly on LaY and YY zeolites for degrees of exchange of 20–30%. In the range of 30–50% exchange, the concentration of radical-ions increases only slightly, but rises by an order of magnitude on passing to specimens obtained with non-equivalence of the exchange of sodium for triply-charged cations. Such non-uniformity in the increase of the concentration of the paramagnetic species as a function of the degree of exchange may be associated with the non-equivalence of various sites occupied by the sodium cations in the zeolite introduced by the exchange process. It is important to note that the concentration of the radical-ions formed on the specimen freed from cations and on zeolites with triply-charged cations for degrees of exchange in the range 20–30% are approximately the same, while for the magnesium-form the concentration is several times smaller. Zhavoronkov et al.[15] note different types of behaviour of X and Y zeolites with adsorbed anthracene in relation to atmospheric oxygen. Contact of type Y zeolites with air for several days hardly alters the concentration of the anthracene radical-cations formed. On the MgX, LaX, and NaY zeolites, radical-cations are also not formed immediately after adsorption, but exposure of these specimens to air for several days leads to the formation of paramagnetic centres at concentrations of 4.7×10^{16}, 5.7×10^{15}, and 1.6×10^{16} spins g^{-1} respectively.

Zhavoronkov et al.[15] do not discuss the role of the cations introduced into the zeolite in electron-transfer reactions. Richardson[16] and Neikam[17] investigated this problem. Richardson[16] used the ESR method to determine the degrees of ionisation of anthracene, naphthalene, perylene, and pyrene adsorbed on faujasites in which approximately 60% of the Na$^+$ ions had been replaced by K$^+$, Li$^+$, Ba$^+$, Sr^{2+}, Ca^{2+}, Mg^{2+}, Ag$^+$, Cd^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, or Cu^{2+} ions. The specimens were first dehydrated in air for 12 h at 400°C and the hydrocarbons were adsorbed from 0.01 M benzene solutions.

According to Richardson[16], the adsorption is accompanied by electron transfer from the adsorbate to the cation. The number of radical-cations varies exponentially with the difference between the ionisation energy of the adsorbate and the electron affinity of the cation. The conclusion that the cations are involved in the oxidation of anthracene to the radical-cation was reached on the basis of the following experiment. A series of specimens of the magnesium-form of the zeolite containing 2% of copper were heated for 2 h at 100°C. An ESR signal without the HFS characteristic of dehydrated Cu^{2+} ions was observed for these preparations and the adsorption of anthracene did not lead to the formation of radical-cations. The remaining specimens of this series were dehydrated at increasing temperatures and the ESR signals due to the Cu^{2+} ions were recorded also after the adsorption of anthracene. It was shown that the HFS characteristic of dehydrated Cu^{2+} ions and the spectrum of the anthracene radical-cations appear only after heat treatment above 300°C. The author's attempt to measure the changes in the intensity of the Cu^{2+} signal intensity due to electron transfer from anthracene to Cu^{2+} was unsuccessful, since the number of electrons involved in the reaction is too low to cause an appreciable decrease of the Cu^{2+} signal.

However, this experiment probably cannot be regarded as a direct confirmation of the involvement of cations in the oxidation of anthracene to the radical-cation. The results indicate only an agreement between the dehydration temperatures necessary, on the one hand, for the appearance in the spectrum of the HFS due to the Cu^{2+} ions and, on the other hand, for the formation in the zeolite of centres capable of oxidising anthracene. We believe that there are no grounds in this instance for the hypothesis that the changes in the environment of Cu^{2+} ions on dehydration, accompanied by the appearance of the HFS, need necessarily lead to the formation of anthracene radical-cations.

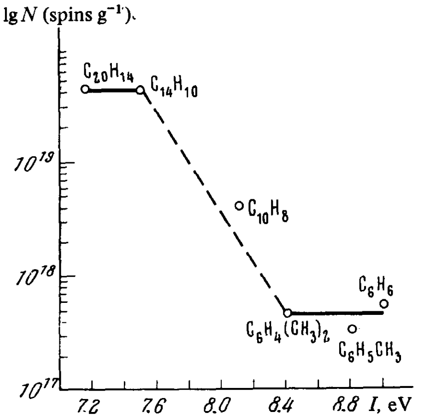


Figure 4. The yield of radical-ions (lg$N$) on the 13.3% CeY zeolite as a function of the ionisation potential of the adsorbate[17].

Neikam[17] investigated the activity of the lanthanide cationic forms of type Y zeolites in the formation of benzene, toluene, *p*-xylene, naphthalene, anthracene, perylene, and coronene radical-ions. The hydrocarbons were adsorbed from solutions in carbon tetrachloride on the zeolite activated at 500°C in air or in an oxygen atmosphere. It was shown that the concentration of the radical-ions formed following adsorption on the CeY zeolite is approximately an order of magnitude higher than on the LaY, SmY, and DyY zeolites. The adsorption on GdY leads to the appearance of very weak ESR radical-ion signal ($<10^{16}$ spins g^{-1}). The important role of O_2 in the formation of active centres was demonstrated by comparative experiments in which the 13.3% CeY zeolite was activated in helium, molecular hydrogen, or air. Fig.4 illustrates the variation of the logarithm of the concentration of the radical-ions (for the 13.3% CeY zeolite) with the ionisation potential of the adsorbed molecule.

The theoretical interpretation of this relation is based on the hypothesis[16] that the concentration of the radical-cations formed on adsorption ($N^{\dot{+}}$) obeys the Boltzmann distribution: $[N^{\dot{+}}] = N_0 e^{-\Delta E/kT}$, where N_0 is the number of adsorbed molecules and $\Delta E = I + A + W$. The ionisation potential of the adsorbate (I), the electron affinity of the adsorbent (A), and the charge-transfer energy (W) correspond to the following processes: $Ar \rightarrow Ar^{\dot{+}} + e(I)$ $S^{+} + e \rightarrow S(A)$, and $S + Ar^{\dot{+}} \rightarrow S \ldots Ar^{\dot{+}}(W)$. S and R denote the adsorbent and adsorbate respectively. It is readily seen that, when A and W vary only slightly for different adsorbates, the relation between lg$[N^{\dot{+}}]$ and I should be linear. Physically, this implies the energetic homogeneity of the electron-accepting zeolite centres.

The data presented in Fig.4 show that this is not the case. The presence of two regions with a constant concentration of the radical-cations formed, separated by a transition region, demonstrates the energetic inhomogeneity of the electron-accepting zeolite centres. It follows from Fig.4 that approximately 4×10^{17} centres in the 13.3% CeY zeolite have sufficient energy for the oxidation of molecules with $I \leqslant 9.0$ eV and approximately 4×10^{19} centres are capable of oxidising molecules with $I \leqslant 7.5$ eV. Centres of the third type correspond to the oxidation of naphthalene ($I \simeq 8.1$ eV). The author[17] explains on the basis of this model the similarity of the concentrations of anthracene and perylene radical-cations oxidised by centres with energy $\leqslant 7.5$ eV. Such agreement is also observed for benzene, toluene, and *p*-xylene, which may be oxidised to radical-cations only on centres whose energy is approximately 9.0 eV. We may note that the concentration of perylene radical-cations on a type Y zeolite freed from cations is approximately four times higher than the number of anthracene radical-cations[8] (Table 3).

The distribution of active centres with respect to energies depends on the cerium content in the zeolite. A decrease of the cerium content from 13.3% to 8.7% reduces the number of weak centres (7.5 eV) by a factor of 4 and the number of strong centres (9.0 eV) by a factor of 50. ESR signals were not observed in the adsorption on the 8.7% CeY zeolite of molecules whose ionisation potential is higher than that of naphthalene. On the basis of these data and the measurements of the magnetic susceptibility of the CeY zeolites, the author[17] concludes that the strong electron-accepting centres (9.0 eV) are distributed within the small cavities of the zeolites and include a pair of Ce^{4+} cations. However, it is suggested that the Ce^{4+} cations themselves, formed from Ce^{3+} when the zeolite is heat-treated in the presence of O_2, do not function directly as electron acceptors. The role of the Ce^{4+} cations reduces to an increase in the electron affinity of the active centres already formed in the zeolite under the influence of chemisorbed oxygen during heat treatment.

Fig.5 and the data in Table 5 illustrate the relation between the concentrations of the radical-cations formed and the number of adsorbed molecules. For perylene, curves *1* and *2* in Fig.5 coincide.

Comparison of the sizes of the adsorbed molecules with the diameters of the windows in the large zeolite cavities (7.5 Å) and allowance for the yield of the radical-cations led Neikam[17] to the conclusion that the weak oxidation centres (7.5 eV) are located on the outer zeolite surface. The low concentration of the coronene radical-cations (compared with perylene) indicates, according to the author, that the size of the adsorbed molecule is an important factor in the formation of radical-cations also in adsorption on the outer surface. The author believes that the results obtained by Stamires and Turkevich[2] for a type Y zeolite from which metal cations had been eliminated also confirm the conclusion that the oxidation centres are located on the outer surface.

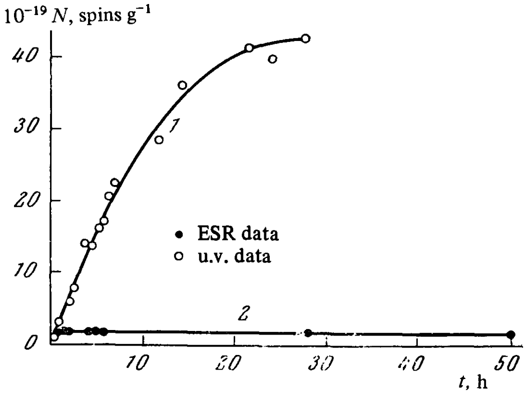

Figure 5. Variation of the degree of adsorption of anthracene and the concentration of the radical-cations formed (N) with contact time (t): 1) degree of adsorption based on the analysis of ultraviolet spectra; 2) the concentration of radical-cations based on ESR data (13% CeY zeolite)[17].

Table 5.

Molecular size	N_0	$[N^{+\cdot}]$, spins g^{-1}	$[N^{+\cdot}]/N_0$
Anthracene, 6 Å	$5.05 \cdot 10^{20}$	$4.17 \cdot 10^{19}$	1:12
Perylene, 7.7 Å	$4.37 \cdot 10^{19}$	$4.34 \cdot 10^{19}$	1:1
Coronene, 10.4 Å	$1.63 \cdot 10^{19}$	$6.8 \cdot 10^{17}$	1:11.4

This conclusion conflicts with probably all the previous experimental data obtained for zeolites. It is unlikely that the difference of almost two orders of magnitude between the concentrations of the perylene and coronene radical-cations (Table 5) is caused solely by the difference between the sizes of these species, if adsorption on the outer surface alone is postulated. This is particularly true, since Dollish and Hall[7] assume that the size of the windows in the large type Y zeolite cavities is 8–9 Å and not 7.5 Å as in Neikam's study[17]. It is apparently not permissible to reach such far-reaching conclusions solely on the basis of small differences between the dimensions of the perylene molecule (7.7 Å) and the inlet windows of the zeolite (7.5 Å). As will be seen below, in cases where the difference between the dimensions is large (in the adsorption of perylene on H-mordenite), the formation of radical-cations is not observed.

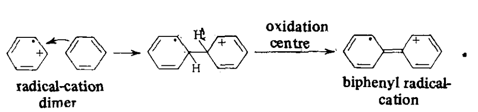
III. THE OXIDISING AND REDUCING PROPERTIES OF MORDENITES

1. The Characteristics of the Formation of Radical-ions on Mordenites

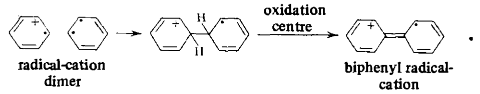
Analysis of studies on the oxidising and reducing properties of zeolites of types X and Y has shown that the adsorption of hydrocarbons with a high ionisation potential (approximately 9.0 eV) on zeolites of this type under normal conditions does not lead to the formation of the corresponding radical-cations. Naturally, we are not considering studies in which the formation of radical-ions was observed after additional treatments of the zeolite–adsorbate system, say, after ultraviolet irradiation. The formation of benzene, toluene, and *p*-xylene radical-cations has been observed[17] after adsorption on the CeY zeolite. However, no data concerning the nature of the ESR spectra (with the exception of the concentration of the radicals formed) are quoted in this report. Other workers[10,14] have also merely stated that weak and poorly resolved ESR spectra appear in the adsorption of benzene and its methyl derivatives on certain cationic forms of zeolites of types X and Y. The interpretation of these spectra is extremely difficult. After the publication of the first communications[18,19] about the ESR spectra of the radical-cations of benzene and its methyl derivatives, observed when they are adsorbed on a synthetic mordenite, there was a sharp growth of interest in the study of the oxidising and reducing properties of zeolites of this type. The point is that only on mordenites under normal conditions is the adsorption of hydrocarbons with a high ionisation potential (benzene, toluene, and xylene) accompanied by the appearance of intense ESR spectra with a well resolved HFS, which make it possible to identify the radical-cations formed on adsorption.

The study by Corio and Shih[18] is probably to be regarded as the first investigation in which an attempt was made to interpret the ESR spectra appearing after the adsorption of benzene and its methyl derivatives on the hydrogen-form of mordenite. The preliminary treatment of H-mordenite consisted in heating for 1 h at 500°C in an atmosphere of oxygen with subsequent evacuation for about 3 h at the same temperature. Liquid hydrocarbons were adsorbed at room temperature and solid hydrocarbons were fused and mixed with the zeolite. The ESR spectra were recorded at room temperature. Immediately after the adsorption of benzene on H-mordenite, the ESR spectrum consists of at least 7 HFS components and its overall width is approximately 30 G. The splitting between the components in the central part of the spectrum is approximately 2.2 G immediately after adsorption, increasing to approximately 3.8 G when 1 h has elapsed since the adsorption of benzene. Corio and Shih[18] assume that a radical-cation dimer, in which the unpaired electron is delocalised over the two benzene rings arranged in the form of a sandwich, is formed immediately after the adsorption of benzene. The subsequent time variation of the ESR spectra is due to the rapid establishment of equilibrium between the dimeric and monomeric forms of the radical-cations.

Other workers also concluded that the radical-cation dimers of benzene are formed when it is adsorbed on H-mordenite[19]. In this investigation the ammonium-form of mordenite was subjected to a preliminary heat treatment for 18 h in air at 520°C. The authors[19] reached the following conclusion on the basis of the time variation of the ESR spectra appearing after the adsorption of a 1.8 M benzene solution in carbon tetrachloride on H-mordenite and a comparison of these spectra with the spectrum obtained after the adsorption of a 0.1 M solution of biphenyl in n-hexane. The ESR spectrum observed immediately after the adsorption of pure benzene results from a superposition of the spectra of the benzene radical-cation dimer and the biphenyl radical-cation. At room temperature the spectrum of the dimer disappears after approximately 24 h and that of the biphenyl radical-cation (HFS constants of 6.74, 3.37, 0.52 G) remains. The adsorption of toluene and *o*-xylene under analogous conditions leads to the appearance of ESR spectra characteristic of the corresponding biphenyl radical-cations (the 4,4′-dimethylbiphenyl radical-cation for toluene and the 3,4,3′,4′-tetramethylbiphenyl radical-cation for *o*-xylene). The formation of toluene and *o*-xylene radical-cation dimers was not observed. Kurita et al.[19] postulate two mechanisms for the formation of biphenyl radical-cations when the benzene cation and neutral molecule react on an oxidation centre of H-mordenite. The ionic mechanism is as follows:



In methylbenzenes, the interaction may be between the carbon atom with the maximum positive charge in the cation and the carbon atom with the maximum negative charge in the neutral molecule. The second, radical mechanism is



In methylbenzenes, the interaction via the radical mechanism can occur between the carbon atom having the maximum spin density in the cation and the carbon atom having the maximum free valence in the neutral molecule. However, calculations by the simple Hückel method of the charge, spin density, and free valence in the cations and neutral molecules of toluene and *o*-xylene did not enable the authors[19] to make a choice between the radical and ionic mechanisms.

A more detailed analysis of the temperature variation (in the range 77–300 K) of the ESR spectra of tetramethylethylene and cyclopentene adsorbed on H-mordenite has been described by Corio and Shih[20]. The methods used in the preliminary treatment of the zeolite and in the adsorption of the hydrocarbons were the same as in their earlier study[18]. They showed that the activation energy for the rotation of cyclopentene on the surface of H-mordenite is 1.4 ± 0.2 kcal mole^{-1}. Such a low activation energy indicates virtually free rotation of the adsorbed cyclopentene molecule.

In the studies quoted above[18-20], the formation of radical-cations in the adsorption of various hydrocarbons (mainly aromatic hydrocarbons) on H-mordenite was postulated. However, the study of the ESR spectra of C_3–C_5 olefins adsorbed on H-mordenite led Leith[21] to a different conclusion. He showed that the adsorption of propene at room temperature on H-mordenite evacuated for 12 h at 450°C and then treated in oxygen at the same temperature leads to the appearance of an ESR spectrum consisting of 19 HFS components with a splitting of 8.1 G. Analogous spectra were observed also in the adsorption of but-1-ene and pent-1-ene. Fig. 6 presents the experimental spectrum of the adsorbed propene and its theoretical interpretation (a superposition of a triplet with the HFS constant $a_1 = 33.6$ G, a quintet with $a_2 = 16.8$ G, and a triplet with $a_3 = 8.1$ G). This spectrum does not correspond to the propene radical-cation, the formation of which would have been extremely difficult in any case owing to the high (9.73 eV) ionisation potential of propene. Leith[21] suggests that the observed ESR spectrum is due to the formation of the allyl radical

$$\mathrm{CH_3{-}CH \overset{\cdots}{-} \dot{C}H \overset{\cdots}{-} CH{-}CH_2{-}CH_3}.$$

The triplet with $a_1 = 33.6$ G was assigned to the splitting of the energy levels of the unpaired electron at the β-proton and a proton in the methyl group. The quintet with $a_2 = 16.8$ G was assumed to be due to the interaction with two α-protons, the β-proton, and another proton of the methyl group. Finally, the triplet with $a_3 = 8.1$ G was attributed to the interaction with the central proton of the allyl group and the remaining proton in the methyl group. Bearing in mind the identity of the ESR spectra from adsorbed propene, but-1-ene, and pent-1-ene, it is suggested that the olefin is dimerised after adsorption with subsequent abstraction of a hydrogen atom and the formation of the allyl radical.

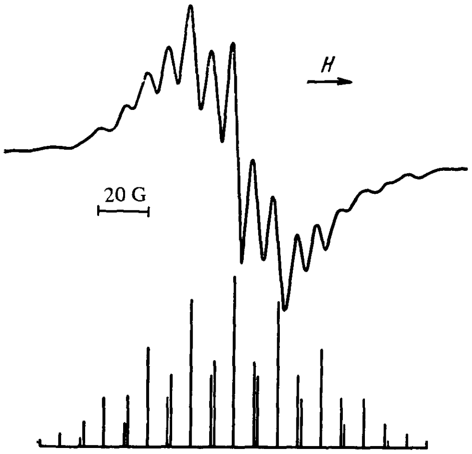


Figure 6. The ESR spectrum of propene adsorbed on H-mordenite and its theoretical interpretation[21].

2. The Influence of Heat Treatment and the Role of Chemisorbed Oxygen

The important role of oxygen in the formation of radical-ions following the adsorption of hydrocarbons on amorphous and crystalline aluminosilicates has been demonstrated in a series of studies. The problem has been investigated in relation to mordenites[22,23], a detailed study[22] having been made of the influence of the vacuum heat treatment of H-mordenite as well as the influence of H_2 and O_2 on the yield of benzene radical-cations. H-mordenite was first heated in air for 16 h at 500°C and then rehydrated for several days in a moist atmosphere. The standard heat treatment consisted in evacuation for 16 h at the given temperature in the range 100–800°C.

The treatment in hydrogen included the following stages: contact with H_2 at a pressure of 1 atm for 15 min at the standard heat treatment temperature and evacuation of H_2; repeated contact with H_2 under the same conditions with its subsequent evacuation for 3 h and cooling of the specimen *in vacuo*. Fig. 7 illustrates the influence of the temperature of the standard heat treatment of H-mordenite on the yield of benzene radical-cations (when 0.5 ml of benzene is adsorbed on 1 g of the zeolite) and on the specific surface of the zeolite determined by the BET method at 77 K from the adsorption of N_2. The weak maximum near 400°C can be attributed to the inaccuracy of the determination of the concentration of the radical-cations (errors of ±10%). However, it appears that the experimental error is not the real cause, since the changes in the concentrations of radical-cations on specimens evacuated at 300° and 500°C and treated in hydrogen are significantly different (Table 6). This finding probably indicates the formation of two different types of oxidation centres in specimens treated at 300° and 500°C respectively.

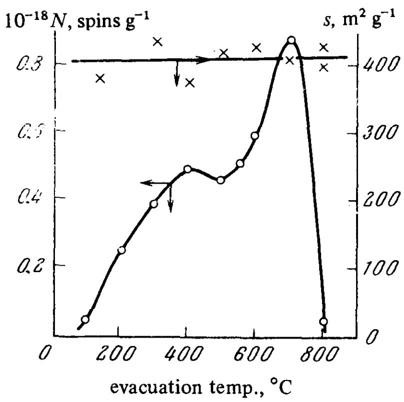

Figure 7. The influence of the heat treatment of H-mordenite on the concentration of benzene radical-cations (N) and the specific surface of the zeolite (s, determined by the BET method)[22].

The maximum number of benzene radical-cations is reached in the adsorption of 0.1 ml of benzene per gram of H-mordenite. The total adsorption capacity with respect to benzene at 25–28°C corresponds to approximately 0.09 ml per gram of zeolite. Consequently the maximum yield of the radical-cations is observed only when the mordenite channels are fully saturated by benzene. It must be emphasised that under these conditions approximately only 0.1% of the adsorbed molecules are oxidised to the radical-cations.

The data in Table 6 illustrate the influence of O_2 on the concentration of the radical-cations formed. It is evident from a comparison of these results with those presented in Fig. 6 that a particularly marked increase in the concentration of the radical-cations under the influence of O_2 is observed on the specimen evacuated at 800°C. The authors[22] showed that the ratio of the maximum number of radical-cations (2.1×10^{18} spins g^{-1}) and the number of O_2 molecules chemisorbed after treatment in hydrogen is 1 : 1.2. The treatment in hydrogen probably removes the most strongly chemisorbed oxygen remaining in the zeolite after the standard treatment. The evacuation of the O_2 adsorbed at room temperature and a pressure of 745 mmHg before the admission of benzene reduces the yield of radicals by approximately only 30% compared with the yield in the presence of O_2. Consequently chemisorbed by not physically sorbed oxygen plays an important role in the formation of the radical-cations. It is suggested that the chemisorption of an O_2 molecule on an H-mordenite active centre (or close to it) leads to the formation of a strong electron-accepting centre capable of oxidising benzene to the radical-cation. The yield of the radical-cations is limited by the amount of chemisorbed oxygen.

Table 6. The influence of treatment in hydrogen and of the oxygen pressure on the concentration of radical-cations formed.

Evacuation temperature, °C	Treatment in hydrogen	O_2 pressure, mmHg	Concentration of radical-ions, 10^{-17} spins g^{-1}
550	no	2.7	21.0
550	no	9.5	17.5
550	no	11.0	20.4
800	no	6.0	6.19
300	yes	0	1.18
500	yes	0	<0.01

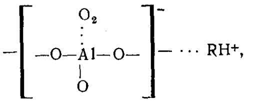
It was shown on the basis of the estimates quoted in the report of Sagert et al.[22] that only one mordenite unit cell in 100 contains a strong oxidation centre. The exact nature of these centres is unknown, but their formation is probably associated with mordenite crystal lattice defects. These centres are located in the principal mordenite channels. This conclusion is confirmed, on the onehand, by adsorption measurements and, on the other, by experiments with perylene. In the adsorption of perylene, which has a significantly lower ionisation potential and a larger molecular size than benzene, the authors[22] failed to observe the formation of radical-cations. According to other data[24], approximately 20% of the overall adsorbed species are located on the outer surface of mordenite. Thus the absence of perylene radical-cations shows that the oxidation centres are located within the mordenite structure and not on its outer surface.

More definite conclusions about the nature of the oxidation centres of mordenite responsible for the formation of benzene radical-cations were reached by Tokunaga et al.[23], who also investigated the influence of the preliminary heat treatment and the adsorption of O_2 and SO_2 on the yield of the radical-cations of benzene in its adsorption from the gas phase on NH_4Na-mordenite with a degree of exchange of 32%. It was shown that the benzene radical-cations are formed only after the evacuation of the zeolite at temperatures of the order of 500°C and that their concentration increases almost by an order magnitude with increase of the vacuum heat treatment temperature to 700°C. The parameters of the ESR spectrum and its time variation are analogous to those described by Kurita et al.[19] and correspond to the formation of benzene radical-cation dimers, which are converted after a time into biphenyl radicals. The yield of benzene radical-cations increases by a factor of approximately 5 as a result of the subsequent adsorption of O_2 at room temperature after the removal of benzene from the gas phase. The increase of the concentration of radicals has also been observed when O_2 was adsorbed before the adsorption of benzene, the magnitude of the effect depending in this case on the temperature of the preliminary adsorption of O_2: with increase of temperature from room temperature to 400°C, the concentration of benzene radical-cations increased by a factor of approximately 15. The adsorption of SO_2^- has the same effect on the yield of benzene radical-cations as the adsorption of oxygen.

Perhaps the most interesting result of this investigation[23] is the observation of the ESR signal of the SO_2^- radical-anion as a result of the adsorption of SO_2 on mordenite after the preliminary adsorption of benzene. A significant increase of the intensity of the benzene radical-cation signal was observed simultaneously with the appearance of the SO_2^- ESR spectrum.

The authors[23] suggest that the oxidation centre of mordenite includes a tricoordinate aluminium ion, the electron-accepting properties of which are enhanced under the influence of O_2 or SO_2 owing to the inductive effect. The negative charge is distributed between the aluminium ion involved in the one-electron transfer and the nearest adsorbed O_2 molecule. Such charge distribution for SO_2 leads to the formation of the SO_2^- radical-anion.

The above mechanism does not of course differ significantly from the mechanism involving the adsorption complex



$$-\left[-O-\overset{\overset{O_2}{\vdots}}{\underset{\underset{O}{|}}{Al}}-O-\right]^{-}-\cdots RH^+,$$

proposed[1] to account for the influence of O_2 on the formation of radical-cations in the adsorption of hydrocarbons on amorphous aluminosilicates. However, this complex can be formed on any aluminosilicate and is not a characteristic feature of mordenites. Nevertheless, as already mentioned above, the radical-cations of benzene and other molecules with high ionisation potentials are formed under normal conditions only on mordenites. We shall consider this process in greater detail below. In conclusion of the analysis of the study of Tokunaga et al.[23], we shall mention here that the ESR spectrum of the SO_2^- radical-anion observed by them is very remarkable. In discussing earlier investigations[2,12], we already noted the fact that, in the ESR study of the radical-cations formed in the adsorption of hydrocarbons on zeolites, it was impossible to detect the unpaired electron captured by the solid. The possible causes of this phenomenon were also briefly discussed, one of them being associated with the delocalisation of the captured electron over the entire bond system of the solid. One cannot rule out the possibility that the appearance of SO_2^- radical-anions observed by Tokunaga et al.[23] is in fact due to the localisation of the captured electron at the sulphur atom.

3. The Oxidising Properties of Mordenites from Which Metal Cations and Aluminium Have Been Eliminated

Few studies on the influence of the elimination of metal cations and aluminium from mordenites on their oxidising and reducing properties are described in the literature. It has been shown[25] that the sharp increase of the ESR signal intensity following the adsorption of anthracene on specimens freed from metal cations is observed for degrees of exchange in excess of 50% (Table 7, Nos. 1–6). The size of the adsorbed molecule is significant in adsorption on mordenites. The dimensions of the small and large elliptical channels in mordenite are 3.8–4.7 Å and 5.8–7.0 Å respectively. The narrow channels (~4 Å) are inaccessible to anthracene molecules. During the metal cation-elimination process, Na^+ ions are removed from the large channels, which increase the effective diameter of the latter[26] and thus the rise of signal intensity may be caused both by the increase in the number of oxidation centres and by the greater accessibility of the bulk of the zeolite to anthracene molecules.

Table 7. Dependence of the number of anthracene radical-ions (N) on the degree of elimination of metal cations and aluminium from mordenite.

No. of specimen	Type of zeolite	SiO_2/Al_2O_3	Degree of exchange of Na^+ for H^+, %	10^{-17} N, spins g^{-1}
1	NaM	10.14	—	no signal
2	»	10.14	15.0	ditto
3	»	10.14	25.0	very weak signal
4	»	10.14	50.0	2.2
5	»	10.14	80.0	7.2
6	HM	10.14	99.4	7.6
7	»	13.3	99.4	10
8	»	16.8	99.4	10
9	»	20.6	99.4	15
10	»	48.0	99.4	4.4
11	»	55.0	99.4	6.7
12	»	73.0	99.4	7.6

The dealumination of an HM specimen is accompanied by an increase in the ESR signal intensity, which reaches a maximum for the preparation with the ratio SiO_2/Al_2O_3 = 20.6. The maximum in catalytic activity observed in a series of investigations for mordenite with this SiO_2/Al_2O_3 ratio[27,28] may be associated with the optimum oxidising properties of this catalyst.

Analysis of the results shows that oxidation centres arise mainly when metal cations are removed from NaM, while dealumination of an HM specimen is accompanied by only a twofold increase of the concentration of these centres.

A detailed study of the oxidising properties of mordenite in relation to the formation of benzene, naphthalene, and anthracene radical-cations has been made[29]. Fig. 8*a* presents the ESR spectrum arising immediately after the adsorption of benzene on an HM zeolite heated in air at 300°C.

The nature of the ESR spectra arising in the adsorption of benzene on an HM zeolite and the influence of O_2 on their appearance, investigated in the above study, confirm the earlier literature data[18,19,22,23]. The HFS constant, equal to 2.3 G, corresponds to the formation of the biphenyl radical. This is confirmed by the presence of 11 HFS components in the adsorption of benzene, i.e. the unpaired electron interacts with 10 equivalent protons. The hypothesis[18] of the formation of a "sandwich" of two benzene molecules appears unlikely, bearing in mind the geometry of the large mordenite channels. Furthermore, in such a model it is not clear which central mordenite lattice cation should be involved in the formation of this "sandwich". The initial activation of the benzene molecule by interaction with an electron-accepting centre and the formation of a charge-transfer complex followed by rapid oxidative dehydrogenation and the formation of a biphenyl radical-cation therefore appear more likely.

Experiments with adsorption of C_6H_5D and 1,4-$C_6H_4D_2$ have shown that there is no preferential abstraction of a D atom in the formation of the biphenyl radical-cation. In fact, if mainly the D atoms were abstracted in the oxidative dehydrogenation, the resulting ESR spectrum would have been identical with that arising in the adsorption of C_6H_6. Examination of Figs. 8 and 9 shows that this is not the case. The spreading of the HFS and the narrowing of the ESR spectrum observed in the adsorption of deuterated benzenes are characteristic of radical-cations in which some of the hydrogen atoms have been replaced by deuterium atoms[30].

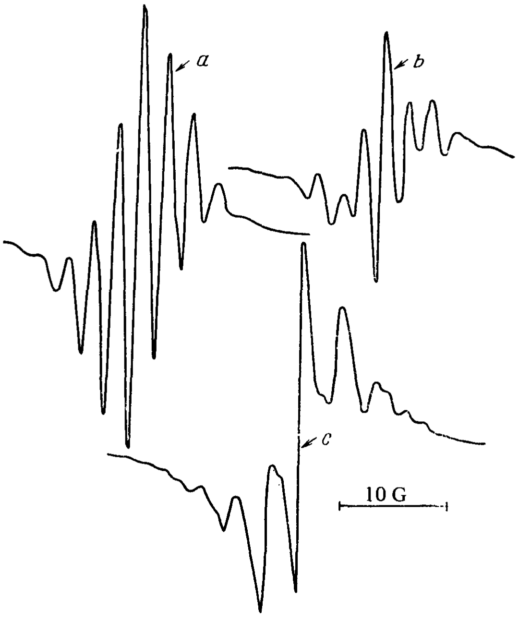


Figure 8. The ESR spectrum of the radical-cations of benzene adsorbed on H-mordenite heated in air at 300°C: *a*) immediately after adsorption; *b*) after 1.5 h; *c*) after 24 h [*a*) and *b*) identical amplification; *c*) amplification greater than in cases *a* and *b*][29].

A characteristic feature of the ESR spectra of adsorbed C_6H_6 is their rapid time variation (Fig. 8), particularly on heating the zeolite. This is associated with the subsequent occurrence of processes leading to the formation of polyphenylene radicals, giving rise to a singlet ESR line. In contrast to C_6H_6, the adsorption of naphthalene and anthracene on an HM zeolite is accompanied by the appearance of much more stable radical-cations, the ESR signals of which (Fig. 10) hardly vary at room temperature over a long period (1 month in the case of anthracene). The different stabilities of the benzene, anthracene and naphthalene radical-cations can probably be explained by the greater reactivity of the biphenyl radicals, leading to the formation of polyphenylenes.

In all the studies on the ESR spectra of molecules with cojugated bonds adsorbed on type X and Y zeolites made hitherto, the adsorbents were subjected to a rigorous preliminary heat treatment (at about 500°C), since it was assumed that centres capable of the formation of radical-cations arise only under these conditions. Fig. 11 illustrates the changes in the concentration of the anthracene, naphthalene, and benzene radical-cations as a function of the temperature of the heat treatment of the HM zeolite in air[29]. Evidently the lower the ionisation potential of the hydrocarbon, the lower the temperature of the heat treatment after which the ESR spectrum of the radical-cation appears. An intense signal of the anthracene radical-cations appears at a heat-treatment temperature as low as ~150°C, although this temperature is too low even for the elimination of the entire molecular water from the mordenite channels. Thus, powerful oxidation centres appear in H-mordenite even at low dehydration temperatures.

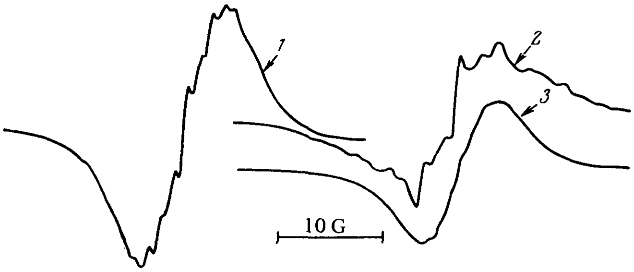

Figure 9. The ESR spectra of deuterated benzenes adsorbed on H-mordenite heated in air at 450°C: 1) immediately after adsorption of C_6H_5D; 2) 24 h after adsorption of C_6H_5D; 3) immediately after adsorption of 1,4-$C_6H_4D_2$ (identical amplification)[29].

One should note that an increase of dehydration temperature entails an increase not only in the number of oxidation centres but probably also in their activity. A dehydration temperature of 150°C is sufficient for the formation of centres capable of oxidising anthracene to the radical-cation, but is insufficient for the appearance of centres on which benzene radical-cations are formed.

The different activities of the oxidation centres suggest that the molecules of aromatic hydrocarbon differing in their ionisation potentials will interact with these centres, forming charge-transfer complexes with different bond strengths. It might therefore have been expected that the anthracene molecule, which has the lowest ionisation potential compared with naphthalene and benzene, would be linked to the electron-accepting centre most strongly and anthracene molecules should therefore displace the radical-cations formed in the adsorption of benzene and naphthalene. It has indeed been found that, when a zeolite with adsorbed naphthalene radical-cations (Fig. 10*a*) is exposed to anthracene in carbon tetrachloride solutions, the spectrum of the naphthalene radical-cations vanishes after 15 min and that of the anthracene radical-cations appears (Fig. 10*b*). It is remarkable that the rate of the displacement process is fairly high, despite the difficulty of the migration of relatively large molecules in the narrow mordenite channels.

One of the fundamental problems in the study of the mechanism of the formation of radical-cations on aluminosilicates and zeolites is that of the nature of the

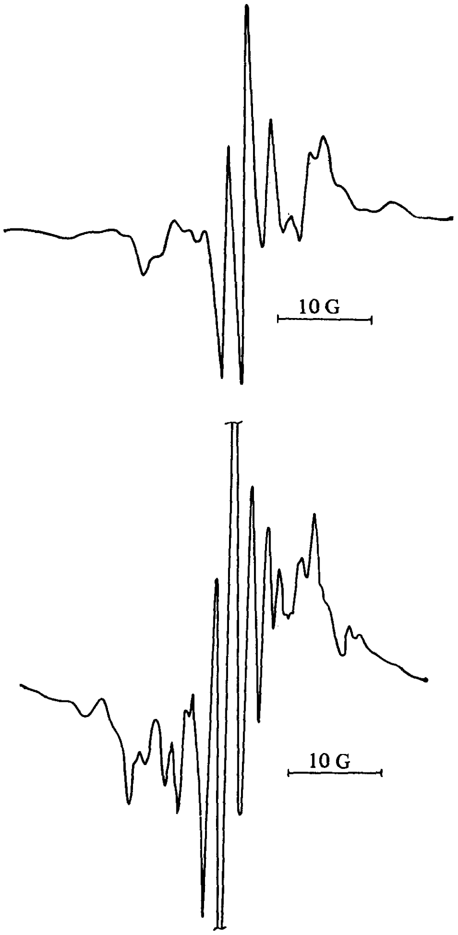

Figure 10. The ESR spectra of the radical-cations of naphthalene (*a*) and anthracene (*b*) adsorbed on H-mordenite[29].

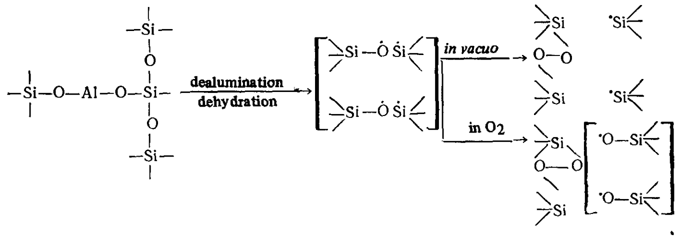
electron-accepting centre and of the role of oxygen. It has been suggested that the electron-accepting centre consists of an Al^{3+} ion. The role of oxygen in the formation of radical-cations, for example in the adsorption of benzene on H-mordenite, reduces to the inductive effect on the Al^{3+} ion, which facilitates the electron transfer[23]. We already noted above that this mechanism does not differ in any significant way from the adsorption complex mechanism proposed[1] to account for the influence of O_2 on the formation of radical-cations in the adsorption of hydrocarbons on amorphous aluminosilicates. It was also emphasised that this mechanism does not explain the appearance of radical-cations in the adsorption of benzenes on H-mordenite, because H-mordenite is the only one of the zeolites investigated hitherto on which benzene radical-cations are formed readily at room temperature without any additional influences on the system, for example ultraviolet irradiation. Consequently the activity of the electron-accepting centres in H-mordenite, at any rate in the formation of benzene radical-cations, should significantly exceed the activity of the electron-accepting centres in other zeolites and amorphous aluminosilicates.

Since treatment of mordenite with oxygen is a necessary condition for the generation of centres responsible for the formation of benzene radical-cations and the mechanisms involving Al^{3+} ions alone does not account for this process, the centres are presumably formed[29] as a result of the interaction of oxygen with silicon. Judging from the intensity of the ESR signal, the number of such centres is small, amounting to approximately one centre for 100 unit cells in anthracene, the number in benzene being smaller by a factor of 2–3.

If it is supposed that dealumination takes place at certain sites in the structure during the formation of mordenite, the subsequent formation of centres can be represented by the following scheme:



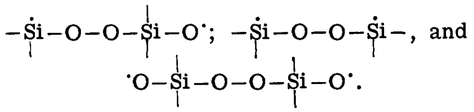
(I)

The pairs of radicals $>$Si–O$^{\cdot}$ and $>$Si$^{\cdot}$ arising in the dehydration process cannot lead to the formation of the Si–O–Si linkage. The point is that there are four different sites in mordenite where Si(Al) atoms are located[31], for which the distance between the nearest Si atoms has been shown by calculations to vary in the range 4.36–5.77 Å. The average Si–O bond length for the same lattice sites varies in the range 1.59–1.63 Å.[31] Consequently the Si–Si distance exceeds by approximately 1 Å twice the Si–O bond length, so that only Si–O–O–Si linkages can formed. On the other hand, the formation of such a peroxy-bridge between two other silicon atoms in the interaction with oxygen is probably impossible owing to steric hindrance.

The $>$Si$^{\cdot}$ centres are relatively unreactive with respect to the adsorption of hydrocarbons, since the unpaired electron is delocalised in these centres over the Si–O bonds. The adsorption of O_2, leading to the formation of Si–O$^{\cdot}$ radicals, thus creates strong electron-accepting centres, active in the formation of radical-cations.

The mechanism described apparently accounts for the appearance of the intense ESR signals in the adsorption of benzene on hydrated H-mordenite heated at low temperatures (Fig. 11). Heat treatment of H-mordenite at low temperatures (~200°C) in the presence of C_2 already gives rise to structure (I), which is active in the formation of benzene radical-cations. Naturally, apart from these centres, the mordenite contains also the usual electron-accepting centres incorporating Al^{3+} ions, which are responsible for the formation of anthracene and naphthalene radical-cations at still lower heat-treatment temperatures (~150°C).

The possibility of the formation of structure (I) is to some extent confirmed by the results of a study by Low[32], who obtained and investigated active silica gels. By methoxylating aerosil with subsequent pyrolysis and heat treatment, he succeeded in obtaining a silica gel which adsorbed considerable amounts of H_2 and O_2. On the basis of adsorption and infrared spectroscopic studies, he postulated[32] the presence on the adsorbent surface of a small number of unusual centres, incorporating silicon atoms, linked by a peroxy-chain:



$-\overset{\bullet}{\underset{|}{\mathrm{Si}}}-O-O-\overset{|}{\underset{|}{\mathrm{Si}}}-O^{\bullet}$; $-\overset{\bullet}{\underset{|}{\mathrm{Si}}}-O-O-\overset{\bullet}{\underset{|}{\mathrm{Si}}}-$, and

$^{\bullet}O-\overset{|}{\underset{|}{\mathrm{Si}}}-O-O-\overset{|}{\underset{|}{\mathrm{Si}}}-O^{\bullet}$.

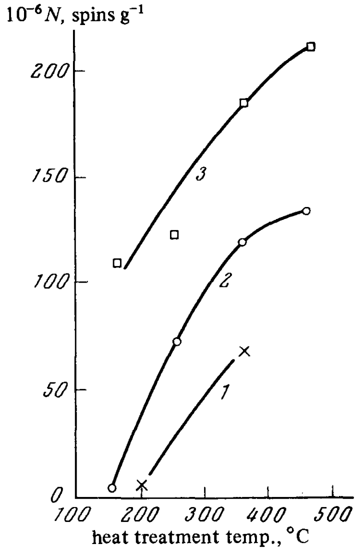


Figure 11. Dependence of the concentration (N) of the radical-cations of benzene (curve *1*), naphthalene (curve *2*), and anthracene (curve *3*) on the temperature of the heat treatment of H-mordenite[29].

Wheareas preliminary methoxylation with subsequent pyrolysis and a fairly severe heat treatment are necessary conditions for the formation of such centres in SiO_2, in mordenite with its unusual crystal structure, centres of this kind can arise under much milder conditions.

IV. CONCLUSION

The studies discussed above have shown that there has been a continuous growth of interest in the study of the oxidising and reducing properties of zeolites. This is due not only to the theoretical importance of the problem but also to its practical aspects, since it has been suggested that the oxidation-reduction centres in aluminosilicate catalysts are involved in the catalytic transformations of hydrocarbons[33].

The characteristic features of the formation of radical-cations on zeolites compared with amorphous aluminosilicates arise from several causes, in particular (1) the specific geometrical structure of zeolites and (2) the presence of more powerful oxidation centres in zeolites. As a result of the latter, radical-cations are formed on zeolites following the adsorption of molecules with high ionisation potentials (benzene and olefins), which is not observed in adsorption on amorphous aluminosilicates.

One of the fundamental problems arising in the study of the oxidation-reduction centres is the elucidation of their nature. The main oxidation centre is believed nowadays to be the tricoordinate Al^{3+} ion (a Lewis centre), but the complete set of data obtained cannot be accounted for solely by the presence of such centres, particularly for H-mordenite. The problem therefore arises whether or not the formation of radical-cations is a specific instance of a general acid–base interaction or whether the oxidation-reduction centres constitute a special group. The elucidation of these problems is of greatest importance for the understanding of the nature of the centres on the surfaces of amorphous and crystalline aluminosilicates and of the mechanism of acid–base catalysis. In this respect, the study of the oxidising and reducing properties of zeolites having a known geometrical structure and susceptible to different types of modification can render invaluable assistance in the solution of the problems formulated above.

Nuclear Magnetic Resonance Study of Ion-exchange Resin-Solvent Systems

G.S.Bystrov, G.A.Grigor'eva, and N.I.Nikolaev

The results of measurements of NMR spectral parameters (chemical shifts, line widths, and relaxation times) of water molecules, counterions, and adsorbed molecules in the ion-exchange resin phase are discussed in detail and compared and the conclusions concerning their state and motion are analysed. The scope and difficulties in the application of the NMR method to the investigation of ion-exchange equilibria and kinetics are demonstrated.
The bibliography includes 91 references.

CONTENTS

I. INTRODUCTION

Ion-exchange resins are insoluble substances which, however, swell in the solvent and are capable of absorbing from an electrolyte solution positive or negative ions in exchange for equivalent amounts of other ions of like sign[12,13]. The skeleton of synthetic ion exchangers consists of an irregular network of hydrocarbon chains, usually polystyrene chains, connected by a necessary number of cross links. In cation exchangers, fixed groups bearing negative charges ($-SO_3^-$, $-CO_2^-$, $-PO_3^{2-}$, etc.) are grafted to the resin matrix, while in anion exchangers there are similar groups bearing positive charges ($-NH_3^+$, $>NH_2^+$, $>S^+$, etc.).

A dry ion-exchange resin is virtually of no practical interest. All ion-exchange processes, including the dissociation of the ionogenic groups, the diffusion of counterions, and the ion exchange between the external solution and the resin phase take place only in the presence of a solvent. The selectivity of ion exchange is likewise related to the size of the water—exchangeable ion hydrate complex. The electrical conductivity of the ion-exchange resin depends on its water content. In order to optimise ion-exchange processes, it is necessary to investigate the mechanisms of the interaction of all the components in the resin phase. The state of water and of the hydrate complexes in the ion exchanger can be investigated successfully by NMR.

Nuclear magnetic resonance (NMR) yields much information in the study of substances in any state of aggregation. The essential physical features and theory of NMR and the characteristics of the relevant apparatus as well as the results of studies carried out over a period of many years by this method have been described in a number of monographs[1-6] and reviews[7-11]. In the NMR method, the directly measured parameters are the chemical shifts, widths, and integral intensities of the spectral lines and the longitudinal and transverse relaxation times.

More than 10 years have elapsed since the beginning of studies on synthetic ion-exchange resins by nuclear magnetic resonance. However, the wide physicochemical variety of ion-exchange resins, their increasing practical importance, the endeavour to optimise technical exchange processes, and the necessity to investigate the solvent structure within the resins in order to apply the latter as dielectrics or electrolytes are all factors which have now given rise to increased interest in ion-exchange resins. Extensive experimental NMR data on the solvent (usually water) structure in specific types of ion exchangers have accumulated. The parameters of the NMR spectra yield information not only about the state of the external or internal, with respect to the resin, solvent, but also about the state of inorganic or organic exchangeable ions. These parameters usually depend on the initial material of the matrix, the method of preparation of the resin, the nature of the fixed groups and counterions, the percentage content of divinylbenzene (DVB) or another cross-linking agent, the total exchange capacity of the ion exchanger, the shape and size of the resin grains and the proportion of defects they contain, the contamination of the resin, the presence, the concentration and nature of impurity or defect paramagnetic centres in the resin, the content of water or another solvent, and the temperature of the specimen.

II. THE CHEMICAL SHIFT OF INTERNAL WATER PROTONS

1. Characteristics of the Experimental Methods for the Ion-exchange Resin—Water System

The ion-exchange resin—water system consists of swollen resin grains, the space between which may be filled by the solvent. The first NMR study[14] on a suspension of Dowex-50 sulphonic acid cation-exchange resin in water showed that the ^{1}H NMR spectrum of water consists of two lines of approximately equal intensity, belonging to the internal and external water. The chemical shift between the external and internal water may be due to various causes.

It is frequently stated that the structure of internal water is disrupted to a greater extent than that of the external water. This effect[1] must cause a displacement of the line due to the internal water relative to that due to the external water in the direction of higher fields. The displacement of the internal water line can also be caused by the influence of the benzene ring currents on the shielding constant of the nearest protons. It is known[1] that the gradual diluton of a solution with an aromatic solvent leads to an upfield displacement of the proton signal. The major proportion of the signal due to the methyl protons of the solvent in the resin has been attributed to this effect[14]. In the study of the chemical shift in an ion-exchange resin, the influence of aromatic rings on the position of the line is frequently either not considered at all or its contribution is believed to be insignificant.

Another cause of the chemical shift between the water absorbed by the ion-exchange resin and pure water is the difference between the volume magnetic susceptibilities (χ_V) of water and the ion-exchanger material. Gordon[14] estimated χ_V for spherical grains of pure cross-linked polystyrene and, having observed the influence of these grains on the chemical shifts of water, toluene, dioxan, and acetonitrile, concluded that the position of the external solvent line is determined by the effect of volume magnetic susceptibility. For the internal solvent, there is no need[14] to apply a correction for χ_V if the resin grains are ideally spherical. However, it is known[15] that the number of defective grains in the KU-2 and AV-17 resins, most widely used in the USSR, reaches 50–60%. The few available experimental data on the influence of the artificial disruption of resin grains on the ^{1}H NMR chemical shift of water are contradictory. The majority of investigators worked solely with spherical grains or with a small number of defective grains. In subsequent studies, it was shown that the difference between χ_V of water and the swollen resin increases with increase of the degree of cross-linking of the latter, its exchange capacity, and the atomic weight of the counterion. Nevertheless, all workers believe that this difference is small and neglect the correction for this effect; using the rotating tube method, Weiner and Howery[16] determined the absolute values of χ_V in a swollen Dowex-50W cation-exchange resin (with 4, 8, and 12% of divinylbenzene) in 10 ionic forms (H^+, Na^+, NH_4^+, NMe_4^+, Rb^+, Ba^{2+}, Mg^{2+}, Zn^{2+}, Cd^{2+}, and La^{3+}). The chemical shifts of the external and internal water relative to a standard were corrected for χ_V taking into account the results. The contribution of the χ_V correction to the chemical shift of the internal water was indeed found to be insignificant.

Since the concentration of the counterions in the resin phase is fairly high, the next factor influencing the position of the ^{1}H NMR line of the internal water is the polarising action of diamagnetic ions on the water molecules, as happens in electrolyte solutions.

The technology of the preparation of ion-exchange resins is such that the latter contain a large percentage of impurities, including paramagnetic impurities. In salt solutions containing parmagnetic ions, fairly large shifts of the ^{1}H NMR signals are observed[1] due to the contact interaction between the unpaired electrons of the paramagnetic ions and protons. The artificial introduction of a small number of Fe^{3+} or Fe^{2+} ions into the KU-2 cation-exchange resin causes[17] an appreciable shift of the ^{1}H NMR line of the water absorbed by the resin. Information about the state of the paramagnetic impurities obtained by other physical methods is therefore of definite value even when the resin is carefully purified.

The dimensions of industrial ion-exchange resin grains vary between 0.002 and 2.0 mm.[13,18] In addition, the majority of investigators have measured the chemical shift of the ^{1}H NMR line due to the water absorbed by the resin relative to the ^{1}H NMR signal of the external water as a standard. It is therefore important to know how the position of the resonance lines of the external and internal water depends on the particle size. Darickova et al.[19] suggested that all resin grains be divided into three groups in terms of their dimensions. The first group includes resins consisting of large grains for which the external water chemical shift is approximately the same as for pure water, while the chemical shift of the internal water is equal to the shift for the aqueous solution of acid at the equivalent concentration. The second and third groups comprise resins with intermediate and fine grains (for sulphonic acid cation-exchange resins, the diameter is less than ~0.1 mm), the decrease of the size of which is accompanied by the mutual approach of the ^{1}H NMR signals of the external and internal water. This phenomenon is explained by an increase of the rate of exchange of water molecules between the resin phase and the external solvent which is confirmed by the dependence of the effect on temperature and the number of cross links. We may add that the average number of hydrogen bonds per molecule in the external water decreases and the effect of volume magnetic susceptibility becomes more pronounced with decrease of the diameter of the resin grains.

It follows from the foregoing that certain causes of the displacement of the ^{1}H NMR resonance lines of an aqueous suspension of an ion exchanger are eliminated in the preparation of the specimen which involves the removal of defective grains and the elimination of paramagnetic and organic impurities from the resin. The presence of impurities in the resin is a cause of the non-reproducibility of the results. Other causes of non-reproducibility may be the non-identity of resins having the same designation but manufactured by different companies and also the different diameters of the resin grains investigated. Small discrepancies may arise in consequence of the differences between the methods used to eliminate the external water (absorption of water by filter paper, centrifugation in tubes with a porous bottom, the passage of a stream of dry air through the column, etc.).

In order to interpret the chemical shift data, it is almost always necessary to have quantitative data for the water content in the resins. It has been shown[20] that there is a satisfactory agreement between the results of the determination of the water content by the Fischer titration method, by the drying method, and from the integral intensities of the ^{1}H NMR signals. However, the titration method is free from the limitations of the drying and ^{1}H NMR methods and yields a rapid and exact estimate of the moisture content (10 wt.% and above) for the majority of resins.

Knowing the water content and capacity of the resin, it is possible to calculate its molality. Reichenberg and Laurenson[21] established that the chemical shift between the lines of the external and internal water is an unambiguous function of the number of water molecules per sulphogroup. Since the chemical shift of the internal water line is proportional[21,22] solely to the molality of the ions in the resin phase, such molality can be determined directly from the chemical shift. However, in a later study[19] it was shown that the concentration of fixed ions can be determined by the ^1H NMR method only for large-grained ion-exchange resins and that the minimum permissible grain size depends on the chemical shift between the internal and external water, i.e. on the degree of cross-linking and molality in the resin phase. According to Darickova et al.[19], the independence of the difference between the chemical shifts of the external and internal water of the resin grain size should serve as a criterion of the possibility of measuring the internal molality in the resin by NMR.

2. Dependence of the Chemical Shift of the Concentration of Counterions

There exist several model representations of ion-exchange resins. The ion exchanger is sometimes[23] compared with a concentrated electrolyte solution, subject to allowance for the characteristics introduced by the resin matrix. ^1H NMR studies on the internal water confirmed[14,24-30] the validity of such comparison. In this case one can use in the interpretation of the chemical shifts in the resin phase certain assumptions and empirical formulae which have been employed previously[9] in the study of aqueous electrolyte solutions by high-resolution NMR. The shift of the ^1H NMR line of the internal water must be mainly determined by the interaction of the water dipoles with the counterions and fixed groups. The molal chemical shifts should reveal positive or negative hydration of the counterion. Here it is necessary to bear in mind that the internal molality in the resin depends on the degree of cross-linking of the latter and the nature of the counterion.

The electrostatic nature of the interaction between water molecules and counterions is expressed by the linear relation between the ^1H NMR signal shift and the square of the reciprocal of the radius of the cation[28] (K^+, Na^+, Ba^{2+}, Sr^{2+}, Ca^{2+}, Li^+, and Mg^{2+}) in the KU-2 resin or the corresponding quantity for the anion[29] (F^-, Cl^-, Br^-, and I^-) in the AV-17 resin, the molal chemical shifts in cation exchangers ($\delta^0_{M^+}$) and anion exchangers ($\delta^0_{M^-}$) saturated by univalent and polyvalent counterions are identical as regards sign and order of magnitude[24,25,28,30] with the corresponding values in aqueous solutions of diamagnetic salts. The maximum discrepancy between the resin and solution is observed for H^+ and F^- ions and has been explained by the high capacity of these ions for the formation of ion pairs with the fixed groups.

The consistently lower values of $|\delta^0_\pm|$ in resins for univalent cations[25] and anions[28] compared with the values of $|\delta^0_\pm|$ in the corresponding electrolyte solutions are regarded by the authors as evidence for intensifying ion–ion interactions in the resin. It is emphasised[25,27,28] that the counterions in the resin exhibit their "structure forming" or "structure breaking" properties almost to the same extent as in pure water. The dependences of the ^1H NMR chemical shifts δ of the internal water on the internal molality m† in ion-exchange resins resemble the corresponding plots for aqueous electrolyte solutions and have similar deviations from linearity at high concentrations of the ions in the resin. An exception is the hydrogen-form of the resin, where the linearity persists up to $m = 7$. The values of δ for all the counterions extrapolate to zero when $m \to 0$; thus, the external and internal water have the same chemical shifts at $m = 0$. Since δ tends to zero when $m \to 0$ and does not depend on the grain size, the authors explain the shift of the internal water signal relative to the external water as a result of ion–dipole interactions between the counterions and the solvent.

The deviation from linearity towards decreasing values of $|\delta|$ for the Mg^{2+}-, Be^{2+}-, and Al^{3+}-forms of the cation-exchange resin is more marked than for univalent counterions and begins at lower concentrations. Whereas $|\delta|$ for Be^{2+} and Al^{3+} increases up to 16% DVB under these conditions, albeit at a reduced rate, the plot of $\delta = f(m)$ for Mg^{2+} passes through a maximum and $\delta = 0$ at $m = 3.52$ (which corresponds to 16% DVB). Sharma and Subramanian[27] explain the shape of the $\delta = f(m)$ curve for the Mg^{2+}-form of the cation exchanger by the conversion of the $SO_3^-{-}H_2O{-}Mg^{2+}$ ion pair into the $SO_3^-Mg^{2+}$ contact ion pair (i.e. the fixed group substitutes one water molecule in the first coordination sphere of the counterion). The authors explain the decrease of the overall effect of this cation on the water structure (or on δ for the internal water) by an increase of the number of water molecules outside the first hydration shell. Owing to their high charge density, the Be^{2+} and Al^{3+} counterions retain their first hydration shells in the cation exchanger with 16% DVB. Thus associated species of the type fixed group–solvent–counterion continue to exist and there is only a decrease in the number of molecules outside the first hydration shell. We may add that an increase of the negative shift of the internal water for the Be^{2+}- and Al^{3+}-forms of a sulphonic acid cation-exchange resin with increase of the internal molality is correlated with the capacity of these ions for the protolytic cleavage of the molecules of the water of hydration, as has been pointed out by Zundel[31].

3. Temperature Dependence of the Chemical Shift

(a) The range of positive temperatures. Hydration numbers. Malinowski et al.[32] developed a method for the determination of the total effective hydration numbers of ions h in an electrolyte solution from the temperature dependence of the ^1H NMR chemical shift. Here h is defined as the number of moles of water of hydration per unit molality of the salt. It was assumed that the chemical shift of the water of hydration is independent of concentration and temperature. Since the states of the external and internal water are different in aqueous suspension of an ion-exchange resin, Greekmore and Reilly[33] applied Malinowski's method to the calculation of h in the resin phase using the difference between the temperature dependences of δ_{int} and δ_{ext}. The formula for the calculation of h is

$$h = \frac{55.55}{m}\left[\frac{d\Delta/dt}{d\delta_{H_2O}/dt}\right], \qquad (1)$$

where m is the molality in the resin, $\Delta = \delta_{ext} - \delta_{int}$, and δ_{H_2O}, δ_{ext}, δ_{int} are the chemical shifts of pure water and the external and internal water in an aqueous ion-exchange resin suspension respectively. The Table lists the total effective hydration numbers for different ionic forms of Dowex-AG-50W and KU-2 cation-exchange resins and of Dowex-AG-1 and AV-17 anion-exchange resins taken from a number of communications[27,28,33,34].

A qualitative correlation between the values obtained in the resins and in the corresponding electrolyte solutions

---

† The molality was altered by changing the degree of cross-linking of the resins.

is evident. The hydration numbers of the counterions in the cation-exchanger phase are systematically lower than the values of *h* for the analogous cations in salt solutions. This fact can be explained by the stronger interaction between the counterion and the fixed group than between the anion and the cation in solution, and also by the more pronounced hydration of anions in solution compared with the fixed groups. It is suggested that one coordination site of a univalent counterion may be occupied by a sulpho-group. The high hydration numbers of bivalent counterions can be explained by the fact that their influence extends to the second hydration shell.

The total effective hydration numbers in different ionic forms of resins.

Mank et al.[35] investigated the KB-4P2 carboxylic acid cation-exchange resin in the H^+- and K^+-forms. They obtained $h(H^+) = 2$ and $h(K^+) = 2.9$. They concluded that the water molecules form strong hydrogen bonds with the carboxy-group of the type  $C(=O\ldots H_2O)OH\ldots OH_2$. In the resin containing the K^+ counterion, only some of the COOK groups are dissociated.

The results of measurements of the temperature dependence ($t > 0$°C) of the ^1H NMR chemical shifts of aqueous suspensions of resins with different degrees of cross-linking and in different ionic forms have also been reported in other communications[36-41].

The entire water in the resin can be conveniently divided[12] into free and bound, i.e. the water of hydration. Sharma and Subramanian[28] determined the relative contents of the free and bound water using for this purpose the effective hydration numbers and concluded that the amount of free water for a given content of divinylbenzene is almost constant in resins saturated by alkali metals.

A distinctive feature of a swollen resin compared with an electrolyte solution is that the space between the hydration shells in the resin is "filled" by the hydrophobic matrix. For this reason, *h* can characterise correctly the number of molecules hydrating the fixed group and the counterion, but may not agree with the value of *h* for the corresponding salt solution. An attempt has already been made[28] to relate the hydration numbers to the selectivity of the ion exchanger.

(b) The negative temperature range. Systematic studies by microwave spectroscopy of the state of water in ion-exchange resins in the region of negative temperatures were begun by Nikolaev and coworkers[37,40-42] and then by Mank and coworkers[34,38,39]. As the temperature of an aqueous resin suspension is reduced to zero, the external water crystallises and the intensity of its spectral line becomes negligible owing to its marked broadening as a result of the increasing dipole–dipole interaction of the water protons. The crystallisation of an equivalent Na_2SO_4 solution (1.45 M) or a solution of toluenesulphonic acid takes place[41] at −7° or −30°C respectively. With decrease of temperature below zero, the NMR signals of the internal water protons shift downfield to a greater extent the lower the degree of cross-linking of the resin. This is explained[37,40] by an increase of concentration in the internal solution, which occurs as a result of the freezing out of the "free" water from the resin phase. An interesting experimental result has been obtained[37,40]: for a given ionic form of the resin, there is a definite temperature at which the ^1H NMR chemical shift of the internal water is independent of the amount of cross-linking agent and tends to a limiting value. The latter may be determined by the nature of the counterion. At any rate, the chemical shifts of the internal water in ion exchangers at temperatures below −70°C will be useful for the investigation of stable hydration structures or counterion–water–fixed group complexes.

Mank and coworkers[34,39] noted the possibility of determining the ion hydration numbers from the number of water molecules whose translational motion does not cease below 0°C. By comparing the areas under the experimental ^1H NMR spectral curves at temperatures of aqueous suspensions above and below 0°C, they were able to reach the conclusion that the water which is not bound to the cations crystallises in the resin phase. They found that $h(Ba^{2+}) = 6$ and $h(NH_4^+) = 5$.

The amount of "free" water (not influenced by the counterions and the fixed groups) can be increased sharply by creating artificially large pores within the resin. The states of water in the gel component of the resin and within its pores should differ significantly. However, owing to the rapid proton exchange above 0°C, a single resonance line is observed for the internal water in macroporous cation-exchange resins[41,45]. At −2°C the proton exchange is retarded[37] so much that the line of the internal water in the KU-23 resin splits to give a doublet. A separate ^1H NMR line of the water in the pores is observed down to −15°C and then vanishes owing to its marked broadening, while the signal due to the water in the gel component of the KU-23 resin continues to be recorded down to −70°C. Both lines shift downfield with decrease of temperature.

The study of the state of water in synthetic ion-exchange resins at negative temperatures yields important practical results[37]. The absence of the crystallisation of the internal water gives rise to the hope that ion exchangers with a gel structure are fairly resistant to the action of low temperatures (down to approximately −70°C). On the other hand, the presence of defects and cracks within the resin grains (with a size exceeding 100 Å), in which the phase transition to a crystalline state takes place, leads to the disruption and cracking of resins on cooling. The results obtained for the state of water in the resins on cooling are of interest for the analysis of the changes in the state of water when the temperature is reduced below 0°C in ion-exchange membranes and living cells.

III. THE INTERNAL WATER ^{1}H NMR LINE WIDTH

The width of the ^{1}H NMR spectral lines due to the internal water in synthetic ion-exchange resins depends on a number of factors and is usually appreciably greater than the line width for pure water. In order to interpret the results, it is very important to isolate the dominant cause of the broadening of the line and to exclude the broadening due to preventable effects.

The presence of inorganic paramagnetic impurities in commercial resins leads[14,17] to a significant broadening of the spectral line due to the internal water. Spectrographic studies of the ash of resins, even those which have been carefully washed, reveal[22,43] small amounts of iron and manganese. The paramagnetic centres arising on formation of different defects in the matrix structure, or in the spontaneous scission of sulpho-groups, or as a result of the oxidation of phenolic groups[44] can also be a cause of line broadening.

The line broadening due to the difference between the volume magnetic susceptibilities of water and the resin in spherical grains should not occur[14]. The creation of defects in the grains of the IR-120 sulphonic cation-exchange resin in the H^+-form by a sharp change of temperature[36] or mechanical grinding[22] hardly alters the resonance line width. The opposite result has been obtained[21] for the grinding of a specially prepared sulphonic acid cation-exchange resin to a grain size less than 0.076 mm, the increase in the ^{1}H NMR line width of water following the disruption of the grains depending on the ionic form of the resin. In all the studies where the shape of the grains was stated, spherical resin particles were investigated. However, the effect of volume magnetic susceptibility can be expressed[14] by the influence of the grain size on the line width and can be accounted for by the creation within the grain of inhomogeneous local magnetic fields due to the nearest neighbours. A change in the sulphonic acid cation exchanger grain size (8–15% DVB) by a factor of 2–3 does not alter[21,36] the internal water ^{1}H NMR line width.

Howery and coworkers[16,30] and then Frankel[36] showed by means of various experiments that the main cause of the broadening of the line is the effect of volume magnetic susceptibility.

The internal inhomogeneity of the resin grain (a non-uniform distribution of the cross-links and fixed groups) also leads to an increase of the width of the internal water ^{1}H NMR line, provided that the proton exchange between the chemically non-equivalent equilibrium positions of the water molecules is fairly slow. Otherwise the line width is not a measure of the homogeneity of the resin. This was emphasised by Gordon[14], when he characterised the internal resin grain phase as homogeneous. The fact that resins with very different physical structures (gel and macroporous resins) give comparable line widths[36,37] confirms the occurrence of rapid proton exchange between the inhomogeneous sections of the resin. The existence of a single internal water resonance line, the low rate of proton exchange between the resin grains, and the marked dependence of the position of the internal water line on the counterion molality demonstrate, according to Gordon[14], the narrow limits of the inhomogeneous region between the grains as regards the number of cross-links, the degree of sulphonation, etc. The rate of exchange can be reduced by lowering the temperature of the specimen. Thus the resolution of the ^{1}H NMR signals for water within the macropores and in the gel component of the resin was achieved in the macroporous KU-23 sulphonic acid cation-exchange resin at −2°C.[37] In the range of negative temperature, an appreciable broadening of the internal water resonance line was also observed in gel-type resins[40,42,45].

In certain cases the difference between the line widths for pure water and the water absorbed by the resin may be a result of an incomplete averaging of the dipole–dipole interactions following a decrease of the mobility of the water molecules within the resin grains. The independence of the line width of the degree of cross-linking of the resin[14,36] (the DVB content was varied from 2 to 12%) and of its ionic form[41] ($\Delta\nu \simeq 10$ G for the Cs^+-, K^+-, Na^+-, and Li^+-forms of the KU-2 × 8 cation-exchange resin) shows that, for univalent counterions at temperatures above 0°C, the above cause of the broadening is not dominant. The conversion of the resin into the ionic form saturated by polyvalent counterions leads to a broadening of the internal water line even in highly acidic cation-exchange resins. For example[27], the line widths in the spectra of the Dowex-AG-50W × 16 resin in the Be^{2+}- and Al^{3+}-forms are 72 and 90 G respectively, the line becoming broader with increase of the degree of cross-linking of the resin or with decrease of temperature. This effect has been observed for the Zn^{2+}- and La^{3+}-forms[27] and for the Mg^{2+}-form.[27,33] The dependence of $\Delta\nu$ on the DVB content and temperature has been explained[27,33] by the presence of "free" water and the water of hydration, the large difference between the relaxation times of the two types of water, and the low rate of exchange between their molecules. The narrowing of the line in the spectrum of Dowex-AG-50W × 16 resin in the Mg^{2+}-form may be[27] a result of the formation of a contact ion pair comprising a fixed group and a counterion, i.e. the capture by the SO_3^- group of one coordination site in the first hydration shell of the counterion.

The line widths of the adsorbed water in the spectra of weakly acid and weakly basic resins usually amount to several tens of G, i.e. are much higher than in the spectra of highly acid and highly basic resins[14,22,35,36] and on conversion of the resins into a salt-form the resonance lines are significantly narrowed. The high value $\Delta\nu = 130$ G in the spectrum of the KB-4P2 resin in the H^+-form has been explained[35] by the binding of two water molecules by each COOH group via strong hydrogen bonds. The activation energy for molecular motion $E_a = 4.9$ kcal mole^{-1}, comparable to the dissociation energy of a single hydrogen bond, has been determined[36] from a plot of $\ln(\Delta\nu)^{-1}$ against $1/T$, $\Delta\nu$ being the line width in G and T the absolute temperature. The broadening of the line to $\Delta\nu$ = 30 G in the spectrum of the KU-1 sulphophenol cation-exchange resin is attributed[41] to the influence of the phenoxy-radicals recorded[44] by ESR.

The study of the state of water in synthetic ion exchangers at negative temperatures[38,40–42,45] is of particular interest. In contrast to pure water, the transition to the region of negative temperatures is accompanied by a small increase of the line width, reaching several hundred G at −70°C. The ^{1}H NMR line width for pure ice at −70°C is[41] 65 000 G. If the mechanism of the broadening of the ^{1}H NMR lines of pure water molecules, pure ice, and the water in the resin phase is the same and is associated solely with the mobility of the molecules, then the line width in such systems can be proportional to the correlation time τ_c for the dipole–dipole interaction. Knowing[2] that $\tau_c = 10^{-12}$ s for water, it is possible to estimate the correlation time for ice ($\tau_c \simeq 10^{-7}$ s) and the resin ($\tau_c \simeq 10^{-9}$ s). Thus at -70°C the mobility of the water molecules in the resin is higher by at least two orders of magnitude than in ice, since in reality the ^{1}H NMR line width for the water in the resin can undergo additional broadening owing to the effects discussed above. Mank et al.[45] suggested that the correlation time in an ion exchanger at negative temperatures be determined from the formula

$$\tau_c = A\,\Delta\nu, \tag{2}$$

where $\Delta\nu$ is the line width in G and the constant $A = 1.7 \times 10^{-10}$ G^{-2}. At negative temperature, there is an effect of the degree of cross-linking of the cation-exchange resin[41] and the nature of the counterion[40,45]. The greater the capacity of the cation for hydration the wider the resonance line at a given temperature[45]. Unfortunately the very important experimental data concerning the change in the integral intensity of the ^{1}H NMR signals due to the internal water with decrease of temperature virtually do not exist. Only Mank et al.[39] showed that, on passing from positive to negative temperatures, the number of mobile H_2O molecules per NH_4^+ counterion in the KU-2 cation-exchange resin decreases sharply, from ~12 to ~5, and remains almost unchanged in the range between 0° and -30°C. This effect has been explained[39] by the crystallisation of the free water in the resin.

The dependence of the ^{1}H NMR line width on the internal water content has been investigated in the Dowex-AG-50 (H^+-form; 4, 8, and 16% DVB)[43] and KU-2 (Li^+-form)[46] cation-exchange resins. The marked broadening of the spectral line in the course of the removal of water has been attributed[43] to several causes, the main one of which is the inhomogeneity of the magnetic field in the resin phase. The decrease of the mobility of the water molecules[46] and the structural inhomogeneity of the resin itself[43] can also cause the broadening of the internal water line during the dehydration of the ion exchanger. When the water content corresponds to less than approximately two molecules per counterion, the line width increases without limit[43]. We may recall that, according to Zundel[31], the fixed groups and the hydrogen counterions are associated for this degree of hydration of the sulphonic acid cation exchanger. The sharp increase[46] of the water ^{1}H NMR line in the spectrum of the Li^+-form of the cation exchanger with a moisture content corresponding to approximately 4 H_2O molecules per Li^+ ion has been explained by the stronger sorption of water for low moisture contents in the resin and is also consistent with Zundel's ideas[31]. The diameter of the cavities occupied by water molecules has been estimated[46] from the line width in the spectrum of the fully swollen cation exchanger; it amounts to approximately 8 Å.

A study has been made[45] of the temperature dependence of the line width in the spectrum of the KU-2 cation-exchange resin with different water contents. The decrease of the water content in the Li^+-form of the cation exchanger down to approximately 4 moles of water per equivalent of the resin has little influence on the nature of the $\Delta\nu = f(T)$ curve. This finding confirms yet again that, on passing to negative temperature, only the fraction of the water in the resin which does not form part of the hydration shell of the cations crystallises. The activation energies for molecular motion in the KU-2 resin in the Ca^{2+}-form have been estimated from the slopes of the linear plots of $\ln(\Delta\nu)$ against $1/T$. The values of E_a vary from 16 kcal mole^{-1} for the swollen resin to 8 kcal mole^{-1} for the resin with a water content of approximately one water molecule per Ca^{2+} ion.

Frankel[47] pointed out that additional mechanisms of the broadening of the spectral lines, associated with the existence of concentration profiles in the grains and with a non-uniform distribution of the grains containing different counterions, have been observed in studies on ion-exchange kinetics by ^{1}H NMR.

IV. THE RELAXATION TIMES T_1 and T_2

The system of magnetic nuclei is not isolated, since each nucleus in the molecules is involved in thermal motion and gives rise to a local variable or constant magnetic field at the site of a neighbouring nucleus. The time T_2 is called the spin–spin relaxation time (or the phase memory time) if it yields the average lifetime of a definite spin state due exclusively to a spin–spin interaction. It is frequently called the transverse relaxation time in order to characterise the average lifetime of the spin state, independently of the nature of the interactions bounding it. The time T_1 is called the spin–lattice relaxation time; it represents a measure of the time during which the energy passes from the spin system to other degrees of freedom. In weakly viscous liquids, $T_1 = T_2$, while in solids $T_1 > T_2$.

In an aqueous suspension of Dowex-50W × 8 cation-exchange resin at 31°C,[48] $T_1 = 2.9$ s for the external water and $T_1 = 0.45$ s for the internal water were obtained. The decrease of the internal water relaxation time can be explained by the increase of the correlation time τ_c as a result of the restriction of the mobility of the water molecules by the resin matrix and by the rapid exchange of the excess proton between the water molecules.

Using the nuclear spin echo method, Bleadel et al.[49] investigated the dependence of T_1 and T_2 on the number of water molecules per exchange group (r) in the Dowex-50W cation-exchange resin phase (Na^+-form; 2, 4, 8, and 12% DVB). They observed that, for the same water content in the resin, the times T_1 and T_2 were independent of the degree of cross-linking of the resin with the exception of a small difference in the presence of a high moisture content. This behaviour of the relaxation times may be expected if the internal water molecules are located mainly around the fixed groups and the counterions. In the region where $r > 6$, T_2 hardly varies, while T_1 increases slightly. In the region where $r < 6$, the transverse relaxation time decreases by three orders of magnitude, while the longitudinal relaxation time passes through a minimum near $r = 1.8$ and then increases again. This type of variation of T_1 and T_2 indicates a marked decrease of the mobility of the water molecules in the sulphonic acid cation-exchanger phase following a decrease of the moisture content from six water molecules per Na^+ counterion. The correlation time for the magnetic dipole–dipole interaction for $r = 1.8$ can be estimated from the data of Bleadel et al.[49]: $\tau_c = 4.1 \times 10^{-8}$ s.

T_1 and T_2 for the water protons in the sulphophenol KU-1 cation-exchanger and the sulphonic acid KU-2 cation-exchanger phases (2, 4, 8, and 12% DVB) in the ionic form produced by saturation with alkali metals have also been investigated[50,51] by a pulse method at negative temperatures. The variation of the form of the bifunctional KU-1 cation-exchange resin alters the relaxation parameters of water. An anomalously high ratio T_1/T_2 is observed, which can be explained either by the presence of paramagnetic centres in the KU-1 resin[44] or by the existence of several correlation times. At −25°C, the rate of proton relaxation of water in the KU-2 × 8 resin exceeds by more than an order of magnitude the rate of relaxation of the water protons in a frozen LiCl solution. This finding indicates a larger number of water molecules surrounding the cation–anion pair in the frozen electrolyte solution than is present around the counterion–sulpho-group pair in the resin phase. The increase of the rate of proton relaxation of the internal water with increase of the number of cross-links in a sulphonic acid cation exchanger at −10°C has also been explained by the difference between the water contents. The influence of the type of counterion on the mobility of water molecules in the KU-2 × 8 resin is greatly reduced or masked by other interactions. The increase of the ratio T_1/T_2 with decrease of temperature might be due to the approach of T_1 to its minimum value at the point where $\omega_0\tau_c = 0.6158$. In this case, the correlation time is of a smaller order of magnitude than 10^{-8} s and the activation energy for molecular motion should be estimated from the temperature variation of T_2. The average activation energy for all the forms of the cation exchanger is approximately 9 kcal $mole^{-1}$. The mobility of water molecules in the swollen cation-exchange resin at −50°C is higher than at 25°C in the same cation exchanger, which, however, contains two water molecules less per exchange group, and is much higher than in ice.

Thus the relaxation parameters of the water absorbed by the cation-exchange resin indicate a similarity between the resin phase and the frozen electrolyte solution. The hydrated regions in the resin are surrounded by a virtually immobile matrix while in solutions they are surrounded by ice.

V. MAGNETIC RESONANCE OF THE COUNTERION NUCLEI

Direct information about the state of the hydration shells of the counterions, the intensity of the ion–ion interaction, and the mobility of the counterions can be obtained by studying the NMR parameters of the counterion nuclei in combination with the ^{1}H NMR parameters of the solvent.

1. ^{1}H NMR (nuclear spin $I = 1/2$). ^{1}H NMR can be observed for counterions containing slowly exchanged protons. The ^{1}H NMR spectrum of a suspension of the Dowex-AG-50W × 2 resin in an aqueous $N(CH_3)_4Cl$ solution ($m = 2.5$) contained[14] two lines due to the methyl protons in the counterions present in the resin phase and the cations in the external solution. The ^{1}H NMR line width for the counterions increases with increase of the degree of cross-linking of the resin and approaches smoothly the value corresponding to an aqueous solution of $N(CH_3)_4Cl$. This behaviour of $\Delta\nu$ indicates a decrease of the mobility of the counterions with increase of the degree of cross-linking of the cation exchanger.

The temperature variation of the ^{1}H NMR spectrum of the NH_4^+ counterions in the KU-2 cation-exchange resin has been observed[39]. In the range 20–0°C, the spectrum consists of a triplet due to the spin–spin interaction of the protons with the ^{14}N nucleus. The constant for this interaction is 48 ± 1 G. Above 20°C and below 0°C, the triplet structure signal is converted into a singlet structure.

The ^{1}H NMR spectra of a number of aminoacids absorbed by the Dowex-AG-50W × 4 sulphonic acid cation-exchange resin have been published[52].

2. ^{7}Li NMR ($I = 3/2$). The structural changes near ions whose nuclei have a spin $I > 1/2$ can be studied because these nuclei have an electrical quadrupole moment Q. The nuclei do not possess an electric dipole moment and the energy of the nucleus is therefore independent of its orientation in a homogeneous electric field. However, as a result of the Brownian motion of the species surrounding the resonating nuclei, fluctuations of the electric field gradient arise at the nuclei. In consequence of the presence of Q, an inhomogeneous electric field can induce transitions between the magnetic energy levels, i.e. can create an additional effective magnetic relaxation mechanism. The results of the high-resolution NMR,[53] broad line[54], and spin echo[55] studies published in the first communications demonstrated the likely usefulness of ^{7}Li magnetic resonance in studies on cation-exchange resins.

Mank et al.[46] investigated the dependence of the ^{7}Li NMR chemical shift and line width on the degree of hydration of the sulphonic acid KU-2 cation-exchange resin. The chemical shift of the line due to the counterion nuclei relative to the ^{7}Li NMR signal in an aqueous solution of LiCl is within the limits of the experimental accuracy of the measurement of this quantity when the water content varies from twelve (fully swollen resin) to approximately two water molecules per counterion, i.e. the electron density at the lithium ion remains unchanged. The authors correctly explained the sharp upfield shift of the signal by approximately 16 p.p.m. after the complete dehydration of the resin by the formation of a chemical bond between the counterion and the fixed group, as a result of which the electron density around the lithium nucleus increases.

The breakdown of the structure of the hydration shell of the counterion and the enhancement of the electrostatic ion–ion interaction during the dehydration of the resin must be reflected in the broadening of the ^{7}Li NMR line. A decrease of the degree of dehydration of the resin from the fully hydrated state to approximately four water molecules per counterion is accompanied[46] by a slow increase in the width of the ^{1}H NMR line of the internal water and the NMR line of the lithium counterions. On further dehydration of the resin, the ^{7}Li and ^{1}H NMR line widths increase sharply. Presumably, when the hydration shell of the counterion is strongly deformed after the elimination of even one water molecule from the first coordination sphere, a sulpho-group tends to take its place. This results in an intensification of the ion–ion interaction.

Bystrov and Nikolaev[56,57] showed that the rate of longitudinal relaxation of the lithium counterion nuclei in the KU-2 (or KRS) sulphonic acid cation-exchange resin increases with increase of the molality (i.e. with increase of the number of cross-links in the resin). The activation energies for the relaxation processes E_a were calculated from the temperature variation of T_1 for the lithium counterion nuclei[54]. They decrease in succession with increase of the degree of cross-linking of the resin and are listed below:

DVB, %	soln. LiCl	2	4	8	12
E_a, kcal $mole^{-1}$	4.1	4.2	3.6	3.2	2.3

According to Hertz[58], the activation energy for the reorientation of water molecules in the hydration shell of the Li^+ ion is 4.3 kcal $mole^{-1}$. One may conclude that the modulation of the magnetic and quadrupolar interactions in weakly cross-linked sulphonic acid cation-exchange resins is achieved via the reorientation or jumps of the water molecules in the first hydration shell.

The rate of relaxation of ^{7}Li in an electrolyte solution can be expressed by the sum of several terms:

$$\left(\frac{1}{T_1}\right)_{\rm exp} = \left(\frac{1}{T_1}\right)_{\rm m.d.d.} + \left(\frac{1}{T_1}\right)'_{\rm el.qu.} + \left(\frac{1}{T_1}\right)''_{\rm el.qu.} \cdot \qquad (3)$$

Here the first term characterises the magnetic dipole–dipole relaxation mechanism, which cannot be neglected for the ^{7}Li nucleus[59]. It is proportional to the lifetime of the water molecules in the first hydration shell τ_h^+. The term $(1/T_1)'_{\rm el.qu}$ is determined by the electric field gradient which has arisen as a result of the Brownian motion of the water molecules in the hydration shell of the ion and is characterised either by the reorientation time of the water molecules near the ion τ_r^+ or by τ_h^+. The third term of Eqn.(3) reflects the extent of the direct ion–ion interaction and is proportional to the correlation time τ_{ci}, which characterises the translational diffusion of the ions relative to one another. In the sulphonic acid cation-exchanger phase, the relative values of the terms of the equation may be different from those in solution.

Experiments with light and heavy water showed[57] that at 25°C the ratio of the contributions of the magnetic dipole–dipole and electric quadrupolar relaxation mechanisms to the overall rate of relaxation remain the same as in an electrolyte solution[59]. Thus the times τ_R^+ and τ_r^+ (characterising related motions) increase with the degree of cross-linking of the resin, while the structure of the hydration shell of the lithium counterion (at any rate in cation exchangers with 8% of DVB and less) is deformed insignificantly compared with the hydration shell of the ion in pure water. The changes in τ_r^+ and τ_h^+ during isotope substitution may be neglected[60], while the decrease of the degree of swelling of the cation-exchange resin[61] and the accumulation of residual H_2O in the hydration shells of the counterions[62] on passing from H_2O to D_2O only increase the rate of relaxation of the lithium counterions in D_2O.

The diffusion coefficients of the counterions are known[12,14] to change to a greater extent as the ion-exchange resin structure is altered than those of water molecules. One can therefore expect an increase of the time τ_{ci} with increase of the number of cross links. In order to explain the decrease of E_a on passing from weakly cross-linked to more cross-linked resins, one must suppose that the correlation time τ_{ci} varies with temperature less than do τ_r^+ or τ_h^+. Thus the activation energy characterises different types of motion in each specific case: the Brownian motion of water molecules in the vicinity of the counterion in the KU-2 × 2 cation-exchange resin; the oscillation of the hydrated counterion about the equilibrium position in the KU-2 × 12 resin, where the electric field gradient at the counterion nucleus is a maximum.

In the region of 0°C, the temperature dependence of T_1 undergo[56,57] an abrupt change simultaneously and show a break. This is associated with the displacement of part of the water from the resin on crystallisation of the external water. The sensitivity of the longitudinal relaxation time to structural differences between resins is indicated yet again by the experimental finding that the rate of relaxation of ^{7}Li in a sulphonic acid cation-exchange resin of type KRS (4% DVB) is greater than in the KU-2 sulphonic acid cation exchanger (4% DVB). This apparently reflects the more effective cross-linking in the KRS resin (purified DVB was used) than in KU-2 (industrial DVB was used).

^{13}C NMR ($I = 1/2$). The low abundance of the ^{13}C isotope (approximately 1.1%) and the low relative intensity of the resonance signals (smaller by a factor of approximately 60 than for protons in identical fields) is the main cause of the small number of ^{13}C NMR studies. There has been only one study, by Sternlicht et al.[52], in which a substance (aminoacid) sorbed on the resin (Dowex-AG-50W containing 4 and 8 wt.% DVB) was investigated by ^{13}C NMR. A common feature of the majority of aminoacids is that the ^{13}C line widths for the protonated specimens proved to be only 3–4 times greater than for the deuterated analogues, contrary to the expected increase by a factor of 10–15. Furthermore, $T_1 \gg T_2$ for all measurements and T_2 depends on the degree of cross-linking much more strongly than does T_1. These results can be explained by anisotropic rotations, which persist after the absorption of aminoacid molecules by cation-exchange resins, which leads to a non-zero time-average interaction. It is suggested that internal rotations about one or more intermolecular bonds, for example about the $D_3H^+ \ldots O_2S{-}R$ linkage, may occur in aminoacids. This rotation determines the rate of the spin–lattice relaxation T_1^{-1}. The slow vibrations of the resin matrix determine the rate of the spin–spin relaxation T_2^{-1}. For internal rotation at room temperature, the correlation times are approximately 10^{-9} s, while the vibrations of the ion-exchange resin lattice are described by longer correlation times.

^{19}F NMR ($I = 1/2$). The ^{19}F chemical shifts in the AV-17 anion-exchange resin and KU-2 cation-exchange resin phases have been measured[63] as a function of concentration in the aqueous solutions in which the resins were treated. The amount of adsorbed electrolyte in the resin depends greatly on the concentration in the external solution $c_{\rm HF}$. In a cation or anion exchanger, there is a possibility that the fluorine may exist in the same forms as in aqueous hydrofluoric acid solution, i.e. as cations or the F^- and HF_2^- counterions, as well as HF molecules and associated species $(HF)_n$. However, single ^{19}F resonance lines have been observed in all the systems, which indicates a rapid exchange of fluorine atoms between all the possible states. It has been found that (1) the $\delta = f(c_{\rm HF})$ curve for the KU-2 resin exhibits a positive shift and that for the AV-17 resin a negative shift relative to an aqueous HF solution, (2) in the region where $c_{\rm HF} <$ 5 M, the ^{19}F NMR line for the anion exchanger undergoes a sharp upfield shift, and, in addition, (3) up to the concentration $c_{\rm HF}$ = 18 M the experimental $\delta = f(c_{\rm HF})$ curve for the anion-exchange resin has undergone a downfield displacement relative to the calculated curve. The authors explain the first result by structural differences between anion- and cation-exchange resins, the second result by the existence of several forms of fluorine in the anion-exchange resin, and the third result by the effects of the solvation of the fixed groups by HF molecules. All the results can probably be accounted for by the different proportions of the fluorine species in the anion- and cation-exchange resins.

The chemical shift of the fluoride counterions in the Dowex-1 anion-exchange resin undergoes a downfield displacement[33] with increase of the number of cross links: −0.49 p.p.m. (1% DVB), −0.83 p.p.m. (2% DVB), and −2.24 p.p.m. (8% DVB). The negative ^{19}F NMR shift in anion-exchange resins relative to KF solution can be accounted for by the deshielding of the nucleus of the F^- ion as a result of the formation of an electrostatic linkage between the counterion and the fixed group.

Frankel[47] reported a study of the kinetics of the exchange of F^- and Cl^- counterions in an anion-exchange resin by ^{19}F NMR, but no quantitative interpretation is given.

^{23}Na NMR ($I = 3/2$). It is known that the dominant mechanism of the energy exchange between the spin system and the lattice in electrolyte solutions involves the interaction of the electrical quadrupole moment with the electric field gradient at the site of the nucleus, generated by the neighbouring species. The first term in Eqn.(3) is neglected [T_1(p.p.m.) > 20 s]. The mechanism of the quadrupolar relaxation of the ^{23}Na nuclei in solutions is determined in this case either by the collisions of the hydrate complexes during Brownian motion[64], or by the translational motion of water molecules from the first hydration shell of the ion and back again[64,65], or by a reorientation of the water molecules in the first hydration shell of the ion[58]. Under certain conditions, one of these types of thermal motion may become dominant.

The marked broadening of the resonance line due to the nuclei of the sodium counterions in Dowex-AG-50W × 8 compared with electrolyte solutions was pointed out for the first time by Jardetsky and Wertz[66]; it has been explained by the formation of a strong linkage between the Na^+ ion and the fixed group. The dehydration of the KU-2 cation-exchange resin is also accompanied[54] by a broadening of the resonance line due to the nuclei of the sodium counterions. The line broadening begins when the water content is below approximately 40 wt.%. A molecule of free water is probably removed initially and is followed by molecules from the hydration shell of the counterion. According to Smirnov[54], the dehydration of the cation-exchange resin is manifested much sooner in ^{23}Na NMR than in ^{7}Li NMR. Possibly this reflects the postulated[67] six-molecule hydration shell of the Na^+ ion and the four-molecule shell of the Li^+ ion. In this case one might claim that the individual hydration properties of the Na^+ and Li^+ ions persist also in the cation-exchanger phase. This conclusion was in fact reached by Bystrov and Nikolaev[56], who measured the longitudinal relaxation times T_1 of the sodium and lithium counterions in swollen KRS sulphonic acid cation-exchange resins containing 2 and 4 wt.% DVB and found that at 28°C the ratios of the rates of relaxation of ^{23}Na and ^{7}Li in an aqueous electrolyte solution and in the KRS-2 and KRS-4 cation-exchange resins are respectively 277, 265, and 254, i.e. are virtually constant. If the conclusion[57] concerning the structure of the hydration shell of the lithium counterion is correct, then the hydration shell of the sodium counterion should also not be distorted by, for example, the incorporation of a sulpho-group in the latter.

The hypothesis that one of the four coordination regions around the Na^+ counterion in Dowex-50W is occupied by a sulpho-group was put forward by Greekmore and Reilly[33] on the grounds that the hydration number $h(Na^+) < 4$ (see Table) and that there is broadening of the ^{23}Na NMR line with increase of the degree of cross-linking of the cation-exchange resin. It was concluded that the electrostatic interaction of the counterion with a fixed group is intensified and that the correlation time for the quadrupolar interaction increases with increase of the number of cross links.

However, according to other data[49], obtained in a study of the Dowex-50W cation-exchange resin in the Na^+-form containing 2, 4, 8, and 12% DVB, the relaxation times T_1 and T_2 for ^{23}Na with the same number of water molecules per Na^+ counterion depend strongly on the degree of cross-linking. On the other hand, T_1 and T_2 for the water protons are virtually independent of the number of cross links. When the mechanism of the relaxation of ^{23}Na is considered, the charge density and distribution per unit volume are apparently of considerable importance. During the dehydration of the resin, T_1 and T_2 for the Na^+ counterion nuclei diminish sooner and to a greater extent the lower the degree of cross-linking of the resin. When the water content is less than six water molecules per counterion ($r < 6$), the relaxation times in such resins become comparable and, when $r = 3$, they are virtually equal. This can be explained by the breakdown of the hydration shell as a result of the ion–ion interaction when $r < 6$ and by the formation of a contact ion pair when $r = 3$. The types of variation of the correlation time and of the quadrupolar coupling constant when water is removed from a cation-exchange resin cannot be determined separately.

^{133}Cs NMR ($I = 7/2$). There exist only two preliminary reports of ^{133}Cs NMR studies on cation-exchange resins. The line width for the nuclei of the Cs^+ counterions in the Dowex-AG-50W × 12 sulphonic acid cation-exchange resin has been measured[28] and found to be $\Delta\nu \simeq 500$ Hz. For comparison, we may quote the ^{7}Li NMR line width for the KU-2 sulphonic acid cation-exchange resin (8–10% DVB):[46] $\Delta\nu \simeq 165$ Hz. The longitudinal relaxation times T_1 for the nuclei of the Li^+ and Cs^+ counterions in the bifunctional KU-1 cation-exchange resin are approximately the same[55]: $T_1(^7\text{Li}) \geqslant 10^{-1}$ s and $T_1(^{133}\text{Cs}) \simeq 2 \times 10^{-2}$ s. A rough comparison of $\Delta\nu$ and T_1 shows that, on passing from electrolyte solutions to cation-exchange resins, the rate of relaxation of ^{133}Cs increases more than the rate of relaxation of ^{7}Li. This demonstrates a greater probability of the formation of contact ion pairs of the type $R-SO_3^-{-}Cs^+$.

In conclusion of the section on the magnetic resonance of counterion nuclei, we may mention that the experimental studies described are so far in many respects non-systematic, which greatly hinders comparison of the results. The conclusions reached in the course of the discussion in this Section must therefore be regarded as preliminary. The magnetic resonance of nuclei such as ^{14}N, ^{27}Al, ^{31}P (studies have been made on extraction by organophosphorus compounds; see, for example, Rozen et al.[68]), ^{35}Cl, ^{79}Br or ^{81}Br, ^{85}Rb or ^{87}Rb, ^{127}I, etc. has not been considered at all.

VI. THE STATE OF EQUILIBRIUM OF THE ION-EXCHANGE RESIN–SOLVENT SYSTEM

If the ion-exchange resin remains in contact with the solution for a sufficiently long time, an equilibrium, characterised by a constant ratio of the concentrations of the solute in the resin and in the solution, is established.

1. Determination of the Dissociation Constant

^{1}H NMR studies have been made[69,70] on aqueous solutions of a number of acids (HCl, $HClO_4$, HNO_3, and toluene-*p*-sulphonic acid) over a wide range of concentrations, the chemical shift being used to determine the acid dissociation constant. The observed chemical shift relative to pure water is determined[1] by the fraction of protons present in the hydronium ions (P):

$$\delta_{\text{obs}} = P\,\delta_{H_3O^+},$$
$$P = 3\chi/(2-\varkappa),$$

where χ is the stoichiometric mole fraction of the acid. Dinius et al.[43] investigated Dowex-50 resins with 4, 8, and 12% DVB hydrated to different extents. They postulated that $\delta_{H_3O^+}$ remains approximately constant and compared the relative acid strengths of resins cross-linked to different extents and aqueous acid solutions on the basis of the slopes of the plots of δ_{obs} against P. According to their data, Dowex-50 with 4% DVB, for example, is a stronger acid than HCl or toluene-*p*-sulphonic acid and is comparable in strength to $HClO_4$. The authors point out that the increase of acid strength with decrease of the degree of cross-linking of the resins may be only apparent and may be the result of the different degrees of formation of ion pairs in the resins due to the difference between electrical constants [differing local dielectric constants (Ed. of Translation)]. The method described suffers from a disadvantage—the determination of the position of the line and of P is inaccurate.

Ochiai and Seto[71] used a procedure free from the disadvantage. They investigated a resin fully swollen in water and converted into a mixed form (saturated with hydrogen and metal ions). The resin was kept in solution with specified concentrations of the necessary components and was then separated from it. The concentrations of the components in the resin were inferred from the analysis of the electrolyte composition. The authors[71] obtained the dissociation constant $K = 0.7$. Naturally, the degree of dissociation of the SO_3H group depends on the nature of the second counterion. It was concluded that toluene-*p*-sulphonic acid and the ion-exchange resin are dissociated to approximately the same extent and that the ion exchanger belongs to the category of strong acids.

2. The Adsorption of Solutes

The distribution of the solute between the liquid in the pores and the external solution is frequently referred to as the adsorption of the solute[12].

The adsorption of non-electrolytes. The concentration of the solute in the resin is usually not equal to its concentration in the solution with which the resin is in equilibrium and is characterised by the partition coefficient. The important factors which must be taken into account in the study of non-electrolyte adsorption processes are the sieve effect, the salting-out effects, different kinds of interaction forces, and complex formation processes. The adsorption is also influenced by properties of the resins such as the degree of cross-linking, the matrix structure, and the nature of the ion saturating the resin. The adsorption depends on the properties of the solute—the structure and size of its molecules and its tendency towards complex formation. In addition, the adsorption is influenced by the concentration of the solution and temperature.

Gordon[14] obtained the ^1H NMR spectra of suspensions of anion- or cation-exchange resins in a 5% solution of t-butyl alcohol or an 80% solution of dioxan in water. In the former case, the spectrum of the hydrogen-form of the resin consisted of four lines: two lines due to hydroxyl protons in the resin phase and in solution and two analogous lines due to the methyl protons of the alcohol. The positive shift of the methyl protons of the internal liquid relative to the external solution can be explained mainly by the large diamagnetic anisotropy of the aromatic portions of the matrix due to the circulation of the mobile π-electrons under the influence of the external magnetic field. The effects due to the solvation of the fixed groups and counterions are neglected. In the second case the resonance line of the dioxan protons in the resin phase coincides with the line due to the external dioxan. Gordon concluded from his results that the partition coefficients of the components of the binary solution between the resin phase and the solution can be measured.

Howery et al.[72] investigated the ^1H NMR spectra of suspensions of Dowex-50W × 8 resin (H^+-form) in aqueous solutions of acetone, dioxan, ethyl, isopropyl, and t-butyl alcohols, and dimethyl sulphoxide. The lines due to the internal water were displaced downfield for all the binary mixtures relative to the line of the internal water when the resin was swollen in pure water; the chemical shift of the internal water protons increases with increase of the mole fraction of water in the system. In some cases, selective absorption of the organic solvent by the resin was observed in the presence of a relatively large mole fraction of water. The increase of the chemical shift of the external water with increase of the mole fraction of the organic component in the binary mixture is attributed to the increasing proportion of ruptured hydrogen bonds between water molecules. The opposite effect for the internal water is explained by the polarising action of the cations. Under these conditions, the physical structure of the resin phase consists of hydrated counterions surrounded by molecules of the organic solvent. Apart from preferential hydration, the possibility of a more favourable interaction of the organic molecules with the resin matrix is considered.

The selective absorption of the solvent by weakly basic (Amberlite IR-45) and strongly basic (Amberlite IRA-400) anion-exchange resins in contact with aqueous dimethyl sulphoxide and acetonitrile solutions was investigated by Frankel[73]. Howery et al.[72] analysed the composition of the mixture in contact with the resin, while Frankel[73] removed the external solvent by centrifugation after the attainment of equilibrium in the system and determined by integration of the areas under the spectral lines for the internal liquid. The selectivity coefficient is defined by the expression $K = x_{\text{i}}\bar{x}_{\text{w}}/\bar{x}_{\text{i}}x_{\text{w}}$, where x_{w} and x_{i} are the mole fractions of water and the organic component in the binary solvent and $\bar{x}_{\text{w}}$ and $\bar{x}_{\text{i}}$ are the analogous mole fractions in the resin. It proved to be 3.12 for the fluoride-form of the resin, 1.6 for the chloride-form, 1.4 for the bromide-form, 1.01 for the iodide-form, and 0.7 for the free base. The values of K greater than unity correspond to the preferential adsorption of water. It was concluded that the dominant effects are caused by preferential solvation and the structure of the added solvent and not by the solvation of the fixed groups or steric factors.

Grigor'eva[41] measured the temperature variation of the chemical shifts of the protons of the water and acetone present in the KU-2 × 8 cation-exchange resin in the Rb^+-form. They noted a very interesting experimental fact: the presence of the organic solvent in the external phase leads merely to a decrease of the crystallisation temperature of the external water to −20°C, as happens in mixed solutions[74], while in the resin phase the crystallisation of water is not observed even at −100°C.

Ion-exchange resins in organic solutions. In order to understand the processes involving the selective absorption of one of the components of the binary solution, it is important to know the mechanisms of the interaction of ion-exchange resins with organic solvents of different types.

^1H NMR data for suspensions of the Dowex-AG-50W × 8 cation-exchange resin in dioxan and acetonitrile as well as additional infrared spectroscopic data enabled Gordon[14] to conclude that the equilibrium

$$RSO_3H \cdots X \rightleftarrows RSO_3^- \cdots HX^-$$

in the hydrogen-form of the sulphonic acid cation-exchange resin is displaced to the right when X is dioxan and to the left when X is acetonitrile.

It has been shown[27,75] that the position of the lines due to the hydroxyl and methyl protons of methanol in the ion-exchanger phase is independent of grain size (between 0.297–0.149 and 0.074–0.037 mm), the degree of cross-linking of the resin (between 1 and 8% DVB), and its form (Li^+, Na^+, K^+, Rb^+, Cs^+, Be^{2+}, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, and Al^{3+} for cation-exchange resins and F^-, Cl^-, Br^-, and I^- for anion-exchange resins). The results can be explained by the formation of contact ion pairs within the resin phase. The maximum chemical shift between the methyl and hydroxyl protons when the cation-exchange resin is in the H^+-form is caused[75] by the displacement of the hydroxyl proton lines towards lower fields due to the proton exchange between the counterions and the OH groups of methanol.

Adsorption of strong electrolytes. When the ion-exchange resin is brought into contact with an electrolyte solution containing ions of the same type as the counterions, there is a possibility of the simultaneous sorption from solutions of ions of both charge types. The amount of adsorbed substance depends on the nature of the solutes, the degree of cross-linking of the resin, the nature and degree of ionisation of the functional groups of the resin, the electrolyte concentration, and a number of other factors.

Dinius and Choppin[76] investigated the distribution of an acid (HCl or $HClO_4$) between an aqueous solution of the acid and the Dowex-50 (4% DVB) sulphonic acid cation-exchange resin and established that the amount of sorbed HCl is smaller than that of $HClO_4$. The difference between the distributions of hydrochloric and perchloric acids is attributed by the authors to the different effects of HCl and $HClO_4$ on the water structure. It has been established by NMR[69] and infrared spectroscopy[77] that the dissolution of $HClO_4$ in water leads to a greater breakdown of the water structure than the dissolution of HCl. In their communication[43], Dinius et al. point out that the water structure in the resin phase is disrupted to a greater extent than in pure water. They therefore suggest that the ions derived from $HClO_4$ are sorbed more readily by the resin than those derived from HCl.

Reichenberg and Laurenson[21] found that the chemical shift of the signal due to hydronium ions from the position of the line for pure water is 11.5 p.p.m., and that the experimental relation $\delta = f(P)$ deviates from linearity with increase of P. Dinius and Choppin[76] also showed that the behaviour of the chemical shift for the internal liquid is very similar to that observed in acid solutions. At moderate acid concentrations, the slope of the $\delta = f(P)$ curves decreases in the sequence (HCl + HR) > ($HClO_4$ + HR) > HR, which is attributed to the decrease of the structure-forming effect in the same sequence. The deviation of the curves from linearity begins much sooner for HCl and only slightly sooner, but much more markedly, for $HClO_4$ than in the corresponding acid solutions. The results have been explained by the earlier association of the HCl ions than the association of the $HClO_4$ ions, and in the latter case there is a possibility that the association of RSO_3H begins sooner, in conformity with the qualitative determination[43] of the acid strengths: $HClO_4 > HSO_3R >$ HCl.

The ion-exchange equilibrium. The NMR spectrum of water in the Dowex-AG-50W sulphonic acid cation-exchange resin–water system, in which the resin exists in the mixed ($H^+ + NH_4^+$)-form, consists[14] of two lines (corresponding to the external and internal liquids). This indicates a rapid proton exchange between the hydration shells of the H^+ and NH_4^+ ions. Howery and coworkers[30,78] investigated by NMR the Dowex-50W (4, 8, and 12% DVB) cation-exchange resin in equilibrium with an aqueous HCl and NaCl solution (the overall molar concentration of cations was 0.02, the ratio of the cations in solution being varied). The proton chemical shift of binary electrolyte mixtures is known[1,79] to be an additive quantity, and to depend on the nature and concentration of each ion separately. It has been found that the position of the line due to the internal water in the cation exchanger in the mixed ($H^+ + Na^+$)-form depends analogously on the ratio of the concentrations of the counterions. The experimental results and the theoretical values calculated assuming additivity of the proton chemical shifts proved to be very similar. Since the moisture content in the resin changes on passing from one form of the latter to another, it has been suggested that the expected chemical shift be calculated, taking this effect into account, by the formula[30]

$$\delta = \frac{\delta_H \bar{x}_H w_H + \delta_{Na} \bar{x}_{Na} w_{Na}}{\bar{x}_H w_H + \bar{x}_{Na} w_{Na}},$$

where δ_H and δ_{Na} are the shifts for the internal water in the cation exchanger in the H^+- and Na^+-forms, $\bar{x}_H$ and $\bar{x}_{Na}$ the equivalent fraction of the H^+ and Na^+ ions in the resin, and w_H and w_{Na} the water contents in the corresponding forms of the resin. Thus each counterion influences the chemical shift of the nearest protons independently of other counterions. This very important conclusion enabled Howery and coworkers[30,78] to regard an ion-exchange resin as a concentrated electrolyte solution. Furthermore, they suggest that the ^1H NMR method be used to determined the equivalent fraction of a specific counterion when the chemical shifts of water in each ionic form of the resin differ by not less than 20 Hz.

VII. EXCHANGE PROCESSES

1. Proton Exchange Between the Resin Phase and the Solution

As already mentioned, the spectrum of a suspension of resin grains in water consists of two lines. For simplicity, we shall assume that all the water protons in the ion-exchange resin phase exist in a single state A and have a resonance frequency ω_A, their lifetime in this state is τ_A, and the population of the state is P_A. The protons of the water filling the space between the grains are in a state B and have the corresponding values of ω_B, τ_B, and P_B, and $P_A + P_B = 1$. If the lifetimes τ_A and τ_B are long compared with $(\omega_A - \omega_B)^{-1}$, then the spectrum consists of two separate signals located in the vicinities of the frequencies ω_A and ω_B (slow exchange). In the other limiting case (rapid exchange), τ_A and τ_B are smaller than $(\omega_A - \omega_B)^{-1}$; the spectrum then consists of a single line centred on $\omega_{av} = P_A\omega_A + P_B\omega_B$. The intermediate cases, frequently encountered in practice, have been discussed in detail in the book by Pople et al.[1] On the basis of the distance between the signals, Gordon[14] established the lower limits (0.004–0.1 s) to the average lifetime of water in any phase. Frankel made a similar estimate for the macroporous Amberlite-200 cation-exchange resin[36]. The rate of exchange of the solvent between the external and internal water is less than 100 s^{-1} for the hydrogen-form and 20 s^{-1} for the sodium-form of the resin. Since individual lines for the water in the pores and in the gel fraction of the resin were not obtained, the rate of proton exchange between these components of the resin must be more than 2×10^3 s^{-1} (at 25°C). Such high rates of exchange in the macroporous cation-exchange resins can be explained by a high surface area.

Dinius et al.[43] used heavy water to determine the lifetime of the protons in a particular phase. The resin grains swollen in H_2O were placed in D_2O (the reverse experiment was also performed). The rate of diffusion was determined from the time variation of the shape of the spectrum, i.e. from the increase of the signal due to the water protons which have diffused from the ion-exchange grain and from the decrease of the signal due to the internal water. For the Dowex-50 × 4 resin (grain size approximately 0.15 mm), the duration of the exchange was 13 s, which corresponded to a diffusion coefficient of 8×10^{-6} cm^2 s^{-1}. Using a similar method, Greekmore and Reilly[48] also found that the exchange was almost completed in 10 s. Using the double resonance method, the authors then found the rate constant for the free exchange of the water protons between the internal and external phases in a suspension of Dowex-50W × 8 resin, the result being $k = 7.3 \times 10^{-1}$ s^{-1}. However, they emphasise that the observed constant characterises only the type of ion exchanger investigated, since it depends on the degree of cross-linking, the grain size, the nature of the counter-ion, etc.

The possibility that the observed rates of proton exchange characterises the exchange of water molecules between the external and internal phases, since the rate of proton exchange is close to the rate of exchange of ^{18}O and the self-diffusion coefficients of water measured by the tracer atom method (^{18}O) and the proton magnetic resonance method are the same, is pointed out in both investigations[43,48].

2. Kinetics of Ion Exchange

Since the chemical shift of the protons of the water in the resin phase depends significantly on the ionic form of the resin, it is natural to employ the ^1H NMR method to follow the transition of the resin from one form to another, i.e. to investigate the kinetics of ion exchange. Attention was already drawn to this factor in an early study by Gordon[14].

Frankel[47] carried out a thorough investigation of the kinetics of the exchange between a mixture of granular resins in two different ionic forms (the exchange of H^+ for Na^+ and NH_4^+). In some of the experiments, the space between the grains was filled with cyclohexane, which facilitated the interpretation of the ^1H NMR spectra, since the signal due to the external water was eliminated. Analysis of the ^1H NMR spectra obtained and the kinetic curves permitted a number of important conclusions: the dependence of the rate of exchange on the square of the grain radius confirmed the internal-diffusion mechanism of exchange. A correlation was noted between the results obtained by the radioisotope method and the NMR method for ion-exchange resins of different types and different degrees of cross-linking: For the successful employment of the NMR method, it is necessary to achieve an effective resolution of the lines of the internal and external water or the lines corresponding to different forms of the resin. In particular, Frankel was unable to follow the kinetics of the exchange between the resins in the F^-- and Cl^--forms owing to the inadequate resolution of their ^1H NMR spectra. The application of the NMR method to the investigation of the kinetics of ion exchange has not been brought to a sufficient level of perfection—the fundamental methodological problem concerning the identity of the observed chemical shifts of the protons and the degree of exchange undergone by resins under dynamic conditions. At the same time, a number of new fundamental possibilities have arisen, for example the possibility of studying diffusion processes in the absence of a Donnan electrolyte in the resin phase or the exchange between the grains in a mixture of resins.

A series of studies undertaken to investigate further ion-exchange resin–solvent systems by the NMR method were published in 1974–1976.[80–90] Kurilenko and coworkers[80,82] have published a general discussion based on their earlier investigations. The nature of the bonds and the mobility of the exchangeable ions H^+, NH_4^+, Li^+, Na^+, Al^{3+}, and F^- in ion-exchange resins with different water contents have been studied by Zubenko and Mank using the NMR method[83]. They concluded that the exchangeable ions and their water of hydration move together both below and above 0°C. According to the results, the rate of the joint migration diminishes below temperatures between −20° and −30°C. They calculated the activation energy for the migration of the exchangeable ions and attempted to determine the type of bonds formed by the counterions with the fixed ionogenic groups and the surrounding water. The authors noted a high mobility of H^+ ions in the dehydrated KU-2 resin.

Studies on water in the KU-2 × 8 resin carried out by Kvlividze and coworkers[84–86] are of undoubted interest. Almost all the studies discussed above were performed on specimens saturated with water to the maximum extent. Measurements have been made[84,85] of the longitudinal (T_1) and transverse (T_2) relaxation times for water in the resin phase at the start of the saturation of the resin with water. The specimens were carefully washed free of paramagnetic impurities[85,86], since the relaxation times of the water protons in the resin phase depend significantly on the content of such impurities (the relaxation times decrease by up to two orders of magnitude in the presence of Mn^{2+} ions in the specimen at a concentration of 1.3×10^{-2} wt.% [86]).

Bukin and Kvlividze[84] showed that water does not crystallise down to 240 K in a specimen of the KU-2 × 8 resin with 23% of water; at 220 K, the signal due to the water protons is much narrower than the matrix signals and, at approximately 200 K, the spectra of the water contain broad and narrow components; only below 160 K do the NMR spectra consist of broad doublets, indicating a rigid fixation of the water molecules and a weak intermolecular interaction. The experimental data on the variation of the relaxation times T_1 and T_2 with the water content have been presented within the framework of the theory of relaxation in a two-phase system[85]. The transverse relaxation in the two phases is due to identical processes. The average correlation time for the rotation of H_2O molecules ($\tau_c \simeq 10^{-8}$ s) and the translational diffusion time ($\tau_d \simeq 10^{-7}$ s) have been determined. These data agree well with the results of Seredin and Nikolaev[91], who obtained $\tau_d = 0.8 \times 10^{-7}$ s in connection with the estimation of the coefficient of self-diffusion of water by measuring the degree of dynamic adsorption in the KU-2 resin in the Cu^{2+}-form. In the range of water contents compared, the NMR line width for the resin is determined mainly by the motion of the sorbed water protons[85].

The magnetic relaxation time of the water protons in a carboxylic acid resin (cross-linked polymethacrylic acid and its sodium and caesium salts) has been investigated by Narebska and Erdmann[81].

There has been a recent growth of interest in NMR studies on ion-exchange resin—non-aqueous solvent systems. Preliminary data have been obtained[89] from NMR studies of the sorption of ammonia by the KU-2 × 8 cation-exchange resins at reduced temperatures. Mank et al.[87] investigated the NMR spectra of the methanol protons in the KU-2 sulphonic acid cation-exchange resins with degrees of cross-linking corresponding to between 4 and 20% DVB. They established that $CH_3OH_2^+$ ions are formed when the adsorbed alcohol molecules interact with the cation exchanger and that their fraction increases with the degree of cross-linking.

The hydration of the KU-2 sulphonic acid cation-exchange resin in equilibrium with sulphuric acid solutions has been investigated[88,90].

Analysis of the results of studies on ion-exchange resin—solvent system by NMR has led to many possibilities in securing valuable and frequently unique information, although many of the research results refer to some extent to specific instances only. Evidently further systematic investigation of ion-exchange resins by NMR is required.

The Influence of Polar Substituents at Carbon-Carbon Multiple Bonds on the Properties of Linear Unsaturated Compounds

L.A.Yanovskaya and G.V.Kryshtal'

Data on the influence of polar substituents at multiple bonds on the physicochemical properties of unsaturated molecules are discussed and reviewed primarily in the light of quantitative estimates of the transmission of influence via multiple bonds. The bibliography includes 202 references.

CONTENTS

I. INTRODUCTION

The problem of the influence of polar substituents at multiple carbon–carbon bonds on the properties of linear unsaturated compounds is part of the general problem of the mutual influence of atoms and atomic groups in an organic molecule and is of considerable theoretical and practical interest in connection with the great importance of unsaturated compounds in nature and technology. During recent years, there has been an appreciable growth of interest in the study of the characteristics and mechanism of the influence of substituents at multiple bonds, because the principle of linear free energies (LFE) has been extended to unsaturated compounds and thus a basis has been created for a quantitative estimation of the influence of substituents in terms of correlation equations of the type of the Hammett equation[1-3]. Fairly extensive data have now accumulated on the influence of polar substituents at multiple bonds on the properties of unsaturated molecules and in many cases quantitative estimates of this influence have been made and certain characteristics of the transmission of the influence via multiple bonds have been discovered. Some advances have been achieved also in the elucidation of the nature and mechanism of the transmission of the influence of substituents via multiple carbon–carbon bonds. Although the individual aspects of the problem have been considered in several reviews[4-8], the data as a whole have not been surveyed.

In the present paper an attempt is made to review the information obtained in the last 10–15 years concerning the influence of polar substituents in compounds of the type $X(CH{=}CH)_nY$ and $X(C{\equiv}C)_nY$, primarily in the light of quantitative estimates of the transmission of influences via multiple bonds.

II. GENERAL POSTULATES

The Hammett equation, which is widely used nowadays to estimate the influence of polar substituents in different classes of organic compounds, has the following general form:

$$Q = \rho\sigma, \tag{1}$$

where Q is the molecular property to be correlated, ρ the reaction constant (a measure of the sensitivity of the property Q to the polar effect of the substituent), and σ the substituent constant (a measure of the polar effect of the substituent relative to the hydrogen atom).

The applicability of Eqn. (I) to unsaturated compounds was demonstrated by Jaffe[8] as early as 1953 and has been proved convincingly by Charton and Meislich[9] in 1958 in relation to unsaturated aliphatic compounds.

A quantitative estimate of the influence of polar substituents on the properties of unsaturated compounds obeying the Hammett equation can be achieved in two ways: (1) by comparing the constants ρ obtained in the correlation analysis of identical properties Q determined under identical conditions using the same method for similar series of saturated, ethylenic, or acetylenic compounds, which makes it possible to determine the relative efficiencies of the transmission of polar influences via *cis*- and *trans*-vinyl groups or via ethynyl linkages compared with the corresponding saturated bridges; (2) by calculating the so called transmission factor[1-3], which makes it possible to estimate the degree of attenuation of the influence of the substituent on molecular properties when a multiple bond is interposed between the substituent and the rest of the molecule.

In its initial form, the transmission factor was defined as the ratio of the reaction constants ρ for the given series X–M–Y [X is the variable substituent, Y the fixed part of the molecule, and M the bridge, i.e. $-(CH{=}CH)_n-$ or $-(C{\equiv}C)_n-$] and ρ_0 for a standard (reference) series X–Y:

$$\pi' = \rho/\rho_0. \tag{2}$$

Thus π' shows to what extent the influence of the substituent is weakened when a multiple bond is inserted between X and the remaining part of the molecule Y, i.e. is a measure of the transmission of electronic effects via the bridge M. Apart from π', the transmission factor is sometimes designated in the literature by the symbols Z and τ.

For a quantitative estimation of the influence of substituents, a transmission factor designated by the symbol γ and defined by the ratio[1,7]

$$\gamma_M = \rho_M/\rho_{-C_6H_4-}, \tag{3}$$

is sometimes used. Here ρ_M is the reaction constant for the series X–M–Y, and $\rho_{-C_6H_4-}$ the reaction constant for the p-XC_6H_4Y series.

In this case, the attenuation of the influence of the substituent is estimated relative to the *p*-phenylene group, the electronic conductivity of which is assumed to be unity. Thus γ is a measure of the transmission of electronic effects via the bridge M relative to the *p*-phenylene system. It follows from Eqns. (2) and (3) that

$$\gamma_{-C_6H_4M-} = \pi'_M.$$

The average accuracy of the transmission factors is to within ± 15% (in the range between 1.6 and 33%).[1, 10]

The quantitative estimate of the influence of polar substituents with the aid of transmission factors is fairly general and rigorous. However, this procedure involves a number of difficulties due primarily to the difficulty of selecting a suitable reference series. In order to obtain correct results, it is necessary to maintain the following conditions: (1) The reference series and the series being compared must differ only in the structure of the bridge in the latter. (2) All the members of the selected series must have the same or similar conformations. (3) The properties compared must be of the same type. For example, in the correlation analysis of kinetic data, the mechanisms of the reactions of the reference series and the series being compared must be identical or, in the correlation analysis of ultraviolet spectroscopic data, the maxima analysed must correspond to the same electronic transitions, etc. (4) The properties Q to be correlated must be determined by the same method under strictly identical conditions. These rules must be observed also in those cases where, owing to the absence of a reference series, the polar influence of the substituents is estimated by comparing the values of ρ for analogous saturated and unsaturated series.

It is noteworthy that cases are frequently encountered where the transmission factors are determined by the ratio of the values of ρ for the test series and ρ_0 for incorrectly chosen reference series. For example, in the determination of π' per double bond (π'_{1F}), acetophenones $XC_6H_5COCH_3$ were chosen as the reference series for the series of chalcones $XC_6H_4CH{=}CHCOC_6H_5$ instead of benzophenones $XC_6H_4COC_6H_5$, which should have been selected[11]. In another study[12] π'_{1F} was found from the ratio of the values of ρ for the chalcols $XC_6H_4CH{=}CHCH(OH)C_6H_5$ (test series) and the chalcols $C_6H_5CH{=}CHCH(OH)C_6H_4X$ (reference series) instead of the $XC_6H_4CH(OH)C_6H_5$ series.

In order to reach a conclusion about the nature and mechanism of the transmission of the influence of substituents via multiple bonds, it is necessary to be able to separate the σ and π effects in correlation analysis. The overall polar effect (P) of a substituent at a multiple bond consists of the sum of the σ and π effects:

$$P = I_\sigma + I_\pi + F + M + C,$$

where I_σ (σ-inductive effect), I_π (π-inductive effect), and F (field effect) refer to the σ effects, while M (mesomeric effect) and C (the effect of direct polar conjugation) refer to the π effects.

Unfortunately the problem of the complete separation of the σ and π effects has not been completely solved[1-3,7,13-16]. However, an approach to this problem is available and makes it possible to infer to some extent whether the σ or π effects makes the dominant contribution to the electronic effect of the substituent and hence the nature and mechanism of the influence of the substituent can be deduced.

This approach consists in the employment of the two-parameter Hammett equation in the form proposed by Taft and Lewis[17-19]:

$$Q = \alpha\sigma_I + \beta\sigma_R; \tag{4}$$

where α and β are reaction constants reflecting the sensitivity of the property Q to the inductive and mesomeric effects respectively. The two-parameter equation proposed by Swain and Lupton[20] has a somewhat different significance. In agreement with Dewar and Grisdale[21], these workers assume that, among the σ effects, the main role is due to the field effect F:

$$Q = fF + rR, \tag{5}$$

where F is the field effect constant of the substituent, R its resonance (mesomeric) constant, and f and r are the regression coefficients for F and R respectively.

The contribution of the resonance influence of the substituent to the correlated property Q is expressed in the form

$$P_R = \frac{\beta \cdot 100}{\alpha + \beta} \tag{6}$$

when Eqn. (4) is used and in the form

$$R = \frac{r \cdot 100}{f + r} \tag{7}$$

when Eqn. (5) is used. P_R and R in Eqns. (6) and (7) represent the resonance (mesomeric) contribution (expressed as a percentage) to the overall polar effect P of the substituent X. The main difference between Eqns. (4) and (5) consists in the set of constants employed.

An approximate estimate of the resonance influence of substituents can be obtained in correlation analysis in terms of the usual one-parameter equation [Eqn. (1)] with the substituent constants varied until the optimum correlation is achieved. The values of P_R are zero for σ_I, 25% for σ_M, 40% for σ_n^0, 50% for σ_n, 62% for σ_n^+, 60% for σ_n^-, and 100% for σ_R.

The number of studies which have now been made on the correlation analysis of the properties of series of the type $X(CH{=}CH)_nY$ and $X(C{\equiv}C)_nY$ is fairly large. For certain types of unsaturated compounds, correlation analysis has been used successfully in relation to vibrational spectra[7,10,11,22-48], proton[7,12,49-56] ^{13}C[56] and ^{19}F[57,58] nuclear magnetic resonance, dipole moments[7,27,44,45,59-62], ultraviolet spectra[7,44,45,60,63], mass spectra[7,64-66], basicity and acidity[7,8,11,37,67-86], polarographic reduction[7,44,45,87-94], reaction kinetics[7,44,67,95-115], and finally the electron densities at the oxygen atom (q_0) of certain carbonyl compounds[89,116].

III. GENERAL CHARACTERISTICS OF THE INFLUENCE OF POLAR SUBSTITUENTS ON THE PROPERTIES OF UNSATURATED COMPOUNDS

1. Vibrational Spectra

The positions of the characteristic absorption bands in the infrared spectra for a constant substituent Y in compounds of the type $X(CH{=}CH)_nY$ and $X(C{\equiv}C)_nY$ depend primarily on the force constant of the C–Y bond, which is determined by the electron distribution about the bond. It is assumed that infrared spectra are very sensitive to structural changes in the molecule and the method is therefore widely used to investigate the mutual influence of substituents. Carbonyl compounds have been particularly widely investigated among unsaturated compounds, because the stretching vibrations of the carbonyl group are relatively insensitive to the mass of the substituents attached to the carbon atom of the carbonyl group.

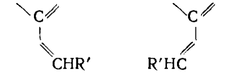
Among carbonyl compounds, ketones have been most thoroughly investigated. Thus studies have been made on the infrared spectra of the series $XC_6H_4(CH{=}CH)_n.COCH_3$ [38,41,117,118], $XC_6H_4(CH{=}CH)_nCOC_4H_9$-n [30], and $XC_6H_4(CH{=}CH)_nCOC_4H_9$-t [42] and particularly detailed studies on the series of chalcones and their vinylogues $XC_6H_4(CH{=}CH)_n.COC_6H_4X'$ [10,11,27,29,33,37,40,45,60,119,120] as well as numerous heteroanalogues of chalcones: 1-(2′-furyl)-3-phenylpropenones [29,121], 3-phenyl-1-(2′-thienyl)propenones [24,29], 3-phenyl-1-(2′-pyrrolyl)-propenones [28], 3-phenyl-1-(2′-selenolyl)propenones [34], 3-phenyl-1-(2′-quinolyl)propenones [122], 3-α (or β)-naphthyl-1-(2′-thienyl)propenones [123], etc. as well as the ferrocene analogues of chalcones [32,33]. In addition, there are infrared spectroscopic data for one series of diketones (2-arylideneindan-1,3-diones) [36] and a single series of acetylenic ketones of the type $C_6H_5COC{\equiv}CC_6H_4X$. [46]

The influence of substituents on the absorption band of the carbonyl group [ν(CO)] in aldehydes has been studied much less, but purely aliphatic aldehydes of the type $X(CH{=}CH)_nCHO$ [43,44,124] and aliphatic-aromatic aldehydes of the series $XC_6H_4(CH{=}CH)_nCHO$ [25,26,42-44,124,125] have been investigated. There have also been several studies on the influence of substituents on ν(CO) for acids and esters in the aliphatic series $X(CH{=}CH)_nCOOR$ (R = H or C_2H_5) and the aliphatic-aromatic series $XC_6H_4(CH{=}CH)_n.COOR$ (R = H or C_2H_5) [9,22,28,35,126]. The influence of substituents on other groups has been studied very little. These investigations are restricted to the XC_6H_4CN, $XC_6H_4CH{=}C(C_6H_5)CN$, and $XC_6H_4CH{=}CHCH{=}C(C_6H_5)CN$ series [31,39,127,128] and there has been a single study of the influence of substituents on the symmetrical and asymmetric vibrations of the nitro-group in the series of ω-substituted α-(5-nitro-2-furyl)polyenes [129].

Table 1 gives a selection of typical examples of the influence of substituents on ν(CO) for some of the series listed above. It shows that the introduction of electron-accepting substituents increases ν(CO) compared with unsubstituted compounds and $\Delta\nu(CO) = \nu(CO)^X - \nu(CO)^H$ decreases with increase of the number of double bonds, Δν(CO) for compounds with 3–4 double bonds hardly exceeding the error of the measurement, which is ± 1–2 cm^{-1} (see Table 1, series 1, 4, and 6). On the other hand, the introduction of electron-donating substituents decreases ν(CO) and a tendency towards a decrease of Δν(CO) down to zero is also observed (Table 1, series 1, 4, and 6). Similar results have been obtained for nitriles [31,39,127,128]. The stretching vibration wave-numbers of the nitro-group in the series of α-(5-nitro-2-furyl)polyenes (series 1) are relatively insensitive to the nature of substituents and an increase in chain length does not affect $\nu(NO_2)^{sym}$:

where R = CHO, $COCH_3$, COOH, COOR′, $CH(OCOCH_3)_2CH{=}NNHCOCH_2CN$, etc. On the other hand, like ν(CO) and ν(CN), $\nu(NO_2)^{asym}$ increases appreciably when the proton is replaced by an electron-accepting group. An increase in chain length in this case also leads to a decrease of $\Delta\nu(NO_2)^{sym}$ down to zero.

Interesting features have been observed in series containing a variable substituent X in the benzene ring. In the first place, the influence of X on ν(CO) is in this case less marked than in aliphatic series (see, for example, series 1 and 2 in Table 1), which can be accounted for by an appreciable weakening of the influence of X during its transmission through the benzene ring. Furthermore, a strong influence of the conformation of the compound on ν(CO) has been noted, in particular ν(CO) for the *cis*-conformers is always smaller than the value for the *trans*-conformers (series 3 and 4 in Table 1). The most interesting feature is that the transition in series 3 and 4 from members of the series with *n* = 0 to members with *n* = 1 is seen to entail an appreciable increase of ν(CO) for the *cis*-conformers, sometimes reaching 10 cm^{-1}, instead of the expected decrease with increase in the length of the conjugation chain. The increase of the rigidity of the C=O bond following its relative approach to the double bond in *S-cis*-conformers can probably be accounted for by the strong interaction of these bonds [131,132]:



S-cis *S-trans*

*Carbon tetrachloride [124].

**The following values of ν(CO) (in CCl_4) have been published [125] for X = C_6H_5 (the values of *n* are given in brackets): 1710 (0), 1689 (1), 1688 (2), 1685 (3), 1684 (4), and 1683 (5); the values of ν(CO) (CH_2Cl_2) are: 1704 (0), 1679 (1), 1677 (2), 1675 (3), 1674 (4), and 1673 (5,6).

***The following values of ν(CO) (CCl_4) have been published [22] for X = $COOC_2H_5$ (the values of *n* are given in brackets): 1730 (1), 1721 (2), 1715 (3), 1714 (4), and 1713 (5,6).

This feature can probably be used as an additional criterion for the assignment of an α-carbonyl β-unsaturated compound to the *S-cis-* or *S-trans*-form, apart from the usual criteria (the ratio of the intensities of the stretching vibrations of the C=O and C=C bonds and their difference[133]). This means that, when ν(CO) increases after the insertion of a double bond between the carbonyl group and the remainder of the molecule, the isomer obtained belongs to the *S-cis*-series and, when ν(CO) decreases, the isomer belongs to the *S-trans*-series.

In all cases, except for amino-derivatives, the accumulation of double bonds (see series 1 and 8) leads to a decrease of ν(CO). For amino-derivatives, a decrease of ν(CO) is initially observed, but subsequently it increases. The difference between the wavenumbers for adjacent members of the series diminishes and tends to zero.

In relation to the wavenumbers of functional groups or substituents, Eqn. (1) becomes

$$\Delta\nu = \nu - \nu_0 = \rho\sigma, \tag{1a}$$

or

$$\nu = \rho\sigma + \nu_0, \tag{1b}$$

where $\Delta\nu$ is the difference between the wavenumbers for the substituted and unsubstituted members of the series.

A correlation analysis has also been carried out for the intensities A of the vibrational bands, which are functions of the changes in the dipole moments and lengths of the vibrating bonds. The problem of the correlation of A still remains unresolved. Eqn. (1) was used in the following forms:

$$\lg (A/A_0) = \rho\sigma; \tag{1c}$$

$$\Delta A^{1/2} = \rho\sigma; \tag{1d}$$

$$\frac{A^2 - A_0^2}{A_0^2} = \rho\sigma. \tag{1e}$$

It has been noted that the application of Eqns. (1*c*), (1*d*), and (1*e*) frequently yields identical results[39,127,128].

Best results in the correlation analysis of series 1–8 (Table 1) were obtained when the constants σ^+ of σ^0_R were used.

A new correlation equation has been proposed recently[134] for the interpretation of ν(CO) data for aromatic and aliphatic-aromatic carbonyl compounds:

$$\nu(\text{CO}) = 1583 + 38.2\,[X(\text{R}') + X(\text{R}'')]\ (\text{cm}^{-1}), \tag{8}$$

where $X(\text{R}')$ and $X(\text{R}'')$ are constants which depend on the nature of R′ and R″ in the carbonyl compounds R′COR″. The new constants X(R) and the Hammett–Taft substituent constant are linked by the relation

$$\delta' = 0.482\,\sigma^*,\ \delta' = X(\text{R}) - X(\text{CH}_3),\ \text{and}\ \delta = \beta\sigma/10,$$

where $\delta = X(\text{R}) - X(\text{C}_6\text{H}_5)$ and β depends on the type of substituent in the aromatic ring (*para-* or *meta-*) and on the nature of the substituent (electron-donating or electron-accepting). Somewhat later[10,135] Eqn. (1) was extended to unsaturated aliphatic-aromatic compounds of the type RCOCR′ = CR″R‴, the constants X(R) being replaced by new constants X^+(R) (calculated from the electrophilic constants σ^+), which yield an appreciably higher correlation coefficient than the Hammett σ constants. The new constants X^+(R) are empirically related to the σ^+ constants by the equation

$$X^+(\text{R}) = 0.238\,\sigma^+ + 1.077, \tag{9}$$

and when the benzene ring contains more than one substituent, we have

$$X^+(\text{R}) = 0.238\sum_{n=1}^{n} \sigma_i^+ + 0.007n + 1.070.$$

The values of X^+(R) for many substances have been calculated by Eqn. (9) and their applicability to 287 compounds of the type R′CH=CHCOR″ with *meta* and *para*-substituents in the benzene ring has been demonstrated.

It is noteworthy that both Eqns. (1*a*) and (1*b*) and Eqn. (8) with the constants X^+(R) proved to be inapplicable to members of series 4 with n = 2 or 3 (Table 1). This distinguishes series 4 from series 1, 2, and 6, which obey the Hammett equation also for members with n = 2–4.

Table 2. The fundamental wavenumbers (cm^{-1}) in the Raman spectra of the $C_2H_5O_2C(CH{=}CH)_nCO_2C_2H_5$ series (solvent—acetone, exciting light—blue mercury line, ν = 22 938 cm^{-1}).

Raman Spectra

Analysis of the Raman spectra of series of polyene esters $C_2H_5O_2C(CH{=}CH)_nCO_2C_2H_5$ (n = 1–8) showed that the vibrational wavenumbers for these compounds change little with increase in chain length[136]. It follows from the data in Table 2 that, with increase of chain length, the addition of each new unit has an increasingly smaller effect on the wavenumbers, i.e. the mutual influence of the atomic groups is weakened.

NMR Spectra

Since chemical shifts characterise the electron density, including the π-electron density, NMR has also found application in the study of the influence of substituents at a multiple bond in unsaturated compounds. The influence of substituents on the chemical shift of olefinic protons has been studied in the *trans*-$CH_3CH{=}CHX$ and *trans*-$C_6H_5CH{=}CHX$ series[49–51], methyl esters of *trans*-α- and *trans*-β-substituted cinnamic acids[50,51], *trans*-β-substituted methyl vinyl ketones and acryloyl chlorides[51], *cis*- and *trans*-cinnamic acids[51–53], chalcols[12,54], substituted styrenes $XC_6H_4CH{=}CH_2$[55], and 1-arylpropynes[56]. Table 3 presents typical examples of the influence of substituents on the chemical shifts of the hydrogen atom in the β-position relative to the substituent. It shows that electron-accepting substituents cause an upfield displacement of the signal due to the proton in the β-position with respect to the substituent, while electron-donating substituents have the opposite effect.

Table 3. Typical examples of the influence of substituents on the chemical shifts δ (p.p.m.) of hydrogen atoms in selected series of unsaturated compounds [solvent—CCl_4, internal standard—tetramethylsilane (TMS)].

*The chemical shifts of the underlined hydrogen atoms in the β-position with respect to the substituent are quoted.

Apart from ^1H NMR, the influence of substituents in unsaturated compounds has been investigated by ^{13}C NMR.[56] Table 4 presents the chemical shifts of ^{13}C in the β-position with respect to the aryl group containing the substituent for the series of 1-arylprop-1-enes and 1-arylprop-1-ynes. The introduction of electron-donating substituents causes an upfield shift of the ^{13}C signal, while electron-accepting substituents give rise to a downfield shift.

Table 4. The chemical shifts of the β-^{13}C atoms in the unsaturated group (δ in p.p.m., standard—TMS, no solvent)[56].

$XC_6H_4C{\equiv}\underline{C}CH_3$	84.7	85.6	86.4	—	87.7	88.2

Finally, studies have been made[57,58] on the influence of substituents on the chemical shift of the ^{19}F nuclei in $XC_6H_4CH{=}CHC_6H_4F$-p (Table 5). In this case substituents have an appreciable influence on the position of the ^{19}F signal, electron-donating and electron-accepting substituents producing opposite effects on the position of the signal.

A satisfactory correlation has been observed when Eqn. (1) was used in the form

$$\Delta\delta = \delta - \delta_0 = \rho\sigma,$$

where Δδ is the difference between the ^1H, ^{13}C, or ^{19}F chemical shifts for substituted and unsubstituted members of the series.

Dipole Moments

The dipole moment is a direct characteristic of the electronic structure of the molecule. A change in the structure or the introduction of the substituent involves a redistribution of electron density and a change in the dipole moment. In unsaturated compounds, the relative contribution of the conjugation effects is expressed by the mesomeric effect (μ_m), defined as the difference between the dipole moments of the corresponding saturated and unsaturated compounds[137]. With increase in the length of the conjugated system, μ_m also increases[138,139] for all substituents except halogens, whose mesomeric effect is small[140].

Table 6. The dipole moments of certain disubstituted compounds of the type $X(CH{=}CH)_nCHO$ (μ, D; solvent—benzene).[62]

n	1		2		3		4	
X	μ_{exp}	μ_{int}	μ_{exp}	μ_{int}	μ_{exp}	μ_{int}	μ_{exp}	μ_{int}
CH_3	3.49	1.00	3.98	1.49	4.47	1.98	4.95	2.46
$COOC_2H_5$	3.15	1.85	3.19	1.77	3.40	1.98	3.55	1.78
$(CH_5)_2N$	6.24	2.95	7.62	4.33	8.24	4.95	8.50	5.21

The presence at the ends of the conjugated system of substituents of different types (electron-donating and electron-accepting) causes a displacement of electrons from the electron-donating to the electron-accepting groups, which leads to the appearance of an additional dipole moment. The vector difference between the experimental and calculated dipole moments is called the interaction moment (μ_{int}).[141]

It has been shown for a series of substituted benzenes XC_6H_4Y and styrenes $XC_6H_4CH{=}CHY$ that the values of μ_{int} are higher for ethylenic compounds when X and Y are of different electronic types and lower when X and Y are both powerful electron acceptors[142,143]. The same rule holds also for the series of linear polyene aldehydes[62,144]. The insertion of a multiple bond between the substituents in the disubstituted compounds probably promotes the mutual enhancement of conjugation for electron-donating and electron-accepting substituents and weakens the conjugation for two electron-accepting substituents owing to the competitive interaction of the functional groups with the π-electron system of the multiple bonds. The above features of the influence of substituents on the dipole moments of unsaturated compounds are illustrated by examples in Table 6. It is noteworthy that high interaction moments (μ_{int}) are observed for all aliphatic polyenes, the moments increase with chain length in an acceptor–donor system, change little in an acceptor–acceptor system, and increase regularly in a methyl–acceptor system.

A completely different behaviour is observed in systems of the type $XC_6H_4(CH{=}CH)_nCOC_6H_5$ (Table 7). In this case, the dipole moments of compounds with n = 1–3 are very close to those for substituted benzophenones, and the μ_{int} are very low, except for amino-derivatives. The features of chalcones and their vinylogues noted above indicate a weak interaction between the carbonyl group and the π-electron system of the C_6H_4X-p group (except for amino-derivatives). This can be explained both by the appreciable weakening of the influence of the group X owing to the benzene ring and by the non-planar structure of such compounds. X-Ray diffraction and Rayleigh light scattering data for benzophenones[146] and X-ray diffraction analysis of chalcones and their vinylogues[147,148] have shown that the rings are rotated by an angle of 30–31° in benzophenone, 36–37° in p-bromochalcone, 51° in the vinylogue with n = 2, and 3° in the vinylogue with n = 3. Furthermore, the angle between the plane of the ring of p-BrC_6H_4 and the plane of the double bond is 27° in p-bromochalcone, 16° in the vinylogue with n = 2, and 18° in the vinylogues with n = 3. Thus the compounds are non-planar and the transmission of the electronic influence via the mesomeric mechanism should be weakened, i.e. the values of μ_{int} should also be small, which is in fact observed experimentally. The high values of μ_{int} for amino-derivatives can be attributed to the direct polar conjugation between the amino- and carbonyl groups, which presupposes an appreciably smaller (owing to the $=C-C_{Ar}$ bond order) deviation from the planar conformation in the amino-derivative compared with other substituted derivatives.

Table 7. The dipole moments of certain members of the *trans*, *cis*-p-$XC_6H_4(CH{=}CH)_nCOC_6H_5$ series.[45,61,145].

The applicability of the Hammett equation in form (1) to the correlation of the dipole moments of non-aromatic unsaturated compounds was first demonstrated by Charton[59]. The optimum correlation is achieved using the constants σ_R^+ for electron-donating substituents and σ_R^- for electron-accepting substituents. Apart from Eqn. (1) in the form

$$\Delta\mu=\rho\sigma,$$

use is made of Eqn. (1*f*) (where account is taken of the distances d^X and d^H between the centres of the substituent Y and the variable substituent X or H at the ends of the unsaturated chain), which was proposed by Exner[149] on the basis of the analysis of numerous dipole moments of aromatic compounds:

$$\frac{\mu^X-\mu^H}{d^X-d^H}=\rho\sigma. \tag{1f}$$

Ultraviolet Spectra

The characteristics of the electronic structures of linear conjugated molecules are manifested most clearly in the ultraviolet absorption spectra. It has been established that the introduction of each new double bond causes a shift of the absorption bands in the spectra of series of disubstituted unbranched polyenes[150–165] towards the visible part of the spectrum, the shift diminishing with increase of the number of double bonds. The dependence of the wavelength of the main absorption maximum on the number of double bonds in the molecule is expressed fairly satisfactorily by the semi-empirical equation of Lewis and Calvin[166]:

$$\lambda^2_{max}=kn.$$

Examples are quoted in a number of communications[123,154,157–159,167–169].

2	330	353	—	329	333	333
3	361	382	—	—	—	—

The following characteristic features have also been noted for linear disubstituted polyenes. The replacement of an ethyl group in dimethylpolyenes by an electron-accepting or electron-donating substituent causes a bathochromic shift of the main absorption maximum, which increases in the following sequence of substituents: $C_2H_5O < COOC_2H_5 < CHO \leqslant COCH_3 < NO_2$. The replacement of the methyl group in the methylpolyenals $CH_3(CH{=}CH)_nCHO$ or the polyenoic esters $CH_3(CH{=}CH)_nCOOC_2H_5$ by an electron-accepting substituent results in small bathochromic or hypsochromic shifts. The replacement of the methyl group by an electron-donating group leads to significant bathochromic shifts (see Table 8, *a*). A similar behaviour has also been observed in the $XC_6H_4(CH{=}CH)_nCHO$ and $XC_6H_4(CH{=}CH)_n.COOC_2H_5$ series[63] (Table 8, *b*).

A detailed study of the ultraviolet spectra of chalcones and their vinylogues[40,45,170-173] and also of the hetero-analogues of chalcones and their vinylogues[174-181] showed that an increase in the length of the conjugated chain also leads to a bathochromic shift of the principal absorption maximum, the shift being particularly marked when electron-donating and electro-accepting groups are introduced simultaneously at the opposite ends of the molecules. Regardless of the nature of the substituents, substitution in the *para*-position of the cinnamoyl part of the molecule leads to a bathochromic shift of the absorption maximum, which increases in the sequence $H < Cl{=}Br < NO_2 < OCH_3 < N(CH_3)_2$ (Table 8).

The correlation of the ultraviolet spectroscopic data leads to satisfactory results when the σ^+ constants are used in Eqn. (1) in the form

$$\frac{1}{\lambda_H} - \frac{1}{\lambda_X} = \rho\sigma.$$

Mass Spectrometry

The possibility of the correlation of the ionisation potentials with the Hammet σ constants when the two-parameter Eqn. (4) is used for substituted ethylenes and unsaturated carbonyl compounds was observed by Charton[7,64]. On the other hand, the correlation between the relative intensity of the common ion peak and the Hammett σ constants in terms of the simple Eqn. (1) in the form

$$\lg Z/Z_0 = \rho\sigma,$$

where Z and Z_0 are respectively the relative intensities of the peaks of the common fragment ion peaks in substituted and unsubstituted compounds, was established by Bursey and McLafferty[183] in relation to benzophenones (with a common benzoyl ion) and was later extended to chalcones and their vinylogues[45,65,66]. An excellent correlation was achieved using the Hammett σ constants for the entire $C_6H_5CO(CH{=}CH)_nC_6H_4X$ series (where $n = 1{-}3$).

The mass-spectrometric method has a number of advantages compared with methods based on measurements in solutions, where it is extremely difficult to take into account quantitatively the interactions between the solvent and solute (the solvation and steric interactions), which distorts the results obtained. Fragmentation in the mass-spectrometer takes place in the gas phase at pressures guaranteeing the absence of collisions of molecules with one another. Thus the use of the mass-spectrometric method makes it possible to determine the exact quantitative characteristics of the efficiency of the transmission of electronic influences by various bridge systems.

Basicity and Acidity

The influence of substituents on the basicity and acidity of unsaturated compounds has been investigated in fair detail. Particularly systematic studies have been made on chalcones and their analogues. Investigation of the comparative basicities of chalcones by the measurements of the shift of the stretching vibration wavenumber of the hydroxy-group in phenols [ν(OH)] in carbon tetrachloride in the presence of chalcones owing to the formation of an intermolecular hydrogen bond[11,79] showed that the introduction of electron-donating substituents [CH_3, CH_3O, and $(CH_3)_2N$] increases the basicity of chalcones [increases $\Delta\nu$(OH)], while the introduction of electron-accepting substituents lowers their basicity [decreases $\Delta\nu$(OH)]. The constants K_{ass} for the association of phenol with chalcones have also been determined from the change in the intensity of the stretching vibration band of the phenolic OH group in the presence of chalcones[82]. As a result, it has been established that K_{ass} increases following the introduction of electron-donating substituents and decreases in the presence of electron-accepting substituents in chalcones.

A dependence of $\Delta\nu$(OH) on the nature of the substituents similar to that noted above has also been observed in the study of the hydrogen bonds between 2,3,4,6-tetrachlorophenol and chalcones[83] and between trifluoroacetic acid and chalcones[84]. In the latter case $\Delta\nu$(OH) is particularly sensitive to the electronic effects of the substituents. The influence of the nature of the substituent on basicity [based on $\Delta\nu$(OH) or the constants K_{ass} for association with phenols] has also been investigated for furan, thiophen, selenophen[79,82-84,184,185], and pyrrole[79,184,185] analogues of chalcones. The same relations as for chalcones have been observed for all the compounds.

Table 9. The values of pK_{BH^+} for certain aminostilbenes and tolanes and the values of pK_a for certain hydroxystilbenes and tolanes.

*X = OCH_3.

The basicities in certain other series, particularly in amino-[76,77] and hydroxy-derivatives[78] of *trans*-stilbenes and tolanes, have also been determined. Table 9 lists the basicities (in 50% alcohol) of certain compounds. It is seen that a slight but clear influence of the substituents on basicity is observed in this group of compounds too. Electron-donating substituents increase pK_{BH^+} or pK_a, while electron-accepting substituents cause a decrease. The influence of the substituent is more pronounced in the series of stilbenes.

A number of studies have been made on the influence of substituents on the acidity of unsaturated carboxylic acids of the type $XCH{=}CHCOOH$, $RCX{=}CHCOOH$, or $XC{\equiv}CCOOH$[7,8,68-75,80,81,85-87]. Typical examples are compiled in

Table 10. The introduction of electron donors in the β-position of the unsaturated acid lowers its acidity, while electron acceptors increase it.

The majority of the series investigated exhibit a satisfactory correlation with the σ^- and σ^+ constants in terms of Eqn. (1) in the form

$$\lg K/K_0 = \rho\sigma.$$

Polarographic Reduction

Polarographic reduction constitutes a convenient method for the investigation of the reactivities of unsaturated compounds containing polarographically active groups. The electrochemical reduction of linear polyenals of the type $X(CH{=}CH)_nCHO$ (n = 1–5) and p-$XC_6H_4(CH{=}CH)_nCHO$ (n = 0–3) [7,44,93,125,186] and unsaturated ketones of the type $C_6H_5CO(CH{=}CH)_nC_6H_4X$ (n = 0–3) [45,87,89,90,91,94] has been investigated. It has been noted for both aldehydes and ketones that the accumulation of double bonds facilitates reduction, the increment per double bond decreasing with increase in chain length. Other conditions being equal, electron-accepting substituents facilitate reduction while electron-donating substituents hinder it. As double bonds accumulate, the influence of substituents is abolished (Table 11).

Table 11. The influence of substituents on the half-wave potentials (mV) in selected series of carbonyl compounds (relative to the saturated calomel electrode).

*Not reduced.

Similar relations have been observed for heteroatomic systems [187] of the type

.

Apart from the investigation of carbonyl compounds, the polarographic method has been used to study the transmission of the polar effect via the furan ring and other bridges, including the vinyl group, in the series of α-nitrofuryl-α'-vinyl derivatives [88,92]:

X=H, CH_3, CHO, COOH, $COCH_3$, $COOCH_3$. 
.

There is no unanimous view concerning the interpretation of the dependence of half-wave potentials on the structure of organic compounds [188–191]. Lagutskaya and Dadali [190] believe that the influence of the electronic structure of the substituent and its position in the molecule is reflected in different ways in the electron density at the reaction centre and in the energy levels. They suggest that the free energy of the stage determining the potential of the polarographic process depends primarily on the electron affinity of the molecule and that the influence of substituents on the half-wave potential should be treated from the standpoint of the change in the energy of the lowest vacant molecular orbital. Thus the correlation of the half-wave potentials with the Hammett constants is possible only when there is a direct proportionality between the change in electron density at the reaction centre and the positions of the energy levels, which happens only for a limited range of substituents. Indeed, the correlation between the half-wave potentials and the σ constant is observed solely within narrow series of the same type [44,45].

Eqn. (1) in the form

$$\Delta E_{1/2} = \rho\sigma, \qquad (1g)$$

or the two-parameter Yukawa-Tsuno equation

$$\Delta E_{1/2} = \rho\,(\sigma + r\Delta\sigma_R^+) \qquad (9a)$$

are used for the correlation. In particular, Eqn. (1g) has proved applicable to chalcones using the σ^0 constants and aldehydes of the $R(CH{=}CH)_nCHO$ series using the σ_R^0 constants Eqn. (9a) yielded satisfactory results for the $C_6H_5CO(CH{=}CH)_nC_6H_4X$ (n = 1–3) series.

Reaction Kinetics

The study of the influence of substituents on the reactivity of unsaturated compounds is of particular interest. For this purpose, one can use the influence of substituents on the rate of reaction of a functional group in the $X(CH{=}CH)_nY$ series, where Y is a functional group, or on the rate of addition of an addend to the double bond in the $X(CH{=}CH)_nY$ system, where Y = H or a fixed substituent.

The kinetics of the esterification of unsaturated acids [67,95,101,198] and of the hydrolysis of esters [44,112,192,193] as well as deuterium exchange in monosubstituted acetylenes [99,100,103,194] and in the methyl group of benzylideneacetones [195] have been studied on the widest scale. There are also data for the kinetics of the conversion of benzylideneacetones into oximes [111], the acetylation of aminostilbenes [99] and aminochalcones [110], the formation of complexes of monosubstituted acetylenes with diethylacetamide [108], and also the acid and alkaline cleavage of the $XC_6H_4(C{\equiv}C)_nMR_3$ systems (M = Si or Ge) [96,97,107,197,198]. The influence of substituents on addition to double bonds has been much less investigated. Here one may note studies on the addition of dichlorocarbene to compounds of the type $XC_6H_4(CH{=}CH)_nH$ (n = 1 or 2) [113,115] and the addition of HX in aqueous dioxan to $XC_6H_4C{\equiv}CCOOH$ [106] and of diazomethane to p-$XC_6H_4C{\equiv}CH$. [114]

Table 12 presents typical examples of kinetic data for certain reactions involving functional groups in unsaturated compounds, while Table 13 lists data for the reactions involving double or triple bonds. Depending on the nature of the reaction, the introduction of electron-donating substituents either reduces (Table 12, examples 2, 4, 6, 7, 9) or increases (Table 12, examples 1, 3, and 8) the reaction rate relative to the unsubstituted compound. Electron-accepting substituents act in the opposite direction (the increase of the rate is illustrated by examples 2, 4-7, and 9 in Table 12 and its decrease is illustrated by examples 1, 3, and 8). It is seen from the data in Table 13 that electrophilic reactions are retarded by electron-accepting substituents, while nucleophilic reactions are retarded by electron-donating substituents.

The correlation analysis of kinetic data is carried out using Eqn. (1) in the form

$$\lg K/K_0 = \rho\sigma.$$

IV. THE CHARACTERISTICS AND MECHANISM OF THE TRANSMISSION OF THE INFLUENCE OF POLAR SUBSTITUENTS VIA MULTIPLE BONDS

The quantitative characteristics of the transmission of the influence of substituents via multiple bonds are based on correlation analysis (see Section II) and on the determination of transmission factors. It is noteworthy that, whereas there have been numerous studies on correlation analysis, the transmission factors have been determined in a much smaller number of instances, which is explained mainly by the difficulty of selecting suitable reference series. Table 14 lists the transmission factors for one (π'_{1F}), two ($\pi'_{2F'}$), three ($\pi'_{3F'}$), and four ($\pi'_{4F'}$) double bonds and for one ($\pi'_{1F'}$), two ($\pi'_{2F'}$), and three (π'_{3F}) triple bonds.

Although the total number of series investigated is not as yet very large (21 series) and certain types of compounds have not been studied at all or have been studied inadequately, nevertheless analysis of the data in Table 14 yields information about certain characteristic features of the transmission of influences via multiple bonds. In the first place, the long range of variation of the values of $\pi'_{1F'}$ [from 0.42 (series 9) to 0.87 (series 1)] is probably evidence that π' for the X(CH=CH)$_n$Y systems depends not only on the nature of the bridge [1,199] but also on the nature of the unchanged part of the molecule Y. Thus the values of π'_{1F} found from the correlation analysis of ν(CO) or ν(CN) are 0.74 (series 2), 0.62 (series 6, *S-cis* in CCl$_4$), 0.82 (series 6, *S-trans* in CCl$_4$), 0.64 (series 10), and 0.61 (series 17). It is therefore hardly useful to combine in a single series compounds of different types, as has been done in series 21, which includes all carbonyl compounds regardless of their nature (aldehydes, ketones, carboxylic acids, and their esters and amides).

---

*The values of ρ_{rel} are quoted.

**Series 21 includes cinnamaldehydes, chalcones, styrylketones, cinnamic acids and their esters, dimethylamides, etc.

The dependence of the π'_{1F} on the nature of the property being correlated is very clearly manifested. Thus π'_{1F} for the ketones $XC_6H_4(CH{=}CH)_nCOCH_3$ amounts to 0.47 (*S-cis*-conformers) or 0.54 (*S-trans*-conformers) on the basis of the correlation analysis of ν(CO) and 0.76 on the basis of the correlation of half-wave potentials. The difference between the values of π'_{1F} is apparently determined by the different sensitivities of the properties to the influence of substituents.

The dependence of the values of π'_{1F} on the conformation of the molecules was already noted above (see, for example, series 4, 6, and 22 in Table 14): *S-trans*-conformers are appreciably more sensitive to the influence of substituents. This apparently applies also to geometrical isomers: a *trans*-double bond transmits the influence of a substituent more effectively than a *cis*-double bond (series 11).

In some cases π'_{1F} is affected by the solvent in which the property to be correlated has been determined [see the difference between the values of π'_{1F} found from the correlation analysis of the ν(CO) determined in CCl_4 and $CHCL_3$ (series 2 and 6) or between the values found from the correlation analysis of the half-wave potentials determined in water and dimethylformamide (series 12)]. This may be associated with the different degrees of solvation of the bridge or of the reaction centre or with the specific interaction of the substance with the solvent.

The values of π'_{1F}, π'_{2F}, π'_{3F}, and π'_{4F}, obtained from the correlation analysis of the same parameters [ν(CO), μ, λ_{max}, $E_{\frac{1}{2}}$, and k] of the polyene series 1, 2, 3, 10, and 11, are linked by the relation [44]

$$\pi'_{1F} : \pi'_{2F} : \pi'_{3F} : \pi'_{4F} = \pi'_{1F} : (\pi'_{1F})^2 : (\pi'_{1F})^3 : (\pi'_{1F})^4. \qquad (10)$$

Thus the influence of substituents diminishes in a geometrical progression with increase of the number of double bonds.

This conclusion agrees fully with data obtained by Bowden[71], who believed that π' is a power function of the type

$$\pi' = \varepsilon^n, \qquad (11)$$

where ϵ is the transmission factor of the atomic group entering into the composition of the bridge and n the number of such atomic groups, and calculated on the basis of the analysis of 17 reaction series the values of ϵ for the carbon atom in the sp^3 (0.48 ± 0.04), sp^2 (0.67 ± 0.02), and sp (0.57 ± 0.01) states, and found that π'_{1F} for the $-CH{=}CH-$ group is equal to ϵ^2 (C_{sp^2} = 0.45). If Eqn. (11) holds, then evidently $\pi'_{2F} = (\pi'_{1F})^2$, $\pi'_{3F} = (\pi'_{1F})^3$, and $\pi'_{4F} = (\pi'_{1F})^4$, i.e. Eqn. (10), found in the correlation analysis of the experimental properties of polyenes, is obtained. The validity of Eqn. (10) indicates the equivalence of the double bonds with respect to the transmission of the influence of substituents in these polyenes.

It is of interest that the values of ρ_{rel} (see Table 14, series 16) [107] are in the following proportions:

$0.66 : 0.30 : 0.18 = 0.66 : (0.66)^3 : (0.66)^4$.

Table 15. The calculated and experimental values of $10^3\,\nu_{max}$ (cm^{-1}) and $E_{\frac{1}{2}}$ (V) for certain series of $C_6H_5(CH{=}CH)_n$. CHO polyenes.

ν_{max} (calc.)	—	—	30.3	25.4	21.6	18.6	15.8
			p-$CH_3OC_6H_4(CH{=}CH)_nCHO$				
ν_{max} (expt.)	—	31.1	28.4	26.2	24.9	23.6	22.7
ν_{max} (calc.)	—	—	26.3	24.0	22.2	21.0	20.0

However, Eqn. (10) does not hold for series 6 (see Table 14, data for the correlation of Z/Z_0), which can probably be explained by the different deviations of members of this series from coplanarity[45,147,148].

One should also note that, whereas the π-electron densities q_0 at the carbonyl oxygen atom in the aldehyde series 1 are correlated with the σ_R^0 constants and the values of π'_{1F}, π'_{2F}, and π'_{3F} found from these data obey Eqn. (10), the π-electron densities at the oxygen atom of the keto-group in chalcones and their vinylogues (series 6) are almost independent of the nature of the substituent X.[45]

Comparison of the values of π'_{1F} and π''_{1F} determined for similar series (Table 14, series 6 and 8, 9 and 13, and 11 and 14) in the correlation analysis of identical properties shows that the efficiency of the transmission of influences via a double bond is somewhat greater than via a triple bond.

Using Eqn. (10) and knowing the value of π'_{1F} for the given series, it is possible to calculate beforehand the properties of compounds with 2–5 and even 6 double bonds. Table 15 presents examples of such calculations[44]. Evidently the agreement between calculation and experiment is satisfactory.

As regards the mechanism of the transmission of influences, analysis of the data in Table 14 shows that the best correlation is achieved in most cases when the σ^+, σ_R^+, and σ_R^0 constants are used, i.e. the mesomeric mechanism is most important in the transmission of influences via multiple bonds. A detailed analysis of the two-parameter equation for aliphatic compounds with a single bond has been made by Charton[7]. Table 16 lists the contributions of the mesomeric effect (P_R) to the overall electronic effect of the substituent for a number of typical series. Evidently the contribution is large in most cases. It is striking that P can be influenced by the solvent in which the properties being correlated are determined (Table 16, series 4, 5, and 11).

Table 16. The mechanism of the transmission of influences via multiple bonds [the values of P_R (%) for certain series[7]].

Series	Property	P_R, %	Remarks
1. $XCH = CH_2$	μ	42	
	I	66–69	
	ν	78	Frequency in ^1H NMR spectrum
	δ	53	
	k	37	Addition of Cl_2 to CH_3COOH
	"	21	Addition of Br_2 to CH_3COOH
	"	52	Reaction with $C_6H_5CH = CHCHO$ in dioxan
2. $XCH = CHBr$	μ	42	
	δ	64	
3. $C_6H_5CH = CHX$		44	
4. $XCH = CHCOOH$ *trans-*	pK_a	48	In water
	"	56	In 80% methylcellosolve
	"	75	In 50% alcohol
	k	42–50	Esterification of $(C_6H_5)_2CN_2$ in alcohol
	"	51	Ditto in t-butyl alcohol or ethyl acetate
5. $XCH = CHCOOH$ *cis-*	pK_a	39	In water
	"	71	In 50% alcohol
	k	55	Esterification of $(C_6H_5)_2CN_2$ in ethyl acetate
6. $CH_3C(X) = CHCOOH$ *cis-* *trans-*	pK_a	55	In water
	"	45	Ditto
7. $C_6H_5C(X) = CHCOOH$ *cis-* *trans-*	pK_a	49	In 50% alcohol
	"	59	Ditto
8. $XCH = CHCOOCH_3$	δ	50	Addition to 9,10-dimethylanthracene in dioxan
	k	95	
9. $XCH = CHCOOC_2H_5$	k	63	Alkaline hydrolysis in water
	"	52	Ditto in 70% dioxan

The two-parameter Eqn. (4) and a similar two-parameter equation including the cross term,

$$Q = Q_0 + \alpha\sigma_I + \beta\sigma_R^+ + \gamma\sigma_I\sigma_R^+, \qquad (12)$$

have been used to estimate the contributions of the inductive and mesomeric effects for series 1, 3, and 6 (see Table 14)[44,45]. It was found that, in the

$X(CH=CH)_nCHO$ polyenal series 1, the inductive effect makes the greatest contribution ($n = 1$, $\rho_I \gg \rho_R^+$), while for the remaining series ($n = 2-4$) the mesomeric effect assumes the greatest importance, as expected, because of the rapid decay of the inductive effect. Similar data were obtained also for series 3. One should note that in all the examples application of Eqn. (12) yielded very high cross terms, which shows that the changes in the transmission of inductive and mesomeric effects are probably not quite so independent as is usually believed[20,21].

The application of the two-parameter Eqn. (12) to the series of chalcones and their vinylogues (Table 14, series 6) showed that the inductive effect predominates ($\rho_I > \rho_R^+$) in series with $n = 1-3$; this is consistent with the fact that these compounds are not planar.

The Capacity of Lactams for Polymerisation as a Function of Their Structure

V.V.Korshak, V.A.Kotel'nikov, V.V.Kurashev, and T.M.Frunze

The capacity of lactams of different structures for polymerisation is considered from thermodynamic and kinetic standpoints. It is shown that the significant differences between the enthalpies of polymerisation can be accounted for by the presence of intramolecular hydrogen bonds and also by the resonance stabilisation of the cyclic amide. The probability of the polymerisation of lactams is determined kinetically by the chemical structure of the monomer, namely the conformation of the molecules (the presence of *cis-* and *trans-*isomers), the stabilisation of the amide group by the inductive, mesomeric, and hyperconjugation effects, the polarity of the molecules (the presence of hydrogen bonds or the occurrence of dipole-dipole interactions), and the basicity of the monomer.

The bibliography includes 126 references.

CONTENTS

I. INTRODUCTION

Synthetic heterochain polyamides constitute a class of macromolecular compounds comprising an enormous number of examples and having considerable theoretical and practical importance[1]. Together with the polycondensation reaction, the polymerisation of lactams (cyclic amides) is very important for the synthesis of polyamides. During the last decade, considerable advances have been made in the field of the polymerisation and synthesis of lactams: new methods for their polymerisation have been developed and the range of lactams used to synthesise industrial polyamides (β-lactams, α-pyrrolidinone, α-piperidinone, and ω-dodecalactam) has been extended.

The anionic polymerisation of lactams, on the basis of which a procedure has been developed for the synthesis of polyamide articles by chemical moulding[2,3], which is a great achievement in the synthesis and processing of polymers, has developed particularly in recent years. The use of the ionic polymerisation of lactams made it possible to extend the scope of the synthesis of polyamides having different structures. The method has been used to synthesise both homopolyamides (with linear, branched, and cross-linked structures[4-8]) and copolymers (statistical[9-12], block[13,14], and graft[15-19]), the properties of which vary within wide limits as a function of their structure and the initial monomers.

In connection with the expansion of the range of lactams used to synthesise various types of polyamides, the problem of the dependence of their reactivity on structure has become important. Extensive experimental data have accumulated in the literature on the reactivity of lactams, treated from both thermodynamic and kinetic standpoints, and a number of reviews have been published on the mechanism and kinetics of polymerisation in the presence of various catalytic systems[20-23]. However, the problem of the extent to which the differences between the reactivities of lactams are a consequence of thermodynamic factors and to what extent they are determined by the kinetic conditions arising during these reactions still cannot be regarded as solved.

Examination of the general characteristics of the polymerisation of cyclic amides containing different numbers of units in the ring from thermodynamic and kinetic standpoints is the subject of the present review.

II. THERMODYNAMIC APPROACH

The thermodynamics of polymerisation is known to be determined solely by the propagation stage, since the initiation and chain-termination stage are single steps, while the chain propagation stage involves a large number of addition reactions. The sharp differences in the behaviour of different lactams can probably be accounted for primarily by the sign and magnitude of the free energies of polymerisation:

$$\Delta G = \Delta H - T\Delta S = \Delta G^0 + RT\ln K,$$

where ΔH is the change in the heat content of the system or the heat of reaction, ΔS the change in the entropy of the system, T the absolute temperature, K the equilibrium constant of the reaction, and ΔG° the standard change in free energy on polymerisation referred to the pure monomer and the polymer. If $\Delta G < 0$ for polymerisation, i.e. the free energy of the system decreases, the process is thermodynamically feasible.

The enthalpy of polymerisation of cyclic compounds is associated with the strain of their rings, which depends on the distortion of the valence angles and the interaction of atoms within the ring; the enthalpy depends both on ring size and the presence of substituents. For cyclic amides, ΔH can depend also on (1) the different resonance stabilisations of the monomer and polymer owing to the unequal conjugation or hyperconjugation and (2) the differences between the energies of hydrogen bonds or dipole–dipole interactions in the monomer and polymer.

The entropy of polymerisation depends on the probability of the existence of the monomer in the cyclic form or in the form of the elementary unit of the linear polymer.

1. ΔH for the Polymerisation of Lactams

The first attempt at a thermodynamic treatment of the reversible ring $\rightleftharpoons$ polymer reaction was made in 1950 by Strepikheev[24], who outlined a correct and rigorous procedure for the thermodynamic treatment of the problem of the polymerisation of cyclic compounds. A similar treatment of the thermodynamic stability of cyclic compounds was achieved independently in 1955 by Dainton et al.[25] in connection with the estimation of the free energy of the system. The values of ΔH for the hypothetical polymerisation reaction of cycloalkanes were found as the differences between the heats of formation of the polymer units (these heats were calculated from the contributions of the corresponding groups to the heat of formation) and the experimental heats of formation of cycloalkanes.

The heat of polymerisation can be found in different ways.

1. By direct calorimetric measurements on the polymerisation reaction, which make it possible to determine ΔH. However, the polymerisation process hinders calorimetric measurements, which naturally affects the accuracy of the determination.
2. By calculating ΔH from a comparison of the heats of combustion of the monomer and polymer. The latter quantity is calculated per polymer unit. The accuracy of this method is also low, since a small value of ΔH is calculated from [the difference between] large quantities.
3. By determining the difference between the experimental heats of combustion of the lactams and the heats of combustion calculated additively from the increments for the corresponding groups: 155.85 kcal mole^{-1} for CH_2(liq.), 79.4 kcal mole^{-1} for CONH(liq.), 156.3 kcal mole^{-1} for CH_2(solid), and 77.2 kcal mole^{-1} for CONH(solid).

Table 1. Heats of combustion and ring strain in cycloalkanes[26].

No. of ring units n	Heat of combustion per methylene group, kcal mole^{-1}	Ring strain* per methylene group, kcal mole^{-1}	No. of ring units n	Heat of combustion per methylene group, kcal mole^{-1}	Ring strain* per methylene group, kcal mole^{-1}
3	166.6	9.2	9	158.8	1.4
4	164.0	6.6	10	158.6	1.2
5	158.7	1.3	11	158.4	1.0
6	157.4	0.0	12	157.7	0.3
7	158.3	0.9	13	157.8	0.4
8	158.6	1.2	n-alkane	157.4	0.0

* Ring strain is defined as the difference between the heats of combustion per methylene group of the given cycloalkane and the [corresponding?] n-alkane (157.4 kcal mole^{-1}).

We shall consider initially the thermodynamic stability of cycloalkanes. Comparison of the heats of combustion per methylene group in such cyclic compounds and linear alkanes yields a general estimate of a thermodynamic stability of rings of different size.[26] Table 1 shows that the differences between the heats of combustion of cycloalkanes and n-alkanes per methylene group demonstrate a decrease of thermodynamic stability with increase in ring strain. The strain in three- and four-membered rings is very high, diminishing subsequently on passing to five-, six-, and seven-membered rings, after which it again increases for eight to eleven-membered rings, and finally falls once more on passing to rings of still greater size.

Two components of ring strain are distinguished: angular strain and repulsion due to the presence of substituents. Rings containing less than five atoms are highly strained through high angular strain, i.e. the considerable distortion of their valence angles compared with the normal tetrahedral angle. In five-membered and larger rings, there is no distortion of the valence angle, since the rings can exist in a non-planar form. In rings with more than eight units, the strain due to the distortion of the valence angle is virtually absent, but they are nevertheless thermodynamically unstable, because the hydrogen atoms or other substituents are contained within the ring at distances such that they repel one another. On this basis, it is possible to set up the following sequence of cycloalkanes as a function of ring size in order of increasing thermodynamic stability:

$$3{,}4 < 8-11 < 7{,}12{,}13 < 5 < 6.$$

Rings containing certain other atoms or groups of atoms instead of methylene groups fall in the same sequence. Although the data for cyclic compounds such as ethers, lactones, and lactams are inadequate, the general postulates have been confirmed[27]. Thus Small[28] attempted to extend Dainton's calculations[25] for cycloalkanes to certain series of saturated heterocyclic compounds (cyclic ethers and imines). He showed that the difference between the values of ΔS for the polymerisation reactions of cycloalkanes and the corresponding cyclic ethers and imines is small. The ΔH for the polymerisation reaction show greater differences.

Hall and Schneider[29] confirmed the validity of Dainton's[25] and Small's[28] findings and reached the following conclusions concerning the capacity of various heterocyclic compounds for polymerisation on the basis of their own experimental data.

1. Four-, seven-, and eight-membered cyclic compounds polymerise most readily; the capacity of five- and six-membered carbonyl monomers for polymerisation depends on the class of compound.
2. Substitution of cyclic hydrocarbons by a heteroatom has an insignificant influence on their capacity for polymerisation.
3. Substituents (alkyl or aryl) always decrease the capacity of cyclic compounds for polymerisation.

Other workers[30] also established that the substitution of a CH_2 group by O or NH causes little alteration in the capacity of cyclic compounds for polymerisation. In this case, substitution has hardly any influence on the valence angles in cyclic structures. The ring strain caused by the repulsion of substituents diminishes when the methylene group is replaced by the less bulky carbonyl group or an oxygen atom, which leads to an increase of the thermodynamic stability of the ring. It has also been shown[27] that, in contrast to hydrogen, other substituents in cyclic structures as a rule increase their stability, although the cause of this is not altogether clear.

We shall now consider the variation of the heats of polymerisation of lactams with different numbers of units in the ring. Skuratov and Strepikheev and coworkers[31-38, 43-45] have played a leading role in the study of this problem. Table 2 presents the values of ΔH for the polymerisation of lactams containing between 5 and 13 units in the ring and obtained in different ways. Column *A* lists the ΔH for the polymerisation of lactams measured experimentally with the aid of a double calorimeter using a compensation technique; column *B* lists the ΔH estimated by another procedure—by comparing the experimental heats of combustion of lactams and the corresponding polymers: the ΔH calculated from the enthalpies of cyclisation of different lactams are given in column *C*.

Table 2. Heats of polymerisation of lactams.

Lactam	No. of ring units *n*	ΔH, kcal mole^{-1}	Refs.	ΔH, kcal mole^{-1}	Refs.	ΔH, kcal mole^{-1}	Refs.
		A		*B*		*C*	
α-Pyrrolidinone	5	—	—	+1.3	32,33	−1.1	33
				−1.3	41,42		
α-Piperidinone	6	—	—	−1.1	32,33	−2.2	33
ε-Caprolactam	7	−3.3	34	−3.0	32,33	−3.8	33
		−3.5	39		38,39		
ζ-Oenantholactam	8	−5.2	35	−5.7	32,33,38,42	−5.3	33
η-Caprylolactam	9	−7.8	33	−9.6	38,42	—	—
Pelargolactam	10	—	—	—	—	−5.5	38
Decanolactam	11	—	—	—	—	−2.8	38
Undecanolactam	12	—	—	—	—	+0.5	38
Laurolactam	13	~0	33,38	−1.5	41,42	—	—

It was to be expected that the ΔH for the polymerisation of lactams estimated in different ways should be different, depending on the temperature and the phase state of the monomers and polymers to which they refer. However, Table 2 shows that the values of ΔH are similar. Therefore, in order to calculate ΔH for polymerisation, it is quite admissible to adopt the average of these values (Fig. 1). The ΔH for the polymerisation of lactams have been calculated in this way[38]. Fig. 1 shows that ΔH for the polymerisation of lactams containing between 5 and 9 units in the ring decreases and then rises for lactams containing between 9 and 13 units in the ring to values close to zero.

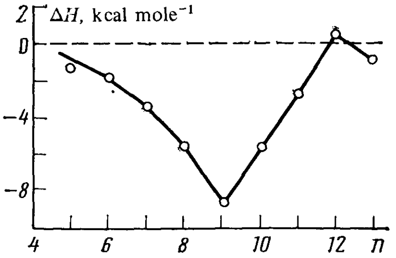

Figure 1. The heats of polymerisation of lactams (ΔH) as a function of the number of units in the ring (n).

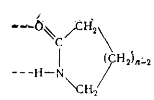
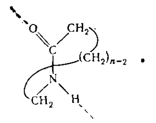
Comparison of the heats of polymerisation of lactams and the corresponding cycloalkanes shows that the enthalpies of lactam ring formation are smaller than the values for their hydrocarbon analogues (Table 3).

Some workers believe[46-50] that such a significant difference between the enthalpies of polymerisation of lactams and cycloalkanes can be accounted for by the presence of intermolecular hydrogen bonds in the lactams†. A comparative study of the free and associated NH groups by infrared spectroscopy led to conclusions about the isomerism and conformations of the rings of the test compounds:



cis-conformation



trans-conformation

Table 3. Comparison of the enthalpies of polymerisation of cycloalkanes and cyclic amides.

No. of ring units *n*	ΔH, kcal mole^{-1}	
	cycloalkane (Ref.25)	lactam (Ref.33)
5	5.2	1.1
7	5.2	3.8
8	8.3	5.3

The energy of formation of intermolecular hydrogen bonds is expressed in terms of quantities of the same order of magnitude as the heat of ring opening and can vary within wide limits depending on the structure of the lactam (Table 4). Table 4 shows that α-pyrrolidinone exists exclusively in the form of the *cis*-isomers. Lactams containing between 6 and 9 units in the ring exist in both *cis*- and *trans*-forms, while (10–13)-membered lactams exist in the thermodynamically more stable (ΔH_{av} = −4.0 kcal mole^{-1}) isomeric *trans*-form.

Table 4. Thermodynamic characteristics of the hydrogen bonds in lactams[47].

No. of ring units *n*	$-\Delta H$, kcal mole^{-1}	
	cis-	*trans-*
5	8.35	—
6	7.30	3.90
7	7.10	4.20
8	6.95	3.70
9	7.05	5.05
10	—	3.82
11	—	3.82
12	—	3.80
13	—	3.75
	mean 7.35	mean . 4.00

According to Ogata's data[50], the *cis*-form is characteristic of (6–7)-membered lactams, ζ-oenantholactam contains equivalent amounts of the *cis*- and *trans*-isomers, and the nine-membered lactam exists preferentially in the *trans*-form. On the basis of Ogata's data, one can calculate, subject to a major assumption and without allowance

---

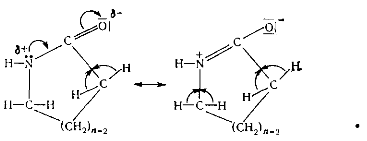
† The intermolecular interaction in the polymer does not play an appreciable role owing to steric factors[27].

for resonance stabilisation, the maximum degree of association of lactam molecules. If it assumed arbitrarily that ΔH for cyclo-octane is approximately equal to ΔH_{tot} for ζ-oenantholactam, then the degree of association of the molecules x can be found as follows:

$$\Delta H_{\text{cyclo-octane}} \simeq \Delta H_{\zeta\text{-oenantholactam}} + \frac{x}{2}(\Delta H_{\text{cis-}} + \Delta H_{\text{trans}});$$

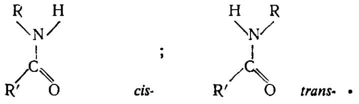
$x = 56.3\%$. We believe that this value is very much too high.

Thus the reduced enthalpy of polymerisation of lactam rings compared with the hydrocarbon analogues cannot be fully accounted for by the energy of formation of intermolecular hydrogen bonds in lactam molecules. Evidently the lower isothermal heat of polymerisation (negative ΔH) of lactams compared with the corresponding [hydrocarbon] ring is also associated with the resonance stabilisation of the lactam, since resonance is possible only in the monomer[27]:

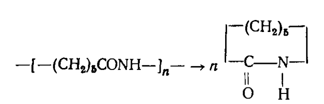


Other workers hold the same view[48-51]. Furthermore, owing to the hyperconjugation of the methylene group with the C=O and C=N bonds, ΔH for the polymerisation of lactams is reduced.

A novel method for the empirical calculation of ΔH for lactams from the change in the number of the so called "*gauche*-interactions" of the butane type on ring closure is discussed by Cubbon[52] in connection with the estimation of the influence of substituents on the polymerisation of lactams. He also believes that, when a seven-membered lactam cyclises, four new *gauche*-interactions occur (two involving CH_2/CH_2 groups, one involving the CH_2/CO group, and one involving the CH_2/NH group). The energy of a single interaction is 0.8 kcal mole^{-1}, so that the total contribution to the enthalpy of cyclisation of ε-caprolactam is 3.2 kcal mole^{-1}. A ^{1}H NMR study of methylacetamide has shown that the *trans*-form of the amide group is more stable than the *cis*-form at least to the extent of 1.4 kcal mole^{-1}:[52]



On the other hand, the overall enthalpy of the reaction



$$-[-(CH_2)_5CONH-]_n- \rightarrow n\ \overbrace{\underset{\overset{\|}{O}}{C}-\underset{|}{\overset{}{N}}H}^{(CH_2)_5}$$

is approximately 4.6 kcal mole^{-1}. We believe that this value is not altogether correct, since it is difficult to accept that ε-caprolactam exists exclusively in the *cis*-form (see above).

2. Estimation of ΔS for the Polymerisation of Lactams (under Standard Conditions)

One of the methods for the calculation of ΔS is based on the determination of the equilibrium constant within the limits of a certain temperature range. However, this method cannot be always applied, because it is difficult to measure the quantity

$$K = \frac{[M_{n+1}^-]}{[M_n^-][M]}.$$

Owing to the presence of a range of molecular weights, the number of terms (n) varies within wide limits.

The method for the determination of the entropy of polymerisation by means of the formula

$$\Delta S^0 = \Delta H^0 / T_{\text{lim}}$$

is promising. The scope of this method is limited only by the accuracy of the measurement of the heat of polymerisation and of the limiting temperature (T_{lim}).

Another, perhaps the most widely used method of calculation is based on the knowledge of the entropies of the monomer and polymer:

$$\Delta S^0 = \frac{1}{n} \cdot S^0_{(n)} - S^0_{(1)},$$

where $S^0_{(n)}$(polymers) and $S^0_{(1)}$(monomers) are calculated from the experimental true heat capacities of these substances at low temperatures.

There exists a method for the calculation of ΔS° using the relation

$$\Delta S^0 = R \ln \frac{k_p}{k_{p^1}},$$

which follows directly from the expressions for the propagation (k_p) and depolymerisation (k_{p^1}) rate constants.

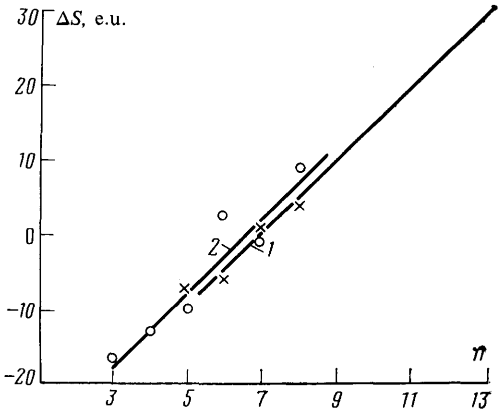


Figure 2. Variation of ΔS for the polymerisation of lactams and cycloalkanes as a function of the number of units in the ring under standard conditions: 1) lactams[38]; 2) cycloalkanes[25].

ΔS can also be obtained by a statistical procedure. In this case one uses the relation according to which the overall entropy of reaction consists of ΔS_{trans}, ΔS_{rot}, and ΔS_{vibr}.

There are very few literature data for the entropies of lactams with different numbers of units in the ring and the corresponding polymers, while for (9–13)-membered lactams there are no data at all.

Skuratov[32,38,44,45], who carried out the most systematic studies on this problem, estimated the entropies of polymerisation of five-, six-, seven-, and eight-membered cyclic amides. The ΔS were calculated from the absolute entropies $S_{298\cdot16}$ and the true heat capacities of these substances in the temperature range 62–328 K. The values of ΔS for (9–13)-membered lactams were found[38] by the linear extrapolation of the values for (5–8)-membered lactams (Fig. 2) in view of the fact that the ΔS obtained for the polymerisation of (5–8)-membered lactams fit satisfactorily on a straight line. These results are naturally extremely approximate.

It is noteworthy that the ΔS for the hypothetical polymerisation of cycloalkanes containing between 3 and 8 units in the ring (except cyclohexane) also vary linearly with the number of such units (Fig. 2, curve *2*).

3. Estimation of ΔG for the Polymerisation of Lactams (under Standard Conditions)

The free energies of polymerisation ΔG of lactams containing between 5 and 13 ring units are presented in Table 5. Evidently ΔG for the polymerisation reaction varies from a positive value (for the five-membered ring) and a value close to zero (for a six-membered lactam) to negative values, which reach a maximum for (9–10)-membered lactams, and then falls somewhat. The polymerisation of α-pyrrolidinone and α-piperidinone is exothermic (negative ΔH) and exoentropic (negative ΔS). The negative ΔS for the polymerisation of five- and six-membered lactams is probably due to the fact that the number of degrees of freedom diminishes on passing from the monomer to the polymer. Consequently the polymerisation of five- and six-membered lactams is favourable from the standpoint of the enthalpy factor but not on entropy grounds. For seven- and eight-membered lactams, the main contribution to ΔG for the polymerisation reaction comes from the enthalpy term, for nine-, ten-, and eleven-membered lactams the contributions of ΔH and ΔS are approximately the same, while for twelve- and thirteen-membered cyclic amides ΔH for the polymerisation reaction is negligible and the polymerisation proceeds mainly as a result of the entropy change.

Table 5. Free energies of polymerisation ΔG of lactams with different numbers of ring units.

No. of ring units n	ΔH *, kcal mole^{-1}	ΔS^{38}	$T\cdot\Delta S_{298,16}$, kcal mole^{-1}	ΔG, kcal mole^{-1}
5	−1.1	−7.3	−2.2	1.1
6	−1.7	−6.0	−1.8	0.1
7	−3.3	1.1	0.3	−3.6
8	−5.4	4.0	1.2	−6.6
9	−8.4	10.0	3.0	−11.4
10	−5.6	15.0	4.5	−10.1
11	−2.8	20.0	6.0	−8.8
12	0.5	25.0	7.5	−7.0
13	−0.7	30.0	9.0	−9.7

*The average values of ΔH obtained from the results of different workers are quoted (see Table 2).

Fig. 3 presents the values of ΔG for the polymerisation of lactams and cycloalkanes[25] as a function of the number of ring units. It is seen that the variation of ΔG for the polymerisation of lactams and cycloalkanes is very similar. The values of ΔG for five- and six-membered rings are close to zero, becoming negative for larger rings. Using the equation

$$\ln[\mathrm{M}]_c = \frac{\Delta H^0}{R\,T_{\lim}} - \frac{\Delta S^0}{R},$$

expressing the dependence of the equilibrium (critical) concentration of the monomer $[\mathrm{M}]_c$ on the limiting polymerisation temperature[27], we calculated the critical monomer concentrations at 25°C (Table 6); the limiting temperatures for six- and seven-membered lactams are also quoted.

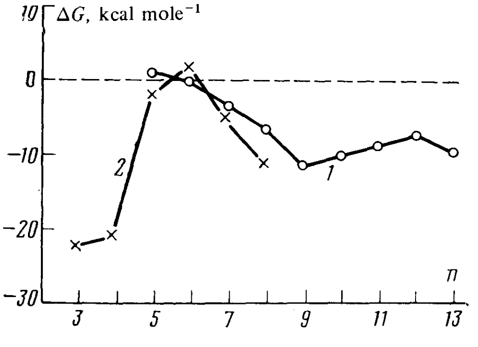

Figure 3. Variation of ΔG for the polymerisation of lactams (curve *1*) and cycloalkanes (curve *2*) as a function of the number of units in the ring (*n*).

Table 6. The "polymerisation ⇌ depolymerisation" equilibrium.

Lactam	$[\mathrm{M}]_c$ at 25°C, M	$T_{\lim}$ for pure monomer, °C
α-Pyrrolidinone	6,3	—
α-Piperidinone	1,2	60[53]
ε-Caprolactam	$2.1\cdot10^{-3}$	254[54]
ξ-Oenantholactam	$1.4\cdot10^{-5}$	—
η-Caprylolactam	$4.3\cdot10^{-9}$	—
Pelargolactam	$4.0\cdot10^{-8}$	—
Decanolactam	$3.6\cdot10^{-7}$	—
Undecanolactam	$7.8\cdot10^{-6}$	—
Laurolactam	$8.2\cdot10^{-8}$	

Since ΔH° is negative, the concentration of the monomer in equilibrium with the polymer increases with temperature and the relation between $\ln[\mathrm{M}]_c$ and $1/T$ is represented by a straight line with a negative slope (slope = $\Delta H^\circ/R$) making an intercept on the ordinate axis equal to $\Delta S^\circ/R$ (Fig. 4). The data presented in Table 6 and in Fig. 4 indicate high critical concentrations in the "polymerisation ⇌ depolymerisation" equilibrium for five- and six-membered lactams, which ultimately determines the comparatively low equilibrium degree of polymerisation of the lactams.

Thus one may conclude that the polymerisation of (7–13)-membered lactams is thermodynamically feasible (ΔG is negative). The small positive values of ΔG for the polymerisation of α-pyrrolidinone and α-piperidinone and the extremely large errors of the determination of the thermodynamic characteristics preclude a conclusion concerning the thermodynamic feasibility of the polymerisation of five- and six-membered cyclic amides.

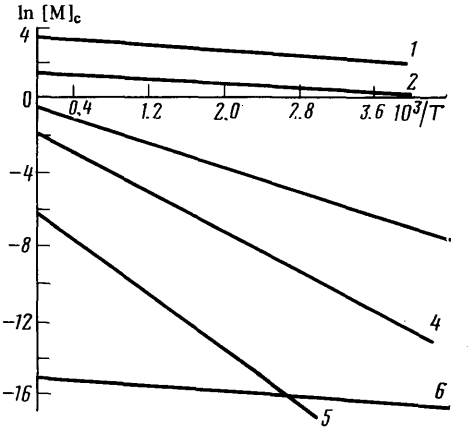

Figure 4. Variation of ln [M]c with $1/T$ in the polymerisation of lactams with different numbers of units in the ring: 1) α-pyrrolidinone; 2) α-piperidinone; 3) ϵ-caprolactam; 4) ζ-oenantholactam; 5) η-caprylolactam; 6) laurolactam.

Taking into account the thermodynamic factors only, it is possible to set up a series based on the reactivities of the lactams as a function of ring size:

$$9>10>13>11>12>8>7\gg 6,5.$$

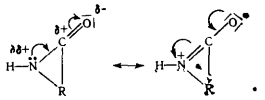
III. KINETIC APPROACH

The negative value of ΔG does not, however, imply that polymerisation is possible under any conditions. The probability of achieving thermodynamically allowed polymerisation depends on its being allowed by kinetic factors, i.e. on whether or not the given process occurs at an appreciable rate under the chosen reaction conditions. The kinetic capacity of monomers for polymerisation is determined by the mobility of the corresponding bonds under the reaction conditions, since thermodynamically unstable compounds can be kinetically quite stable and may not polymerise if they do not contain a labile bond.

One may quote as an example cycloalkanes for which it has been as yet impossible to find polymerisation conditions despite their considerable thermodynamic instability[25,55].

1. The Chemical Structure of the Monomer

Heterocyclic compounds to which lactams belong are capable of selective ring opening at the site of the heterobond. However, this fact is not related to the lower energetic stability of the heterobond compared with the C−C bond (the energy of the C−C bond is 63 kcal mole^{-1}, that of the C−N bond 66 kcal mole^{-1}, and that of the C−O bond 79 kcal mole^{-1}), but is associated with its susceptibility to polarisation under the influence of various chemical agents. The polarisability of the lactam ring can be represented schematically as follows:



The electron-accepting carbonyl group causes a shift of electron density (the $-M$ effect; the inductive effect of the N−H bond may be neglected), as a result of which the amide group is polarised. The possibility of the hyperconjugation effect in the lactam molecule was discussed above.

The presence of the resonance effect in the amide group has been demonstrated by Pauling and Corey[56], who carried out a very thorough investigation of the NH−CO group by X-ray diffraction. The bond angles and interatomic distances in amides are presented in Fig. 5.

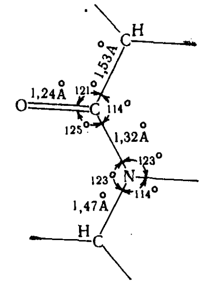


Figure 5. Amide linkages[56].

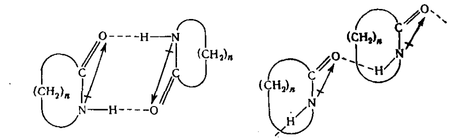
It is evident from Fig. 5 that the C−N bond length in the amide group is shorter than the normal length of the isolated C−N bond, which is 1.5 Å. This result demonstrates a certain amount of double bond character of this linkage. In this case the NH−CO group is planar and all its valence bonds, illustrated in Fig. 5, lie in the plane of the figure; this in fact permits the existence of the *cis*- and *trans*-forms (see above).

The existence of the *cis*- and *trans*-configurations of lactams can be observed by measuring the dielectric constants of their benzene solutions at variable concentrations. Like the acyclic amides, the *cis*-lactam forms a hydrogen-bonded dimer, in which the two electric moments (arrows in the formula) mutually cancel out.



cis-lactam *trans*-lactam

With increase of concentration, the degree of association of the molecules rises and, in the case of the *cis*-lactam, the dielectric constant falls. On the other hand, the *trans*-lactam can form only a linear associated species in which the electric moments are additively combined and the dielectric constant of the benzene solution therefore increases with concentration.

The dipole moments of lactams presented in Table 7 show that they depend little on the number of units in the lactam ring, although the dipole moment of the five-membered lactam is somewhat reduced.

Table 7. The dipole moments of lactams[57] (measured in benzene).

No. of ring units n	5	6	7	8	9	10	11	13
Dipole moment, D	3.55	3.83	3.88	3.86	3.85	3.79	3.78	3.78

Here it is appropriate to examine the studies by Ogata[48-50], devoted to the influence of the resonance effect of the amide group on the ability of lactams to polymerise. He investigated the addition of hydrogen chloride to certain cyclic and linear amides by infrared spectroscopy. The constant for the equilibrium between the amide group and HCl was calculated from the equation

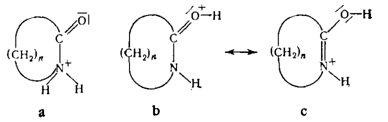
$$K = \frac{[-\overset{+}{N}H_2CO-]}{[-NHCO-]\cdot[H^+]} .$$

Table 8. The equilibrium constants and heats of addition of hydrogen chloride to the amide group[50].

Amide derivative	K			$-\Delta H$, kcal mole^{-1}
	20° C	40° C	55° C	
α-Pyrrolidinone	159	68	—	7.64
α-Piperidinone	164	79	—	6.58
ε-Caprolactam	177	124	91	3.15
ξ-Oenantholactam	107	82	82	1.63
Decanolactam	83	45	45	3.70
N-Methyl-α-piperidinone	49	38	—	2.34
N-Methyl-ε-caprolactam	35	20	12	5.12
NN'-Dibutylacetamide	35	22	—	4.14
N-Hexylacetamide	58	48	—	2.16

The heats of addition of HCl to the amide were calculated from the slope of the curve describing the linear relation between ln$K$ and the equilibrium values of the absolute temperature. Table 8 lists the average equilibrium constants for the above addition reaction involving several amide compounds. On the basis of the results, the author reaches a conclusion concerning the relative basicities of lactams. He believes[50] that seven- and eight-membered lactams are the most basic. With increase in the size of the lactam ring, its basicity falls, as can be seen from Table 8. The capacity of the five- and six-membered rings for protonation is also lower than that of the seven-membered lactam. In view of the disappearance of the characteristic $>$N–H absorption frequency and the appearance of a new frequency characteristic of the $>$NH$_2$ absorption, Ogata concludes that the proton adds to the nitrogen atom of the amide group.

We may note that the protonation of nitrogen (structure a) leads to the disappearance of resonance stabilisation, while the protonation of oxygen does not (structures b and c):



The system with protonated oxygen should therefore be more stable. Nevertheless many investigators[58,59] share Ogata's view concerning the protonation of nitrogen in the amide group of the lactam.

It was stated above that, according to Ogata[49,50], the eight-membered lactam contains equivalent amounts of the *cis*- and *trans*-forms. On this basis, the author concludes that, if the amounts of the two conformations of the amide group become equal, the resonance effect in this group diminishes with a consequent increase of the capacity of the lactams for polymerisation, which we believe to be unlikely. It was shown above that the resonance effect in the amide group of the lactam plays a certain role in the estimation of the reactivity of cyclic amides, but it is by no means decisive.

Thus the kinetic probability of the polymerisation of lactams is to a large extent determined by the chemical structure of the monomer, namely:

(1) by the conformation of the molecules (the presence of *cis*- and *trans*-isomers);

(2) by the stabilisation of the amide group due to the mesomeric, inductive and hyperconjugation effects;

(3) by the polarity of the molecules (the presence of hydrogen bonds or the occurrence of dipole–dipole interactions);

(4) by the basicity of the monomer.

2. The Capacity of Lactams for Polymerisation as a Function of the Type of Initiation

The type of initiator—a radical, cation, or anion—most suitable in a particular instance depends on the chemical structure of the monomer.

There is no information in the literature about the radical polymerisation of lactams. It has proved possible to polymerise via the cationic mechanism virtually all unsubstituted lactams with the exception of the six-membered compound. The method of ionic high-speed polymerisation of lactams made it possible to extend the range of monomers suitable for the synthesis of polyamides. Thus, α-piperidinone and α-pyrrolidinone, which were previously believed to be incapable of polymerisation[28,60,61], were in fact polymerised in the presence of anionic catalysts[62]. Ney and coworkers[63-65] achieved the anionic polymerisation of these lactams in the presence of *N*-acyl compounds and the sodium salts of the lactams on heating the reaction mixture to a temperature exceeding somewhat the melting point of the monomer, but not higher than 60°C. The introduction of an *N*-acyl compound (activator) in the polymerisation reaction made it possible to increase sharply the yield of the polymer compared with the same conditions but in the absence of the activator. Somewhat later, the polymerisation of α-pyrrolidinone were achieved by Ney in the presence of quaternary ammonium bases[66].

Barnes et al.[63] demonstrated the possibility of the polymerisation of a six-membered lactam (α-piperidinone) using the same reaction conditions as in the polymerisation of α-pyrrolidinone[65]. However, the polymerisation of α-piperidinone proceeds with much greater difficulty than that of the five-membered lactam. The above studies by Ney and coworkers are of great theoretical importance, since they established that five- and six-membered lactams, previously believed to be stable and incapable of polymerisation, are quite reactive monomers, forming polyamides under relatively mild conditions. Somewhat later, a number of other patent reports were published on the anionic polymerisation of α-pyrrolidinone[67–78] and α-piperidinone[74–78], confirming the ability of these compounds to form high-molecular-weight products.

The method of the anionic polymerisation of five- and six-lactams in the presence of activating *N*-acylamide compounds has been used successfully to polymerise various lactams containing more than six units in the ring: ϵ-caprolactam, ζ-oenantholactam, η-caprylolactam, and others. The dependence of the capacity of the monomers of polymerisation on the type of initiator is illustrated by the data in Table 9, from which it is clear that, in the presence of such initiators, polymers with a high molecular weight are formed. Although the polymerisation of five- and six-membered lactams is thermodynamically allowed, under these conditions the polymerisation of α-piperidinone is kinetically feasible only in the presence of initiators of a specific type.

Table 9. Examples of the polymerisation of lactams as a function of the type of initiation.

No. of ring units *n*	Monomer	Type of initiation			
		cationic	references	anionic	references
5	α-Pyrrolidinone	+	50	+	85—93
6	α-Piperidinone	—	50	+	85—94
7	ϵ-Caprolactam	+	50,79—81	+	85—100
8	ξ-Oenantholactam	+	81,82	+	87—102
9	η-Caprylolactam	+	79,81	+	87—102
10	Pelargolactam		—	+	87—102
11	Decanolactam	+	50	+	87—102
12	Undecanolactam		—	+	87—89,91—102
13	Laurolactam	+	83—84	+	87,88,91—102

Table 10. The capacity of lactams for polymerisation as a function of ring size.

Type of initiation	Activity series for rings of different size	References
Acetylating agent	$8.7>13\gg5.6$	53,103
Water	$8>7>11\gg5.6$	50
HCl	$7>8\simeq9\gg5.6$	85

When the capacities of lactams for polymerisation were compared as a function of ring size, it was shown that eight- and nine-membered lactams exhibit the greatest tendency towards polymerisation, that of seven-membered lactams being somewhat inferior; the capacity of five- and six-membered lactams for polymerisation is much smaller, particularly that of the six-membered lactams (the available data are presented in Table 10).

The lactam reactivity series is close to the series expected on the basis of the measured free energies, although there are differences. Thus, according to Ogata's data[50], the thermodynamically less stable eleven-membered lactam is less reactive in cationic polymerisation than the thermodynamically more stable seven-membered lactam. We believe that the reason for this apparent anomaly may be that at 257°C ϵ-caprolactam is more reactive than the lactam of capric acid and because of the failure to attain thermodynamic equilibrium for the eleven-membered lactam under the chosen conditions, so that Ogata's data[50] correspond to the polymerisation kinetics under the chosen process conditions only. With increase of reaction temperature, the relative rates of polymerisation of the lactams would probably become equalised and it should be possible to select polymerisation conditions such that the thermodynamically less stable lactam becomes more reactive than the thermodynamically more stable lactam also from the kinetic standpoint.

It is interesting to note that five- and six-membered lactams are much more reactive under the conditions of anionic polymerisation than under the conditions of the polymerisation initiated by hydrochloric acid or water. This can be explained from the standpoint of the different mechanisms under these conditions (Fig. 6). In anionic polymerisation, the lactam ring is activated by the nucleophile. In polymerisation under the influence of water or acids, there is electrophilic attack on the lactam ring. Owing to the low electron density in the amide group, this reaction does not proceed as readily as in the presence of a nucleophile. As a result, anionic polymerisation is faster and less selective than the other two reactions.

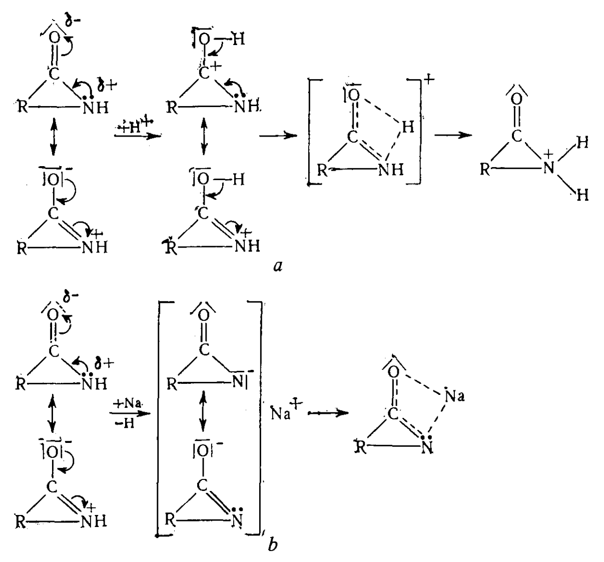


Figure 6. The mechanism of the initiation of the cationic (*a*) and anionic (*b*) polymerisation of lactams.

Lactams incapable of polymerisation in the presence of water or acids, are readily polymerised via the anionic mechanism. These differences in reactivities are also manifested when the temperatures required for polymerisation are compared. Thus polymerisation initiated by water or acid usually requires temperatures of the order of 250°C, as in other instances of cationic polymerisation. Anionic polymerisation takes place at much lower temperatures.

IV. THE INFLUENCE OF SUBSTITUENTS ON THE REACTIVITY OF LACTAMS

There are many data concerning the influence of substituents on the reactivity of lactams, which has proved to be lower than that of unsubstituted cyclic amides[104-111]. Dainton and coworkers[25,28] demonstrated by semi-empirical calculations of the free energies of the hypothetical polymerisation reactions of cycloalkanes that substitution always decreases the reactivity (Fig. 7).

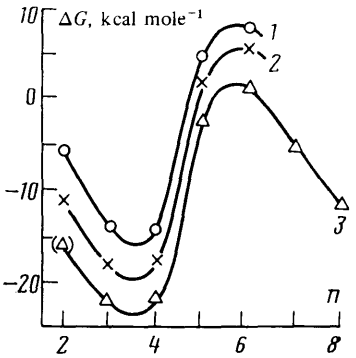

Figure 7. Variation of the free energy of polymerisation of cycloalkanes under standard conditions with ring size (n): 1) 1,1-dimethyl derivatives of cycloalkanes; 2) methyl derivatives of cycloalkanes; 3) unsubstituted cycloalkanes.

The calculations showed that the substituent in the cycloalkane ring influences the enthalpy and entropy of polymerisation of the compound with the given ring size[25,28]. The authors assumed that the results of the calculations will be valid, at least qualitatively, for the polymerisation of heterocyclic compounds, which was subsequently confirmed on the basis of extensive experimental data (Table 11).

It is seen from the Table that the influence of substituents on the capacity of lactams for polymerisation is extremely varied and depends both on the size of the substituent, its position in the ring, and the number of substituents, on the one hand, and on the size of the lactam ring, on the other.

1. *C*-Substituted Lactams

Five- and six-membered rings. Substituents are known[119] to facilitate ring closure, thereby displacing the monomer ⇌ polymer reaction equilibrium towards the monomer. Five- and six-membered lactams lose their capacity for polymerisation even in the presence of only one alkyl substituent at the carbon atom (Table 11).

The study of the cyclisation of 4-bromobutylamines has shown that substituents can greatly increase the rate of formation of the five-membered ring[120]. The estimation of the influence of the thermodynamic characteristics on the capacity of substituted lactams for polymerisation is at present difficult, since the entropies of polymerisation of these lactams are not available. According to Cubbon[52], a substituent in the lactam ring causes only a slight alteration of the entropy compared with the unsubstituted lactam, but greatly increases the entropy of cyclisation of the lactam and to a greater extent the more bulky the substituent.

Table 11. Heats of polymerisation and the capacities for polymerisation of substituted lactams.

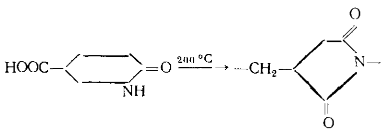
---

* The authors begin the numbering of the ring positions from the heteroatom.

** The 6,6 salt is hexamethylenediammonium adipate.

Thus one may conclude that the entropy and enthalpy effects of the substituent make the free energy of cyclisation of the lactam more negative compared with the unsubstituted analogue, as a result of which the equilibrium is displaced towards the cyclic compound.

The ready conversion of 4-carboxy-α-pyrrolidinone into a polyamide on heating above the melting point of the monomer, described by Klein and Reimschuessel[114], constitutes an appreciable deviation from the usual behaviour of substituted cyclic carbonyl monomers:



Such capacity for polymerisation can in all probability be accounted for by the reactivity of the substituent in the lactam, the latter isomerising to a cyclic imide on heating.

Seven- and eight-membered rings. While the heats of polymerisation of *C*-substituted five- and six-membered lactams are lower than those of the corresponding unsubstituted analogues, ΔH for substituted seven- and eight-membered lactams may be both greater and smaller than the enthalpies for the corresponding unsubstituted cyclic amides. Since the entropies of polymerisation of the above compounds are not available, one can only suppose that in this instance the thermodynamic characteristics of the substituent promote the cyclisation reaction, displacing the polymer $\rightleftharpoons$ monomer equilibrium towards the monomer. This is confirmed by the concentrations found in the polymerisation of substituted lactams with seven- and eight-membered rings (Table 12).

Table 12. The equilibrium concentrations of the monomer in the polymerisation of seven- and eight-membered lactams[52].

Lactam*	Content of lactam at equilibrium, wt.%	*T*, °C	Initiator, %
ε-Caprolactam	7	260	6,6 salt, 5

N-methyl-	20	260	water, 2

* The authors begin the numbering of the ring positions from the heteroatom.

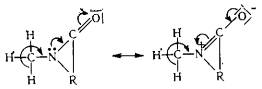
The data in Table 12 show that the introduction of a substituent into the lactam ring leads to an increase of the equilibrium concentration of the monomer in the monomer–polymer system, the influence of the substituent on the lactam polymerisation process being greater the greater the bulk of the substituent.

(9–13)-Membered Rings. There are contradictory data concerning the influence of the substituent on the formation of nine-membered lactam rings[121,122]. However, according to the available results for the polymerisation of various lactams, the influence of substituents on the capacity of lactams for polymerisation is smaller the larger the ring.

2. *N*-Substituted Lactams

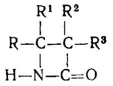
It is seen from Table 11 that the strain in the rings of *N*-substituted lactams is much smaller than in the rings of the unsubstituted lactams and their capacity for polymerisation is correspondingly smaller[112]. Data are available for the capacities for polymerisation of *N*-methyl-ζ-oenantholactam[111] and the *N*-methyl derivative of the lactam of lauric acid[118]. The polymerisation of *N*-methyl-ε-caprolactam has been investigated by many workers[48,53,106,168] under the conditions of both hydrolytic and anionic polymerisation. The possibility of the polymerisation of *N*-methyl-ε-caprolactam, suggested in one of the investigations[124], has been the subject of much doubt[48,53,110,111]. The capacity of *N*-acetoacetyl-ε-caprolactam for anionic polymerisation has also been studied[125] and it has been found that the *N*-acetoacetyl-substituted lactam not only does not undergo polymerisation but actually inhibits the polymerisation of ε-caprolactam.

Prochaska[108] suggested that a necessary condition for the polymerisation of lactams is the presence of a hydrogen atom in the amide group. This view is supported by Jumoto[107] and Hall[113]. On the basis of infrared spectroscopic data for five-, six-, and seven-membered lactams, Ogata[49] concluded that the absence of capacity for polymerisation is a common property of all *N*-substituted lactams. He believes[49] that this is caused by the high stability of such cyclic compounds due to the increase of the resonance effect in the amide group as a result of *N*-substitution and not due to the absence of a hydrogen atom:



The increase of the resonance stabilisation of *N*-substituted lactams owing to the inductive effect of the alkyl groups should lead to an increase of the dipole moment of the molecule. In fact, according to Ogata[110], the dipole moment of *N*-methyl-ε-caprolactam is 4.23 (cf. $\mu = 3.89$ for ε-caprolactam, Table 7). The capacity for polymerisation of *N*-substituted (8–13)-membered lactams indicates a decrease of the influence of the substituent with increase of ring size.[52]

It has been found that even the most reactive four-membered substituted cyclic β-lactams having the general formula



$$\begin{array}{c} \quad R^1\ R^2 \\ R{-}\overset{|}{C}{-}\overset{|}{C}{-}R^3 \\ H{-}\underset{|}{N}{-}\underset{|}{C}{=}O \end{array},$$

where R=H, alkyl, aryl, alkylaryl, or arylalkyl and R^1, R^2, and R^3 = H, CH_3, or C_2H_5, show a decrease of the tendency towards polymerisation with increase of the degree of substitution[126].

Thus examination of the influence of substituents on the reactivity of lactams shows that the following postulates may be regarded as proved.

1. The substituent reduces the reactivity of lactams.
2. The influence of the substituent is greater the smaller the size of the lactam ring.
3. An increase in the size of the substituent in the lactam ring also results in a decrease of the reactivity of the cyclic amide.
4. The reactivity of lactams depends on the position of the substituent in the ring.

It is apparently possible to arrange systematically data for the polymerisation of substituted lactams in terms of the ease of formation of the cyclic monomer. Two factors operate in cyclisation. The first is the enthalpy effect, the magnitude of which is a function of ring size and the presence of substituents. The second is the ease with which groups at the end of the chain can approach one another to a distance necessary for cyclisation, namely the entropy effect. The probability of cyclisation diminishes with increase in chain length, which evidently leads to a decrease of the entropy of cyclisation.

The Mechanisms of the Stabilisation of Thermostable Polymers

O.A.Shustova and G.P.Gladyshev

New data on the stabilisation of thermostable polymers are presented, attention being concentrated on quantitative data and reaction mechanisms. The theoretically feasible polymer stabilisation pathways at temperatures exceeding 250°C are briefly analysed, various methods for the inhibition of thermo-oxidative and thermal degradation of polymer systems are considered, and experimental results concerning the kinetics and mechanisms of these processes are described.

One of the general polymer stabilisation pathways, based on non-chain inhibition reactions, is analysed in detail; procedures for the generation of highly active stabilisers directly in polymeric materials or during their processing and employment are considered, new approaches are proposed to the solution of the problem of the stabilisation of thermostable polymers, and certain experimental data are quoted.

The bibliography includes 203 references.

CONTENTS

I. INTRODUCTION

Studies on the stabilisation of thermostable polymers constitute an independent branch of the science of the ageing of polymers, since in this field one cannot use the general procedures which have become common in the stabilisation of non-thermostable polymer materials. The considerable interest in the problem of the stabilisation of thermostable polymers is indicated by the abundance of monographs, reviews, and experimental studies on this problem[1-44] published in recent years. Unfortunately, most of these are concerned solely with the influence of particular additives on the ageing of polymers or with the problem of stabilisation when the usual antioxidants and inhibitors of thermal degradation, effective at temperatures not exceeding 200–250°C, are used.

Among highly thermostable polymers[†], organosilicon, organofluorine, and other polymers derived from organic derivatives of the elements, phenyl ether resins, polyimides, etc. are of greatest interest[45,46]. The available literature information about the mechanisms of the stabilisation of these polymers is contradictory[28,45-58]. In a number of studies, conclusions have been reached without taking into account the experimental conditions. For example, some workers investigated the relevant processes under conditions where the rate of the latter is limited by the diffusion of oxygen or of the degradation products and yet this factor was not taken into account in the determination of the mechanism.

The most interesting studies dealt with the stabilisation of polymeric liquids[55-57], but the conclusions reached in such investigations concerning the process mechanisms cannot always be extended to solid polymeric systems[59,60].

Several general approaches have been formulated in recent years and new mechanisms of the stabilisation of thermostable polymers have been proposed[4,19,20,35-38]. Although the theory of high-temperature stabilisation is not complete and only a few theoretical studies have been made as yet, important data have accumulated and can be usefully considered.

This review deals with the mechanisms of the stabilisation of thermostable polymers which are experimentally and theoretically justified and also with certain empirical data taken from studies on the stabilisation of thermostable polymers published in 1969–1975. Studies which are of practical interest alone, the references to which may be found in a number of monographs[5-7,14,15,17,18,43] and reviews[21,29,31,32-35], are not discussed.

II. GENERAL APPROACHES TO THE PROBLEM OF THE STABILISATION OF POLYMERS

It has come to be assumed that polymers may be stabilised in two ways: by the introduction of special additives (stabilisers) or by modification using different procedures. The first method is most widely used. Stabilisers are normally involved in the following reactions:

1. Interaction with free radicals leading to the deactivation of active centres and chain termination.
2. Interaction with the molecular degradation products involved in [further] reactions and leading to the decomposition of the polymer.
3. Interaction with active agents penetrating the polymer from an external medium[4,37].
4. The blocking (deactivation) of the reactive centres of macromolecules (weak bonds).
5. Deactivation of impurities by the binding of the latter into stable complexes.

[†] Polymers which can be used at temperatures above 200–250°C will henceforth be referred to for brevity as thermostable.

From the thermodynamic standpoint, the hypothesis that the chemical reactions leading to stabilisation should result in the formation of stronger bonds compared with those whose presence in the polymer is responsible for its thermodynamic instability under the given conditions is frequently valid[4]. It can be shown that this principle holds also from the kinetic standpoint, since the chemical bond energy is both a thermodynamic and a kinetic criterion of the occurrence of bond dissociation processes under the influence of heat and chemical agents. Knowing the detailed polymer decomposition mechanism, one can therefore select stabilisers for thermostable polymers on the basis of the chemical bond strengths.

Inhibited processes can be divided into two groups: those involving chain and non-chain inhibition[19,20]. Chain inhibition presupposes the deactivation of the active centres for the chain process, i.e. their conversion into inactive products from the standpoint of chain propagation. Non-chain inhibition is associated with the deactivation of a substance involved in any reactions leading to the degradation of the polymer. In chain polymer degradation processes, non-chain inhibition is associated with the deactivation of the substances initiating the chains or involved in the chain propagation reactions. In non-chain polymer degradation processes, non-chain inhibition presupposes the deactivation of the active centres responsible for the degradation.

Thus, there are two general ways of inhibiting the polymer degradation processes.

1. Inhibition of the chain processes by the introduction into the system of substances leading to chain termination.
2. The removal from the system of chemical agents (present in the polymer composition or formed as a result of ageing), weak bonds, etc.

A rigorous kinetic criterion of non-chain inhibition, associated with the deactivation of a particular compound, is a zero rate of initiation (reaction) with participation of the given substance X′ during the ageing of the polymer:

$$w_{X'} = 0$$

Quantitative criteria of the efficiency of non-chain inhibition can be readily obtained from the following ratios:

$$w_{Z+X'}/w,$$

where $w_{Z+X'}$ and w are the rates of the non-chain inhibition and the overall rate of the process in the absence of the stabiliser Z.

Chain processes are inhibited by inhibitors of thermal (thermostabilisers) or oxidative (antioxidants) degradation of polymers. The inhibition of the decomposition of the polymer is associated with chain termination, which can be represented by elementary reactions of the following type:

$$\mathrm{R^{\cdot} + InH \rightarrow RH + In^{\cdot}}$$
$$\mathrm{R^{\cdot} + In^{\cdot} \rightarrow RIn}$$
$$\mathrm{RO_2^{\cdot} + InH \rightarrow ROOH + In^{\cdot}}$$
$$\mathrm{RO_2^{\cdot} + In^{\cdot} \rightarrow} \text{ inactive products,}$$
$$\mathrm{2In^{\cdot} \rightarrow In - In}$$
$$\mathrm{R^{\cdot}, R_2^{\cdot} + X \rightarrow} \text{ inert products, etc.,}$$

where R˙ is the active radical propagating the chain, InH the inhibitor molecule, X a stable radical or molecule containing a short [multiple ?] bond, etc.

The assortment of stabilisers effective below 200–250°C is fairly extensive[5,14–18,27,31,61]. However, at higher temperatures the mechanism of the degradation of polymers changes and the "low-temperature" stabilisers such as phenols, amines, etc. frequently vaporise or are themselves converted into initiating agents. The assortment of suitable stabilisers under these conditions is therefore restricted. Inhibiting activity is shown at elevated temperatures by compounds such as certain phosphites[26,35], inorganic acids[62–66], alkalies[67,68], metals and their compounds[35,69–87], and polyconjugated systems[21,77].

Furthermore, at high temperatures the method involving the generation of radicals directly in polymer compositions is effective. Such acceptors must be themselves firmly stable and must not participate in chain initiation and chain transfer processes[4].

The procedures for the elimination of active degradation products have been used for a long time in polymer chemistry[5]. On the other hand, methods for the removal of weak bonds and other initiating components from systems have been inadequately studied. Although it has been known for a long time that oxygen acceptors inhibit oxidation, the lack of knowledge about the mechanism as a whole precluded the determination of the optimum conditions for the application of these substances, led to contradictory data, etc. This approach became very promising only after it had been shown theoretically[4,19,20,37,38] that the oxidative ageing of polymers can be fully suppressed by using appropriate oxygen acceptors. The essential feature of the elementary interaction of O_2 (as well as other agents causing the degradation of polymers) with the acceptor, called non-chain inhibition[19,20], is that, under conditions of a fairly high reactivity and concentration of the stabiliser Z, oxygen is not involved in initiation reactions of the type

$$\mathrm{RH + O_2 \rightarrow R^{\cdot} + HOO^{\cdot}}$$
$$\mathrm{2RH + O_2 \rightarrow 2R^{\cdot} + H_2O_2}\text{ ,etc.}$$

and is fully absorbed in the reaction with the stabiliser:

$$nZ + \frac{m}{2}O_2 \rightarrow Z_nO_m \text{ (inert product).}$$

Table 1. Schematic description of polymer stabilisation pathways.

Type of initiation of degradation	Stabilisation method	Substances involved in reactions (examples)
1. Dissociation of main macromolecular chains, scission of side (terminal) groups: $R_m{-}R_n \rightarrow R_m^{\cdot} + R_n^{\cdot}$ $R_m{-}YX_2{-}R_n \rightarrow R_m{-}YX{-}R_n + \dot{X}$	(a) chain inhibition: $R^{\cdot} + YR' \rightarrow RY + R^{\cdot}$ $R' \longrightarrow R'R$ $R^{\cdot} + Z'^{\cdot} \rightarrow RZ'$ R′R and RZ′ are inert products.	YR′-InH-antioxidant, thermostabiliser; Z′˙—stable radical
	(b) non-chain inhibition, structural stabilisation	substances forming clathrate compounds
2. Reactions with chemical agents: $R_m{-}YX_2{-}R_n \xrightarrow{X'} R_m{-}Y\dot{X}{-}R_n + X'X^{\cdot}$ (or active ionic forms)	(a) chain inhibition: $R'^{\cdot} + Z'^{\cdot} \rightarrow$ inert products (b) non-chain inhibition: $X' + Z \rightarrow$ inert product	Z′˙—radical acceptor; X′—chemical agent (O_2, O_3, H_2O, HCl, etc.) Z—acceptor X′ (metal, metal oxide, sulphide, etc.)
3. Reaction of weak bonds and active impurity groups: $R_m{-}Y{-}Y{-}R_n \rightarrow R_mY^{\cdot} + R_nY^{\cdot}$ $R_m{-}X_1{-}R_n \xrightarrow{Y_2} R'^{\cdot}$ + products (where $X_1 = {>}C{=}C{<}$, $-C{\equiv}C$, etc.)	(a) chain inhibition: $R'^{\cdot} + Z' \rightarrow$ inert products (b) non-chain inhibition: $R_m{-}X_1{-}R_n \xrightarrow{Z_1}$ inert product $Y_2 + Z_2 \rightarrow$ inert product	Z′—stabiliser (InH, stable radical) Z_1-chemical agent (H_2, F_2, etc.); Z_2—acceptor of chemical agent; Y_2—chemical agent

The employment of non-chain inhibition in combination with the generation of highly active oxygen acceptors directly in polymeric systems made it possible to increase significantly the lifetime of certain thermostable materials[4,37,38]. A number of chemical processes permitting the generation of highly active stabilisers of different types[37,75] in polymer compositions virtually in any specified temperature range have been proposed recently (Section IV). Thus the non-chain inhibition method has been extended to various types of ageing.

Table 1 summarises the possible polymer stabilisation pathways. The methods listed in Table 1 are applicable to the stabilisation of not only thermostable, but, in principle, any polymers undergoing decomposition via different mechanisms.

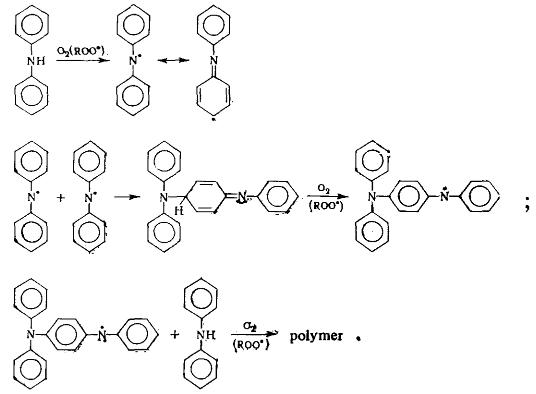
Methods for increasing the stability of polymers based on their modification[1,16,88-95] and structural stabilisation[19,96-98] and the structural-chemical stabilisation of chemical agents and stabiliers[4,19], etc. are also known. These procedures, involving the employment of the cage effect[45,99-101], the reduction of the rate of diffusion of active agents in polymers[5,102,103], etc. are not considered in detail in the present review. Special stabilisation methods[104,105] used in light- and radiation-induced ageing processes[1,106,107] are not analysed either.

III. THE MECHANISMS OF THE STABILISATION OF THERMOSTABLE POLYMERS

As already stated above, a number of inhibiting systems retarding the chain degradation of polymers at elevated temperatures are known. Stabilisation methods can be based on both chain and non-chain inhibition procedures. Since the stabilisation of many polymer compositions involves the application of both these procedures, it is useful to consider the mechanisms of the inhibition of degradation on the basis of the nature of the stabiliser.

Berlin, who investigated the inhibiting properties of various polyconjugated systems, showed that they are frequently effective inhibitors of high-temperature chain processes[21,77].

Many polyconjugated systems, including those formed in consequence of chemical transformations of antioxidants and substrates, exhibit a high inhibiting activity. Thus, polydiphenylamines, with a higher inhibiting activity than the initial amines, are formed in the oxidative dehydropolymerisation of secondary aromatic amines[21]. One of the hypothetical mechanisms of the formation of these polymers may be as follows:



Stemniski et al.[84] pointed out the possibility of inhibiting the thermal degradation of polyphenyl ethers at 420–440°C and their thermo-oxidative degradation at 250–300°C by organic derivatives of variable-valence metals (Co, Cu, Ti, Al, Mn, Ni, Fe, Be, and Cr) and proposed a mechanism for their action. Thus they showed that the decomposition of a polyether involves, on the one hand, the formation of relatively stable free radicals of the type  or their derivatives. On the other hand, variable-valence metal compounds interact with hydroperoxides in the following way:

$$M^{2+} + ROOH \rightarrow M(\dot{O}H)^{2+} + RO^{\cdot} \quad ,$$
$$M(\dot{O}H)^{2+} + ROOH \rightarrow M^{2+} + HOH + ROO^{\cdot} \quad .$$

Archer and Bozer[87] suggest that the stabilisation of polyphenyl ethers by organic cobalt salts is associated with the interaction of the metal ions and active radicals:

$$Co^{3+} + R^{\cdot} \rightarrow Co^{2+} + R^{+} \quad . \tag{1}$$

One may postulate that analogous processes occur also in the reactions of RO•, ROO•, etc. radicals. There is reason to believe[57] that the efficiency of reaction (1) is not very high when inorganic salts are used.

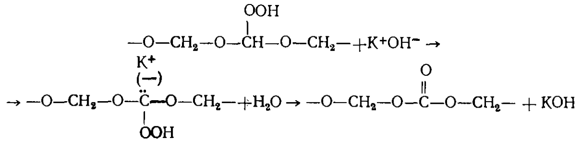
According to Ravner et al.[57], the high-temperature stabilisation in the presence of alkalies, for example KOH, is associated with the occurrence of the following reactions:

$$\text{I.}\quad ROO^{\cdot} + KOH \rightarrow ROH + KOO^{\cdot} \quad ,$$
$$KOO^{\cdot} + R'O^{\cdot} \rightarrow KOR' + {}^{\cdot}OO^{\cdot}\,(=O_2) \quad ,$$
$$KOR' + H_2O \rightarrow KOH + R'OH \quad ,$$
$$\text{II.}\quad 4\,KOH + 3O_2 \rightarrow 4\,KOO. + 2H_2O \quad ;$$
$$KOO^{\cdot} + ROO^{\cdot} \rightarrow KOOR + O_2 \quad ,$$
$$KOOR + R'O^{\cdot} \rightarrow ROR' + KOO^{\cdot} \quad .$$

Peroxides of the type ROOM can be generated similarly from basic salts of other alkali metals. However, the details of this interesting mechanism require experimental tests.

The stabilisation probably involves mechanism (I) when the decomposition of peroxy-radicals is base-catalysed; in other cases, mechanism (II) may obtain. It is noteworthy that there is a correlation between the stabilising activity of alkali metal [and alkaline earth] hydroxides and the ability of the alkali metals to form peroxides; calcium and strontium hydroxides are exceptions.

Alkali metal hydroxides are also effective stabilisers of trioxan–dioxolan copolymers[48]. It is suggested that alkalies decompose hydroperoxides without breaking macromolecular bonds. Thus the secondary hydroperoxy-groups present in the polymer can react with KOH via the following mechanism:



$$-O-CH_2-O-\underset{}{\overset{OOH}{\overset{|}{C}H}}-O-CH_2- + K^{+}OH^{-} \rightarrow$$
$$\rightarrow -O-CH_2-O-\underset{\underset{OOH}{|}}{\overset{K^{+}\,(-)}{\ddot{C}}}-O-CH_2- + H_2O \rightarrow -O-CH_2-O-\overset{O}{\overset{\|}{C}}-O-CH_2- + KOH \quad .$$

It is noteworthy that an inhibiting activity of KOH is observed at comparatively low temperatures in the thermal decomposition of polyethylene[67,68]. This involves a decrease of the branching of the polymer, lowers the concentration of "weak" sites in the macromolecules, and prevents the formation of fragments with unsaturated terminal groups[68].

Nielsen[55,56] used iron and cerium compounds as stabilisers in the study of the oxidation of liquid siloxanes. It was found that below 150°C iron(III) compounds accelerate the thermo-oxidative degradation. At higher temperatures the same compounds have a stabilising effect, a definite Fe³⁺ concentration, ensuring the minimum rate of oxidation, corresponding to each temperature. The author believes that the following reactions occur in the degradation of liquid siloxanes.

Initiation:

$$\equiv SiCH_3 + O_2 \rightarrow \equiv SiCH_2 + {}^{\cdot}OOH \text{ and (or)}$$
$$\equiv SiCH_3 + O_2 \rightarrow [\equiv SiCH_2OOH] \rightarrow \equiv Si^{\cdot} + {}^{\cdot}OH + CH_2O \quad .$$

Chain propagation:

$$\equiv SiCH_2^{\cdot} + O_2 \rightarrow \equiv SiCH_2OO^{\cdot} \quad ;$$
$$\equiv SiCH_2OO^{\cdot} \rightarrow \equiv SiO^{\cdot} + CH_2O \quad ;$$
$$\equiv SiO^{\cdot} + O_2 \rightarrow \equiv SiOO^{\cdot} + O \quad ;$$
$$\equiv SiCH_3 + \equiv SiO^{\cdot} \rightarrow \equiv SiOH + \equiv SiCH_2^{\cdot} \quad .$$

Chain branching:

$$\equiv SiCH_2OOH \rightarrow \equiv Si^{\cdot} + {}^{\cdot}OH + CH_2O \quad ;$$
$$\equiv SiOOH \rightarrow \equiv SiO^{\cdot} + {}^{\cdot}OH \text{ or } \equiv Si^{\cdot} + {}^{\cdot}OOH \quad ;$$
$$HOOH \rightarrow 2{}^{\cdot}OH \quad ;$$
$$CH_2O + O_2 \rightarrow {}^{\cdot}CHO + {}^{\cdot}OOH \quad .$$

Chain termination:

$$\equiv Si^{\cdot} + {}^{\cdot}OH \rightarrow \equiv SiOH \quad ;$$
$$\equiv Si^{\cdot} + {}^{\cdot}OSi\equiv \rightarrow \equiv Si{-}O{-}Si\equiv \quad ,$$

etc.

It is suggested that free radicals are destroyed as a result of the reduction of the metal ion:

$$M^{x+1} + {}^{\cdot}R \rightarrow M^{x} + R^{+} \text{ (where } R^{\cdot} \equiv Si^{\cdot} \text{ or } \equiv SiCH_2^{\cdot}) \quad , \qquad (2)$$

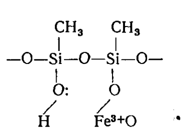
and that at a fairly high oxygen concentration there is a possibility of the regeneration of the metal ion M^{X+1} via the reaction

$$M^{x} + O_2 \rightarrow M^{x+1} + O_2^{-} \quad . \qquad (3)$$

Further studies[56] suggested also the occurrence of non-radical processes of the type $\equiv SiCH_3 + Fe^{3+}O$ complex $\rightarrow \equiv SiOH + Fe^{2+}$ complex followed by oxidation of the product and regeneration of the initial compound:

$$Fe^{2+} \text{ complex} + O_2 \rightarrow Fe^{3+}O \text{ complex.}$$

It is suggested that the stabilisation of liquid dimethylsiloxane by iron octoate [octanoate ?] involves the formation of a chelate structure of the type



There have been a number of other studies on stabilisation in the presence of metal ions. However, the majority of the results refer to low temperatures. Nevertheless, some of them are important in the consideration of high-temperature processes. We may mention a study[74] where the influence of variable-valence metals on the resistance of polyurethanes to thermo-oxidation was investigated. It was shown that, when the system contains hydroperoxides (120°C), its stabilisation is associated with the following reactions:

$$ROOH + M^{2+} \rightarrow M^{3+} + OH^{-} + RO^{\cdot} \quad ;$$
$$ROOH + M^{3+} \rightarrow RO_2^{\cdot} + H^{+} + M^{2+} \quad .$$

Presumably the oxidation of certain thermostable polymers at temperatures not exceeding 200–250°C in the presence of complex inhibitors can be described in terms of the scheme for the inhibited oxidation of hydrocarbons[74,108,109]:

$$\gamma \rightarrow r^{\cdot} \quad ;$$
$$r^{\cdot} + \text{polymer} + O_2 \xrightarrow{w_i} RO_2^{\cdot} \quad ;$$
$$RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{\eta k_6} \text{products} + h\nu \quad ;$$
$$MA_2 + L \overset{K_p}{\rightleftarrows} ML \quad ;$$
$$RO_2^{\cdot} + ML \xrightarrow{k_7} \text{inactive product} \quad ;$$
$$RO_2^{\cdot} + L \xrightarrow{k_7'} \text{inactive product} \quad ,$$

where γ is the initiator decomposing at a rate w_i, $r^{\cdot}$ the radical initiator, L the ligand (for example urethane) molecule, MA_2 the variable-valence metal salt, ML the molecule of the complex, η the overall chemiluminescence yield, and the constants k with the appropriate subscripts are the rate constants for the elementary reactions.

When the concentration of peroxy-radicals corresponds to a steady state and $[M] \gg [L]$, the following expression holds:

$$\frac{I_0 - I}{\sqrt{I_0 I}} = \frac{[MA_2]_0}{\sqrt{w_i k_6}} \left[\frac{k_7 \cdot K_p [L]_0}{1 + K_p [MA_2]_0} + k_7 \right] \quad , \qquad (4)$$

where I_0 and I are the initial and final intensities of illumination and K_p is the equilibrium constant. Eqn. (4) holds satisfactorily in many instances, which confirms the above stabilisation mechanism.

It has been noted[42] that, at temperatures of the order of 350°C and above, the mechanism of the stabilisation of polyorganosiloxanes in the presence of metal-phthalocyanines can be attributed not only to the interaction of the paramagnetic species with the radicals but also to trans-coordination accompanied by the formation of complicated chelate compounds.

The stabilising action of metals and their oxides at high temperatures is attributed by some workers[42,47,51,75,86] to the orienting effect of the dispersed particles, which serve as centres for the formation of secondary structures, or to the formation on degradation of new polymers with metal heteroatoms in the chain. These mechanisms do indeed occur, but they are not always decisive. There is no doubt that in a number of cases the stabilising action of many metals at high temperatures is largely associated with a non-chain inhibition reaction or with oxidation–reduction processes.

Analysis of a number of studies[29,51,56,74,75] has shown that the influence of metals and many inorganic compounds on the ageing of polymers cannot always be accounted for unambiguously. Thus it has been stated that iron and tin[74] salts, aluminium, chromium, zinc, phosphorus, and boron[76] oxides, and metallic lead and cadmium[51] accelerate the oxidation process under certain conditions. On the other hand, it has been noted in other investigations[5,75] that these compound have an inhibiting effect. Cobalt, copper, and cerium[74] salts and iron, magnesium, and other oxides[80] usually stabilise thermostable materials at temperatures in the range 300–390°C; at low temperatures or at 400°C and above, they do not inhibit or actually accelerate polymer decomposition processes[56,76,80]. Many apparent contradictions in the interpretation of the action of a wide variety of stabilisers used in the high-temperature ageing of polymers can be readily explained by taking into account the conditions under which the studies were carried out and also the characteristics of the methods, which are sometimes imperfect.

Examination of Table 1 in the preceding section shows that the use of non-chain inhibition processes leads to new possibilities for the solution of the problem of the stabilisation of thermostable polymers. This approach attracted the attention of investigators only in recent years[36,110-112] after the determination of the mechanism of stabilisation in the presence of oxygen acceptors, generated in polymer compositions or articles[4,19,20,38,113]. Subsequently Shustova showed that the application of a non-chain inhibition method can be sometimes effective in the stabilisation of thermostable materials, losing many of their useful properties under the influence of various chemical agents[37,111,186].

We shall now examine the characteristics of the mechanism of non-chain inhibition[4,37,112,114]. The oxygen acceptors generated in polymer compositions or acceptors introduced into the polymer during its processing may serve as highly effective inhibitors, preventing oxidative degradation via a non-chain inhibition mechanism. Acceptors of the first group exhibit a high activity already at room temperature and for technical reasons cannot therefore be introduced in the usual way. On the other hand, acceptors of the second type exhibit a low activity under these conditions, but become fairly effective at high temperatures.

We shall now consider the general kinetic scheme (A) for the oxidative degradation of polymers containing mobile hydrogen atoms involved in initiation processes[4,20].

I. Initiation:

$$\begin{array}{ll}
\text{weak bond} \xrightarrow{k_{\text{in}}} 2\dot{R}_{\text{pri}}\ ; & \text{(a)}\\
\dot{R}_{\text{pri}} + RH \xrightarrow{k'_{\text{in}}} R^{\cdot} + R_{\text{pri}}H\ ; & \text{(b)}\\
RH + O_2 \xrightarrow{k_0} R^{\cdot} + H\dot{O}_2\ ; & \text{(c)}\\
2RH + O_2 \xrightarrow{k'_0} 2R^{\cdot} + H_2O_2\ . & \text{(d)}
\end{array} \qquad \text{(A)}$$

II. Chain propagation:

$$R^{\cdot} + O_2 \xrightarrow{k_1} R\dot{O}_2 \quad ; \qquad \text{(a)}$$

$$\begin{array}{l}
R\dot{O}_2 + RH \xrightarrow{k_2} R^{\cdot} + ROOH \xrightarrow{k_3} \text{inert products;}\\
\quad\text{branching} \downarrow k_3\\
\quad\quad \text{products} \rightarrow 2R'^{\cdot} \quad .
\end{array} \qquad \text{(b)}$$

III. Chain termination:

$$R^{\cdot} + R^{\cdot} \xrightarrow{k_4} R{-}R$$

$$R\dot{O}_2 + R^{\cdot} \xrightarrow{k_5} ROOR$$

$$R\dot{O}_2 + R\dot{O}_2 \xrightarrow{k_6} \text{products.}$$

IV. Non-chain inhibition:

$$Z + O_2 \xrightarrow{k_2} \text{inert products.}$$

If k_Z is fairly high, it is possible to select conditions such that the oxygen reacts virtually only with Z and is not involved in other elementary reactions.

On the basis of published data[109,115,116], we shall adopt the following rate constants for the elementary reactions (Ic), (Id), and (IIa) and the concentrations of the components (250–350°C):

$$k_0 = 10^{-2} - 1 \text{ litre mole}^{-1}\,\text{s}^{-1};\ k'_0 = 10^{-3} - 10^{-1} \text{ litre}^2\,\text{mole}^{-2}\,\text{s}^{-1};$$

$$k_1 = 10^8 \text{ litre mole}^{-1}\,\text{s}^{-1}$$

$$[RH] = 10 \text{ M} \quad ; \quad [O_2] = 10^{-4} \text{ M} \quad ;$$

$$[R^{\cdot}] = 10^{-8} - 10^{-7} \text{ M} \quad .$$

The rates of the corresponding elementary processes involving oxygen are:

$$w_{RH+O_2} = k_0[RH]\cdot[O_2] = 10^{-5} - 10^{-3} \text{ mole litre}^{-1}\,\text{s}^{-1};$$

$$w_{2RH+O_2} = k'_0[RH]^2\cdot[O_2] = 10^{-5} - 10^{-3} \text{ mole litre}^{-1}\,\text{s}^{-1};$$

$$w_{R^{\cdot}+O_2} = k_1[R^{\cdot}]\cdot[O_2] = 10^{-4} - 10^{-3} \text{ mole litre}^{-1}\,\text{s}^{-1}.$$

Next we assume that $w_{Z+O_2} = 10^{-2}$ mole litre^{-1} s^{-1}. After recalculation for a heterogeneous process, these values correspond to the real case of the stabilisation at 350°C of siloxane elastomers by pyrophoric iron generated in the polymer on decomposition of iron oxalate[37,113] (iron concentration 5 wt.%; surface area $S \simeq 10$ m^2 g^{-1}; oxidation rate constant $k_{Fe} = 10^{-14}$ g^2 cm^{-4} s^{-1}).

Thus we have the following relation for a number of systems:

$$w_{Z+O_2} \gg w_{R^{\cdot}+O_2},\ w_{RH+O_2},\ w_{2RH+O_2}.$$

Bearing in mind that the equilibrium concentration of O_2 in polymers is low, it can be easily shown that, as long as Z does not react with oxygen, reactions (Ic), (Id), and (IIa) hardly play an appreciable role.

It is noteworthy that the above estimate is based on unduly low values of S and k_{Fe}. In real systems, it is possible to obtain pyrophoric metals with surface areas of 100 m^2 g^{-1} and more[117,118]. Furthermore, the oxidation rate constant may be greater than 10^{-14} g^2 cm^{-4} s^{-1}. Thus, in the presence of copper 350–400°C, we have $k \simeq 10^{-8}$ g^2 cm^{-4} s^{-1} and the rate of the reaction $Cu + O_2 \rightarrow Cu_2O \xrightarrow{O_2} CuO$ should reach 10^2 mole litre^{-1} s^{-1}.

When the mechanism of the oxidative degradation of polymers is known, it is easy to obtain quantitative criteria of the efficiency of the stabilisers Z. Thus, at low temperatures, when the oxidation of the polymer[109] proceeds in accordance with the classical mechanism A, one can usefully consider three cases.

If the oxygen concentration in the polymer is low and the reaction rate $-d[O_2]/dt$ is directly proportional to the oxygen pressure p_{O_2}, effective inhibition is observed when the following condition is fulfilled:

$$fk'_Z[Z] \gg \frac{k_1 w_{\text{in}}^{1/2}}{k_4^{1/2}},$$

where f is the number of oxygen molecules interacting with one stabiliser molecule ($fk'_Z \equiv k_Z$) and w_{in} is the rate of initiation.

At a high oxygen concentration in the polymer, when the rate of oxidation is independent of p_{O_2}, effective inhibition should be observed provided that

$$fk'_Z[Z] \gg \frac{k_2 w_{\text{in}}^{1/2}}{k_6^{1/2}}\,\frac{[RH]}{[O_2]}.$$

In the intermediate case, where chain termination in the absence of stabilisers proceeds via reactions (4)–(6), effective inhibition requires that

$$fk'_Z[Z] \gg \frac{k_2 w_{\text{in}}^{1/2}}{k_6^{1/2}}\,\frac{[RH]}{[O_2]}\,\gamma,$$

where

$$\gamma = f([O_2], [RH]).$$

As oxygen diffuses into the specimen, the stabiliser Z is consumed via reaction (IV), while the lifetime of the article is determined by the rate of diffusion of oxygen. Calculations have shown[4] that, even for polymers whose oxygen permeability coefficients are high and amount to approximately 10^{-6} cm^3/cm^2/s.cm/atm [cm^2 s^{-1} atm^{-1} ?],[4,119-122] the lifetime of specimens 0.1–1 cm thick can reach many tens and hundreds of hours in the temperature range 300–400°C.

As an example, we shall consider the specific instance where the entire oxygen diffusing into the system interacts with the active stabiliser Z and the lifetime of the specimen is determined by the rate of diffusion of oxygen[37, 38]. We assume that the lifetime of the polymer τ is equal to the time during which the specimen decomposes to the extent of 80% ($t_{80\%}$). If the specimen is a plate, oxygen diffuses from both sides and the two fronts of the reaction

$$Z + O_2 \rightarrow \text{inert product}$$

move at right angles to the surfaces of the plate towards the centre (there is no countercurrent diffusion of Z).

The following equation holds in this case:

$$P = -D_{O_2}(\partial c/\partial x), \tag{5}$$

where P is the permeability (the amount of substance transferred per unit time, per unit area, and per unit thickness at the normal concentration or pressure difference), D_{O_2} the diffusion coefficient, and $\partial c/\partial x$ the concentration gradient. Next, one can write

$$P = D_{O_2}\frac{[O_2]_0 - [O_2]_x}{x}, \tag{6}$$

where $[O_2]_0$ is the concentration of oxygen at the interface (mole cm^{-3}) and $[O_2]_x$ the concentration in the specimen at a depth x.

Having denoted by w' the specific rate of reaction between Z and O_2 (equal to the number of moles of Z which have reacted per unit time and per unit area in the reaction zone), we obtain

$$w' = [Z]\frac{dx}{dt}, \tag{7}$$

where [Z] is the concentration of the substance (mole cm^{-3}), x the distance (cm), and t the time (s).

Since the rate of reaction (assuming that one mole O_2 reacts with one mole of Z) is equal to the flux of oxygen in the reaction zone and $[O_2]_0 \gg [O_2]_x$, one can write

$$w' = [Z]\frac{dx}{dt} = \frac{D_{O_2}[O_2]_0}{x}, \tag{8}$$

$$x\,dx = \frac{D_{O_2}[O_2]_0}{[Z]}\,dt. \tag{9}$$

Integration of Eqn. (9) yields

$$\frac{x^2}{2} = \frac{D_{O_2}[O_2]_0}{[Z]}t.$$

Thus the movement of the reaction front in the specimen is described by a parabolic law.

Next we obtain

$$t_{80\%} \equiv \tau = \frac{x^2}{2}\cdot\frac{[Z]}{D_{O_2}\cdot[O_2]_0} \simeq k_0\frac{l^2[Z]}{D_{O_2}[O_2]_0}, \tag{10}$$

where l is the thickness of the specimen and k is a coefficient equal to approximately 0.1 and determined by the stoichiometry of reaction (IV) and the assumptions made.

Taking into account the temperature variation of D_{O_2} and $[O_2]$, we have

$$\tau = \frac{kl^2[Z]}{D_0e^{-E_D/RT}\cdot\sigma_0'\cdot e^{-\Delta H/RT}},$$

where E_D is the activation energy for diffusion, ΔH the heat of solution of the gas, and D_0 and σ_0' are the corresponding pre-exponential factors.

However, ΔH is small for many polymers (between −2 and +2 kcal mole^{-1}), and one can therefore assume that

$$\tau = k\frac{l^2[Z]}{D_0e^{-E_0/RT}[O_2]_0}. \tag{11}$$

Since the diffusion coefficients in polymer compositions may be low, of the order of 10^{-8} and even 10^{-9} cm^2 s^{-1}, the lifetimes of polymeric materials can reach many thousands of hours.

Eqns. (10) and (11) have been obtained on the assumption that, in the absence of a stabiliser Z, the polymer decomposes almost at once. In the general case, the following expression is valid:

$$\tau = k\frac{l^2[Z]}{D_{O_2}[O_2]_0} + \tau' = k'l^2[Z] + \tau', \tag{12}$$

where τ' is a quantity comparable to the lifetime of the non-stabilised specimen.

Eqn. (12) has been obtained for the case where there is no diffusion of the stabiliser and the changes in the concentration of oxygen owing to its reaction with a polymer may be neglected. A detailed mathematical model without allowance for these limitations has been examined[39, 110] and it has proved possible to explain theoretically the causes of the appreciable deviations from Eqn. (12) for fairly large thicknesses of the polymeric specimens. It has also been shown that τ' may be set equal to the lifetime of the non-stabilised specimen only for highly efficient stabilisers such that $\tau' \ll \tau$. If the stabilisation effects are small, one must bear in mind that

$$\tau' = t_p + (2t_pt_D^{(1)}\alpha)^{1/2}.$$

where t_p is the polymer decomposition time subject to the condition that the concentration of oxygen is $[O_2]_0$ at all points in the polymer, $t_D^{(1)} = l^2/D_{O_2}$ is the time required by oxygen to diffuse into the specimen, and $\alpha = [Z]_0/\nu[O_2]_0$, ν being the stoichiometric coefficient of non-chain inhibition (the number of stabiliser molecules which have reacted with one oxygen molecule).

If the stabiliser Z inhibits not only oxidative but also thermol degradation and interacts with the primary radicals forming stable compounds of the type RZ (chain inhibition), then a simplified kinetic mechanism (B) of inhibited degradation is valid in the simplest instance:

$$\text{I.}\quad \text{weak bond} \xrightarrow{k_{in}} \dot{R}_{pri}\;;$$

$$\text{II.}\quad \dot{R}_{pri} + Z \xrightarrow{k_Z'} R_{pri}Z\;;$$

$$\text{III.}\quad O_2 + Z \xrightarrow{k_Z} \text{inert products.}$$

The mechanisms (A) and (B) described above do not take into account the possibility of chain-transfer processes via the stabiliser ($R_1R_2 + Z^{\cdot} \rightarrow R_1^{\cdot} + ZR_2$) and certain other elementary reactions. However, the satisfactory agreement of the calculations with the experimental results shows that the mechanism of the stabilisation processes considered here can operate[37, 38].

We shall now consider certain reactions of the type $Z + O_2 \rightarrow$ inert products which may be important for the stabilisation of polymers. It has been mentioned in the literature that the oxidation of organic compounds is inhibited by inorganic substances such as sulphides, phosphorus compounds, arsenic, antimony, bismuth, boron, silicon, tin, lead, sulphur, and others[123]. However, the mechanisms of these reactions have not been studied in detail and some of the above substances have not been used at all to stabilise polymeric materials[5].

Demonstration of the possibility of inhibition via a non-chain mechanism[4,37] necessitates the study of the rates of interaction of the above inhibitors with oxygen in order to find the optimum conditions for their utilisation as stabilisers. Together with classical data, quantitative studies published in recent years are considered below.

The kinetics of the oxidation of cobalt sulphide have been investigated[124] and it has been shown that, at temperatures of the order of 500°C, the process is described satisfactorily by the equation

$$\frac{d\alpha}{dt}=K(1-\alpha)^n,$$

where α is the degree of oxidation, $K = f(T, P_{O_2}, S_0)$ and n are constants, P_{O_2} is the oxygen pressure, and S_0 the surface area of the specimen.

It has been established[125] that Co_9S_8 is vigorously oxidised at 200°C with formation of the complex $Co_9S_8O_8$. The temperatures of the maximum rates of oxidation of the sulphides Sb_2S_3, AlFeS, FeS, Cu_3FeS_3, $CuFeS_2$, Fe_7S_8, MoS_2, ZnS, PbS, Cu_2S_3, CdS, and others, have been determined in a number of studies[126], and the reaction mechanisms have been established[127]. Thus it has been shown that chalcopyrite is oxidised via the mechanism

$$n\,CuFeS_2 + 4O_2 = 2\,FeO + Cu_2S\,(n-2)\,CuFeS_2 + 3SO_2 \quad ;$$
$$3\,FeO + \frac{1}{2}O_2 = Fe_3O_4 \quad ;$$
$$2\,Fe_3O_4 + \frac{1}{2}O_2 = 3\,Fe_2O_3,$$

and that the mechanism of the oxidation of iron and copper sulphides is[128]:

$$2\,FeS \xrightarrow{O_2} [2FeSO \xrightarrow{O_2} 2\,FeSO_2 \rightarrow Fe_2SO_3\cdot 2SO_2] \xrightarrow{-2SO_2} Fe_2O_3 \quad ;$$
$$Cu_2S \xrightarrow{O_2} [Cu_2SO \xrightarrow{O_2} Cu_2SO_2 \xrightarrow{O_2} Cu_2SO_3 \xrightarrow{-SO_2} Cu_2O\cdot SO_2] \xrightarrow{O_2} Cu_2O \rightarrow 2CuO \quad .$$

We may note that many sulphides are also effective synergistic agents, decomposing peroxides via a molecular mechanism[129,130]. Thus it has been shown[130] that WS_2 appreciably reduces the yield of radicals in the decomposition of hydroperoxides, while increasing its rate.

Antimony is slowly oxidised below 350°C, while at 500°C the process is rapid and involves the formation of Sb_2O_3 and then Sb_2O_4.[131] Vigorous oxidation of silicon and lead is observed above 400°C.[132-134]

The oxidation of a number of variable-valence metal hydroxides has been thoroughly studied, namely the oxidation of $Fe(OH)_2$, $Co(OH)_2$, $Mn(OH)_2$, etc. Manganese(II) hydroxide absorbs oxygen vigorously even at low temperatures[135]:

$$Mn(OH)_2 + \frac{1}{2}O_2 \rightarrow MnO_2 + H_2O \quad .$$

Certain variable-valence metal oxides are also effective oxygen acceptors[136-138]. For example, the kinetics of the oxidation of CoO in accordance with the equation

$$3\,CoO + \frac{1}{2}O_2 \rightarrow Co_3O_4$$

can be described by the equation

$$1-(1-\alpha)^{1/3} = kt \quad ,$$

where k is a constant.

Dithionites (for example sodium hyposulphite $Na_2S_2O_4$) can be used as oxygen absorbers. In the presence of alkalies, they readily interact with O_2 in the following way[132]:

$$S_2O_4^{2-} + 2OH^- + O_2 \xrightarrow{MOH} SO_4^{2-} + H_2O.$$

However, dithionites are as a rule unstable and decompose on heating:

$$2M_2^I\,S_2O_4 \xrightarrow{t^\circ > 100^\circ} M_2^IS_2O_3 + M_2SO_3 + SO_2.$$

The double salts of alkali metals and zinc dithionite ZnS_2O_4 are more stable.

Sulphites[139-141], pyrogallol mixed with alkalies[142-145], and other compounds[135,146,147] can sometimes serve as oxygen acceptors in model reactions.

Highly dispersed metals generated in polymers at high temperatures are active oxygen acceptors. Thus, copper with a high surface area absorbs oxygen even at low temperatures[148]. In the temperature range 400–500°C, the rate of the process is extremely high, but owing to the high dissociation pressure of CuO, oxygen cannot be removed completely from the system at these temperatures[135]. Metallic silver and silver on carriers (Al_2O_3, etc.) absorb O_2 at temperatures of 200–300°C; palladium catalyses the reaction of H_2 with O_2 at low temperatures, which proceeds rapidly and completely[149-151]. Finely dispersed iron reacts vigorously with oxygen even at low temperatures, forming oxides[117,149-152]. The thermodynamics of the oxidation of metals and various substances in the solid phase has been thoroughly studied[149-151]. Studies devoted to the thermodynamic aspects of the protection of highly thermostable materials against oxidation by the introduction of metals have also been made[153].

The kinetics of the oxidation of solids are frequently complex and, depending on their nature, the nature of the surface, and the thickness of the oxide film, are described by equations of different types[117,118,135,149-151,154,155]. For a constant concentration gradient of the component diffusing during oxidation, a parabolic law holds:

$$(\Delta l')^2 = 2k't \quad \text{or} \quad \left(\frac{\Delta m}{s}\right)^2 = k''t, \tag{13}$$

where l' is the thickness of the oxide layer (cm), k' a constant ($cm^3\ s^{-1}$), $\Delta m/s$ the increase in the weight of the oxide per unit area ($g\ cm^{-2}$), and k'' another constant ($g^2\ cm^{-4}\ s^{-1}$).

If the rate of oxidation is determined at interfaces, the following linear law holds:

$$\frac{\Delta m}{s} = k'''t, \tag{14}$$

where k''' is a constant ($g\ cm^{-2}\ s^{-1}$).

In a more complex case, where account must be taken of both laws, the following equation is frequently valid:

$$\frac{\Delta m}{s}\cdot\frac{1}{k'''} + \left(\frac{\Delta m}{s}\right)^2\frac{1}{k''} = t. \tag{15}$$

A cubic relation between $\Delta m/s$ and time is observed in the oxidation of very thin films or superdisperse metals:

$$\left(\frac{\Delta m}{s}\right)^3 = k_c''t \quad , \tag{16}$$

where k_c'' is a constant ($g^3\ cm^{-6}\ s^{-1}$); sometimes logarithmic or inverse logarithmic relations are valid:

$$\begin{aligned}\Delta l' &= k_1 - \text{const}\cdot\ln t,\\ \frac{1}{\Delta l'} &= k_1 - \text{const}\cdot\ln t.\end{aligned} \tag{17}$$

The use of Eqns. (13)–(17) makes it possible to calculate the rates of reactions Z + O_2 →inert product as a function of the degree of dispersion of the substance (metal, sulphide, etc.) and one can find the optimum conditions for the employment of the polymer stabilised by one or other active stabiliser.

If a highly active stabiliser Z exists in the polymer in an atomic, molecularly disperse, or finely disperse state, the rate of its oxidation is determined, as already stated, by the diffusion of oxygen into the specimen and the movement of the reaction front (in the absence of counter-current diffusion of Z) obeys a parabolic law rigorously.

IV. THE GENERATION OF HIGHLY ACTIVE STABILISERS IN POLYMERIC COMPOSITIONS

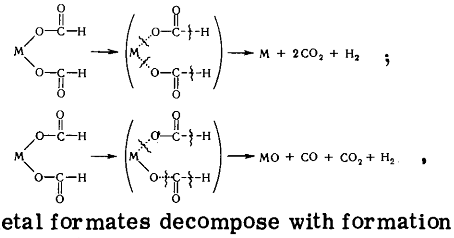
Many chemical processes yielding highly active compounds which are effective acceptors (absorbers) of oxygen or free radicals are known. Many of these reactions can be used for the high-temperature stabilisation of polymers or can serve as models for a detailed study of the mechanism of the inhibited ageing of thermostable polymeric materials. Naturally, in view of the wide variety of mechanisms of such processes, the conditions governing their occurrence, and the subsequent reactions of their products, in choosing the stabilising systems account must be taken of the characteristics of the particular polymeric system.

We shall consider a number of processes involving the generation of highly active stabilisers, which can serve as models. The formation of finely dispersed metals and lower-valence metal oxides from organic salts of the metals is of greatest interest[75,132,137].

Table 2. Temperature ranges corresponding to the decomposition of formates[156].

Formate	Temp. range of decompn., °C	Gaseous decomposition products
$Na(HCOO)$	320—420	H_2, CO, CO_2, CH_4 etc.
$K(HCOO)$	360—480	ditto
$Ca(HCOO)_2$	400—495	»
$Sr(HCOO)_2$	340—500	»
$Ba(HCOO)_2$	400—460	»
$Mg(HCOO)_2$	330—460	»
$Mn(HCOO)_2$	260—410	»
$Zn(HCOO)_2$	210—360	»
$Cd(HCOO)_2$	230—305	»
$Cu(HCOO)_2$	170—225	only H_2, CO, CO_2, and CH_4
$Co(HCOO)_2$	245—300	ditto
$Ni(HCOO)_2$	260—290	»
$Pb(HCOO)_2$	260—340	»

The decomposition of various formates, which can result in the formation of pyrophoric metals or their oxides is well known. Cobalt, nickel, copper, and lead formates decompose via the following mechanisms[156]:



while alkali metal formates decompose with formation of oxalates and carbonates:

$$2\,HCOOM \begin{cases} \nearrow M_2C_2O_4 + H_2 \\ \searrow M_2CO_3 + H_2 + CO \end{cases} .$$

Side reactions of the type

$$3H_2 + CO \rightarrow CH_4 + H_2O \quad ;$$
$$2H_2 + CO \rightarrow CH_3COH \quad ;$$
$$H_2 + CO \rightarrow HCHO \quad ;$$
$$2\,HCHO \rightarrow HCOOCH_3 \quad ,$$

occurring in the decomposition of these substances, lead to the formation of other products. However, the role of side reactions in the decomposition of cobalt, nickel, copper, and lead formates is small and the main products are M, MO, CO, CO_2, and H_2.

Tables 2 and 3 present data for the decomposition reactions of various formates[156].

Table 3. The ratios of the amounts of reaction products in the decomposition of certain formates[156].

Formate	$[M^{2+}]/[M^{2+}+M]$, %	$[CO]/[CO+CO_2]$, %	Formate	$[M^{2+}]/[M^{2+}+M]$, %	$[CO]/[CO+CO_2]$, %
$Co(HCOO)_2$	49.1	24.5	$Cu(HCOO)_2$	9.6	4.0
$Ni(HCOO)_2$	19.7	10.3	$Pb(HCOO)_2$	16.3	7.5

The metals and their oxides can be readily generated by the decomposition of the oxalates (Table 4). The process can be described by the general mechanism

$$M(COO)_x \rightarrow M + CO + CO_2 + M_nO_m \quad .$$

It presupposes the occurrence of various reactions of the following type[157-160]:

$$M(COO)_2 \rightarrow M + 2CO_2 \quad ;$$
$$M + CO_2 \rightarrow MO + CO \quad ;$$
$$M(COO)_2 \rightarrow MO + CO + CO_2 \; ;$$
$$MO + CO \rightarrow M + CO_2 \quad , \text{etc.}$$

The oxalates of transition metals, for example iron and nickel, decompose with formation by pyrophoric products:

$$FeC_2O_4 \rightarrow Fe + 2\,CO_2\,(FeO + CO + CO_2) \; ;$$
$$NiC_2O_4 \rightarrow Ni + 2\,CO_2,$$

while alkali and alkaline earth metal oxalates are converted into stable oxides on decomposition, for example:

$$MgC_2O_4 \rightarrow MgO + CO + CO_2 \quad .$$

Table 4. Temperature ranges corresponding to the decomposition of oxalates[159,160,162,163].

Oxalate	Temp. range of decompn., °C	Oxalate	Temp. range of decompn., °C
$Mg(COO)_2$	390—430	$Ni(COO)_2$	200—290
$Mn(COO)_2$	340—370	$Cu(COO)_2$	270—330
$Fe(COO)_2$	320—340	$Ag(COO)_2$	100—160
$Co(COO)_2$	310—330	$Zn(COO)_2$	310—350
$Ni(COO)_2$	260—320	$Pb(COO)_2$	310—370

The kinetics of the decomposition of oxides are frequently described satisfactorily by Erofeev's equation[157,159-161]:

$$\alpha = 1 - \exp(-kt^n).$$

When metals are used as radical acceptors, one must also take into account their efficiency as chain-transfer agents and their capacity to abstract certain atoms from molecules[181]. These reactions may lead to initiation rather than inhibition of the decomposition of the polymer.

At relatively high temperatures, polymer chain decomposition processes may be retarded by radical acceptors such as CO, SO_2, etc.; these compounds enter into copolymerisation type reactions, which lead to the formation of the radicals $R{-}CO^{\cdot}R{-}SO_2^{\cdot}$ and others which are less reactive than the initial radicals $R^{\cdot}$.[179]

The use of clathrate compounds occupies a special place among methods for the generation of stabilisers[4,182]. This procedure has been called the "structural-chemical stabilisation of the filler or stabilisers". A very active stabilising substance in such compounds is structurally isolated and cannot interact with oxygen and other chemical agents when it is introduced into the polymer. On the other hand, during heat treatment or employment of the polymer the clathrate compound decomposes with liberation of the stabiliser.

A satisfactory model whereby one can investigate the generation of a stabiliser of this type is provided by vinyl polymerisation in the presence of the amylose–I_2 complex[182]. The processes occurring in such a system can be represented as follows:

1. Decomposition of the initiator: initiator $\rightarrow 2R^{\cdot}_{pri}$ (w_{decomp}).
2. Decomposition of the clathrate compound (generation of the inhibitor): clathrate compound $\rightarrow I_2$ (w'_{decomp}).
3. Initiation: $R^{\cdot}_{pri} + Mo \rightarrow R^{\cdot}_i$.
4. Chain propagation: $R^{\cdot}_n + Mo \xrightarrow{k_p} R^{\cdot}_{n+1}$.
5. Biradical chain termination: $R^{\cdot}_n + R^{\cdot}_m \xrightarrow{k_0}$ products.
6. Chain termination by the inhibitor:

$$\begin{aligned} &R^{\cdot}_n + I_2 \xrightarrow{k'_0} RI + I^{\cdot} \quad ; \\ &R^{\cdot}_n + I^{\cdot} \xrightarrow{k''_0} RI \quad . \end{aligned} \tag{C}$$

Here $R^{\cdot}_{pri}$ is a primary radical, Mo the monomer, $R^{\cdot}$ the growing radicals, and w_{decomp} and w'_{decomp} are the rates of decomposition of the initiator and the clathrate compound.

It follows from mechanism (C) that the rate of inhibited polymerisation w_{inh} is

$$w_{inh} = k_p\,[R^{\cdot}]\,[Mo] = \frac{k_p}{k_0^{1/2}}\,[Mo]\,(w_{in} - w_{I\,gen})^{1/2} \quad ,$$

where w_{in} and w_{gen} are the rates of initiation and generation of the inhibitor. Next it is easy to show that the following relation holds:

$$\lg\,(w_n^2 - w_{inh}^2) = \text{const} - \frac{2E_p - E_0 + E_{gen}}{2.3\,R} \cdot \frac{1}{T} \, ,$$

where w_n is the rate of the non-inhibited reaction and the quantities E with the appropriate subscripts are the activation energies for the corresponding processes.

Fig. 1 presents the variation of $\lg w$ with $1/T$ for the case under consideration; evidently, at a certain temperature the process begins to be sharply retarded owing to the generation of a powerful inhibitor on decomposition of the clathrate compound.

V. INTERPRETATION OF CERTAIN QUANTITATIVE RESULTS

It is seen from the above data that there is much evidence for the mechanisms of both chain and non-chain inhibition of the ageing processes of thermostable polymers. The chain inhibition mechanisms have already been investigated for a long time, but many of these are based on all possible hypotheses and analogies: hardly any constants for the elementary processes are available. This is probably because of the lack of a single general mechanism of inhibited degradation. On the other hand, although the mechanisms of non-chain inhibition have been discovered only recently in many important instances[4], their validity can be readily demonstrated because of their considerable generality.

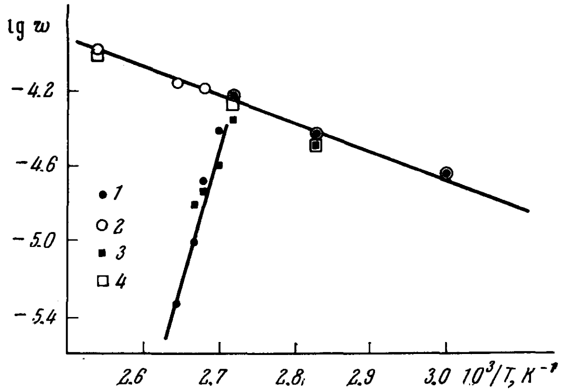


Figure 1. Variation of the logarithm of the rate of polymerisation of styrene at a constant rate of initiation with the reciprocal of temperature; $w_{in} = 3 \times 10^{-7}$ mole litre^{-1} s^{-1}; initiators: azobisisobutyronitrile ($T < 95°C$) and cumenyl peroxide ($T \geqslant 95°C$): 1) 18 g litre^{-1} of clathrate compound $\{[I_2] = 7 \times 10^{-4}$ M$\}$, dimethylformamide (DMF): styrene (ST) = 2.1; 2) clathrate compounds absent, DMF : ST = 2 : 1; 3) 18 g litre^{-1} of clathrate compound $\{[I_2] = 7 \times 10^{-4}$ M$\}$, DMF : ST = 5 : 1; 4) clathrate compounds absent, DMF : ST = 5 : 1.

Bearing in mind the possibility of non-chain inhibition in the presence of metal oxides, sulphides, and other compounds, it is possible to explain certain previously incomprehensible facts. Thus the stabilising activity of cobalt and other metal acetylacetonates[183] can be attributed not only to the termination of oxidation chains but also to the absorption of O_2 via a non-chain inhibition reaction. Similarly, other systems containing Co^{2+} [146,147,171] can convert oxygen into an ionic form and hence into a state which is inactive from the standpoint of the radical mechanism:

$$Co^{2+} + O_2 \rightarrow Co^{3+} + O_2^- \, . \tag{18}$$

It is noteworthy that reaction (18), which can be represented in the general case by Eqn. (3), is frequently one of the elementary stages in the chain mechanism and can also be classified as a non-chain inhibition process. However, the lack of quantitative data precludes the assessment of its importance in stabilisation.

The stabilising activity of certain sulphides[5], colloidal metals formed electrolytically in the polymer[75,184], and other compounds[53,67,72,185] can be attributed, as already pointed out, not only to a chain mechanism but also to a non-chain inhibition reaction between Z and O_2.

We have obtained a number of results which make it possible to demonstrate the possibility of the inhibition of the oxidative degradation of polymers by a non-chain procedure and to explain certain facts known previously. Thus the proposed stabilisation mechanism[4,37,113] operates when high-temperature oxidative ageing (300–500°C) of polyorganosiloxanes stabilised by active oxygen acceptors (Fe, Cu, Co, NiO, FeO, etc.), generated by the decomposition of the oxalates in the polymeric materials, is investigated. The non-chain mechanism of the stabilisation of polyorganosiloxanes in the presence of Fe, FeO, and Cu is proved by the following data:

1. The amount of oxygen acceptor generated in the polymer on decomposition of the oxalates corresponds to the amount calculated for the reactions

$$M(COO)_2 \rightarrow M + 2CO_2 \quad ;$$

$$M(COO)_2 \rightarrow MO + CO + CO_2 \quad .$$

2. As oxygen diffuses into the specimen, the entire metal (oxide) is converted into the corresponding stable oxide:

$$M + O_2 \rightarrow M_nO_m \quad ;$$

$$MO + O_2 \rightarrow M_nO_m \quad . \tag{19}$$

3. The polymer, which is almost immediately decomposed in the absence of a stabiliser, in the presence of metals (acceptors) begins to decompose vigorously only after the entire metal has been consumed.
4. The theoretical equation (12) holds satisfactorily.
5. The calculated value of τ agrees well with the experimental value.
6. The rates of reaction of O_2 with RH and $R^{\cdot}$, calculated from the rate constants and concentrations of the components, are much lower under the experimental conditions than the rate of reaction (19).
7. The stabilisation effect is determined by the ability of the metal or the lowest-valence metal oxide to form a stable oxide and by the rate of absorption of oxygen under the experimental conditions.

Data for the stabilisation of thermostable polymers in the presence of metals or their mixture with the lowest-valence metal oxides, generated on the decomposition of the oxalates and other compounds in polymers, are presented below. Henceforth it is assumed that oxygen is accepted by the metal–oxide mixture, which will be referred to for brevity as the metal.

Fig. 2 illustrates the variation of the relative elongation and tensile strength of a siloxane rubber. Evidently the specimens stabilised by finely dispersed metals retain their properties over a period 3–4 times longer than the specimens stablised by one of the best stabilisers known previously for this system—redoxide.

Table 8 shows that specimens of the polymer based on methylphenylsiloxane, stabilised by finely dispersed Fe and CoO, retain their properties within permissible limits for a longer period than the specimens stabilised by one of the best stabilisers based on a cerium(III) salt.

Table 9 presents data for the absorption of oxygen by specimens[112] containing finely dispersed metals generated in the polymer. Evidently the amount of absorbed oxygen is close to the value calculated for the reaction Z + O_2 → oxide; certain deviations from the calculated values are associated with the additional absorption of oxygen by the surface layer of polymer, after the consumption in the latter of the stabiliser, and with certain other unspecified factors.

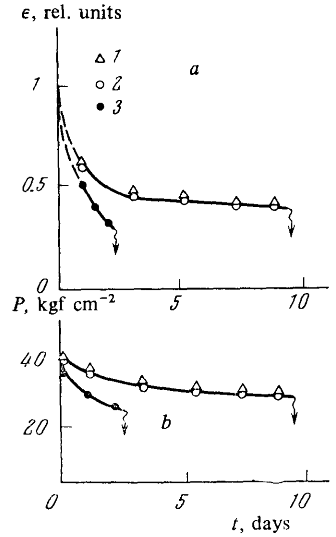

Figure 2. Variation of the relative elongation ϵ (*a*) and the tensile strength P (*b*) of methylphenylsiloxane rubber specimens during thermal ageing at 350°C: 1) stabilisation by finely dispersed Fe; 2) stabilisation by finely dispersed Cu; 3) stabilisation by Fe_2O_3 (redoxide); the arrows indicate the instant of decomposition of the specimens. The initial values of ϵ amount to 200–300%.

Table 8. The ageing of a polymer based on methylphenylsiloxane at 400°C in air [TiO_2 filler (30%); thickness of polymer specimen 1 mm (according to Shustova)].

Stabiliser (1%)	Time corresponding to retention of initial strength, h(P_0 = 15 kgf cm^{-2})	Time elapsed at instant corresponding to 60% relative elongation ϵ on rupture*, h
Without stabiliser	5.0	5.0*
Cerium(III) salt	7.0	10.0*
CoO	12.0	19.5*
Fe	24.5	19.5**

* ϵ_{init} = 100%.
** ϵ_{init} = 160%.

Fig. 3 illustrates the variation of the lifetime of trimethylcyclopolysiloxane films of different thickness in air at 400°C in the presence of finely dispersed iron[37] and Fig. 4 presents the kinetic curve for the absorption of oxygen. The region where the rate of absorption of O_2 represented by the curve in Fig. 4 decreases is consistent with the lifetime of the specimen τ_{crack} and corresponds to the instant of the complete consumption of the stabiliser via the reaction $Fe \xrightarrow{O_2} Fe_2O_3 + Fe_3O_4$. It also follows from

Fig. 4 that the initial rate of absorption of oxygen by the specimen w_{inh}^{i} is approximately four times greater than the rate of oxidation of the polymer w after the consumption of the stabiliser. Even if it is assumed that the oxidation of the stabiliser proceeds in the kinetic region, we have $4w = w_{\mathrm{inh}}^{i}$. The latter implies that the fundamental criterion of non-chain inhibition holds satisfactorily in the initial instant and the stabilisation under the given conditions is largely associated with the reaction of the finely dispersed iron with oxygen. Figs. 3 and 4 show that Eqn. (12) holds satisfactorily for the system investigated.

Table 9. The absorption of oxygen in the polymer by the stabiliser generated in a trimethylcyclopolysiloxane specimen (400°C).

Stabiliser	Reaction	Amount of O_2 absorbed by specimen, cm^3	
		calc.	expt.
Fe	$Fe + O_2 \rightarrow Fe_2O_3\ (Fe_3O_4)$	1.00	1.02
		1.28	1.33
Cu	$Cu + O_2 \rightarrow Cu_2O \rightarrow CuO$	1.00	1.05
		1.30	1.32

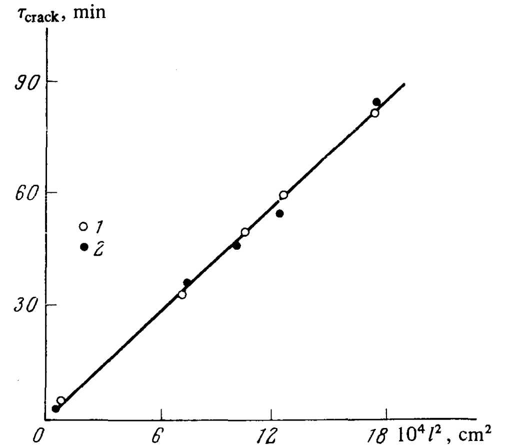

Figure 3. Variation of the lifetime τ_{crack} of hardened trimethylcyclopolysiloxane films stabilised by finely dispersed Fe {[Fe] = 0.3 mole kg^{-1}} with the square of the thickness of the specimen l^2 at 400°C; the lifetime of the specimens was determined from the cracking of the films (1) and from the absorption of oxygen (2).

Figs. 5 and 6 present the results[186,187] of the determination of the time required for the consumption of the stabiliser and the lifetime of polymer compositions based on trimethylcyclopolysiloxane stabilised by finely dispersed iron at 500°C. As the iron is converted into the iron(III) oxide, the intensity of the signal with $g = 2.0$ increases, the increase terminating at the instant τ_{ESR}.

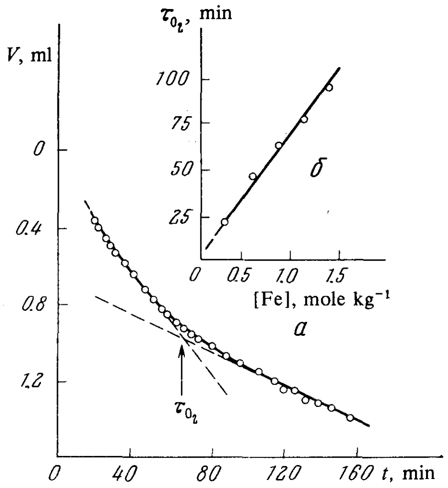

Figure 4. Kinetics of the absorption of oxygen by trimethylcyclopolysiloxane film {l = 140–150 μm, [Fe] = 0.3 mole kg^{-1}} stabilised by pyrophoric iron (a) and the variation of the lifetime of the specimen τ_{O_2} with the concentration of pyrophoric iron ($б$).

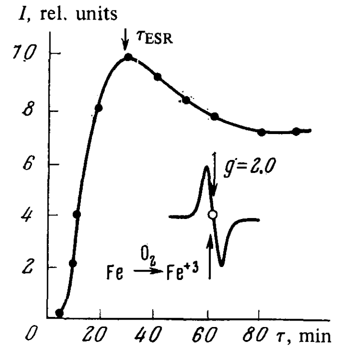

Figure 5. Determination of the time required for the consumption of the stabiliser τ_{ESR} in trimethylcyclopolysiloxane films {l = 160 μm, [Fe] = 0.3 mole kg^{-1}} by ESR from the variation of the signal intensity I (rel. units) at 500°C.

Thus the values of τ determined by the "cracking" method (τ_{crack}), by measuring the rate of absorption of oxygen (τ_{O_2}), and by ESR (τ_{ESR}) agree satisfactorily with one another[186,187].

It is noteworthy that, in the study of the degradation of thick films, deviations are observed from the parabolic law [Eqn. (12)], owing to the considerable absorption of oxygen by the polymer after the consumption of the stabiliser[39,110].

Table 10 lists the rates of the non-chain inhibition reaction $Z + O_2 \rightarrow$ oxide (recalculated in terms of the rate of the homogeneous process) evaluated to within a factor of 3 using the experimental data and the parabolic equation (13). It follows from Table 10 that the general phenomenological criterion (see Section III) $w_{Z+O_2} \gg w_{R+O_2}$, w_{RH+O_2}, w_{2RH+O_2} holds satisfactorily.

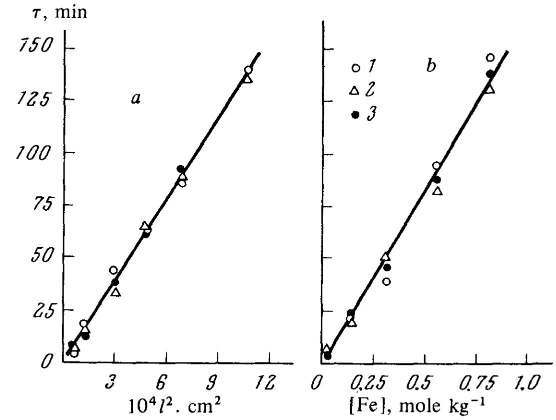

Figure 6. Dependence of the lifetime of trimethylcyclopolysiloxane polymeric films, stabilised by finely dispersed iron in the presence of components decomposing with evolution of H_2, on the square of the thickness of the specimen (*a*) and on the stabiliser concentration (*b*); the lifetime of the film specimens was determined from their cracking (1), from the absorption of oxygen (2), and by the ESR study of the consumption of the stabiliser (3).

Table 10. The rates *w* of the reaction between Z and O_2 in oxidative degradation calculated from experimental data[117,149,151,188] (350°C).

Stabiliser generated in polymer (5%)	Specific surface, $cm^2\ g^{-1}$	*w*, mole $litre^{-1}\ s^{-1}$
Fe	10	10^{-2}
	100	10^{-1}
Cu	10	10^{-1}
	100	1

The results presented suggest that, together with the chain inhibition methods, the procedures for the non-chain inhibition of oxidative degradation can be used successfully to stabilise many thermostable polymers.

Recently devised tests make it possible to estimate the reactivities of non-chain inhibition stabilisers[163]. Furthermore, a group of tests has been devised whereby one can estimate the reactivities of any inhibitors in radical chain reactions[40,189-191].

Apart from their practical importance, these studies are of theoretical interest. Thus it has been possible to show that the rate constants for many bimolecular radical reactions have a constant pre-exponential factor of $10^{7.2\pm0.2}$ (litre $mole^{-1}\ s^{-1}$) in the liquid phase and $10^{8.8\pm0.1}$ (litre $mole^{-1}\ s^{-1}$) in the gas phase[190,191]. Subsequently Tsepalov established that the pre-exponential factors for these reaction rate constants are different only in the case of radical substitution reactions. For many radical recombination reactions in both liquid and gaseous phases, the pre-exponential factors are $10^{8.8}$. It has also been established that the absolute values of the rate constants for these reactions in the gaseous and liquid phases are identical, which suggests that the rate constants are indeed elementary only for reactions with a constant pre-exponential factor of $10^{8.8}$ litre $mole^{-1}\ s^{-1}$. In reactions with a constant pre-exponential factor of $10^{7.2}$ litre $mole^{-1}\ s^{-1}$, the rate constants are apparently effective quantities produced by a combination of two or several elementary rate constants.

Studies have been published recently on the mechanism of the formation and degradation of metallopolymers[192-195]. It has been shown that these materials as well as certain polymeric and other heterogeneous compositions in which metals were generated[196,197] possess valuable properties. However, the increased resistance of these systems to thermo-oxidative degradation is not attributed by these workers[192-195], as in earlier studies[75,197], to the interaction of the active metals with oxygen, i.e. to non-chain inhibition processes[20,37,38]. As a rule, these studies[192-195,197] were carried out under conditions such that the rates of the thermal degradation reactions of the metallopolymers may be limited by the diffusion of oxygen and the degradation products. In many cases the high termo-oxidative stability of metallopolymers as well as polymers stabilised by metals[4,5,35,69,198] may be attributed not only to the nature of these materials but also to their stabilisation via a non-chain inhibition mechanism.

Interesting results have been obtained for the oxidation of polyethylene melts on metallic surfaces and in the presence of finely dispersed metals[199,200]; the characteristics of these processes can be explained in conjunction with known chain and non-chain inhibition mechanisms.

The non-chain inhibition of oxidative degradation at high temperatures is effective when pyrophoric lower-valence metal oxides, such as FeO and CoO, [37] sulphides, finely dispersed silicon, [201] and other oxygen acceptors[202,203] are used. The authors of this review have shown recently that the stabilisation of organosilicon coatings by FeO and by silicon makes it possible to increase by a factor of several tens their useful life at temperatures in the range 500–1000°C.

Modern Ideas About the Mechanism of the Formation of the Structure of Graphitising Coke

B.N.Smirnov, L.S.Tyan, A.S.Fialkov, T.Yu.Galkina, and G.S.Galeev

The review considers studies on the mechanism of low-temperature carbonisation, which determines the fundamental structural characteristics of carbonaceous materials. Particular attention has been devoted to the mesophase transformation as the principal factor responsible for the formation of the structure of graphitising coke. The structural features of various types of coke, whose formation proceeds via the mesophase transformation stage, are described.
The bibliography includes 53 references.

CONTENTS

I. INTRODUCTION

The unique properties of carbon-graphite materials have ensured their wide-scale application in various branches of modern engineering. The development of the technology of their manufacture has required the solution of many complex problems associated with the preparation of materials having specified properties. The principal raw materials in the technology of carbon-graphite materials are petroleum, pitch, and shale coke, which are converted into graphite on heat treatment at 2300°C and above. The raw materials for the preparation of such coke consist of heavy hydrocarbon residues from the processing of petroleum, coal, and bituminous shale.

It has been established by microscopy in polarised light that the above types of coke have complex and varied structures, but the mechanism of their formation remained unknown for a long time. The most realistic hypothesis [1] concerned the relation between the structure of coke and the complex chemical composition of the raw coking material, and the formation of particular regions in the microstructure was believed to be genetically linked to a particular group component of the raw material.

The ideas about the mechanism of structure formation in coke, which developed mainly on the basis of chemical research techniques, have been described most fully in the monographs of Krasyukov [1] and Onusaitis [2]. The inadequacy of these concepts became evident after Brooks and Taylor [3,4] and later a number of other workers [5,6] investigated by microscopy in polarised light the products of the low-temperature carbonisation of substances from which graphitising coke is obtained. Even before this, it was observed that the graphitising coke obtained at 450°C already had a textured layer structure [7,8]. It was also firmly established that graphitising coke may be obtained solely from substances melting at 350-500°C [9,10]; a characteristic feature of low-temperature types of coke, which makes it possible to infer unambiguously their capacity for graphitisation, is the presence of regions of optical anisotropy [11]. However, the most important stage in the understanding of the mechanism of structure formation in graphitising coke was the so called mesophase transformation discovered by Brooks and Taylor [3,4].

II. THE MESOPHASE TRANSFORMATION—THE MAIN STAGE IN THE FORMATION OF THE STRUCTURE OF COKE

1. General Description of the Phenomenon

The formation of the structures of all types of graphitising coke proceeds via the mesophase transformation. The latter occurs in the temperature range 390-520°C and consists of a phase transition in the liquid state during which large polymerised aromatic molecules in the isotropic mass of the pitch are arranged in parallel and form anisotropic liquid crystals of the mesophase [4]. The temperature range of the mesophase transformation varies somewhat for different substances and its extent depends significantly on many factors, which will be discussed below.

The liquid crystals of the mesophase arise in the isotropic liquid mass of the pitch, following an increase of temperature to 390-400°C, in the form of approximately 0.1 μm particles observed on ultrathin sections with the aid of an electron microscope, but Brooks and Taylor have no doubts about the existence at this stage of spherical formations of even smaller size. With increase of the temperature and the duration of treatment, the spherical formations grow in size and the proportions of the pitch and the mesophase change in favour of the latter. As long as the ratio of the phases in specified volumes does not exceed 1 : 1, the growth of the spherical formations takes place at the expense of the surrounding pitch; their shape remains rigorously spherical and their diameter may reach tens of micrometres. When the proportion of the mesophase is high, the coalescence of the individual spherical particles begins with formation of larger particles of different shapes (Fig. 1). At the instant of the complete conversion of the pitch into the mesophase, the multiple coalescence of the spherical particles results in the formation of a complex structure, which Brooks and Taylor [4] called the mosaic structure although it does not in fact consist of sharply delimited regions.

The structure of the mesophase spheres at the instant of their formation and during their initial growth was investigated by microscopy in polarised light[3,4,12], by electron diffraction[4], and by X-ray diffraction[13]. It was established that the mesophase spheres are optically monoaxial positive liquid crystals with straight extinction belonging to the hexagonal system. The planar aromatic layers are arranged at right angles to one diameter of the sphere becoming bent at its edges in such a way that they become perpendicular to its surface (Fig. 2). The distance between the layers is 3.43–3.49 Å. The fact that the planar molecules forming the sphere have a radial arrangement near the surface promotes the initial coalescence of the spheres. The coalescence results in the formation of mesophase regions with a more complex structure than that of the initial spheres.

Figure 1. Particles of the mesophase in coal tar pitch. Coalesced formations observed together with individual spheres. Polarised light; magnification × 350.

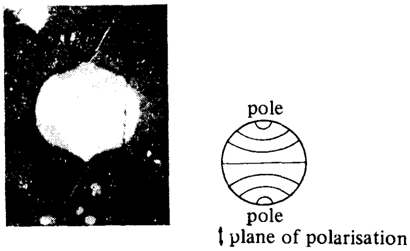

Figure 2. Sphere in which the lamellar layers are distributed at right angles to the surface of the polished section passing through the centre of the sphere. The "poles" refer to the ends of the principal axis of symmetry of the sphere. Polarised light[3].

At the instant of complete conversion of the pitch into the coalesced mesophase, the coking material consists of a very viscous liquid. At a somewhat higher temperature, the mesophase swells under the influence of the evolved gases and is converted into solid semicoke. During swelling, the mesophase is markedly deformed and the microstructure produced at this time hardly changes on subsequent heat treatment and on conversion into coke.

Different versions of the coalescence of the mesophase spheres and the resulting structures as well as the structures formed on deformation of the coalesced mesophase have been investigated in detail[12,14,15]. The relation between the microstructure of coke and the structure of the coalesced mesophase and its deformation has been described[16]. Owing to the high viscosity of the mesophase and the insufficient time during which it exists in the fused state, there is insufficient time during the coalescence of two and more spheres for the formation of a regular arrangement of their layers and a simple layer structure. Furthermore, the structural result of the coalescence depends on the mutual orientation of the C-axes of the coalescing spheres[12]. In the multiple coalescence of spheres, the above factors lead to the formation of a complex structure of the coalesced mesophase, including linear defects in the packing of the planar layers, discontinuities, and pronounced bending. The extensive deformation of the mesophase on swelling increases by several orders of magnitude the number of defect structures[12]. Linear defects are the preferred site of the generation of contraction cracks on subsequent heat treatment[15].

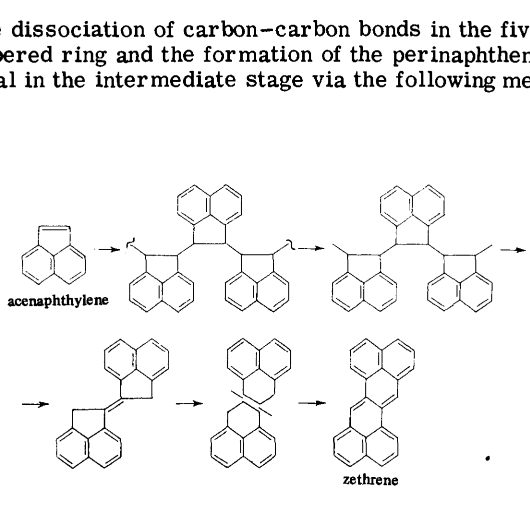
2. The Chemistry of Carbonisation Processes

The chemical composition of isotropic pitch in which the mesophase spheres are formed and grow is extremely complex. In broad outline, the chemistry of the processes occurring during coking in the temperature range 380 to 460°C is described as a sequence of thermal dehydropolycondensation reactions. Detailed studies on these processes involve considerable difficulties associated with the complexity of the chemical composition of the coking raw material and with secondary interactions—the recombination of radicals, mutual influence and interaction of various hydrocarbons with different activities, and polycondensation processes.

The mechanisms of coking reactions have been inferred[1,3] from the results of a detailed analysis of the volatile products and simple measurements of certain properties of the condensed phase, such as density, the C/H ratio, group composition, etc. In recent years vigorous research has been undertaken on the intermediate stages in the carbonisation process using ESR, ultraviolet and infrared spectroscopic, mass-spectrometric, and NMR methods. In combination with special methodological procedures, it was possible to obtain certain data on the mechanisms of the reactions occurring in the condensed phase.

Certain fundamentally important results were secured in the study of the carbonisation of individual hydrocarbons, including those forming graphitising coke, such as acenaphthylene, anthracene, phenanthrene, naphthacene, dibenzanthrene, etc.[17-20]. Acenaphthylene has been most thoroughly investigated. Its carbonisation was initially achieved via low-temperature polymerisation with subsequent thermal depolymerisation above 350°C, resulting in the formation of fragments which react, giving rise to larger condensed aromatic molecules[20]. The mesophase transformation in the carbonisation of acenaphthylene begins at 405°C.

Ruland[17] established by X-ray diffraction that the formation of carbon in the carbonisation of acenaphthylene proceeds via the formation of zethrene followed by condensation of the zethrene elements into extended polycyclic aromatic systems. This rearrangement is accompanied by the dissociation of carbon–carbon bonds in the five-membered ring and the formation of the perinaphthenyl radical in the intermediate stage via the following mechanism:



Singer and Lewis[18,19] studied the carbonisation of acenaphthylene and other aromatic hydrocarbons by ESR in order to identify the intermediate radicals generated and refine the mechanism of the chemical reactions occurring at various stages of the process. The ESR spectra of various types of semicoke usually observed consist of a single line without hyperfine structure, the width and intensity of which depend on the treatment temperature. Such spectra do not yield information about the free radical structures present in the carbonised system. In order to overcome this difficulty, the authors[17,18] carried out the carbonisation in an inert solvent—*m*-pentaphenyl. Dissolution decreased the probability of the combination of free radicals and thereby permitted their detection and identification by ESR. It was established[17] that the carbonisation of acenaphthylene proceeds via the scheme described by Ruland with the intermediate formation of the perinaphthenyl or dimethylperinaphthenyl radicals[17].

The results of the study of six different compounds led to the conclusion that the intermediates in the formation of large condensed molecules are free radicals arising as a result of the thermal dissociation of the bond at the most active site of the molecule. Depending on their reactivity, these aromatic free radicals can either condense with loss of hydrogen into large aromatic fragments or can undergo an internal rearrangement. If the intermediate free radical products have a planar configuration, then the carbonisation of the compound proceeds via the mesophase transformation and high-temperature treatment yields ordered graphite; on the other hand, when non-planar radicals are formed, the formation of the mesophase is not observed and the subsequent graphitisation is unsatisfactory.

Evans and Marsh[20] observed by mass-spectrometric measurements that the principal component of the carbonisation products at 405–500°C (the region of the mesophase transformation) is decacyclene, while at higher temperatures molecules with zethrene configuration begin to predominate. The molecules of both types are planar (in the decacyclene molecule the acenaphthylene units are inclined at an angle of 3° with respect to the plane) and their further condensation leads to the formation of large planar structures capable of an ordered arrangement to give the liquid crystals of the mesophase.

The mechanism of the carbonisation of anthracene, phenanthrene, and naphthacene is simpler and consists in the formation of dimers and trimers, which are capable, by virtue of their configuration, of giving rise to large planar structures, ensuring the formation of ordered graphite.

Extremely interesting results were obtained in a study of the products of the carbonisation of acenaphthylene at 625°C, i.e. after the completion of the mesophase transformation[20]. In order to investigate spectrometrically this high-molecular-weight involatile compound, it was subjected to hydrogenolysis by atomic hydrogen. The material treated in this way gave rise to a mass spectrum which contained peaks due to acenaphthylene, zethrene, decacyclene, acenaphthene, and zethrene dimers, whose intensities corresponded to their abundance. These results show that the carbonisation of acenaphthylene proceeds via identical condensation reactions over the entire region of the mesophase transformation.

The mass-spectrometric and elemental analytical data demonstrated only a slight difference between the compositions of the mesophase and the isotropic material from which it arises. On the basis of the results, the authors[20] concluded that the formation of the mesophase consists in the ordering of the molecules of the isotropic phase and not in the formation of other chemical structures.

In the coking of hydrocarbon raw materials of complex composition (pitches and resins) from which industrial coke is obtained, the chemistry of the processes is complicated by the factors mentioned above, but in the region of the mesophase transformation the fundamental nature of the chemical reactions and the physicochemical processes is the same as in the carbonisation of the individual hydrocarbons.

At the beginning of the mesophase transformation, the substances present in pitches largely consist of polynuclear hydrocarbons and certain nitrogen and oxygen compounds. The ^{1}H NMR spectrum of the soluble fractions from which the mesophase is formed shows that more than 90% of the protons are linked to aromatic rings[14,18]. The average molecular weight of these fractions is 390–450; a stronger absorption is observed in the ultraviolet spectrum in the range between 370 and 450 nm.

Under carbonisation conditions, these compounds decompose via a radical mechanism with evolution of an insignificant amount of hydrogen and subsequent formation of more complex coplanar regions.

The results of elemental analysis of the partly carbonised pitch ($C_{100}H_{53}O$) differ little from the results of the analysis of the insoluble mesophase residue ($C_{100}H_{49}O_{1.4}$), but their average molecular weights differ significantly, amounting respectively to 790 and 1700.[4,5]

Ihnatowicz et al.[5] believe that the insolubility of the mesophase and its higher density compared with the pitch (1.48 and 1.25 g cm^{-3} respectively) are a direct consequence of the fact that the mesophase consists of more highly polycondensed molecules.

Honda et al.[12] found by X-ray diffraction analysis and by measuring a number of physical properties of pitch specimens as a function of the carbonisation temperature and time that the activation energy for the processes occurring in the region of the mesophase transformation is 35–45 kcal mole^{-1}. According to the authors, the growth of the spherical particles of the mesophase is due to a rearrangement of the C–C bonds and the evaporisation of low-molecular-weight substances.

Magaril and coworkers[21,22] obtained similar results. They investigated by infrared spectroscopy, ESR, elemental analysis, and measurements of the molecular weights and densities the intermediates in the carbonisation of petroleum tars and asphaltenes at 350°, 390°, and 410°C in solution in transformer oil. The molecular weight of the asphaltenes (the benzene-soluble fraction), determined cryoscopically in naphthalene, was 940 and the molecular weights of carbenes (the fraction evolved from coke on extraction with carbon disulphide after the removal of benzene-soluble substances), determined osmometrically in carbon disulphide, were 135 600, 122 100, and 117 000 respectively at 360°, 390°, and 410°C. The authors concluded on the basis of ESR and infrared spectroscopic data that asphaltenes, carbenes, and carboids are substances of the same type. The fundamental difference between carbenes and asphaltenes is only a much higher (by two orders of magnitude) average molecular weight of carbenes and the difference between carboids and carbenes is insolubility of the former. The carboids may be insoluble, according to the authors, because their molecular weight is still higher than that of carbenes or because (and this appears much more likely) carboids are cross-linked three-dimensional polymers. It is noteworthy that the above study quotes molecular weights of substances soluble in carbon disulphide higher by almost two orders of magnitudes than the values given elsewhere[3-5,13].

The formation of coke in the thermal decomposition of asphaltenes is represented[22] as a chain process leading simultaneously to the formation of relatively low-molecular-weight products, carbenes, and carboids. The process activation energy obtained from experimental data is 58–60 kcal mole^{-1}, which corresponds to the dissociation energy of the weakest C–C bond in the asphaltene molecule.

The mesophase transformation usually takes place in the temperature range between 400° and 500°C. The conclusion that the same reactions take place over the entire temperature range was reached by Evans and Marsh[20] on the basis of mass-spectrometric data, by Ihnatowicz et al.[5], who demonstrated the constancy of the density of the mesophase and the pitch coexisting with the latter, by Huttinger[6] on the basis of the constancy of the H/C ratio for the mesophase, and by Magiril and Aksenova[22] on the basis of the constant yield of coke relative to the asphaltenes which have reacted and of the reaction rate constant.

Fialkov and coworkers[13,24] and Tyan[25] arrived at a similar conclusion. It has been established by ESR and microscopic methods that, in the range 400–450°C, i.e. from the instant of the generation of the spherolites until the complete conversion of the pitch into the mesophase, the concentration of the free radicals, the line width between the maxima of the derivative ESR absorption line, and the spin–lattice relaxation times remain unchanged, while below and above the limits of this range these characteristics change significantly. The authors concluded that the intramolecular structure of the mesophase responsible for the ESR signal does not change in the range 400–450°C and the formation of the mesophase is due to the increase of the size of the carbon network as a result of thermal degradation and the formation of new C–C bonds.

Thus it may be regarded as established, on the basis of comprehensive studies of the low-temperature carbonisation processes of individual hydrocarbons and their complex mixtures (pitches and tars), that the mesophase transformation involves the ordering of large planar aromatic molecules with formation of nematic liquid crystals accompanied by further condensation with slight losses of hydrogen. As a result of this, the mesophase becomes insoluble. The liquid crystal molecules are formed by reactions involving the thermal dissociation of bonds at the most active site in the molecules and condensation of the resulting free radicals to a large planar aromatic structure.

III. FACTORS INFLUENCING THE MESOPHASE TRANSFORMATION AND THE STRUCTURE OF COKE

The structure of coke is wholly determined by a process involving the generation, growth, and coalescence of the mesophase spheres and the subsequent deformation of the coalesced mesophase on swelling. The study of the factors influencing such processes and of their mechanism is therefore of enormous importance for the solution of the problem of the regulation of the growth of different types of coke.

1. The Coking Conditions

The principal factors influencing the generation and growth of the spheres are temperature and time[3-6,13,16]. There is a limiting temperature below which spheres are not generated even after very prolonged treatment. With increase of the duration of isothermal treatment, a large amount of the pitch is converted into the mesophase, but the time dependence of the increased conversion is asymptotic. At a higher temperature, much less time is needed for the attainment of the specified degree of conversion and the latter is determined solely by temperature. Honda et al.[13] showed that temperature and time are adequate process parameters in the range 390–430°C as regards their influence on the degree of conversion and the properties of the mesophase.

The temperature–time parameters can be used effectively to regulate the structure and properties of coke. Isothermal treatment in the temperature range of the mesophase transformation leads to the formation of coke with a more ordered structure[23]. At the same time there is a significant increase (by 5–8%) in the yield of coke[23,26]. The increase of the rate of coking does not affect the temperature of the onset of the formation of the mesophase, but significantly displaces towards higher temperatures the instant at which the transformation ends, extending thereby the temperature range of the transformation. According to Ihnatowicz et al.[5], a change in the rate of heating of coal pitch from 0.5 to 3 K min^{-1} increases the temperature at which the mesophase transformation is completed by 55 K. At a higher rate of carbonisation, smaller spheres and coke with a mosaic structure are formed. These structural changes are associated with the fact that, when the temperature range of the transformation is displaced towards higher temperatures, there is also an increase in the rate of formation of mesophase nuclei and there is insufficient time for the complete coalescence of the growing spheres.

2. The Composition of the Coking Raw Material

When the influence of the composition of the raw material on the structure of the coke obtained is examined, account must be taken of two aspects—the genetic relation between the structure formed and the composition of the raw material[1,27] and the mutual influence of the components during coking[1,20,28]. The role of the insoluble fractions present in the raw material will be discussed below. The hypothesis that definite components of the raw material are responsible for the formation of a particular type of coke structure[1,27] must be regarded as an exaggeration. The mutual influence of the components is most likely to affect the formation of the structure.

In mass-spectrometric studies of the carbonisation of mixtures of individual aromatic hydrocarbons, intermolecular reactions were not observed, but a decrease of the degree of pyrolysis of the individual components was noted[20]. According to the authors, the latter effect may be a result of the decrease in the intensity of the condensation reactions owing to the mutual dilution of the mixture by the components.

Levinter et al.[28] observed a decrease of the yield of coke in the simultaneous coking of asphaltenes and oils compared with the coking of asphaltenes alone. As a result of the mutual influence of the components, such a mixture behaves during coking as a single group component with intermediate properties. The capacity for graphitisation of the coke derived from asphaltenes alone is poorer than that of the coke obtained from the mixture. Levinter et al.[28] reached the conclusion (similar to that of Lewis and Singer[19]) that dilution of asphaltenes by oils decreases the rate of formation and growth of coke "crystallites", which favours an increase in the degree of order of the coke structure.

In a study of the kinetics of coke formation, Magaril[29] also concluded that there is a relation between the differences in the kinetics and the amounts of coke formed and the differences in the properties of the solvent used in the coking of asphaltenes. The addition to a poor solvent for asphaltenes of an effective solvent lowers the yield of coke, while in the decomposition of asphaltenes in an effective solvent coke formation begins only after the attainment of a threshold concentration. The authors explained their latter finding by the solvation of asphaltenes, preventing their condensation and the onset of coke formation.

The presence in the raw material of certain chemical elements, particularly oxygen, sulphur, and nitrogen, plays an important role in the coking process. In pitch, they usually form part of heterocyclic compounds. During pyrolysis, the presence of the above elements promote, on the one hand, dehydrocondensation accompanied by the formation of partly stable intermediate products and, on the other, the formation of cross links[30,31]. The appearance of such links at the early stages of aromatic condensation leads to the formation of rigid carbon with an extremely non-ordered structure. The formation of cross links and of a three-dimensional network at later stages gives rise to the formation of a highly condensed aromatic system. When the raw material contains halogen atoms (Cl, Br), the thermal stability of the compounds falls, since the energy of the C–Cl and C–Br bonds is smaller than that of the C–C and C–H bonds. Owing to their high affinity for hydrogen, fluorine and chlorine act like dehydrogenating agents[30].

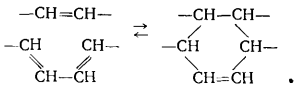
The influence of oxygen and sulphur on the mesophase transformation has been most thoroughly investigated. Ihnatowicz et al.[5] and also Tyan[25] established that the presence of more than 7% of oxygen in the raw material leads to the complete suppression of the mesophase transformation and to the formation of non-graphitising coke. When the oxygen content is less than 5%, the structure differs little from that of the usual graphitisable coke. Oxygen greatly narrows the temperature range of the mesophase transformation by reducing the temperature of its completion. When the oxygen content is 5–7%, coke with a pseudoisotropic structure is obtained. Sulphur has a similar influence on the mesophase transformation[31]. The presence of a small amount of sulphur does not cause appreciable changes in the properties of the mesophase, but, when its content exceeds a limiting concentration, for example 5% for PVC pitch, the fluidity of the mesophase and the temperature determining the limit of its plastic state decrease sharply. When the sulphur content is between 5 and 8%, fine spheres and a two-phase structure are formed. The presence of more than 8% of sulphur leads to the formation of an isotropic structure.

Kipling et al.[31] explain the effect of sulphur by the formation of cross links at the early stages of pyrolysis. They suggest the possibility of a catalytic effect of sulphur. It is postulated that the principal function of sulphur is to increase the degree of unsaturation of the molecules of the initial material:

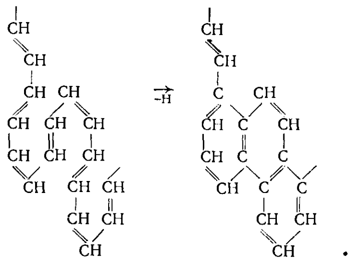
$$-CH_2-CH_2- + S \rightarrow -CH{=}CH- + H_2S \ .$$

The polyenes formed undergo Diels–Alder condensation reactions, which may be accompanied by dehydrogenation:

(a) intermolecular condensation:

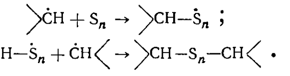


(b) intramolecular condensation:



At a fairly high temperature, one may expect that aromatisation will take place with elimination of hydrocarbons and hydrogen, which combines with sulphur to give hydrogen sulphide.

The reaction of sulphur with the free radicals produced in the pyrolytic process results in the incorporation of a certain amount of sulphur in the resulting structure:



$$\rangle\dot{C}H + S_n \rightarrow \rangle CH-\dot{S}_n \ ;$$
$$\rangle CH-\dot{S}_n + \dot{C}H\langle \rightarrow \rangle CH-S_n-CH\langle \ .$$

The radical formed, being comparatively long-lived, can react with other hydrocarbon radicals, forming cross links, which prevent the mutual orientation of the molecules.

It has been noted[15] that, despite the wide variety and complexity of the pyrolytic reactions, they can be characterised by the structure formed as a result of the coalescence of the mesophase spheres. Microstructure studies on different types of semicoke derived from starting materials with different contents of heteroatoms demonstrated a decrease in the size of the mesophase spheres with increase of the sulphur content. This finding can be accounted for by the increase viscosity of the mesophase due to the formation of cross links at early stages of the pyrolysis. The influence of increasing viscosity has also been noted by Kipling et al.[31]; the increase in viscosity complicates the reorientation of the molecules in the liquid stage.

3. The Influence of Additives

The influence of various additives on the coking processes has been investigated in many studies. All the additives employed can be divided, in terms of the nature of their activity, into chemically active, catalytic, and plasticising[32].

The most common way in which the properties of the coking raw material are affected is by oxidation with atmospheric oxygen or various chemical agents. When oxygen is passed through the starting material, peroxides are usually obtained in the first instance and are then converted into stable compounds on subsequent decomposition. The decomposition of peroxides may result in the formation of cross links leading to the formation of a rigid carbon structure[30]. The role of oxygen probably reduces to the initiation of the condensation and polymerisation reactions of multicomponent aromatic compounds present in the pitch owing to the formation of free radicals during oxidative dehydrogenation. The radicals can give rise to peroxide compounds, which initiate the subsequent process and also interact with one another, forming molecules capable of further growth[32].

Various substances are used to initiate the oxidation reactions. Variable-valence metal salts are familiar catalysts and the mechanism of their action has been investigated in detail[33-36]. The valence of the metal changes during the process and free radicals are formed, probably as a result of the direct involvement of the catalyst in the reaction between oxygen and the hydrocarbon. The role of the catalyst reduces to initiating the oxidation reaction in the initial stage of its development, which ensures as high a rate of chain initiation. However, Denisov[35] suggested the involvement of the catalyst also in the chain propagation processes, assuming that the catalysis takes place throughout the reaction via a sequence of macroscopic stages and not via a single mechanism. Peroxy- and azo-compounds are frequently used as initiators. Gas-phase initiation, where nitrogen dioxide produces the maximum effect, has been employed.

Apart from passing air through the starting material, many different oxidising additives are used; the influence of any of these can be accounted for by its effect on dehydrogenation and polycondensation processes. Sulphur is an agent closest to oxygen as regards its action. A mechanism has been put forward for its interaction[30]. When sulphur is added, the dehydrogenation temperature falls, and and, in addition, sulphurisation leads to aromatisation. The hydrogen liberated combines to form H_2S. Kipling et al.[31] made a detailed study of the mechanism of the catalytic action of sulphur present in the starting material. When sulphur is introduced at later stages of the pyrolysis, its role is to the dehydrogenation and aromatisation processes. In practice, when the pitch is treated jointly with sulphur and air, the carbonisation process is accelerated. The influence of aluminium chloride has been considered in a number of investigations[30,32,37]. Its catalytic action is probably based on the formation of intermediate complexes of the catalyst and the reactants.

Fitzer et al.[30], who investigated the influence of anhydrous $AlCl_3$ on the pyrolysis of different types of pitch, concluded that small amounts of the catalyst (0.1–0.5%) produce appreciable changes when the electron density in the aromatic ring is increased, for example by the presence of phenolic groups. Such compounds are always present in pitch. The favourable influence of the introduction of nitro-groups (NO_2) has been noted[38,39], the oxidative dehydrogenation of pitch being promoted. Such treatment of pitch is useful in connection with the reactivity of the nitro-group in dehydrogenation reactions and with its initiating effect on hydrocarbon oxidation processes[32].

The influence of boric acid and ammonium sulphate on the coking of petroleum residues has been examined[37]. It is suggested that these substances dissociate at 140° and 330°C respectively and promote the oxidative condensation of hydrocarbons of comparatively low molecular weights.

The influence of metals on coke formation in catalytic cracking is also noteworthy. Masagunov and Tikhanovskaya[40] concluded that the influence of the metal on coke formation depends on its dehydrogenating activity. Highly dehydrogenating metals (nickel, copper, and cobalt) lead to a sharp increase of coke formation even when their content is negligible.

Demidova[32] examined the influence of various types of additives, both chemically active (aluminium, bismuth, and potassium nitrates) and catalytic (finely dispersed nickel powder), directly on the mesophase transformation. The addition of aluminium, bismuth, and potassium nitrate increases the coking capacity as a result of condensation processes leading to the preferential growth of the content of carboids. The addition of finely dispersed nickel increases coke formation owing to the intensification of the dehydrogenation reactions of the low-molecular-weight compounds in the pitch in the range 200–300°C.

ESR and differential thermal analysis (DTA) data have shown that thermal degradation and the formation of the polymer structure of semicoke in modified types of pitch occur at lower temperature. Demidova[32] suggests that the formation of the semicoke structure in the modified pitch is completed at an earlier stage than in the initial pitch, as a result of the initiation of dehydropolycondensation processes mainly by the solid oxides derived from the decomposed metal nitrates. The introduction of condensing and catalytic dehydrogenating additives also promotes the initiation of the formation of mesophase spheres at 410°C. Mainly fine spheres are formed in the presence of additives. According to the author, the formation of the spheres and the limitation of their growth in pitch with added nitrates occur either in consequence of the shielding of their surface by the solid phase of the additive or because of the multiplicity of crystallisation centres, which may consist of finely dispersed oxides produced from the decomposed nitrates.

The decrease in the size of the spheres during oxidation was also noted by Averina[41], the increase in the number of spherical particles and the decrease of their dominant size being promoted by the increase of temperature and the rate of oxidation. An appreciable increase of the number of nuclei of the mesophase particles in the oxidised starting material was observed following the addition of catalysts, particularly iron(II) oxalate. According to the author, the catalyst prevents the coalescence of the mesophase particles, which leads to the formation of a fine-grained structure.

Oxygen and sulphur also increase the viscosity and the period of the mesophase transformation[15,31]. Kipling et al.[31] assume that the increase of viscosity, due to the increase of the degree of cross-linking of the molecules, complicates their reorientation and the formation of an ordered structure.

4. The Influence of Dispersed Additives; Mechanical and Other Influences

The influence of dispersed additives on crystallisation of high-molecular-weight compounds from the melt is generally known and is widely used to modify their structure. These additives are usually nucleus-forming agents and are present in the centres of the growing spherolites[42].

Brooks and Taylor[3] investigated the influence of various dispersed insoluble additives on the mesophase transformation and the structure of coke. They found that any solid surface constitutes the preferred site for the formation of the mesophase, but, in contrast to the crystallisation of polymers, dispersed additives remain on the surface and are never detected within the growing mesophase spheres (see Fig. 1). This factor significantly restricts the scope of the regulation of the structure and complicates the process. Because of this, the influence of dispersed particles on structure formation in carbonisation must be treated not only from the standpoint of the formation of nuclei but also taking into account their behaviour at the mesophase–pitch interface. Dispersed particles are almost always present in the starting materials from which coke is obtained. They differ significantly in structure and their behaviour in the coking process is likewise different[6,7,43,44].

Sedimentation of the dispersed components of pitch during its conversion into coke leads to large structural inhomogeneities along the height of the coke "pie"[6,44-46]. Numerous point structures, consisting of aggregates of the dispersed components of pitch, are observed in its lower part. The smallest particles remaining in the pitch at the instant of the onset of the mesophase transformation are distributed non-uniformly. After the appearance of the mesophase, they collect on the surface of the spheres and prevent their growth by depriving them of the ability to coalesce (Fig. 3).[16] The pitch phase is then liberated from the dispersed particles and the new spheres formed in it grow to a much greater size via coalescence. As a result, when the pitch is fully converted into the mesophase, the fine spheres blocked by the dispersed particles give rise to mosaic structures and the large spheres give rise to acicular, fibrous, streaming, or oriented structures (the differences between them are merely a matter of terminology).

The structure of coke obtained from starting materials containing dispersed particles is extremely inhomogeneous. In most cases where a readily graphitising coke is required with a homogeneous acicular or layer structure, one endeavours to liberate the fused pitch from the dispersed component with the aid of various technological procedures (filtration, centrifugation, etc.)[47,48]. It is also possible to obtain a homogeneous mosaic structure by introducing dispersed additives, which form a three-dimensional coagulation network throughout the bulk of the material and prevent the coalescence of the spheres[49].

Compact coagulation in the pitch phase, which is usually characteristic of the dispersed component of pyrolytic tars, leads to the formation of aggregates in the form of grains, whose size ranging from 0.5 to 5 mm upwards, known in the literature[43,46] as spherulitic structures. As a result of partial sedimentation, the content of spherulitic structures increases at the bottom of the coke "pie". When the viscosity of the pitch phase is fairly high, for example in the coking of the oxidised residues, the spherulites remain distributed throughout the bulk of the coke[44]. The dispersed components of the starting material, distributed in the main bulk of the coke, have the greatest influence on its properties. Thus insoluble dispersed particles play a very important role in the formation of the structure of coke and can be used to control it.

Apart from the factors described above, mention should be made of the effect of mechanical influences and the magnetic field on the structure of the mesophase. Simple stirring of the coke material at the stage of the mesophase transformation improves the coalescence of the spheres and rotary stirring, apart from intensifying coalescence, gives rise to a coaxial orientation of the aromatic layers in the coalesced mesophase and leads to the formation of textured coke[3,4].

The application of a 6.0 kG magnetic field for 1.5 h during the mesophase transformation causes the orientation of the *C*-axes of the spheres parallel to one another and to the direction of the magnetic field. Sanada et al.[50] suggest that such orientation of the spheres is caused by the forces arising from the effect of the magnetic field on the magnetically anisotropic polycondensed aromatic molecules in the spheres. These forces have been estimated approximately as 1–3 dyn g^{-1} from measurements of the magnetic susceptibility. The coalescence of the spheres results in an oriented mesophase, but defects are observed in the arrangement thus produced. According to the author, the forces generated by the magnetic field applied in the coalescence stage are too low to form a defect-free structure.

A specific type of mechanical influence on the coalesced mesophase of gaseous coking products plays a very important role in the formation of the coke structure. It is known[1,51] that the maximum rate of gas evolution in the coking process is observed at the temperature corresponding to the end of the mesophase transformation. Since the mesophase has a much higher viscosity than the pitch phase, it prevents free gas evolution and swells under the pressure of the gases evolved. During swelling, the volume of the coking mass increases by a factor of 4–9 [1] and its very rapid solidification, the mechanism of which has not so far been investigated, takes place. After swelling, the coalesced mesophase consists of a porous material with a spongy structure.

During the swelling process, the mesophase matrix is extended and deformed and its constituent layer structures are oriented in the direction in which the stretching stresses are applied. The mesophase is deformed most markedly at the sites which have become the walls between the pores and to a lesser extent at the functions of several walls. The layers of the mesophase are oriented along the walls, forming a texture within the limits of each. The instant at which swelling comes to an end and mesophase solidifies can be regarded from the morphological point of view as the instant of the termination of the formation of the coke structure. Intra- and inter-molecular rearrangement processes occurring on further increase of temperature do not have an appreciable influence on the structure.

Among the factors discussed above, influencing the mesophase transformation, the following have found the most extensive practical applications: regulation of the behaviour of the dispersed components of the starting material, isothermal treatment in the temperature range of the mesophase transformation, oxidation of the starting material at a temperature below the onset of the mesophase transformation. The first two factors are usually employed to obtain anisotropic types of coke with a distinct oriented layer structure, which are readily converted into graphite and have a high electrical conductivity and reactivity. For this purpose, the coking starting material is freed from solid particles at a temperature below the onset of the mesophase transformation by filtration, centrifugation, or by being allowed to stand[47,48]. Oxidation of the starting material is used to obtain coke with isotropic properties[41].

IV. STRUCTURAL CHARACTERISTICS OF VARIOUS TYPES OF COKE

The structures of all types of graphitising coke are based on layer structural elements formed in the stages of the mesophase transformation and on subsequent deformation during the swelling of the mesophase. In this sense, the structure of each type of coke can be fully described by the dimensions and nature of the relative disposition of these structural elements[41]. Furthermore, different industrial types of coke have structural features, which are wholly determined by the composition and properties of the starting material from which they are obtained, mainly by its content of insoluble substances, its reactivity, and the degree of its oxidation[1,16,41,43,45,46].

There is as yet no established terminology in the literature for the structure of coke. This is because studies on the structure of coke have been carried out for a long time without understanding the mechanism of its formation. For this reason, the apparent wide variety of structures could not be treated systematically and each investigator, concentrating attention on a particular aspect of the same layer structure, characterised it by a specific terminology based mainly on morphological considerations. Thus terms such as acicular[47,48], fibrous[45,52], and streaming[41,43] structures arose to characterise sections of the mesophase structure with layers oriented in the direction of stretching on swelling. Much attention has been given to problems of terminology in a study by Averina[41]. Some of the morphological terms and the associated errors have been criticised[16,46], but this problem is outside the scope of the present review.

The following concepts can be used to characterise the structure of coke. The structure of coke is understood as the collection of all the structural elements and their combinations which are encountered within coke. The structure can be simple or complex depending on whether it consists of one or several types of structural elements; it can be homogeneous or inhomogeneous depending on whether the elements are of equal size and have the same orientation and on whether or not their distribution in the bulk phase is uniform. When structural elements of a single type form accumulations in a complex structure in the form of grains or other aggregates, then regions with a structure of the same type are usually referred to as structural components. Finally, a structural element is understood as a morphological unit with optically definable boundaries, characterised by a particular shape and internal structure.

The formation of coke with a specified structure and properties by active interference with the coke formation process has not yet been developed widely on an industrial scale and this is why industry produces a limited range of types of coke, the structure and properties of which are wholely determined by the type of raw material used in the coking process. The starting materials for the preparation of graphitising coke are the heavy residues from petroleum processing and the products of the processing of the tars resulting from the coking of coal and bituminous shale[1,41,51]. The temperature conditions in the prepration of the coking raw material have a definite influence on the structure of coke. Accordingly, all kinds of raw material can be divided into three types[41]: low-temperature raw material—the cracking residue obtained at 500–600°C and virtually free from solid particles; moderate-temperature raw material—the pyrolysis tars obtained at 650–800°C and containing different amounts of 0.5–4 μm solid spherical particles with a radial ray internal structure; high-temperature raw material— coking tars obtained at 800°C and above and containing solid soot particles smaller than 0.1 μm. The insoluble dispersed components of the raw material are the basic cause of the formation of the complex and inhomogeneous structure of coke[16,41-46]. Certain characteristics of the different types of raw material, based on the data published by Krasyukov[1] and Stepanenko et al.[51], are presented in Table 1.

Table 1. Characteristics of different types of coking raw material.

Parameter	Cracking residue	Pyrolytic tars mild regime	Pyrolytic tars severe regime	Coal tar pitch
Density, g cm^{-3}	0,94	1,12	1.17	1.33
"Ring and sphere" softening temperature, °C	liquid	liquid	liquid	145
Group composition, wt.%	74	82	66.5	28
Tar malthenes	21	9.8	8.7	
Asphaltenes	5	7.1	12.3	24
Carboids	0.3	1.0	12.5	48
Sulphur content, %	0.4	0.5	0.5	0.7
Coking number, %	9.0	18.1	30.4	74.0

The temperature of the processes in which the coking raw material is obtained determines not only its content of dispersed components and their structure[41,44] but also its reactivity and a number of other properties[1] influencing its behaviour in coking and the structure of the coke obtained.

We shall now consider the structural characteristics of the commonest industrial types of coke. The petroleum-cracking electrode coke (PCEC) is obtained by the coking in stills of a low-temperature raw material–the petroleum cracking residues[1]. This coke has the simplest and most, homogeneous structure among all industrial types of coke, consisting only of lamellar structural elements, forming sections of a structure with a parallel orientation in the walls between the pores and sections with a randomly oriented structure at the junctions of several walls (Fig. 3). The formation of a simple structure is ensured by the absence from the coking material of dispersed components and the only structural inhomogeneity is the orientation inhomogeneity, unavoidable in coking within the bulk of any raw material and associated with the inhomogeneous deformation of the coalesced mesophase on swelling.

Petroleum pyrolytic coke is obtained by the coking in stills of a moderate-temperature raw material—pyrolytic tars[1]. Depending on the pyrolysis temperature, tars corresponding to mild (650–700°C) and severe (750 to 800°C) regimes are distinguished. The mild regime tar is distinguished by a much higher content of carboids. The carboids in pyrolytic tars consist of solid spherical particles with a specific radial ray structure (Fig. 4), which are converted into the coke structure without a change in morphology[43]. For this reason, a characteristic feature of all pyrolytic types of coke is a layer structure consisting of two types of structural elements—spherical elements with a radial ray internal structure and lamellar elements forming the base of the coke. The behaviour of the spherical particles in the coking of mild or severe regime pyrolytic tars is significantly different; this determines also the difference between the structures and properties of the corresponding types of coke.

Figure 3. Petroleum cracking electrode coke. Randomly oriented structure. Replica; magnification × 3500.

Figure 4. Spherulitic structural component of petroleum pyrolytic electrode coke. Replica; magnification × 7000.

The petroleum pyrolytic electrode coke (PPEC) is obtained from mild regime tars. In the coking of such tars, the spherulites coagulate with formation of dense aggregates in the form of grains whose size ranges from a fraction of a millimeter to 4–5 mm [43,46]. Such aggregation takes place until the onset of the mesophase transformation and for this reason the spherulites of the starting material do not have a significant influence on the growth of the mesophase spheres. As a result of aggregation, the spherulitic structural elements form the spherulitic structural component of the PPEC, which is usually located at the base of the coke or in the form of grains at the junctions of several interpore walls. The base of the coke, made up of the mesophase deformed on swelling, consists mainly of a larger structure with parallel orientation. Thus the PPEC structure can be characterised as complex and inhomogeneous, having spherulitic and lamellar structural components with parallel orientation (Fig. 5).

The special petroleum pyrolytic coke (SPPC) is obtained from severe regime tars. Despite the much higher content of sperulites in such tars, they do not coagulate on coking. Remaining uniformly distributed in the coking raw material, the dispersed spherulites prevent the growth and coalescence of the mesophase spheres. This factor and also the packing defects introduced by the spherulites into the structure on deformation of the mesophase matrix during the swelling process rule out the possibility of the formation of structures with parallel orientation. Because of this, SPPC has a complex relatively homogeneous structure consisting of a matrix comprising lamellar randomly oriented structural elements and filled by spherulitic structural elements. Such a structure is referred to[41] as impregnated-spherulitic. The spherical structural elements are sometimes encountered in the form of aggregates, but the latter do not form a clear-cut boundary with the rest of the matrix. The causes of the different types of behaviour of spherulites during the coking of mild and severe regime tars have not as yet been elucidated. It is suggested[41] that the absence of coagulation is associated with the lower reactivity and greater viscosity of the severe regime tars.

Figure 5. Petroleum pyrolytic electrode coke; magnification × 49.

The pitch electrode coke (PEC) is obtained from a high-temperature raw material—coal tar pitch. The starting material consists of coal tar pitch— a side product from the coking of coal containing, apart from various hydrocarbons, a fairly large amount of soot particles, formed in the coking furnace from gaseous coking products in the concluding stage of the process at temperatures of 900°C and above, and also very small solid particles consisting of certain components of coal. Coal tar is converted into pitch by oxidation, usually carried out by blowing hot air through the tar at 250–300°C. The purpose of the oxidation is further condensation and increase of the yield of coke. PEC has a complex inhomogeneous structure, the formation of which is determined mainly by the behaviour of the soot particles of the raw material in the mesophase transformation stage[16]. The partial sedimentation and aggregation of the largest particles lead to the formation of the so called point structural components (Fig. 6). The smallest of these also remain distributed in the pitch at the instant of the formation of the two liquid phases evolved from it on the surface of the growing mesophase spheres, blocking their growth and preventing their mutual orientation and coalescence. The distributed particles significantly increase the proportion of defects in the lamellar structural component of the pitch coke (Fig. 7).

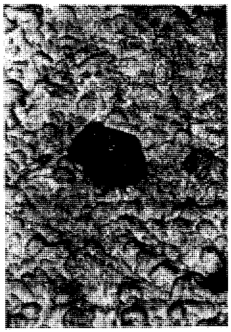


Figure 6. The point structural component of pitch electrode coke. Replica; magnification × 7000.

Figure 7. Pitch electrode coke; magnification × 350.

Different types of shale coke, obtained from the heavy residues remaining after the processing of bituminous shale, have been used increasingly in recent years in the manufacture of carbon-graphite materials. Depending on the purpose of the processing (the formation of petrol, gaseous hydrocarbons, etc.) and its temperature, the residues obtained differ significantly in composition and properties, which determines the wide variety of structures and properties of shale coke[43]. Thus the shale coke from the pyrolytic tars of shale petrol has a structure analogous to that of PPEC, while the structure of the coke from the "gas" tar is analogous to that of PCEC.

Table 2 presents some of the properties of industrial types of coke in accordance with the USSR Government Standards GOST 3278-62 and GOST 3213-58 as well as other data[1,41,45]. Ultimately, almost all the properties of coke are determined by the degree of development of structural anisotropy, arising at the mesophase transformation stage, and by the structural characteristics associated with the dispersed components of the coking raw material. In terms of increasing anisotropy, the types of coke described above can be arranged in the following sequence[41]: PEC < SPPC < PPEC < PCEC. The density of coke is associated directly with the structural anisotropy: the smaller the degree of development of anisotropy the lower the density (Table 2).

Table 2. Characteristics of certain types of coke.

Parameter		PCEC	Streaming component	Spherulitic component	SPPC	PEC
Pyknometric density, g cm^{-3}	1300°	2.10	2.08	2.02	2.04—2.08	2.085
	2400°	—	2.26	2.20	2.19	2.23
Graphitisability d_{002}, Å		3.364	3.369	3.385	3.388	3.380
Degree of graphitisation, %		—	54.5	36.5	70	—

	1300°	17.0	7.5		—	6.0
	2400°	4.8	4.9		—	—

The decrease of the anisotropy of coke is a result of the comminution of the mesophase spheres during coking or of the oxidation of the coking raw material (PEC) or it occurs under the influence of the dispersed components (PEC, SPPC, PPEC). The latter cause the greatest decrease of density when they remain distributed within the bulk of the coke, as, for example, in PEC and SPPC. In this case, the decrease of the density of coke is associated not only with packing defects at the boundaries of the former mesophase spheres but also with the structural defects, which arise at the boundaries between the dispersed particles and the mesophase at the instant of the deformation of the latter on swelling. These defects consist of wedge-shaped pores, apparently mostly closed pores, since they arise as a result of the breakdown of continuity in the microvolume on deformation and not as a result of gas evolution; the pore size depends on the size of the dispersed inclusions. For example, the density of SPPC with 0.5–4.0 μm dispersed particles is significantly lower than the density of PEC with dispersed particles whose size is less than 0.1 μm.

Structural anisotropy is closely related to the capacity of coke for graphitisation (their capacity for conversion into graphite at temperatures above 2300°C), which determines in its turn very many properties, for example electrical conductivity, strength, reactivity, and antifriction properties. The conditions necessary for a satisfactory graphitisability, first formulated by Franklin[53], involve a mutually parallel orientation of crystallites and the absence of cross links between the aromatic layers at the edges of the crystallites.

The oxidation of the coking raw material at a temperature below the range of the mesophase transformation has the strongest influence on the graphitisability of coke. Oxidation immediately impairs both conditions for satisfactory graphitisability, since, together with the comminution of the mesophase spheres and the sharp decrease of anisotropy, cross links are formed in the oxidation process between the aromatic layers in the form of oxygen bridges. The dispersed components of the raw material affect only the first condition for graphitisability.

Among the types of coke described above, PEC graphitises least satisfactorily, since it is obtained from the types of pitch described above which contain a large amount of dispersed components, while PCEC graphitises most satisfactorily.

Structural anisotropy and the properties associated with it determine to a large extent the technological behaviour of coke and the properties of the articles made from it.

o0o

The advances in recent years in the understanding of the mechanism of structure formation of graphitising coke have served as a basis for the development of new methods for the preparation of coke with a specified structure and properties. The development of a new class of one-component carbon-graphite materials, the so called "mesophase carbons" with a regulated structure and properties, is being prosecuted at the present time on the basis of the above advances. At the same time, vigorous research is being continued on the structure and properties of mesophase products of different origins and also on the synthesis of new substances, the heat treatment of which results in the formation of a mesophase with the required properties and capable of being converted into carbon on subsequent carbonisation without a significant change in structure. Further study of the mechanism of the mesophase transformation and of the formation of the structure of graphitising coke is one of the fundamental trends in the chemical technology of carbon and the science of carbon-graphite materials.

Investigation of the Formation of Complexes of Organic Molecules and Lanthanide Ions in Solutions by the Electronic Energy Transfer Method

V.L.Ermolaev, E.V.Sveshnikova, and T.A.Shakhverdov

Studies on the non-radiative energy transfer between organic molecules and lanthanide ions in solutions and on the utilisation of this phenomenon in the investigation of coordination-chemical processes involving lanthanide ions are reviewed.
The bibliography includes 98 references.

CONTENTS

I. INTRODUCTION

We considered previously[1] the non-radiative energy transfer between organic molecules and transition metal (TM) ions and its application in the study of the mechanisms of photochemical reactions of coordination compounds. The description of the experimental data in the review was preceded by a brief account of modern ideas about the mechanisms and kinetics of non-radiative energy transfer processes[†].

This review is devoted to studies of energy transfer between organic molecules and lanthanide ions in solutions. The mechanisms of energy transfer involving transition metal and lanthanide (Ln^{3+}) ions have much in common, but there are also differences. One of these is due to the fact that the chromium(III) and cobalt(III) coordination compounds, which have been most thoroughly investigated from the standpoint of energy transfer and photochemistry, exchange ligands with the surrounding medium very slowly[2]. In the case of lanthanide ions, the exchange with the solvent is fairly rapid, so that the luminescence processes and the processes involving energy transfer from and to lanthanide ions show behaviour averaged over the lifetime of their excited state. Another difference is the relatively low sensitivity of the positions and intensities of the bands in the absorption and luminescence spectra of lanthanide ions to changes in the environment compared with transition metal ions. The latter factor facilitates the study of the mechanisms of energy transfer involving lanthanide ions. For this and other reasons, the mechanism of energy transfer with participation of lanthanide ions has now been elucidated more effectively than the mechanism of the same processes involving transition metal ions. All these factors made it possible to use the energy transfer phenomenon to study complex formation reactions between lanthanide ions and organic molecules in the ground and excited states. The application of these methods has already made it possible to observe a number of new phenomena, for example the formation of hitherto unknown types of ion pairs by lanthanide ions and anionic dyes and of stable complexes between aromatic ketones and lanthanide ions, permitted an estimate of the rate of insertion of a ketone in the solvation shell of an excited lanthanide ion, etc. The prospects resulting from the application of the energy transfer method in the study of coordination-chemical processes are discussed below. These methods will probably find wide-scale applications in chemical research by virtue of their simplicity and wide scope.

II. INDUCTIVE-RESONANCE ENERGY TRANSFER BETWEEN ORGANIC MOLECULES AND LANTHANIDE IONS IN SOLUTION

1. Energy and Electron Transfer from Organic Molecules in the Fluorescent State to Lanthanide Ions

For a long time, it was widely believed[3-5], on the basis of several experiments which yielded negative results, that the fluorescence of organic compounds is not quenched by lanthanide ions. Thus Rollefson and Stoughton[6] in 1941 did not observe significant quenching of the fluorescence of quinine sulphate, fluorescein (cation), anthracenesulphonic acid, and acridonesulphonic acid by La^{3+}, Er^{3+}, Sm^{3+}, Pr^{3+}, and Nd^{3+} ions in water. Later Weiss[7,8] and Linshitz and Pekkarinen[9] were likewise unable to observe such quenching for several organic compounds.

Ermolaev and Shakhverdov[10] observed that the fluorescence of a number of dyes and aromatic hydrocarbons in solutions is strongly quenched by lanthanide ions when their fluorescence spectra overlap the most intense absorption bands of the ions. The narrowness of the absorption bands of the lanthanide ions made it possible to avoid the filtering and reabsorption effects in the quenching of the fluorescence. The dependence of the extent of quenching of the fluorescence q_0/q and of the decrease of the fluorescence lifetime (τ_{fl}) on the lanthanide concentration was found to be linear. The proportionality of the quenching rate constant to the overlap integral of the spectra ($\int_0$) shows that the fundamental quenching mechanism involves the inductive-resonance dipole–dipole (*dd*) energy transfer (Table 1) via reaction 1[‡]. The energy level diagram for the above type of transfer, i.e.

$$ {}^1D^* + Ln^{3+} \rightarrow {}^1D + (Ln^{3+})^*, \qquad (1)$$

[†] The fundamental definitions and the significance of the quantities used in the present review were also given in the previous article[1].

[‡] Here and henceforth D, A, Ln^{3+} on the one hand and D^*, A^*, and $(Ln^{3+})^*$ on the other denote the energy donor molecule, the energy acceptor molecule, and the lanthanide ion in the ground and lowest excited states respectively.

is illustrated in Fig. 1. The hypothesis of energy transfer in such systems was confirmed by the observation of the luminescence of Nd^{3+} in the 8 : 1 $POCl_3$–$SnCl_4$ system sensitised by organic compounds (rubrene, trypaflavine, Acridine Orange, Acridine Yellow, etc.). The experiments on the flash photoexcitation of the systems also showed that the quenching of the fluorescence of organic compounds is not associated with their induced transition to a triplet state in the presence of paramagnetic heavy metal ions[10].

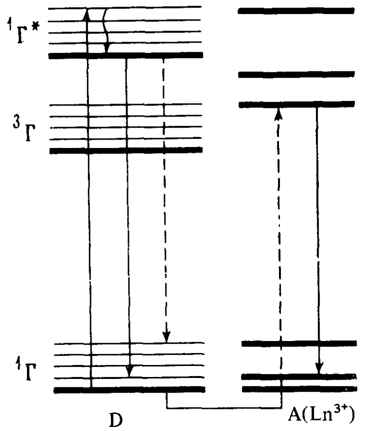

Figure 1. Schematic representation of the electronic levels in the energy transfer from organic molecules in the fluorescent state ($^1\Gamma^*$) to lanthanide ions.

The quenching of fluorescence by the Eu^{3+} ion, for which the $k_q/\int_0$ ratio is anomalously high (Table 1), involves reversible electron phototransfer via the mechanism

$$^1D^* + Eu^{3+}(^7F_0) \rightarrow {}^2D^+ + Eu^{2+}, \qquad (2)$$

as shown by Shakhverdov[11]. The Eu^{3+} ion exhibits the highest electron affinity among all the tervalent lanthanide ions[12] and can be readily reduced to Eu^{2+}. The constant k_q depends mainly on the ionisation potential of the organic molecules in the excited singlet state $I_p - E_{exc}$ (Table 2). In the flash photoexcitation of aromatic hydrocarbons in various solvents (acetone, methanol, etc.) in the presence of Eu^{3+}, a short-lived absorption due to their radical-cation ($^2D^+$) was observed; this decayed according to second-order kinetics[11]. The temperature variation of the quenching of the fluorescence of organic compounds by Nd^{3+} and Eu^{3+} ions also indicates different mechanisms of quenching by these ions.

Eisinger and Lamola[13,14] likewise found that the fluorescence of a number of biologically important compounds (for example tryptophan) is quenched by Eu^{3+} ions in H_2O and D_2O. They attributed this to energy transfer via molecular collisions, since the constant $k_q = 5 \times 10^9$ litre × mole^{-1}s^{-1} for tryptophan proved to be close to the rate constant for the reaction controlled by diffusion ($k_d \simeq 7 \times 10^9$ litre mole^{-1} s^{-1}). On this basis, they suggested[15] that Eu^{3+} be used to determine the decay times of the fluorescence of other compounds (nucleotides), assuming that $k_q = k_d$ in this case too. However, the absence of the sensitised luminescence of Eu^{3+} in the quenching of the fluorescence of tryptophan provides no grounds for such conclusion. The quenching of the fluorescence of tryptophan by the Eu^{3+} ion is probably due to reversible electron phototransfer via mechanism (2). Recent experiments by Ricci and Kilishowski[16] on the quenching of the fluorescence of indole derivatives by lanthanide ions confirm this view. They found that the Eu^{3+}, Yb^{3+}, and Sm^{3+} ions, i.e. those showing the greatest tendency towards reduction to the bivalent state, exhibit the strongest quenching effect, the rate constants for quenching by Yb^{3+} and Sm^{3+} ions being appreciably lower than the rate constant for diffusion through the solvent.

Table 1. The quenching of the fluorescence of organic compounds by lanthanide ions in acetone (293 K, in air)[10].

Donor	Acceptor	$10^{-9}k_q^*$, litre mole^{-1} s^{-1}	$10^{18}\cdot\int_0^{**}$	$10^{-26}\cdot k_q/\int_0$

* k_q is the rate constant for the quenching of the fluorescence of organic compounds by lanthanide ions.

** $\int_0 = \int_0^\infty I_D^H(\nu)\epsilon_A(\nu)\nu^{-4}d\nu$ is the overlap integral of the spectra; $I_D^H(\nu)$ is the distribution of the quantised spectral density, normalised with respect to a unit area, in the fluorescence spectrum of the energy donor and $\epsilon_A(\nu)$ is the decadic molar extinction coefficient of the energy acceptor. The values of ln 10 $\int_0$ were adopted as the "overlap integrals" in the study of Ermolaev and Shakhverdov[10].

Table 2. The quenching of the fluorescence of organic compounds by Eu^{3+} (acetone, 293 K, in air)[11].

Calculation of the critical energy transfer radius for the cases presented in Table 1 yields $R_0^{theor} \leqslant 10$ Å§. The mean square diffusion distance during the lifetime of

---

§The values of R_0^{theor} quoted previously[10] are somewhat too high.

the excited state ($\sqrt{\bar{r}^2}$), amounting to 40–70 Å, exceeds $3R_0^{\text{theor}}$, which leads to a linear variation of q_0/q with the acceptor concentration C_A. In order to compare the experimental results with the theory of the dipole–dipole energy transfer in liquid solutions, a study was made[17] of the quenching of the fluorescence of various dyes by Nd^{3+} ions. Table 3 presents some of the systems investigated. The distances of closest approach between the interacting molecules ($R_{\min}$) were calculated by the summation of their radii, obtained from their molar volumes (V_M) assuming spherical symmetry. The diffusion rates were also calculated from the V_M by the familiar empirical formula of Wielke and Change[18]. The values of k_t^{theor} were obtained with the aid of a computer from these values of the parameters on the basis of the theory of dipole–dipole energy transfer developed by Rozman and coworkers for liquid solutions[19]. It is noteworthy that very similar values of k_t^{theor} were also obtained by calculations based on the Galanin–Frank[20] and Tunitskii–Bagdasar'yan[21] theories corresponding to the case of "total mixing" or "infinite" diffusion coefficients.

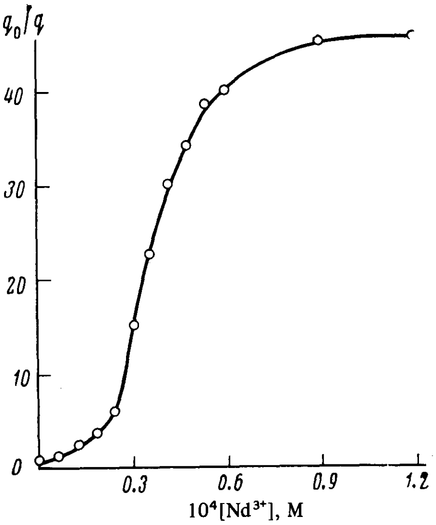

Figure 2. Dependence of the quenching of the eosin fluorescence ($C = 3.0 \times 10^{-5}$ M) on the Nd^{3+} concentration in dimethyl sulphoxide at 293 K under conditions corresponding to the formation of solvated ion pairs.

This is due to the low viscosity of acetone and the low value of R^{theor}. Table 3 shows that the experimental values of k_q for dyes exceed somewhat the values calculated theoretically. For rubrene, k_q and k_t^{theor} are virtually identical. Possibly the energy transfer for dyes with active groups is influenced by the chemical electron donor–electron acceptor interactions. The occurrence of such interactions promotes a more effective penetration of energy donors into the solvation shell of Nd^{3+}, i.e. decreases $R_{\min}$. The fluorescence of other aromatic hydrocarbons (phenanthrene, anthracene, 1,4-benzanthracene, and pyrene) is quenched by Nd^{3+} much less effectively ($k_q > 6 \times 10^8$ litre mole^{-1}s^{-1}) owing to the low value of its overlap integral ($J_0 < 0.06 \times 10^{17}$) with the absorption spectrum of this ion.

Table 3. The quenching of the fluorescence of organic compounds by $Nd(NO_3)_3.6H_2O$ in acetone (293 K, in air; $k_d = 2.1 \times 10^{10}$ litre mole^{-1}s^{-1})[17].

*The measurements of τ_0 for the fluorescence of these compounds were kindly carried out by V. Veselova on a GOI phase fluorimeter.

**The theoretically calculated rate constants for the energy transfer.

In moist acetone, where the first studies on the quenching of the fluorescence by lanthanide ions were performed, the lanthanide ions exist in the form of the neutral complexes $Ln^{3+}(NO_3^-)_3.4(5)H_2O$.[22] On the other hand, Shakhverdov showed recently[23] that, when the energy transfer takes place in water, dimethylformamide, dimethyl sulphoxide, and other solvents which are powerful electron donors (in which lanthanide ions exist in the form of triply charged complexes with neutral solvent molecules and the dyes are also employed in the form of charged ions), then such transfer is influenced significantly by the electrostatic repulsive or attractive forces between the energy donor and acceptor.

2. Energy Transfer as an Indicator of a New Type of Ion Pair (Dye–Lanthanide Ion)

In a study of the influence of the solvent on energy transfer from anionic dyes [eosin(2–)] to lanthanide ions, Shakhverdov[23] found that in such a system one can observe several types of interaction between the energy donor and acceptor. Each of these types is clearly manifested in the characteristic dependence of the fluorescence quenching on the concentration of lanthanide ions and in the absorption spectra of the dyes. The measurements made it possible to discover three cases: (1) The quenching of the fluorescence of the donor varies non-linearly with the concentration of lanthanide ions, the absorption spectrum of the dye remaining unchanged. (2) The quenching of the fluorescence increases rapidly at lanthanide concentrations comparable to the concentration of the dye, after which it reaches saturation and remains constant (in the range of C_A from 10^{-4} to 10^{-2} M and above with $C_D \simeq 10^{-5}$ M; see Fig. 2). At the same time there is some enhancement of the absorption (by a factor up to 1.2) or a slight bathochromic shift (< 10 nm) of the absorption band. (3) The donor fluorescence is completely quenched even by low concentrations of the acceptor of the order of $C_A \simeq C_D$ and appreciable changes are observed in the absorption spectrum of the dye.

It was found that two fundamental characteristics of the solvent, namely the dielectric constant ϵ and the donor number *DN* as defined by Gutman[24], are of decisive importance for the type interaction between the dye and the lanthanide ion. The first type includes solvents with high values of ϵ or *DN*, for example formamide and water, and the second includes solvents with moderate values of ϵ and fairly high values of *DN* (glycerol, ethylene glycol, methyl and ethyl alcohols, pyridine, dimethylformamide, and dimethyl sulphoxide). The third class of solvent includes moist acetonitrile and acetone (low values of *DN* and moderate values of ϵ).

Since the energy donor and acceptor have charges of opposite signs (2- and 3+), they can remain free (I) or can form various types of solvent-separated (II) or contact (III) ion pairs as well as covalent complexes (IV):

$$\underset{(I)}{D^{2-}+A^{3+}} \rightleftharpoons \underset{(II)}{D^{2-}|\text{solvent}|A^{3+}} \rightleftharpoons \underset{(III)}{D^{2-},A^{3+}} \rightleftharpoons \underset{(IV)}{D^{2-}:A^{3+}}. \tag{3}$$

It was natural to relate the observed behaviour of the system to the above scheme. Indeed, for high values of ϵ and *DN*, the attraction between ions with different charges is reduced; this does not favour their aggregation. On the other hand, an appreciable decrease of these parameters can lead to the formation of a complex of the dye and the lanthanide ions. It has been suggested[23] that the permanent quenching of the fluorescence of dyes by lanthanide ions in solvents of the second type is due to the energy transfer from $^1\Gamma^*$ states of the dye to the acceptor within ion pairs. This hypothesis is confirmed by the observation of the eosin-sensitised luminescence of Nd^{3+} in dimethylformamide and d_6- and h_6- dimethyl sulphoxide. The correlation between k_q and $\int_0$ for four ions absorbing in the region of the fluorescence of D ions (Table 4) permits the conclusion that the mechanism of energy transfer in the postulated ion pairs is of the dipole–dipole (*dd*) type. The slightly higher value of $k_q/\int_0$ for Nd^{3+} compared with other ions may be due to the contribution to its $\int_0$ via the $^4I_{9/2} \rightarrow {}^4G_{5/2;7/2}$ transitions, which are allowed, being of the quadrupole type.

The observed quenching of fluorescence by non-absorbing ions may be explained by electron phototransfer within ion pairs. It is known[12,25] that Eu^{3+}, Sm^{3+}, and Yb^{3+} ions are capable of reversible photochemical reduction to the bivalent state and Ce^{3+}, Dy^{3+}, and Tb^{3+} ions are capable of reversible photochemical oxidation. Electron phototransfer processes with participation of free Eu^{3+} and Ce^{3+} ions have been investigated by Shakhverdov[11]. When an excess of $Gd(NO_3)_3$ is added to a solution of eosin in dimethylformamide, the fluorescence of which has been quenched by $Nd(NO_3)_3$, the eosin fluorescence is re-established and can be restored almost to the initial level. The effect of $Gd(NO_3)_3$ can be explained by the displacement of Nd^{3+} as the counterion from the [eosin(2-) ... Nd^{3+}] ion pair and its replacement by Gd^{3+}, which hardly quenches the fluorescence of the dye. The composition of the ionic associated species has been determined by spectrophotometrical analytical methods[26] [the isomolar series (continuous variations) and molar ratios methods] in dimethyl sulphoxide at 293 K (it was indeed found to be 1 : 1) together with its instability constant, which proved to be 9.4×10^{-7} mole litre^{-1}.

Assuming a *dd* energy transfer mechanism for the quenching of the fluorescence of eosin in ion pairs with Nd^{3+}, Ho^{3+}, Pr^{3+}, and Er^{3+}, the distances between the ions in such pairs were calculated by the Förster–Galanin theory[23,26]. Values ranging from 6.2 to 7.3 Å were obtained (Table 4), i.e. approximately equal to the sum of the radii of the dye and the solvated lanthanide ion. We obtained similar values of *R* (R_{min}) in a study of the reverse energy transfer from Tb^{3+} to eosin in water, where the ions are not bound in pairs[27]. Thus the distance between the components of the ion pair can be determined by studying the energy transfer, which is of considerable interest.

Table 4. The quenching of the fluorescence of eosin (2-) in ion pairs with lanthanide ions in dimethylformamide (293 K; $C_{eosin} \simeq 5 \times 10^{-6}$ M; $\tau_0^{fl} = 3.9 \times 10^{-9}$ s; $q_0^{fl} = 0.76$)[23].

*The first-order rate constants determined from the change in the intensity of the fluorescence of eosin in the presence of lanthanide ions.

We are not aware of data obtained by other methods concerning the possible existence of ion pairs comprising dyes and lanthanide ions¶. The concept of ion pairs is widely used nowadays in the investigation of the interaction of radical-anions and organic carbanions with alkali metal ions[29].

It is noteworthy that the relative extents of quenching of the fluorescence of eosin by lanthanide ions, determined from the decrease of the yield q_0/q and of $\tau_{fl} = \tau_0/\tau$, are not equal. τ was measured with the aid of a phase fluorimeter. $q_0/q = 4.0$ and $\tau_0/\tau = 1.7$ were obtained for Ho^{3+} ions. This difference may be due to both the simultaneous coexistence in solution of several types of ion pairs and to partial dissociation of the ion pairs into individual ions.

The ion pairs formed in aqueous solutions are highly dissociated. The quenching of the fluorescence of eosin by lanthanide ions is in this case slight, is manifested at much higher concentrations than in dimethylformamide and dimethyl sulphoxide ($q_0/q \simeq 4$ for $C_{Nd^{3+}} = 0.04$ M), and is not accompanied by a decrease of τ_0^{fl}. The p*K* values

---

¶The presence of ion pairs of another type involving cationic dyes and lanthanide ions, where the interaction takes place via the anions (Cl^-, Br^-) associated with the dye, has been suggested[28] in a study of the NMR shift induced by lanthanides.

for the 1 : 1 eosin–Nd^{3+} ion pairs in water, measured by the equilibrium shift method modified to allow for quenching of luminescence, were found to be 1.64, 1.79, 1.96, 2.13, and 2.32 at pH 5.5 and ionic strengths of 0.48, 0.24, 0.12, 0.06, and 0.03 respectively. Extrapolation to zero ionic strength (using the Davies equation[30]) yields $pK = 2.85$, i.e. $K = 1.4 \times 10^{-3}$ M. It is noteworthy that the spectrophotometric methods do not yield in this case any information, since the formation of eosin–Nd^{3+} ion pairs ($C \leqslant 0.04$ M) is not accompanied by a change in the absorption spectra. The neutralisation of lanthanide ions in aqueous solutions containing eosin following the addition of sodium acetate, sodium sulphate, sodium nitrate, etc. leads to an appreciable decrease in the efficiency of the fluorescence quenching[22]. The anions of the above salts are more likely to form complexes with Ln^{3+} than in eosin. The sequence of the inhibiting effects of the anions is satisfactorily correlated with the stability constants of their complexes with lanthanide ions.

Table 5. Comparison of the calculated (R_0^{theor}) and experimental (R_0^{exp}) critical radii for energy transfer from $Eu(TTA)_3Phen$ to dyes {2 : 1 ethanol–ether; 77 K; $[Eu^{3+}] \simeq 10^{-4}$ M; $\tau_0^{lum} \simeq 0.7$ ms}[31,32].

*TTA = thenoyltrifluoroacetonate and Phen = 1,10-phenanthroline.

**The above dye (Tũrkis blau G) has been incorrectly referred to in some studies[31-33] as "Turkish Blue G".

***The values of R_0^{theor} were calculated on the assumption that $\bar{\Phi} = \sqrt{2/3}$. According to Maksimov and Rozman[37], $\bar{\Phi} = 0.845\sqrt{2/3}$ for solid solutions, but we were unable to correct R_0^{theor} because q_{OD} was somewhat too high.

3. Energy Transfer from Lanthanide Ions to Dyes in Solutions

Ermolaev and Shakhverdov[31-33] investigated the non-radiative energy transfer from excited lanthanide ions (Eu^{3+}, Tb^{3+}) to dyes in solid and liquid solutions when the luminescence spectra of Eu^{3+} and Tb^{3+} overlapped the intense absorption bands of the dyes. The lanthanide ions were used in the form of complexes with organic ligands and also as their nitrate salts. It was shown that the addition of dyes (anionic and cationic) to the solid solutions containing Eu^{3+} leads to a decrease of the yield and a shortening of τ—the luminescence time of the ion. The quenching was accompanied by the appearance of the sensitised fluorescence of the dyes. By comparing the concentrations of the acceptor which correspond to the quenching of the fluorescence by a factor of two and the $\int_0$ for the spectra, it was shown[31] that the quenching is due to the inductive-resonance dipole–dipole energy transfer. In conformity with the Főrster–Galanin theory, the relative decrease of τ was smaller than the relative decrease of the luminescence yield. At the same time, deviations of the rate of decay of the luminescence from the exponential relation were observed for the quenched solid solutions. The calculated dependence of the efficiency of the quenching of the Eu^{3+} luminescence on the concentration of acceptors and the luminescence decay law for dipole–dipole energy transfer in Refs. 34–36 agreed satisfactorily with experimental data. Table 5 presents several values of the theoretical critical energy transfer radii and compares them with the R_0^{exp}. Evidently the agreement for the first four pairs is satisfactory; the poorer agreement for the last three combinations we believed to be caused by the greater tendency of these dyes towards dimerisation under the experimental conditions.

Thus one can claim with confidence that the quenching of the luminescence of lanthanide ions by dyes in solid solutions is due to *dd* energy transfer when there is no chemical interaction between them leading to a change in the absorption spectra:

$$^1(Ln^{3+})^* + {}^1A \rightarrow Ln^{3+} + {}^1A^* \,, \tag{10}$$

where ^1A and $^1A^*$ are the molecules of the energy acceptor (dye) in the ground and excited singlet states. The energy level diagram for energy transfer of this type is illustrated in Fig. 3.

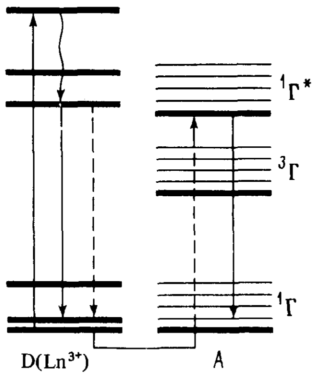

Figure 3. Schematic illustration of the electronic levels in the energy transfer from lanthanide ions to organic dyes with excitation of the singlet excited levels of the latter.

In order to investigate the influence of diffusion on the above energy transfer a study was made of the quenching of the luminescence of Tb^{3+} compounds in liquid solutions[32,33]. The values of $\int_0$ were varied widely (within the limits of three orders of magnitude); compounds with $\int_0 = 0$ were also used. It was noted that τ_0^{lum} decreased, but, in contrast to the solid solutions, the quenching of the Tb^{3+} luminescence remained exponential. The absolute quenching rate constants k_q were obtained from the Stern–Volmer relations between τ_0^{lum}/τ^{lum} and C_A. It was found that the values of $k_q/\int_0$ remained approximately the same, which provided evidence for the assumption that in liquid solutions the quenching of the luminescence of lanthanide ions is caused also by *dd* energy transfer. For low values of $\int_0$ and $\int_0 = 0$, exchange interactions leading to the excitation of the triplet states of the organic molecules† contributed to the quenching of the luminescence. However, the rate constants for such processes were low ($\leq 3 \times 10^5$ litre mole^{-1}s^{-1}) compared with energy transfer to the singlet states.

Table 6 presents data obtained by Shakhverdov and Ermolaev[33] for the quenching of the $Tb(Sal)_3$ luminescence by a number of dyes‡. The measured k_q were compared with the values calculated from the theory of *dd* energy transfer in the presence of diffusion[19] and reasonably satisfactory agreement between them was obtained, bearing in mind the uncertainty in the parameter R_{min}. Table 6 also lists the values of R^{theor}_{min} calculated for the condition that $k_q = k^{theor}_t$. The discrepancy between k_q and k^{theor}_t for $Tb(NO_3)_3$ is greater than for $Tb(Sal)_3$:[33] in the latter case, additional electron donor–electron acceptor interactions between Tb^{3+} and the dyes probably contribute to the energy transfer. Analysis of the results showed that energy transfer from lanthanide ions can be described satisfactorily in terms of the conclusions derived from theories based on the case of infinite diffusion coefficients (Galanin[38], Galanin-Frank[20], Tunitskii–Bagdasar'yan[21]). The mean square diffusional distance ($\sqrt{\bar{r}^2}$) during the period τ_{OD} is approximately 2×10^4 Å, which greatly exceeds R_0^{theor}. This is responsible for the exponential decay of the luminescence of the quenched solutions and for the linearity of the relation $\tau_0/\tau = q_0/q = f(C_A)$. By altering the temperature, it is possible to vary $\sqrt{\bar{r}^2}$. Thus energy transfer from lanthanide ions to dyes constitutes a convenient model for the investigation of the influence of diffusion and dipole–dipole energy transfer.

Table 6. The quenching of the luminescence of $Tb(Sal)_3^*$ by dyes {methanol; 293 K; $[Tb^{3+}] = 2 \times 10^{-4}$ M; $\tau_0^{lum} = 1.0 \times 10^{-3}$ s}[33].

* Sal = salicylate anion (Ed. of Translation).

The change in the overall diffusion coefficients from 10^{-5} cm^2 s^{-1} to infinity for the overall energy transfer from lanthanide ions to dyes ($R_0^{theor} \simeq 60$ Å) has no effect whatever on the transfer rate constant. This greatly facilitates the study of the influence of the chemical nature of the solvent on the energy transfer. Our data for energy transfer from $Tb(NO_3)_3$ to fuchsin are presented in Table 7. In order to compare experiment with theory, the values of R_0^{theor} were calculated in all cases from the $\int_0$ and q^{fl}_{OD}. We obtained the theoretical values of k^{theor}_t from the Tunitskii–Bagdasar'yan formula[21] [see also Eqn. (6) in Ref. 1], assuming that $R_{min} = 8$ Å. The influence of Coulombic interaction on the energy transfer between fuchsin and Tb^{3+} ions, which are positively charged (the 1+ ... 3+ system), is in this case small (see subsection 4) and was disregarded.

* The values of *DN* for the solvents were determined by Gutmann[24] relative to $SbCl_5$. For lanthanide ions, coordination via the nitrogen atom is weaker than via the oxygen atom. Thus the value *DN* quoted for pyridine is much too high in relation to other solvents as regards interaction with lanthanide ions.

Comparison of the theory and experiment showed that the efficiency of such transfer (i.e. k_q/k^{theor}_t) decreases with enhancement of the electron-donating properties of the solvent (*DN*) and is independent of ε (see Table 7). The deviation of pyridine from the above series, observed by Ermolaev and coworkers[39,40], is due to the specific features of its interaction with lanthanide ions. The decrease of the ratio k_q/k^{theor}_t with increase of *DN* may be accounted for by the increase of R_{min}. It is known that an increase of *DN* for solvents entails an increase in their solvating capacity in relation to lanthanide ions. This leads to an increase of the size of the first coordination sphere of such ions. Furthermore, in solvents which are powerful electron donors there is also a possibility of a certain degree of order also in the second coordination sphere of the lanthanide ions, which prevents its penetration by dyes. In solvents which are weak electron donors (acetone, acetonitrile), dyes are also apparently capable of becoming incorporated in the first coordination sphere. Indeed, theoretical calculation of R^{theor}_{min} for solvents of this type (on the basis of the condition $k_q = k^{theor}_t$) yields very low values (down to 4.1 Å). Some influence of the *DN* for solvents on the reverse transfer (from dyes to lanthanide ions) has also been noted, but in this case it is masked by the influence of solvent viscosity.

---

4. The Influence of Electrostatic Interactions of the Donor and Acceptor on the Efficiency of Energy Transfer

We have considered hitherto non-radiative energy transfer mainly between neutral complexes of lanthanide ions and dyes. However, in many solvents lanthanide ions and dyes exist in the form of charged ions. In this case, the rate of non-radiative energy transfer is influenced also by the forces of the electrostatic interaction between the donor and acceptor. Shakhverdov and Bodunov[23,32,41] demonstrated such influence in the energy transfer from the free Tb^{3+} ion in water to anionic (2-) and cationic (1+) dyes, the results being compiled in Table 8, which shows that the efficiency of the quenching of the Tb^{3+} luminescence by dyes (the k_q/J_0 ratio) depends markedly on the sign of the charge of the latter. The interaction of anionic dyes with lanthanide ions is much more effective. To demonstrate the electrostatic nature of the influence of the acceptor charge, sodium acetate (CH_3COONa), whose anions form neutral complexes with Tb^{3+}, was introduced into the solution. This resulted in the opposite effect on the (3+ ... 1+) and (3+ ... 2-) systems. In the former case k_q decreased and in the latter increased (Fig. 4); the values of k_q/J_0 became equal under these conditions. The limiting quenching constants in the presence of sodium acetate (k'_q) and k'_q/J_0 are listed in Table 8.

Table 8. The quenching of the luminescence of $Tb(NO_3)_3$ by organic dyes in water $\{[Tb^{3+}] = 0.03\ M;\ \tau_0^{lum} = 4.5 \times 10^{-4}\ s;\ \tau_0'^{lum} = 7.0 \times 10^{-4}\ s;\ 293\ K\}$[41].

The results of the above experiments were compared with theoretical computer calculations based on Bodunov's theory[42,43], taking into account the influence of the electrostatic interaction between the ions on the dipole-dipole energy transfer. The calculations were performed for two cases, differing in the size of the hydration shell of Tb^{3+}. In the first case, it was assumed that the entire hydration shell (known to comprise approximately 13 water molecules according to diffusion data) determines the value of R_{min}. In the second case, account was taken only of the immediate environment of Tb^{3+} (six water molecules). In the calculations, the change in R_0^{theor}, R_{min}, and τ_0^{lum} on formation of Tb^{3+} complexes with CH_3COO^- was also taken into account. This leads in all cases to an increase of $k_t'^{theor}/k_t^{theor}$ by factors of 1.8

and 1.3 respectively. There was a difference between the absolute values of k_q and k'_q determined experimentally and calculated theoretically. The reason for this is not altogether clear and, as stated above, is apparently due to the solvent. On the other hand, the effect of the electrostatic interactions on the energy transfer is described fairly satisfactorily by the theory[42,43]. Table 8 lists the experimental (k'_q/k_q) and theoretical ($k'^{\text{theor}}_t/k_t^{\text{theor}}$) ratios of the rate constants for the quenching of the Tb^{3+} luminescence by dyes with and without sodium acetate. Evidently, in the system with Coulombic repulsion between the ions (3+ ... 1+), the change in the parameter $R_{\min}$ has no influence whatever on the theoretical rate constant ratio and corresponds to the experimental values of k'_q/k_q. On the other hand, the system with a Coulombic attraction between the ions (3+ ... 2-) is more sensitive to this parameter. The agreement with experiment in this system is found to be better when account is taken of only the first coordination sphere of Tb^{3+}.

5. Energy Transfer from Lanthanide Ions to Organic Radical-Ions

It was of interest to investigate the influence of the multiplicity of the energy states of the energy acceptors on the mechanism of the energy transfer from lanthanide ions. For this purpose, Shakhverdov[44] used for acceptors the radical-cations of aromatic hydrocarbon with a doublet ($^2\Gamma$) ground state. One could then expect the occurrence of an exchange energy transfer, since the Wigner rule (overall spin conservation) holds under these conditions. The experiments were performed in sulphuric acid at 293 K. The quenching of the Tb^{3+} and Eu^{3+} luminescence by three radical-cations was investigated (Table 9). At the same time, experiments were performed with acceptors having a $^1\Gamma$ ground state (the proton complex of tetracene, etc.). In both cases, the experimental results were compared with theory (assuming that $R_{\min}$ = 8 Å). It was shown that the quenching of the luminescence of lanthanide ions by an organic radical is due to *dd* energy transfer. An estimate of the probability of electron phototransfer in such systems showed that it cannot compete with energy transfer. Indeed k_q for the quenching of the Tb^{3+} luminescence in sulphuric acid by one of the most powerful electron acceptors (Ce^{4+} ions) proved to be only ~ 1.2×10^6 litre $\text{mole}^{-1}\text{s}^{-1}$. In the quenching of the Eu^{3+} luminescence by powerful organic electron donors (diphenylamine and triphenylamine) and in the quenching of the Tb^{3+} luminescence by electron acceptors (chloranil, bromanil, *p*-benzoquinone, and *sym*-trinitrobenzene), the values of k_q are likewise low. Thus $k_q \leq 2.2 \times 10^6$ litre $\text{mole}^{-1}\text{s}^{-1}$ for the quenching of the Tb^{3+} luminescence (in methanol) and $k_q \leq 4.8 \times 10^5$ litre $\text{mole}^{-1}\text{s}^{-1}$ for Eu^{3+} (in acetone). The change in the multiplicity of the ground state of the acceptors (from $^1\Gamma$ for dyes to $^2\Gamma$ for radicals) did not therefore lead to a change in the mechanism of the energy transfer.

III. THE EXCHANGE-RESONANCE ENERGY TRANSFER

The exchange-resonance energy transfer between the donor and the acceptor requires overlap of their electron clouds[45,46], which is also needed for the formation of a covalent bond between them. Indeed, a definite correlation can be established in many instances between energy transfer and complex formation. It is particularly pronounced for the interaction of triplet ketones with lanthanide ions and of excited lanthanide ions with aromatic ketones, leading to energy transfer from the excited triplet levels of the latter. Energy transfer involving lanthanide ions to and from the triplet level of organic molecules takes place via the exchange-resonance mechanism[47-49]. As will be shown below, this is why the study of this type of energy transfer has proved particularly fruitful in the development of methods for the investigation of complex formation in solutions.

1. Energy Transfer from the Triplet States of Organic Molecules to Lanthanide Ions

(a) Solid solutions. The first experiments on these lines were published by Smaller et al.,[50] who observed a marked decrease of the amplitude of the ESR signal of the triplet molecules of perdeuteronaphthalene in a 9 : 1 methanol–water solution at 77 K in the presence of Gd^{3+} ions. They believed that the mechanisms of this quenching involved the intercombination transition $^3\Gamma \rightsquigarrow \Gamma_0^1$ catalysed by the paramagnetic ion. Indeed the Gd^{3+} ion has a high magnetic moment (8.2 μ_B). In addition, they also observed a non-rigorous correlation between the rate of quenching of the triplet state and the magnetic moments of Cu^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, Fe^{2+}, and Gd^{3+} ions.

Breuninger and Weller[51] recently investigated the influence of the addition of Gd^{3+}, La^{3+}, and Tb^{3+} ions on the luminescence of perdeuteronaphthalene and triphenylene in a 9 : 1 methanol–water solid solution at 77 K. The fluorescence of naphthalene and triphenylene is not quenched by lanthanide ions up to a concentration of the latter of 0.5 M. The phosphorescence of both hydrocarbons is quenched by Tb^{3+} ions, but not Gd^{3+} and La^{3+} ions. They showed that the decreased amplitude of the ESR signal of triplet perdeuteronaphthalene in the presence of Gd^{3+}, observed by Smaller et al.,[50] is due exclusively to the broadening of the ESR lines of the triplet molecules and not to a decrease in their concentration.

Breuninger and Weller[51] explained the quenching of the phosphorescence of organic molecules by Tb^{3+} (and transition metal) ions as a consequence of non-radiative energy transfer. The occurrence of energy transfer is confirmed by the observation of the triphenylene-sensitised Tb^{3+} luminescence. The energy transfer in the case of Tb^{3+} has an exchange-resonance mechanism; this is supported by the exponential variation of the quenching of the phosphorescence (q_{OD}/q_D) with the concentration of the energy acceptor (Tb^{3+}) and by the approximately tenfold difference between the slopes of the q_{OD}/q_D and τ_{OD}/τ_D curves as a function of Tb^{3+} concentration. The critical radii R_0 and ρ^{-1}§ for the transfer from perdeuteronaphthalene and triphenylene to Tb^{3+} are respectively 11.0 Å and 0.10 for perdeuteronaphthalene and 13.6 Å and 0.14 for triphenylene. The values of R_0 and the ratios of the slopes obtained for the systems investigated are close to the analogous quantities for the triplet–triplet energy transfer between organic molecules in solid solutions via the exchange-resonance mechanism[46,52,53].

The high efficiency of energy transfer from the $^3\Gamma$ states to the Tb^{3+} ion has been explained[51] by the incorporation of the energy donors in the solvation shell of the ion and the formation of complexes. We believe that this explanation is not very probable for the system investigated, since the inner coordination shell comprises polar water and alcohol molecules and their displacement by non-polar aromatic hydrocarbon molecule is unlikely.

The quenching of the benzoquinone phosphorescence by lanthanide ions in solid alcohols at 77 K was investigated by Gevorkyan[54]. An exponential relation was observed between the quenching and the concentrations of Nd^{3+}, Eu^{3+}, and Tb^{3+} ions. The critical transfer distances are 13.0 Å for Nd^{3+}, 12.0 Å for Eu^{3+}, and 11.0 Å for Tb^{3+}. The ratio ρ is close to 10 for quenching by Eu^{3+} and Tb^{3+} and of the order of 4–6 for quenching by Nd^{3+}. We suggest that in the case of Eu^{3+} and Tb^{3+} the exchange-resonance mechanism is decisive, while quenching by Nd^{3+}, which has more intense absorption bands, involves both exchange-resonance and inductive-resonance energy transfer mechanisms.

The energy transfer from two ketones (methyl 2-naphthyl ketone and 2-fluorenyl methyl ketone) to Eu^{3+} and Tb^{3+} ions in solid solutions (1 : 4 methanol–ethanol) at 77 K has been investigated by Minn et al.[55,56] They established the occurrence of energy transfer from the decrease in the decay time and in the intensity of the phosphorescence of the ketones in the presence of lanthanide ions and also from the appearance of the sensitised Eu^{3+} and Tb^{3+} luminescence. Their quantitative data are in poor agreement with modern ideas concerning any of the known mechanisms of non-radiative energy transfer in solid solution. The effective Bohr radii quoted by the authors[55,56] for the system investigated, namely $L = 4.5$–20 Å, also appear to be extremely doubtful, since $L < 2$ Å even for the triplet–triplet energy transfer between two aromatic molecules and the rate of decrease of the electron density for the 4*f* shell of the lanthanide ion must be greater than the rate of decrease of the π-electron density. The mechanism of energy transfer from aromatic ketones to lanthanide ions in solid solutions requires additional investigation.

(b) Liquid solutions. The role of complex formation. Porter and Wright[57] observed the quenching of the triplet state of naphthalene by neodymium ions in ethylene glycol at 298 K; $k_q = 4 \times 10^5$ litre $mole^{-1} s^{-1}$, which is lower by three orders of magnitude than the diffusion rate constant under the same conditions ($k_d = 3.7 \times 10^8$ litre $mole^{-1} s^{-1}$). It was suggested that the effect is due to the intercombination degradation of the triplet molecule to the ground state catalysed by the lanthanide ion:

$$^3D + {^nLn^{3+}} \rightsquigarrow {^1D} + {^nLn^{3+}}. \qquad (11)$$

Matovich and Suzuki[58] and other investigators[59–64] demonstrated the sensitisation by the solvent of the luminescence of Eu^{3+}, Sm^{3+}, Tb^{3+} and Dy^{3+} ions dissolved in aromatic ketones. The phenomenon is due to the non-radiative energy transfer from the lowest triplet levels of the ketones to lanthanide ions:

$$\begin{aligned} &^3D + {^nLn^{3+}} \rightarrow {^1D} + {^m(Ln^{3+})^*}; \\ &^m(Ln^{3+})^* \rightarrow {^nLn^{3+}} + h\nu_{s.l.} \end{aligned} \qquad (12)$$

The fact that the intramolecular energy transfer in complexes of lanthanide ions with organic compounds observed previously[65–68] did not occur under these conditions was demonstrated by the following findings: (1) the coincidence of the absorption spectra of the ketone and the ketone–lanthanide ion system in the range 300–400 nm, where lanthanide ions do not exhibit an absorption comparable to that of ketones; (2) by the disappearance of the sensitised luminescence on freezing. The intensity of the sensitised luminescence of lanthanide ions in ketones increased with increase in the temperature of the solution. On the other hand, Faidysh and coworkers[69] observed a decrease in the intensity of the sensitised luminescence of $Eu^{3+}(NO_3^-)_3$ dissolved in benzophenone with increase of temperature and the sensitised luminescence did not disappear even at 77 K. A complication which prevented an unambiguous interpretation of these relations[58,66] is the migration of the energy of the triplet excitation via the molecules of the aromatic ketones until their capture by the lanthanide ion. Zolin and coworkers[70–72] extended the range of energy donors by sensitising the lanthanide ions with dyes and certain heteroaromatic compounds.

Ermolaev and coworkers[73–78] investigated the kinetics of the energy transfer from aromatic ketones with lowest triplet states of the n, π^* and π,π^* types to lanthanide ions in solutions. The diffusional mechanism of energy transfer and the involvement in the latter of the lowest triplet state of ketones were demonstrated by the method involving competition between the transfer to the lanthanide ion and the triplet–triplet transfer of energy to the acceptor (see Scheme 1 below).

The study of the dependence of the intensity of the benzophenone-sensitised luminescence of Eu^{3+} on its concentration and on the concentration of the triplet energy acceptor (naphthalene) showed that (1) the transfer takes place from the lowest triplet level of the ketone (see Fig. 5), (2) the rate of energy transfer is proportional to the concentration of the ion and independent of the concentration of the ketone, and (3) the quenching of the benzophenone-sensitised luminescence of the lanthanide ion (Eu^{3+}) by the triplet energy acceptor (naphthalene) obeys the Stern–Volmer relation and it follows from the slope of the linear plot that the rate constant for the energy transfer from the ketone to Eu^{3+} in acetone is almost two orders of magnitude lower than the diffusion rate constant k_d and the conclusion reached by Heller and Wasserman[62] and Filipescu and Mushrush[79] that $k_t = k_d$ for the solvent is therefore incorrect. The later conclusion that $k_t \ll k_d$ was confirmed by Wagner and Schott[80], using the same method, and by Ermolaev and Tachin[74], using the method of flash photoexcitation, from the decay of the triplet–triplet

§ $$\rho = \lim_{C_A \to 0} \frac{d(q/q_0)}{dC_A} \frac{d(\tau/\tau_0)}{dC_A}.$$

absorption. Table 10 lists the rate constants for the energy transfer from triplet ketones to Eu^{3+}. It shows that the rate constant for the intermolecular transfer in moist acetone for aromatic ketones without substituents in the benzene rings is an order of magnitude higher in the case of ketones with the lowest triplet state of the n,π^* type compared with ketones in which this state is of the π,π^* type. The introduction of electron-accepting substituents into the benzene rings (in our case halogens) greatly decreases the value of k_t.

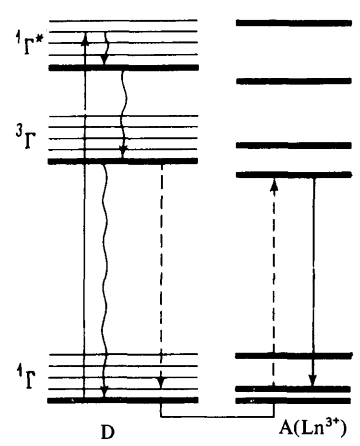

Figure 5. Schematic illustration of the electronic levels in the energy transfer from organic molecules in the triplet state ($^3\Gamma$) to lanthanide ions.

Table 10. The rate constants for the intermolecular energy transfer from the triplet state of ketones to $Eu(NO_3)_3$ in moist acetone at 293 K (according to the data of Ermolaev and Tachin[74] and Morina Sveshnikova[75]).

*The method based on the competition with the exothermic triplet–triplet energy transfer to the organic acceptor molecule.

**The method of flash photoexcitation based on the influence of Eu^{3+} on the rate of decay of the triplet–triplet absorption in the evacuated solution.

Measurements of the rate constants for the energy transfer from aromatic ketones in the triplet state to different lanthanide ions in moist acetone at 293 K showed that the rate constant for the exothermic energy transfer varies within a range of 1–1.5 orders of magnitude and is in all cases more than 10 times smaller than the rate constant for diffusion in acetone. The attempt to find a correlation between the values of k_t and the overlap integrals of the phosphorescence spectra of the ketone donors with the absorption spectra of the lanthanide ions was unsuccessful[74]. The situation was complicated even further by studies of the influence of solvents and temperature on k_t.[40,77,81] It was established that k_t decreases on passing to solvents characterised by higher Gutmann[24] donor numbers *DN*. k_t in moist acetone, methanol and acetonitrile increases with increase of temperature. Furthermore, Sveshnikova et al.[77] established that, in solvents with low and moderate values of *DN*, there is both intermolecular diffusional and intramolecular energy transfer between aromatic ketones and lanthanide ions. The existence in solution of lanthanide complexes of aromatic ketones is indicated unambiguously by the dependence of the quenching of the luminescence sensitised by ketones on the concentration of the organic triplet energy acceptor. Instead of a straight line of the Stern–Volmer type, which obtains for purely intermolecular transfer, a curve is obtained; this is a result of the summation of two straight lines with different slopes. Examples of such relations are illustrated in Fig. 6 for the quenching by *trans*-stilbene of the luminescence of europium sensitised by 4-ethoxy-4′-methoxybenzophenone.

Scheme I

	Expression for the rate of the process

---

* ^1K, $^1K^*$, and ^3K denote respectively the organic molecule of the ketone donor in the singlet ground state, the lowest singlet excited state, and the lowest triplet state respectively and ^1A, $^1A^*$, and ^3A are the corresponding quantities for the triplet energy acceptor molecule—the quenching agent for the ketone-sensitised luminescence of the lanthanide ions.

The relations illustrated in Fig. 6 are described approximately within the framework of Scheme I: (a) in the non-excited state of the solution of ketones and lanthanide ions, there is an equilibrium between the ketone–Ln^{3+} complexes $[^1K-Ln^{3+}]$ and solvated ketones (^1K) and we have $[^1K]+[^1K-Ln^{3+}] = C_K$, where C_K is the overall concentration of the ketone in solution. Under the experimental conditions, $[^1K-Ln^{3+}] \ll [Ln^{3+}]$; (b) the energy transfer from the triplet ketone to the lanthanide ion can take place either within the complex with a first-order rate constant ω_t (s^{-1}) when light is absorbed by the complex (I^{II}_{exc}) or intermolecularly in the encounter between the triplet ketone and the lanthanide ion or the complex when light is absorbed by the free ketone ($I^{\mathrm{I}}_{\mathrm{exc}}$).

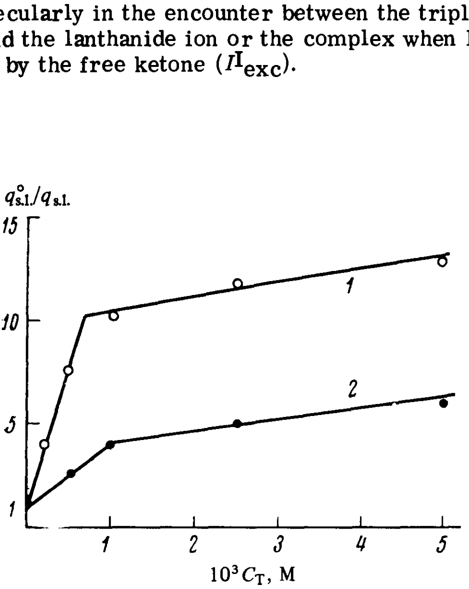

Figure 6. The quenching of the 4-ethoxy-4'-methoxybenzophenone-sensitised (C = 0.01 M) Eu^{3+} luminescence by *trans*-stilbene (concentration C_T) in acetone without O_2 at 293 K; λ_{exc} = 365 nm; Eu^{3+} concentration (M): 1) 0.0128; 2) 0.05.

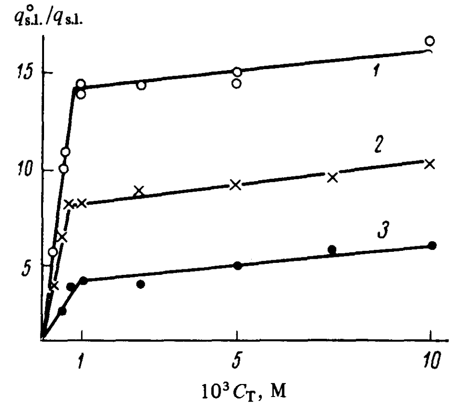

Figure 7. The influence of temperature on the quenching of the 4-methoxybenzophenone-sensitised (C = 0.01 M) Eu^{3+} luminescence (C = 0.05 M) by *trans*-stilbene in acetonitrile at different temperatures (K): 1) 233; 2) 273; 3) 293.

We shall now consider the concentration dependence of the intensity of the sensitised luminescence $I_{\mathrm{s.l.}}$ which follows from Scheme I. The ratio of $I^{\mathrm{I}}_{\mathrm{exc}}$ and $I^{\mathrm{II}}_{\mathrm{exc}}$ depends on the concentrations of the complexes and the free ketone in solution and their extinction coefficients at the wavelength of the exciting light. k'_{d} is the rate constant for the deactivation of the triplet ketone in the de-aerated solution (I-3); (I-4) represents the quenching of the triplet ketone by oxygen; (I-5) is the reaction involving the incorporation of the triplet ketone in the first coordination sphere of the ion; (I-6) and (I-11) represent the exothermic energy transfer from the triplet ketone to the triplet energy acceptor introduced into the solution, the rate of this process being limited by diffusion ($k^{\mathrm{TT}}_{\mathrm{t}} = k_{\mathrm{d}}$); (I-7) is the energy transfer from the triplet ketone to the complex; (I-8) is the dissociation of the triplet complex into the triplet ketone and the non-excited lanthanide ion. The very small temperature dependence of the quenching of the luminescence of the complexes shows that the dissociation process may be neglected compared with the intramolecular energy transfer [ω_{t}, (I-9)] and the photochemical reaction within the complex [ω_{phch}, (I-10)], i.e. $\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} \gg k'_{\mathrm{dis}}$. The quenching of the luminescence of the complex by oxygen (I-12) is also not observed and $\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} \gg k'_{\mathrm{dis}} + k^{\mathrm{O_2}}_{\mathrm{t}}[O_2]$. The lifetime of the luminescent lanthanide ion is long and there is sufficient time for the dissociation of the complex (I-13). Reactions (I-14) and (I-15) correspond to the processes involving the emission of the sensitised luminescence and the degradation of the electronic excitation energy into heat.

Having chosen the experimental conditions, it is possible to simplify the scheme by neglecting a number of processes. By carrying out experiments in de-oxygenated solutions or by establishing a sufficiently high concentration of Ln^{3+}, it is possible to neglect processes (I-3) and (I-4) compared with (I-5) and (I-6). Furthermore, at a relatively low ketone concentration one can disregard process (I-7) involving energy transfer to the complexes, so that

$$k_{\mathrm{t}}[\mathrm{Ln}^{3+}] + k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}] \gg k'_{\mathrm{D}} + k^{\mathrm{O_2}}_{\mathrm{t}}[\mathrm{O_2}] + k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{K}-\mathrm{Ln}^{3+}].$$

Under the conditions formulated, namely

$$\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} \gg k'_{\mathrm{dis}} + k^{\mathrm{O_2}}_{\mathrm{t}}[\mathrm{O_2}]$$

and

$$k_{\mathrm{t}}[\mathrm{Ln}^{3+}] \gg k'_{\mathrm{D}} + k^{\mathrm{O_2}}_{\mathrm{t}}[\mathrm{O_2}] + k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{K}-\mathrm{Ln}^{3+}],$$

the expression for $q_{\mathrm{s.l.}}$ assumes the following form:

$$q_{\mathrm{s.l.}} = \frac{I^{\mathrm{I}}_{\mathrm{exc}}}{I_{\mathrm{exc}}} \cdot \frac{k_{\mathrm{i}}}{k_{\mathrm{i}} + k_{\mathrm{d}}} \cdot \frac{k_{\mathrm{t}}[\mathrm{Ln}^{3+}]}{k_{\mathrm{t}}[\mathrm{Ln}^{3+}] + k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]} \cdot \frac{\omega_{\mathrm{t}}}{\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} + k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]} + \frac{I^{\mathrm{II}}_{\mathrm{exc}}}{I_{\mathrm{exc}}} \cdot \frac{k_{\mathrm{i}}}{k_{\mathrm{i}} + k_{\mathrm{d}}} \cdot \frac{\omega_{\mathrm{t}}}{\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} + k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]},$$

where $I_{\mathrm{exc}} = I^{\mathrm{I}}_{\mathrm{exc}} + I^{\mathrm{II}}_{\mathrm{exc}}$. The experimental ratio of the intensity of the sensitised luminescence in the absence of quenching agent $q^0_{\mathrm{s.l.}}$ to the intensity in its presence at a concentration $[{}^1\mathrm{A}]$ is given by the following expression:

$$\frac{q^0_{\mathrm{s.l.}}}{q_{\mathrm{s.l.}}} = \frac{\left(1 + \frac{k^{\mathrm{TT}}_{\mathrm{t}}}{\omega_{\mathrm{t}} + \omega_{\mathrm{phch}}} \cdot [{}^1\mathrm{A}]\right)\left(1 + \frac{k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]}{k_{\mathrm{t}}[\mathrm{Ln}^{3+}]}\right)}{\left(1 + \frac{I^{\mathrm{II}}_{\mathrm{exc}}}{I^{\mathrm{I}}_{\mathrm{exc}} + I^{\mathrm{II}}_{\mathrm{exc}}} \cdot \frac{k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]}{k_{\mathrm{t}}[\mathrm{Ln}^{3+}]}\right)}. \quad (14)$$

Bearing in mind that $\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} \gg k_{\mathrm{t}}(\mathrm{Ln}^{3+})$, one can examine two limiting quenching agent concentration ranges. At low quenching agent concentrations, where $k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]/k_{\mathrm{t}}[\mathrm{Ln}^{3+}] < 1$ and bearing in mind that $k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}] \ll \omega_{\mathrm{t}} + \omega_{\mathrm{phch}}$ and $I^{\mathrm{I}}_{\mathrm{exc}} \simeq I^{\mathrm{II}}_{\mathrm{exc}}$, Eqn. (13) can be replaced by the approximate expression

$$\frac{q^0_{\mathrm{s.l.}}}{q_{\mathrm{s.l.}}} \simeq 1 + \frac{I^{\mathrm{I}}_{\mathrm{exc}}}{I^{\mathrm{I}}_{\mathrm{exc}} + I^{\mathrm{II}}_{\mathrm{exc}}} \cdot \frac{k^{\mathrm{TT}}_{\mathrm{t}}[{}^1\mathrm{A}]}{k_{\mathrm{t}}[\mathrm{Ln}^{3+}]}. \quad (15)$$

This expression simplifies still further when the concentration of stable complexes in the ground state is low, so that $I^{\mathrm{I}}_{\mathrm{exc}} \gg I^{\mathrm{II}}_{\mathrm{exc}}$. Then

$$\frac{q^0_{\mathrm{s.l.}}}{q_{\mathrm{s.l.}}} = 1 + \frac{k^{\mathrm{TT}}_{\mathrm{t}}[^1\mathrm{A}]}{k_{\mathrm{t}}[\mathrm{Ln}^{3+}]}. \qquad (16)$$

On the other hand, at high quenching agent concentrations, we have $I^{\mathrm{I}}_{\mathrm{exc}} \simeq I^{\mathrm{II}}_{\mathrm{exc}}$ and $k^{\mathrm{TT}}_{\mathrm{t}}[^1\mathrm{A}]k_{\mathrm{t}}[\mathrm{Ln}^{3+}] \gg 1$. We then obtain a linear variation with $[^1\mathrm{A}]$:

$$\frac{q^0_{\mathrm{s.l.}}}{q_{\mathrm{s.l.}}} = \frac{I^{\mathrm{I}}_{\mathrm{exc}} + I^{\mathrm{II}}_{\mathrm{exc}}}{I^{\mathrm{II}}_{\mathrm{exc}}}\left(1 + \frac{k^{\mathrm{TT}}_{\mathrm{t}}}{\omega_{\mathrm{t}} + \omega_{\mathrm{phch}}}[^1\mathrm{A}]\right). \qquad (17)$$

The intercept which this straight line makes on the ordinate axis makes it possible to estimate $(I^{\mathrm{I}}_{\mathrm{exc}} + I^{\mathrm{II}}_{\mathrm{exc}})/I^{\mathrm{II}}_{\mathrm{exc}}$, i.e. the reciprocal of the fraction of light absorbed by the complexes $[^1\mathrm{K{-}Ln}^{3+}]$ in solution at a given concentration of lanthanide ions and therefore permits the estimation of their stability constants.

Since the rate constant for the exothermic triplet energy transfer is equal to the diffusional constant, $k^{\mathrm{TT}}_{\mathrm{t}} = k_{\mathrm{d}}$, and is calculated from the Vavilov–Debye formula[82,83] $k^{\mathrm{TT}}_{\mathrm{t}} = k_{\mathrm{d}} = 8RT/3000\eta$ (litre $\mathrm{mole}^{-1}\mathrm{s}^{-1}$), the slopes of the linear relations (15)–(17) corresponding to low values of $[^1\mathrm{A}]$ make it possible to determine the rate constant for the intermolecular energy transfer from the triplet ketone to the lanthanide ion (k_{t}), while the slope corresponding to high values of $[^1\mathrm{A}]$ permits the determination of the sum of the constants for the intramolecular energy transfer (ω_{t}) and the photochemical reaction within the complex (ω_{phch}). Knowing the yield of the photochemical reaction[76], it is possible to find ω_{t} from the sum. The values of k_{t}, ω_{t}, and the stability constants β of the complexes $[^1\mathrm{K{-}Ln}^{3+}]$ obtained in the above investigation are listed in Table 11.

Scheme I differs from the schemes usually employed for the description of energy transfer by the allowance for the complex-formation reaction with the lanthanide ions involving the ground and triplet states of the ketone. The validity of the hypothesis of the simultaneous occurrence of two processes involving the formation of ketone–Ln^{3+} complexes is confirmed by the following findings: (1) the relations between $q^0_{\mathrm{s.l.}}/q_{\mathrm{s.l.}}$ and the concentration of *trans*-stilbene presented in Fig. 6 for various ratios of the concentrations of the ketone and the lanthanide ion; (2) the variation of the intercept of the low-slope straight lines describing the dependence of $q^0_{\mathrm{s.l.}}/q_{\mathrm{s.l.}}$ on the concentration of the quenching agent (trans-stilbene) with increased ratio of the concentrations of Eu^{3+} and the ketone (Fig. 6); (3) the decrease of $q_{\mathrm{s.l.}}$ following the introduction into the solution of salts of gadolinium(III), which does not quench triplet states but is capable of forming stable complexes with the ketone and competing in this respect with Eu^{3+} ions. The presence of gadolinium ions hardly influences the slope of the two straight lines which describe approximately the variation of $q^0_{\mathrm{s.l.}}/q_{\mathrm{s.l.}}$ with the concentration of *trans*-stilbene.

The validity of the assumption made in the derivation of Eqns. (12)–(16) that one can neglect the dissociation of complexes of the type $[^3\mathrm{K{-}Ln}^{3+}]$, i.e. that $\omega_{\mathrm{t}} + \omega_{\mathrm{phch}} \gg k'_{\mathrm{dis}}$, where k'_{dis} is the rate constant for the dissociation of the complex, is confirmed by the weak influence of a change of temperature on the slope of the low-slope straight line in Fig. 7.

A study was made of the influence of electron-donating and electron-accepting substituents in ketones on the rate constants of the intramolecular and intermolecular energy transfer to lanthanide ions. The values of k_{t} and ω_{t} are listed in Tables 10 and 11. ω_{t} increases when electron-donating groups ($\mathrm{OCH_3}$, $\mathrm{OC_2H_5}$)¶ are introduced into the benzene rings of benzophenone and falls when electron-accepting groups (Br, Cl) are introduced. Substituents have a similar effect also on k_{t}, but the amplitude of the relative changed in k_{t} is smaller under these conditions. It has also been shown that k_{t} and ω_{t} increase with decrease of the electron-donating capacity of the solvent (see Table 11). Unfortunately the solvents employed in the investigation contain an admixture of water, which naturally complicated the observed picture. The admixture of water has a particularly marked influence in the study of energy transfer in solvents which are weak electron donors.

Valuable information was obtained from the study of the temperature dependence of k_{t}. This phenomenon was investigated in greatest detail in acetone and acetonitrile for 4-ethoxy-4′-methoxybenzophenone and 4-methoxybenzophenone as the energy donors and Eu^{3+} as the energy

Table 11. Intermolecular (k_{t}, litre $\mathrm{mole}^{-1}\mathrm{s}^{-1}$) and intramolecular ($\omega_{\mathrm{t}}$, s^{-1}) rate constants for energy transfer from the triplet molecules of aromatic ketones to Eu^{3+} ions in various solvents. ¶ Stable lanthanide complexes with stronger electron donors—aromatic acid anions ($\mathrm{Ar{-}COO^-}$)[84] and alkoxyacetophenones[85]—are also observed in solvents characterised by a higher donor number (methanol)[84].

acceptor. With increase of temperature, k_t rises exponentially and the calculated activation energies for the formation of a complex of the triplet ketone and Eu^{3+} are 1–3 kcal $mole^{-1}$ (Table 11).

Presumably the rate constant k_t for the diffusional energy transfer between the triplet ketone and the lanthanide ion is described by the following expression:

$$k_t = A e^{-\frac{\Delta E}{kT}},$$

where the coefficient A is proportional to the number of encounters between the triplet ketone molecules and the lanthanide ions, i.e. to k_d, and to the duration of each encounter Δt_{enc}, i.e. $A = k_d \Delta t_{enc}$. Since Δt_{enc} is inversely proportional to k_d, A will not vary as k_d increases and can therefore be regarded as independent of temperature. The second factor characterises the probability of the incorporation of the triplet ketone in the first coordination sphere of the lanthanide ion during the encounter. It increases exponentially with increase of temperature. The values of ΔE obtained diminish with decrease of the electron-donating capacity of the ketone. This may be due to the change in the bonding energy between the ketone and the water molecules present in solution. Experiments on energy transfer uncomplicated by the presence of an admixture of water are extremely desirable.

Thus experiment showed that the rate constant for the intermolecular energy transfer from aromatic ketones to lanthanide ions in solution is determined by the chemical incorporation of the triplet ketone molecule in the first coordination sphere of the lanthanide ion and not by the physical energy transfer process. The rate of such incorporation depends on the chemical properties of the triplet state of the ketone. It is much higher for triplet ketones with the lowest level of the n,π^* type compared with ketones in which this level is of the π,π^* type, and increases following the introduction of electron-donating substituents into the benzene rings of the ketones (Table 10).

The study of the dependence of the rate constant for the intermolecular energy transfer from aromatic ketones with n,π^* and π,π^* triplet levels on the atomic number of the lanthanide ion, undertaken in a number of investigations[74-77], showed that, despite the considerable differences between the absolute values of k_t for transfer from the n,π^* and π,π^* levels, the relative changes in k_t in the series of lanthanide ions take place approximately in parallel (see Fig. 8). We believe this to be an additional confirmation of the hypothesis that k_t is mainly determined by the rate of incorporation of the triplet ketone in the first coordination sphere of the lanthanide ion and that this rate varies appreciably in the series of lanthanides.

The values of k_t cannot be unambiguously related to the rate of incorporation in the complex only for very low values of ω_t, which are observed for a highly endothermic energy transfer (to Gd^{3+} for ketones with the $^3\Gamma$ state of the n,π^* type and to Gd^{3+}, Dy^{3+}, Tb^{3+}, etc. for ketones with the $^3\Gamma$ state of the π,π^* type), since in the energy transfer method the indicator is the subsequent quenching of the triplet in the complex. In the interaction with Gd^{3+} and other ions, this quenching cannot occur for energetic reasons and there may be sufficient time for the dissociation of the complex $[^3K\text{–}Gd^{3+}]$.

With increase of temperature, there is also an increase of the relative concentration of stable ketone–lanthanide ion complexes in the ground state in acetone and acetonitrile. This is consistent with Matovich and Suzuki's observation[58] that the temperature dependence of the energy transfer reaction is characteristic of an endothermic process. We believe that the observed type of temperature dependence of the concentration of complexes of the type $[^1K\text{–}Ln^{3+}]$ in acetone and acetonitrile is associated with the competition between various ligands in the first coordination sphere of the lanthanide ion, in particular with the competition between the aromatic ketone and the dissolved water as a ligand.

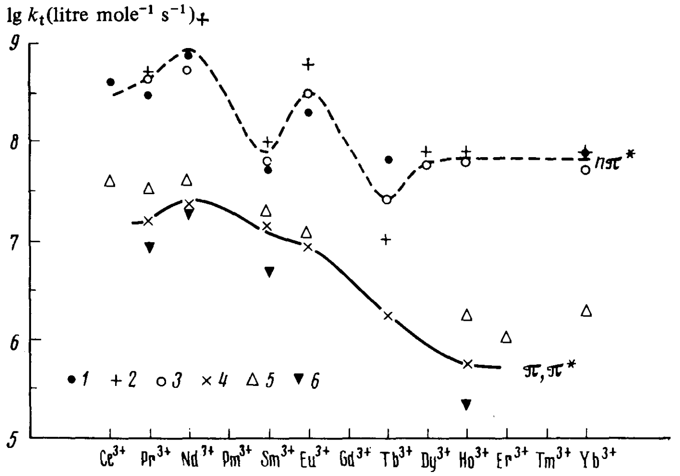

Figure 8. Dependence of the logarithms of the rate constants for energy transfer from aromatic ketones in the triplet state to lanthanide ions on the atomic number of the latter in moist acetone at 293 K: 1) acetophenone; 2) benzophenone; 3) benzoylpyridine; 4) 4-phenylbenzophenone; 5) methyl 2-naphthyl ketone; 6) 9-anthryl methyl ketone. For ketones with the lowest $^3\Gamma$ state of the n,π^* type, the values of k_t were measured by the method of competing lanthanide ions with energy transfer to Eu^{3+}; for ketones with the $^3\Gamma$ state of the π,π^* type, the flash photoexcitation method was used.

2. Energy Transfer from Lanthanide Ions to Organic Molecules with Excitation of the Triplet Level

Vavilov and Sevchenko[86] did not observe a decrease of the luminescence yield of an alcoholic solution of Sm^{3+} in the presence of typical fluorescence quenching agents: aniline, nitrobenzene, resorcinol, KI, etc. However, recently Aleksandrov et al.[87] and Kleinerman[88] noted a decrease in the decay time and in the intensity of the Eu^{3+} luminescence in solution after the addition of aromatic hydrocarbons, whose triplet level lies below the resonance level ($^5D_0$) of the Eu^{3+} ion. Subsequently Ermolaev and Tachin[40,48,49,81,89,92] made a detailed study of this phenomenon and showed that it is due to the non-radiative energy transfer from the lanthanide ions (Tb^{3+}, Eu^{3+}, and Dy^{3+}) to the organic molecules with excitation of the latter to the triplet state. The energy transfer takes place via the exchange resonance mechanism. The luminescence of the

Eu^{3+} ($^5D_0$) ion, which exhibits the maximum electron affinity, is quenched in some cases also via the electron transfer mechanism[89]. Thus two processes are responsible for the quenching:

$$^{m}(Ln^{3+})^{*} + {}^{1}A \rightarrow {}^{n}(Ln^{3+}) + {}^{3}A, \tag{18}$$

$$^{m}(Ln^{3+})^{*} + {}^{1}A \rightarrow {}^{k}(Ln^{2+}) + {}^{2}A^{\dot{+}} \ . \tag{19}$$

The electron energy level diagram for reaction (18) is illustrated in Fig. 9. The energy transfer process is not accompanied by the internal conversion of some of the electronic excitation quanta. This was demonstrated by Tachin and Ermolaev[90], who investigated the energy transfer from $Tb^{3+}(^5D_4)$ to Eu^{3+} in acetone via methyl 2-naphthyl ketone as an intermediate and showed that one excited Eu^{3+} ion corresponds to one quenched Tb^{3+} ion.

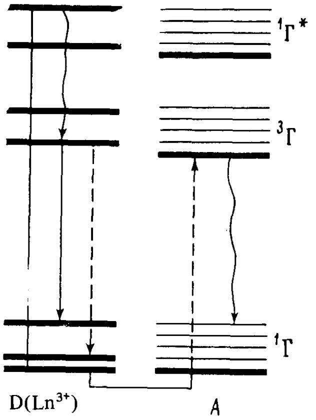

Figure 9. Schematic illustration of the electronic levels in the energy transfer from lanthanide ions to organic molecules with excitation of the latter to the triplet state.

Table 12 lists the values of[89] k_t (in moist acetone) for energy transfer from lanthanide ions to various aromatic molecules. It shows that (1) k_t is much lower than the diffusion rate constant and (2) the k_t for transfer to molecules with substituents ($-COCH_3$, $\rangle$N, etc.) capable of forming coordinate bonds with lanthanide ions are higher by 1–2 orders of magnitude than for energy transfer to molecules of unsubstituted aromatic hydrocarbons. The k_t for energy transfer to aromatic ketones are close to the corresponding values for energy transfer from aromatic ketones ($^3\pi,\pi^*$) to lanthanide ions (cf. Tables 10 and 12 and Fig. 8), provided that the reaction is exothermic in both cases. The closeness of the observed values of k_t demonstrates the complexity of the kinetics of these processes. Presumably the rate-limiting step of the energy transfer from lanthanide ions to aromatic ketones as well as that in the reverse transfer is the incorporation of the aromatic ketone in the first coordination sphere of the lanthanide ion. The difference is that, in the energy transfer from the lanthanide ion, the aromatic ketone in the ground singlet state is incorporated in the hydration shell of the excited lanthanide ion, while in the energy transfer from the triplet ketone the latter is incorporated in the inner solvation shell of the non-excited lanthanide ion. The experimental values of k_t for both types of transfer do not differ greatly, in agreement with the weak influence of the excitation of the shielded $4f$ shells on the chemical properties of lanthanide ions and also with the insignificant changes in the electron-donating properties of aromatic ketones on excitation to the π,π^* triplet state relative to the ground state[91].

Table 12. The rate constants for energy transfer from lanthanide ions to organic molecules with transition of the latter to the triplet state in moist acetone [$k_d = 2.1 \times 10^{10}$ litre $mole^{-1}s^{-1}$; in air; 293 K (data of Ermolaev and Tachin[89]); E_A = energy of the $^3\Gamma$ state of the energy acceptor].

Quenching agent	E_A, cm^{-1}	k_t^*, litre $mole^{-1}$ s^{-1}

* Accuracy of the measurements of $k_t \sim 20–30\%$.

** Quenching via the electron transfer mechanism.

*** An error was made in the study of Ermolaev and Tachin[89]. The corrected value is quoted here.

Ermolaev and Tachin[92] made a comparative study of the influence of temperature and the solvent on k_t for energy transfer from Tb^{3+} to 9-anthryl methyl ketone (AMK) and to anthracene (A). The results obtained are listed in Table 13, showing that k_t for the transfer from Tb^{3+} to the ketone decreases by more than 2 orders of magnitude with increase of the electron-donating capacity of the solvent molecules, while k_t for the transfer to anthracene depends little on the electron-donating capacity of the solvent. A significant difference between these two examples is also observed in the temperature variation of k_t. In the first case, involving energy transfer to the ketone, the process has an activation energy which increases with the increase of the donor number of the solvent and decreases to zero for solvents with a high electron-donating capacity. On the other hand, k_t for energy transfer to anthracene is independent of temperature, except in dimethyl sulphoxide. In solvents with a high electron-donating capacity, the values of k_t for energy transfer to 9-anthryl methyl ketone and anthracene agree within the limits of experimental error. Evidently the anthracene molecule cannot penetrate the first coordination sphere of the lanthanide ion and k_t corresponds in this case to energy transfer to the acceptor molecule in the second coordination sphere. Similarly the 9-anthryl methyl ketone molecule likewise does not penetrate the first coordination sphere in solvents with a high electron-donating capacity. The relatively high rate constant for energy transfer to the ketone in solvents with a low electron-donating capacity (which is at least 3 orders of magnitude lower than the diffusion-limited rate constant) undoubtedly corresponds to the incorporation of the ketone in the first coordination sphere of the excited Tb^{3+} ion.

Table 13. The rate constants for energy transfer (k_t) from Tb^{3+} ($^5D_0$ = 20 500 cm^{-1}) to 9-anthryl methyl ketone (AMK) ($^3\Gamma$ = 15 160 cm^{-1}) and anthracene (A) ($^3\Gamma$ = 14 900 cm^{-1}) in liquid dried solutions at 293 K. The estimated rates of incorporation of AMK in the first coordination sphere of Tb^{3+} [$k_{inc} = k_t(AMK) - k_t(A)$] and the activation energies for this reaction (ΔE_{inc}).

* Moist solution.

** Activation energy $\Delta E[k_t(AMK)]$.

*** Activation energy $\Delta E[k_t(AMK)] = \Delta E[k_t(A)]$.

The observed activation energies ΔE were calculated from the variation of $\ln [k_t(AMK) - k_t(A)]$ with the reciprocal of temperature and probably correspond to the activation energy for the dissociation of the solvent molecule from the first coordination sphere of the lanthanide ion. The last column of Table 13 lists the rates of incorporation of the ketone in the first coordination sphere of the Tb^{3+} ion in the $^5D_4$ state, calculated from the formula $k_{inc} = k_t(AMK) - k_t(A)$. In dimethyl sulphoxide, there is probably an ordered arrangement of the molecules in the second coordination sphere and the activation energy for incorporation in the second coordination sphere is observed.

We believe that the findings described above demonstrate quite convincingly the considerable scope of the energy transfer method in the study of reversible and dynamic complex formation reactions between organic molecules and lanthanide ions in solution. The following observations have been made with the aid of this method: (1) a new type of ion pairs comprising anionic dyes and lanthanide ions in solutions has been discovered; (2) equilibrium in solvents with a low electron-donating capacity between aromatic ketone–lanthanide ion complexes and solvated ketones and lanthanide ions has been demonstrated and the stability constants of the complexes have been estimated; (3) a number of conclusions have been drawn concerning the dynamics of the incorporation of triplet ketones in the inner coordination sphere of non-excited lanthanide ions and the activation energies for this process have been determined; (4) information has been obtained about the incorporation of a non-excited aromatic ketone in the inner solvation shells of excited lanthanide ions and the activation energies for this process in various solvents have been determined.

The experimental technique of studies on complex formation by the energy transfer method is in the main simple and does not require expensive apparatus. In most cases, it comprises the usual photoelectric apparatus for the measurement of the intensity and rate of decay of luminescence. Such apparatus and the required techniques have been described in a recently published translation of Parker's book[93]. More complex flash photoexcitation methods have been described by Shakhverdov[94] and Boag[95] and in the monograph by Calvert and Pitts[96], and laser photoexcitation methods are given in the paper by Porter and Topp[97]. We are certain that the energy transfer method will soon become the normal procedure in chemical laboratories dealing with problems of coordination chemistry.

ADDED IN PROOF

During the preparation of the review for the press, a detailed survey of the processes involving the sensitisation and quenching of the luminescence of coordination compounds (mainly those of transition metal ions) was published by Balzani et al.[98] Their survey and our reviews in this journal complement one another successfully.

Silicon Analogues of Carbenes

E.A.Chernyshev, N.G.Komalenkova, and S.A.Bashkirova

A systematic account is given of data published up to 1975 on the preparation and chemical properties of silicon analogues of carbenes—short-lived bivalent silicon compounds (silylenes). Methods for their formation with the aid of high temperatures as well as other sources of energy (silent electric discharge, photolysis, and radiolysis) are discussed.

The chemical properties of silylenes have been classified in accordance with three types: (1) polymerisation; (2) insertion in single bonds; (3) addition to multiple bonds.

The possibility of employing silylenes (particularly dichlorosilylene) for preparative purposes is discussed. Attention has been concentrated on experimental data relevant to the gas-phase reactions of silylenes.

The bibliography includes 299 references.

CONTENTS

I. INTRODUCTION

The chemistry of bivalent Group IVB elements has been attracting much attention in recent years. The interest aroused by these substances is due to the considerable advances in the theoretical and practical developments of the chemistry of carbenes, which already have a twenty year old history. However, the chemistry of organic derivatives of the elements which are carbene analogues, particularly the chemistry of silylenes, has not so far passed beyond the limits of laboratory tests owing to the complete absence of convenient methods for their synthesis.

Since the publication of the first reviews[1,2] devoted to the most important aspects of the chemistry of silylenes, the number of studies in this field has greatly increased and continues to increase. This is due to the advances in experimental techniques in the last decade—the development of methods for the creation of high temperatures and a high vacuum and also a new technique involving the quenching of the reaction mixture[3], which makes it possible to carry out the reactions of silylenes with a series of reactive organic compounds. Extensive experimental data have now accumulated on the chemistry of inorganic silylenes at low temperatures (−196°C) (the low-temperature condensation method), which has been surveyed in a number of reviews[5-8]; the similarity of the chemical properties of silicon monoxide, which is also of interest for syntheses at low temperatures[9], and those of other silylenes, for example difluorosilylene[7], has been noted. On the other hand, the gas-phase reactions of silylenes have not been described systematically (with the exception of the paper by Schaschel et al.[9]). Interesting communications have been published in which the stabilisation of silylenes by coordination in transition metal complexes is discussed[10-13]. Considerable advances have been made also in research on the physical properties of silylenes[14]. Methods for the generation of bivalent silicon compounds in extremely short time intervals (a millisecond or less), such as flash photolysis, electrical discharge, radioactive nuclear decomposition processes etc., have become common and make it possible not only to detect the presence of unstable species but also to determine their characteristics[15]. The development of methods for the matrix isolation[16-18] of such species greatly supplemented the available information about their nature and properties.

Apart from the purely theoretical interest in silylenes, attempts have been made in recent years to find direct practical applications for such species. From this standpoint, dihalogenosilicon derivatives are particularly promising[19]. Studies demonstrating the great synthetic possibilities of the employment of dichlorosilylene in gas-phase reactions have been published only in the last 3–4 years. Apart from a brief assessment of the present state of chemistry of silylenes, attention is concentrated in the present review of their "high-temperature" gas-phase chemistry, particularly that of dichlorosilylene, and the synthetic aspects of their utilisation.

II. METHODS OF SYNTHESIS

1. METHODS OF SYNTHESIS USING HIGH TEMPERATURES

The commonest methods for the preparation of bivalent silicon compounds involve high-temperature processes. Since pyrolytic methods for the preparation of inorganic and organic silylenes differ somewhat, we believe it to be useful to consider them separately.

A. Inorganic Silylenes

Short-lived silylenes can be isolated in high-temperature processes[3] only when the rate of cooling of these species is much higher than the rate of side reactions. Under the conditions of a high vacuum, it is possible to remove the gaseous species from the hot zone virtually without collisions and then condense them, which enables them to react with one another or with other condensed molecules. The high-temperature processes involving the formation of inorganic silylenes can be divided into processes at atmospheric pressure (1 atm) and low pressure (below 1 mmHg). We shall henceforth adhere to this classification.

1. Processes at atmospheric pressure. High-temperature processes at atmospheric pressure scarcely allow the isolation of silylenes, but they do make it possible to investigate their reactions and to carry out kinetic and thermodynamic studies. The reaction mechanism is then clear only in rare instances and in order to

account for the observed effects it is usually necessary to postulate the intermediate formation of silylenes on the basis of the determination of the composition of the mixture of final products.

Among processes of this type, involving the formation of inorganic silylenes, the reduction of tetrahalogenosilanes by silicon has been known for a long time[20,21]:

$$SiX_4(gas) + Si(solid) \overset{1000-1300°\,C}{\rightleftarrows} 2\ddot{Si}X_2(gas). \qquad (1)$$

The reviews[1,2] do not make it clear how the efficiency of reaction (1) depends on the nature of the halogen in the SiX_4 series, where X = F, Cl, Br, or I. A detailed study has now been made of the case where X = Cl.[22-35] The formation of $\ddot{Si}Cl_2$ has been confirmed by thermodynamic calculations[23,24,26,29-31] and kinetic studies[28]. However, it has been suggested recently that the composition of the gas phase is more complex and that considerable amounts of $\cdot\ddot{Si}Cl$ and $\dot{Si}Cl_3$ are present together with $SiCl_4$ and $\ddot{Si}Cl_2$.[36,37]

Reaction (1) for X = Br has also been investigated in detail[27,31,39] and that for X = I in less detail[27,31,38]. It is is noteworthy that di-iodosilylene can be obtained by this method, since both this species and silicon tetraiodide are appreciably dissociated into silicon and atomic iodine already at temperatures between 900° and 1000°C.[31,39] When X = F, the product is a mixture of gaseous, liquid, and solid subfluorides the composition of which has not yet been established exactly[20,40,41].

The reaction where X = Cl, Br, and I can serve as a source of pure silicon, which is used to coat surfaces with silicon[25,27,32,33,42,43]. In its preparative aspects, it has been used for the synthesis of trichlorosilane[34,44], mixed halogenosilanes[35], and chloromethylsilane[35]. In the absence of acceptors of dihalogenosilylenes, various compounds are formed as a function of reaction conditions—polymers $(-SiX_2-)_n$, linear polysilanes (Si_nCl_{2n+2}),[44] or cyclic polysilanes (Si_nCl_{2n}),[35] but a detailed structural study has not been made. On heating, the polymers are converted into perhalogenosilanes, starting from SiX_4 and extending as far as Si_6X_{14}; the residual subhalides have a molecular weight of approximately 1600.[35,44] It is probable that this entails also the formation of dihalogenosilylenes, the interaction of which with silicon tetrahalides actually leads to the formation of all the perhalogenosilanes.

The intermediate formation of dichlorosilylene also occurs in the reduction of silicon tetrachloride[45-51] or trichlorosilane[49,50,52,53] by hydrogen:

$$SiCl_4 + H_2 \xrightarrow{1000-2000K} \ddot{Si}Cl_2 + 2HCl \quad . \qquad (2)$$

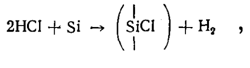
This reaction is widely used as a method for the preparation of pure silicon film coatings[48,49,51,52]. The formation and the important role of dichlorosilylene in these processes have been confirmed by thermodynamic calculations alone. There is no clear-cut information about other evidence or about the use of $\ddot{Si}Cl_2$, formed in this reaction, for synthetic purposes.

The possibility of employing trichlorosilylene in the "direct" synthesis of organochlorosilanes (250–400°C) when organic chlorides interact with silicon has been frequently discussed[54,55]. Andrianov and Golubtsov[56] have shown that it is generated by the reduction of copper(I) chloride by silicon:

$$2CuCl + Si \rightarrow 2Cu + \ddot{Si}Cl_2 \quad . \qquad (3)$$

Numerous facts confirming this view have now been observed[56,57]. Reliable evidence for the formation of dichlorosilylene in the "direct" synthesis was secured by the mass-spectrometric study of reaction (3).[58-60]

The information available previously[57,61,62] about the formation of dichlorosilylene in the "direct" synthesis of trichlorosilane,



$$2HCl + Si \rightarrow \left(\overset{|}{\underset{|}{Si}}Cl\right) + H_2 \quad , \qquad (4)$$

may be supplemented by the following remarks: mass-spectrometric data for the products desorbed from the surface of silicon before and after reaction (4) with the aid of a desorbing gas confirm the probability of the formation on the surface of the $\ddot{Si}Cl_2$ species which is capable of both desorption and of reaction with hydrogen chloride[63,64].

Various chlorosilanes can serve as convenient sources of inorganic silylenes in many instances. Thus is has been established recently that dichlorosilylene plays an important role in many pyrolytic processes occurring with participation of chlorosilanes[65-71].

It has been suggested in a paper by Sirtl and Reuschel[49] and then in a review[2] that the pyrolysis of trichlorosilane proceeds via the following mechanism:

$$HSiCl_3 \xrightarrow{>1100°} HCl + \ddot{Si}Cl_2 \quad . \qquad (5)$$

On the other hand, a detailed study of the products of its pyrolysis showed that, in the temperature range 500–750°C, hydrogen chloride is not formed in appreciable amounts[72]. A reinvestigation of the kinetics of the thermal decomposition of trichlorosilane confirmed these results[73]. It has now been established that the main products of the decomposition of $HSiCl_3$ are silicon tetrachloride, hydrogen, and silicon[72-74]. This suggests the following more probable general mechanism of its pyrolysis with formation of $\ddot{Si}Cl_2$:[67,68]

$$2HSiCl_3 \xrightarrow{650-670°} SiCl_4 + H_2 + \ddot{Si}Cl_2 \quad . \qquad (6)$$

Maksimova's categorical statement[69] that the pyrolysis of trichlorosilane proceeds via the radical mechanism

$$HSiCl_3 \rightleftarrows H + \dot{Si}Cl_3 \qquad (7)$$

at 600°C and via mechanism (5) at 650°C is therefore puzzling. In this case, it is obviously more correct to postulate the dominant role of one of the two reactions, (6) or (7), in a particular temperature range.

It has been established that, apart from trichlorosilane, certain other organochlorosilanes can also serve as donors of dichlorosilylene and it is of interest that pyrolysis can proceed via two pathways[70]:

$$R\overset{H}{\overset{|}{Si}}Cl_2 \xrightarrow{670-690°} R\dot{Si}Cl_2 + H \quad ; \qquad (8)$$

$$2R\dot{Si}Cl_2 \longrightarrow RSiCl_3 + R\ddot{Si}Cl \quad ; \qquad (9)$$

$$R\overset{H}{\overset{|}{Si}}Cl_2 \rightarrow RH + \ddot{Si}Cl_2 \quad , \qquad (10)$$

where R = α-$C_{10}H_7$, C_6H_5, or CH_3.

Mechanism (10) is satisfactorily confirmed by the formation of the corresponding amounts of naphthalene, benzene, and methane. It is noteworthy that, with increase of the temperature of the reaction zone from 640° to 690°C, pyrolysis proceeds via mechanism (10) to a greater extent. A similar pyrolysis mechanism [reaction (9) and (10)] has been proposed for methylsilane[75]:

$$CH_3SiH_3 \rightleftarrows CH_2\ddot{Si}H + H_2 \quad ; \qquad (11)$$

$$CH_3SiH_3 \rightleftarrows \ddot{Si}H_2 + CH_4 \quad . \qquad (12)$$

According to other data[76], the decomposition of methylsilane is not accompanied by the formation of $\ddot{Si}H_2$.

Methane has not been detected among the reaction products in the study by Ring et al.[77] Evidently, more detailed studies are required in order to refine the mechanism of the pyrolysis of methylsilane. However, the simultaneous occurrence of a reaction with formation of a silyl radical [reactions of type (7) or (8)] has been noted in all cases. The radical reactions greatly complicate the pyrolytic processes involving silanes and constitute a significant disadvantage of the latter as silylene donors.

There are literature data showing that the intermediate formation of silylenes is observed also in the pyrolysis of tetrahalogenosilanes and silane:

$$\mathrm{SiX_4 \rightarrow \ddot{S}iX_2 + X_2}\ . \qquad (13)$$

Reaction (13) occurs when X = Cl [24] or I [39] at 900°C and when X = H [78,79] at 400°C.

Despite the fact that the pyrolysis of silane has been investigated in considerable depth for a long time[78], there is at present no unanimous view concerning the mechanism of the initial stage of its decomposition—some workers[78,79] suggest a mechanism involving the formation of silylene [reaction (13)], while others[77] propose a radical-chain mechanism:

$$\left.\begin{aligned} \mathrm{SiH_4} &\rightarrow \mathrm{\dot{S}iH_3 + H} \ ; \\ \mathrm{H + SiH_4} &\rightarrow \mathrm{H_2 + \dot{S}iH_3} \ ; \\ \mathrm{\dot{S}iH_3 + SiH_4} &\rightarrow \mathrm{Si_2H_6 + H} \ ; \\ \mathrm{2\dot{S}iH_3} &\rightarrow \mathrm{Si_2H_6}\ . \end{aligned}\right. \qquad (14)$$

The arguments in support of both points of view depend only on the reliability of the thermochemical information; however, it has been correctly pointed out[79] that the scatter of the available $H-SiH_3$ and $H_3Si-SiH_3$ bond dissociation energies is much greater than the expected differences between the activation energies for reactions (13) and (14). The contradictory nature of the available data on this problem so far precludes a definite conclusion. However, the latest calculations of the absolute entropies of formation of silylene and the silyl radical suggest that preference should be given to reaction (13).[80]

An effective method for the generation of inorganic silylenes proved to be the thermal decomposition of polysilanes and their halogeno-derivatives. The decomposition of hexahalogenodisilanes, which was observed by Friedl and Ladenburg[81] as early as 1880, has not received due attention until the present time:

$$x\mathrm{Si_2X_6} \rightarrow x\mathrm{SiX_4} + (\mathrm{SiX_3})x, \qquad (15)$$

where X = I,[81-83] Cl,[83] or Br.[83]

The hypothesis of the intermediate formation of dihalogenosilylenes in reaction (15) was put forward about 10 years ago[84] and has been frequently quoted[2,76,85], but its mechanism still remains obscure. It was believed previously that hexachlorodisilane is capable of decomposing on pyrolysis via a homolytic mechanism and the formation of dichlorosilylene was explained by the recombination of two trichlorosilyl radicals[84,86]:

$$\mathrm{Cl_3SiSiCl_3 \xrightarrow{\Delta} 2\dot{S}iCl_3}\ ; \qquad (16)$$

$$\mathrm{\dot{S}iCl_3 + \dot{S}iCl_3 \rightarrow \ddot{S}iCl_2 + SiCl_4}\ . \qquad (17)$$

An interesting attempt to predict the direction of pyrolysis of disilanes[76], including hexachlorodisilane, was made very recently and it has been suggested that the thermal dissociation of hexachlorodisilane has a carbenoid mechanism:

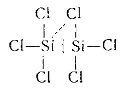
$$\mathrm{Cl_3SiSiCl_3 \rightarrow \ddot{S}iCl_2 + SiCl_4}\ . \qquad (18)$$

The study of the kinetics of the thermal decomposition of hexachlorodisilane under flow conditions in a quartz reactor in the temperature range 360–420°C established that its decomposition is described satisfactorily by the equation for first-order kinetics with $E_a = 49.6 \pm 1.2$ kcal mole^{-1} and lg$A$ (s^{-1}) = 13.8 ± 0.36. The heats of reactions (16) and (18) are respectively 77 ± 5 and 48 ± 5 kcal mole^{-1}.[87] Using these data, it is possible to show approximately that the preferential occurrence of reaction (18) requires that the activation energy for the reverse reaction

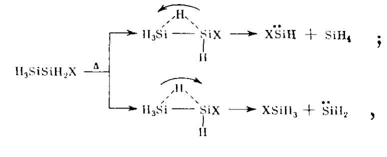
$$\mathrm{\ddot{S}iCl_2 + SiCl_4 \rightarrow Si_2Cl_6} \qquad (19)$$

should not exceed 27–28 kcal mole^{-1}. Although its value has not been determined, it is known that reaction (19) takes place rapidly both in the gas phase and on cocondensation, so that one can assume with a good deal of certainty that reaction (18) is a primary process in the decomposition of hexachlorodisilane.

This is confirmed directly by the results obtained recently in a spectroscopic study of the primary products of the pyrolysis of hexachlorodisilane by the matrix isolation method[88]. The dissociation of Si_2Cl_6 under the conditions described takes place at temperatures in the range 600–650°C. The reaction products are only silicon tetrachloride and dichlorosilylene. These results permit the final conclusion that the pyrolysis of hexachlorodisilane (as well as higher perchloropolysilanes)[89-91] is an example of the α-elimination reaction and involves attack by the chlorine atom linked to one of the silicon atoms on the neighbouring silicon atom with formation of "bridging" chlorine:



The pyrolysis reactions of higher silanes have been investigated comparatively recently and it has never been established reliably that disilane and many substituted disilanes are effective sources of silylene and substituted silylenes. The mode of decomposition of the compounds H_5Si_2X is represented by two pathways involving intramolecular 1,2-transfer of hydrogen:



(20)

(21)

where X = H,[93-97] Cl, F,[98] or CH_3.[99]

It is suggested on the basis of the latest kinetic investigations that the pyrolysis of trisilane likewise proceeds in two ways [Eqns. (20) and (21)] woth formation of silylene and silylsilylene ($H\ddot{S}iSiH_3$).[100]

Two similar decomposition pathways have been found for disubstituted disilanes, but the 1,2-transfer of the atom X was not observed:

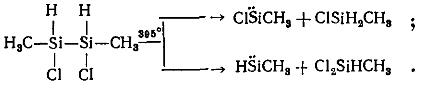
$$\mathrm{1,1\text{-}X_2Si_2H_4 \rightarrow \ddot{S}iH_2 + X_2SiH_2}\ ; \qquad (22)$$

$$\mathrm{1,1\text{-}X_2Si_2H_4 \rightleftarrows \ddot{S}iX_2 + SiH_4}\ , \qquad (23)$$

where X = Cl [98] or CH_3.[99]

Reaction (23) is less favourable for dihalogenodisilanes and reaction (22) only is observed for 1,1-difluorodisilane[98]

Interesting results have been obtained for the decomposition of *sym*-$Cl_2Si_2H_2(CH_3)_2$ [Eqns. (24) and (25)], suggesting that the 1,2-transfer of the Cl atom is nevertheless possible in those cases where the latter and the hydrogen atom are in identical environments[98]:



$$H_3C-\overset{H}{\underset{Cl}{Si}}-\overset{H}{\underset{Cl}{Si}}-CH_3 \xrightarrow{395°} Cl\ddot{Si}CH_3 + ClSiH_2CH_3 \quad ; \qquad (24)$$

$$\qquad\qquad\qquad \xrightarrow{395°} H\ddot{Si}CH_3 + Cl_2SiHCH_3 \quad . \qquad (25)$$

The ratio of the contributions of reactions (24) and (25) is 4:1.

2. Processes at a low pressure in the system. The study of such processes in the last 15 years has developed considerably, since they make it possible to obtain at a high temperature unstable and highly reactive gaseous atomic and molecular species. When the processes are carried out at a low pressure, one can reduce to a minimum the number of mutual collisions of the species and their collisions with the walls. Among the latest advances, particular mention should be made of certain processes involving the formation of inorganic silylenes *in vacuo*:

(a) evacuation of metals, for example:

$$Si(solid) \underset{}{\overset{1400°\,C,\ 10^{-5}\ mmHg}{\rightleftarrows}} \cdot\dot{\underset{\cdot}{Si}}\cdot\ (gas) \qquad (26)$$

followed by the insertion of the atoms in Si–X bond;

(b) reduction methods, for example:

$$Si(solid) + SiO_2(solid) \overset{1200°\,C,\ 10^{-3}\ mmHg}{\rightleftarrows} 2\ddot{Si}O\ (gas); \qquad (27)$$

$$Si(solid) + SiX_4(gas) \overset{115°\,C,\ 1\ mmHg}{\rightleftarrows} 2\ddot{Si}\,X_2\ \ (gas); \qquad (28)$$

(c) thermal decomposition of halogenosilanes.

Methods a and b presuppose the possibility of isolating the silylenes by condensation as a result of extensive cooling (down to –196°C) and also the investigation of their chemical properties by cocondensation with other compounds[3–6,9,101].

(a) Evaporation of silicon. In 1967 Skell and Owen published a study devoted to the chemistry of atomic silicon[102]. Almost simultaneously, another report was published about the high reactivity of atomic silicon[3]. Up to that time, only the molecular composition of silicon vapour had been described in the literature[103]. The above investigators[3,102] were able to isolate from the hot zone at a low pressure extremely reactive atoms, which can be obtained under the conditions of reaction (26), or on thermal evaporation of silicon[102,104], or by bombarding silicon with electrons[5,101,104–106]. Under these conditions, the content of polymeric species in gaseous silicon is much smaller than in carbon vapour[107]; at a low pressure, the dominant species are silicon atoms[5].

(b) The reduction reactions. This method is most convenient for the preparation of a highly reactive silylene—silicon monoxide ($\ddot{Si}O$). Like silicon atoms, it can be isolated only at a very low pressure.

The formation of gaseous $\ddot{Si}O$ as an intermediate in the reduction of silicon dioxide has been known for a long time[108–118]. It has been found that reducing agents may be arranged in the following sequence in terms of decreasing activity[116,117]:

$$Si(gas) > C(solid) > Si(liq.) > Si(solid) > FeSi(liq.) > FeSi(solid) > SiC.$$

It has been reported that silicon monoxide is also formed in the reduction of silicon dioxide by hydrogen[119,121]. Silicon monoxide is likewise formed when silicon is treated with an oxidising agent[122,123] such as a metal oxide, for example by the reaction

$$2Si + Al_2O_3 \overset{1800°}{\rightleftarrows} Al_2O_3\,(gas) + 2\ddot{Si}O\ (gas) \qquad (29)$$

and also on heating silicon dioxide alone above 1600 K.[124–127] However, the best preparative method is the reduction of pure SiO_2 (99.7%) by pure silicon (99.8%) via reaction (27).[9,118,125,127–129] It is of interest that gaseous silicon monoxide can be obtained for preparative purposes by heating "solid SiO" *in vacuo*[9,130,131], the content of the dimer being only 0.1% under these conditions.

Owing to the technical difficulty of maintaining a sufficiently low pressure in the high-temperature system, the gaseous $\ddot{Si}O$ molecule, which has been known for a long time, has not been used in further reactions until recently[9,130,131]. The formation of silicon monosulphide is also a reaction of the same type[132–134]:

$$SiS_2(solid) + Si(solid) \overset{900–1150°,\ <0.1,\ mmHg}{\rightleftarrows} 2\ddot{Si}S\ (gas). \qquad (30)$$

It is much easier to synthesise and isolate dihalogenosilylenes under the conditions described[3]. All the dihalogenosilylenes have been obtained under the conditions of reaction (28), but $\ddot{Si}Br_2$,[135–137] $\ddot{Si}I_2$,[136,138] and $\ddot{Si}Cl_2$,[136,139] are less stable than $\ddot{Si}F_2$.[136] It has been shown that di-iodosilylene cannot be synthesised efficiently by this procedure[138]. Its polymer has been obtained in approximately 1% yield at 800–900°C. The synthesis of difluorosilylene reported previously in fact also involved the formation of the polymer $(-SiF_2-)_n$.[136,140]

Since Timms devised recently a suitable apparatus[3,6,101], which provides for the rapid transfer of dihalogenosilylenes by suction into the region at a pressure of the order of 10^{-5} mmHg, it has been possible to avoid the gas-phase polymerisation of dichloro- and dibromo-silylenes, to prevent their reaction with the corresponding silicon tetrahalides, and hence to obtain them in high yields (95 and 80% respectively)[101,141–143]. Owing to its higher stability, difluorosilylene can be obtained in simpler apparatus than that of Timms[3,144] in fairly high yields (up to 65%) at a residual pressure of 0.1–0.2 mmHg.[145–147]

(c) Thermal decomposition of halogenosilanes. The thermal methods for the synthesis of inorganic silylenes *in vacuo* have not been developed quite so effectively as the analogous methods at atmospheric pressure (see above); nevertheless, it has been stated that the thermal decomposition of hexafluorodisilane[148] [reaction (15)] in a high vacuum is the best method for the generation of difluorosilylene. According to the authors, this procedure makes it possible to obtain $\ddot{Si}F_2$ completely free of oxygen.

The pyrolysis *in vacuo* of the tetrahalogenosilanes $SiBr_4$[149] and SiI_4,[138,149] which is treated merely as a method for the preparation of the polymers $(-SiX_2-)_x$, has been little studied. From the standpoint of the generation of silylenes on a preparative scale, these reactions evidently have no importance.

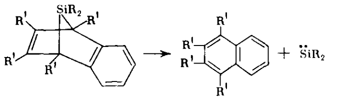
B. Organic Silylenes

Owing to the lack of a suitable method for the preparation of silylenes with organic substituents, these substances have been little studied until recently. There has been a considerable development of the chemistry of organosilylenes during the last ten years and there are now several methods for their synthesis.

1. Reduction of dialkyldichlorosilanes by metals. Analysis of studies of the reactions of dialkyldichlorosilanes with metals has shown that the available information about the possible formation of silylenes in this reaction is fairly contradictory. Skell and Goldstein[150,151] obtained convincing proof of the formation of dimethylsilylene when dichlorodimethylsilane reacts with potassium in the gas phase (t = 260–280°C), having trapped $\ddot{Si}(CH_3)_2$ by trimethylsilane.

However, the analogous formation of silylene in the condensed phase has not been established[152,153]. Despite the fact that the reaction of dichlorodimethylsilane with lithium[154] is also consistent with the hypothesis of the intermediate formation of $\ddot{Si}(CH_3)_2$,[2] convincing evidence for this has not been obtained so far. Since the yields of reaction products are very low (2–10%) when the above source of silylenes is used and more convenient methods for the generation of organic silylenes are available at the present time, the reaction of alkali metals with dialkyldichlorosilanes in solvents has not assumed practical importance in the investigation of silylenes.

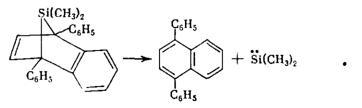
2. Thermolysis of 7-silanorbornadienes. This method, proposed in 1964 by Gilman et al.[155,156], is widely used for the preparative synthesis of dimethyl- and diphenyl-silylenes:



, (33)

where R′ = C_6H_5 and R = CH_3 or C_6H_5.

The conversion of disubstituted 7-silanorbornadiene, which yields $\ddot{Si}(CH_3)_2$ at low temperatures, also merits attention[157]:



. (34)

This method combines the utilisation of mild process conditions with the formation of the least reactive side products.

Attempts have been made to use the adduct of 1,1,-dimethyl-2,5-diphenyl-1-silacyclopentadiene with tolane for the same purposes[157]. However, the adduct not only eliminates dimethylsilylene but also dissociates simultaneously.

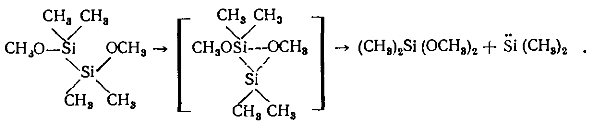
3. Thermal decomposition of polysilanes. The studies by Atwell and coworkers have shown that the most convenient and the most general source of organic silylenes is the thermolysis of alkoxymethylpolysilanes[2,158–162], for example:

$$(CH_3O)_6Si_2 \xrightarrow{175^\circ} (CH_3O)_4Si + \ddot{Si}(OCH_3)_2 \quad ; \tag{35}$$

$$CH_3(CH_3O)_2SiSi(OCH_3)_2CH_3 \xrightarrow{200^\circ} CH_3Si(OCH_3)_3 + \ddot{Si}(OCH_3)CH_3 \quad . \tag{36}$$

It was noted that, with increase of the number of alkoxy-groups, the thermolysis takes place at lower temperatures. These reactions can also be carried out in the gas phase. Following the development of this procedure, organic silylenes became readily available and have been the object of numerous interesting investigations.

The thermolysis of alkoxypolysilanes is a typical example of α-elimination:



. (37)

It has been reported that substituted disilanes $(CH_3)_3SiSi(CH_3)_2X$, where X = Cl, OC_6H_5, or C_6H_5, undergo similar reactions[163] and it is of interest that pentamethyldisilane is also apparently an effective donor of $\ddot{Si}(CH_3)_2$. Presumably, all the methyldisilanes $(CH_3)_{6-x}.Si_2H_x$, where $x = 1 - 6$, and naturally also the similar alkylpolysilanes undergo thermal decomposition into silylene and silane[76] by the intermolecular transfer of a hydrogen atom discussed above.

The pyrolysis of cyclic and linear polymers having the general formula $[Si(CH_3)_2]_n$, where $n > 3$, also leads to the formation of dimethylsilylene[153,164]. However, the yield of its adducts with various trapping agents is low (1–6%).[1,164]

2. OTHER ENERGY SOURCES IN THE SYNTHESES OF SILYLENES

A. The Silent Electric Discharge

The silent electric discharge in the vapours of silane and some of its derivatives has been found[165–173] to result in the formation of silylenes, the mechanism of which is believed to be described by equations similar to those discussed above:

$$SiX_4 \rightarrow \ddot{Si}X_2 + X_2 \quad , \tag{14}$$

where X = Cl,[167–169] F,[170,171] or H[165,166,172] and

$$CH_3SiH_3^{173} \rightarrow CH_3\ddot{Si}H + H_2 \quad ; \tag{11}$$

$$\rightarrow \ddot{Si}H_2 + CH_4 \quad . \tag{12}$$

At the same time decomposition under the influence of the electric discharge is a more complex process than pyrolysis, since it is accompanied by the formation of various charged and neutral species.

This method has not assumed preparative importance and it has been used for spectroscopic studies only.

B. Photolysis

The photochemical method for the generation of silylenes has developed considerably in recent years. The search for convenient sources of silylenes for both spectroscopic investigations and for preparative purposes has continued. Among the compounds investigated, various silanes, whose Si–H bonds are readily photodissociated, have found extensive applications. Flash photolysis of halogenosilanes has proved a very promising procedure for recording highly resolved absorption spectra of halogenosilylenes Their formation is evidently due to the following reaction:

$$H_3SiX \xrightarrow{h\nu} H\ddot{Si}X + H_2 \tag{38}$$

where X = Cl, Br,[174] or I.[175]

$\ddot{Si}H_2$, obtained in the photochemical decomposition of silane, has been identified similarly[176–178]. The vacuum ultraviolet photolysis[178] of silanes leads to the formation of silyl radicals and silicon atoms in addition to silylene.

The mercury-sensitised photochemical decomposition of silane evidently involves initial processes in which silyl radicals and silicon atoms are formed together with silylene via the reaction[179–182]:

$$Hg(^3P_1) + SiH_4 \rightarrow \ddot{S}iH_2 + 2H + Hg(^1S_0) \quad . \qquad (39)$$

However, it is interesting to note that all the methylsilanes are capable of decomposing under these conditions via a radical pathway involving the dissociation of a single Si–H bond[181,182], while silyl radicals disproportionate with formation of silylenes only to a slight extent.

The photolysis of alkylsilanes under the influence of vacuum ultraviolet proceeds via the molecular elimination mechanism and thus constitutes a convenient source of silylenes, which are generated via reactions analogous to reactions (11) and (12):[183–185]

$$CH_3SiH_3 \xrightarrow{1470 Å} \begin{cases} \rightarrow CH_3\ddot{S}iH + H_2 \ ; \\ \rightarrow H_2\ddot{S}i + CH_4 \ . \end{cases}$$

The photochemical decomposition of dimethyl- and trimethyl-silanes proceeds similarly, although less efficiently[186].

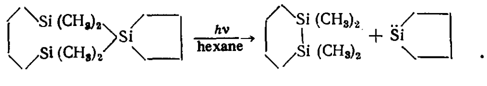
A satisfactory method for the synthesis of dichloro-[187] and difluoro-silylenes[188] to be used in spectroscopic studies is the vacuum ultraviolet photolysis of dichloro- and difluoro-silanes. It is suggested that the $\ddot{S}iF_2$ obtained by this procedure is purer than the product synthesised by Timms' method[145].

The photochemical method can be used to synthesise silylenes with organic substituents. Interesting possibilities in the synthesis of such silylenes arise on photolysis of substituted cyclic[189–191] or linear[191–195] polysilanes, for example:

$$[(CH_3)_2Si]_6 \xrightarrow{h\nu} \ddot{S}i(CH_3)_2 + [(CH_3)_2Si]_5 \ ; \qquad (40)$$

$$(CH_3)_3Si\underset{}{\overset{CH_3\ C_6H_5}{(Si)_2}}Si(CH_3)_3 \xrightarrow{h\nu} 2\ddot{S}i(CH_3)C_6H_5 + (CH_3)_3SiSi(CH_3)_3 \ . \qquad (41)$$

A very promising method for the preparation of silylenes with various substituents involves modification of the substituent at the central silicon atom in 1,2,3-trisilacycloheptane[195], which makes it possible to obtain new, unusual silylenes, for example a cyclic silylene from spirotrisilane:



(42)

C. Nuclear Reactions

Together with the methods indicated above, the recently developed method for the synthesis of silylenes with the radioactive ^{31}Si isotope has assumed considerable importance. The ^{31}Si atoms ($\tau_{1/2} = 2.62$ h) generated by the nuclear reaction $^{31}P(n, p)^{31}Si$ (on bombarding a phosphorus compound with fast neutrons) acquire energies corresponding to their chemical reactions as neutral species and their interaction with phosphine[196–202] or silane[196–198,200] apparently result in the formation of silylenes:

$$^{31}\cdot\dot{\underset{\cdot}{S}}i\cdot \xrightarrow{PH_3} {}^{31}\ddot{S}iH_2 \ , \qquad (43)$$

$$^{31}\cdot\dot{\underset{\cdot}{S}}i\cdot \xrightarrow{SiH_4} H^{31}\ddot{S}iSiH_3 \ . \qquad (44)$$

^{31}Si atoms can interact similarly with phosphorus trifluoride, forming difluorosilylene[203]:

$$^{31}\cdot\dot{\underset{\cdot}{S}}i\cdot + PF_3 \rightarrow {}^{31}\ddot{S}iF_2 \quad . \qquad (45)$$

Quite recently this method made it possible to show that $^{31}\ddot{S}iH_2$ exists in the triplet state to the extent of 80%.[199,202]

III. CHEMICAL PROPERTIES OF SILYLENES

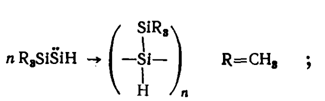
Before discussing the chemical properties of silylenes, the large number of experimental data concerning their physical properties should be noted. Investigators in this field have devoted most attention in the last five years to the examination of the molecular parameters of the species, the knowledge of which is necessary for the prediction of their chemical properties. The results of such studies have been reflected in recently published reviews[14,204] and papers[205–208].

We shall examine the chemistry of silylenes in accordance with their three characteristic intermolecular reactions—polymerisation, insertion in single bonds, and addition to multiple bonds. One should note immediately that, since data for the mechanism of the insertion of silylenes into single bonds are lacking, inferences about the nature of the insertion reaction are drawn mainly on the basis of the structure of the final products and are therefore frequently arbitrary.

The intermolecular reactions of the majority of silylenes can occur at elevated temperatures (in both gas and liquid phases) and at low temperatures on cocondensation with trapping agents. The majority of the reactions of difluorosilylene have little in common with those of other silylenes. The higher stability of $\ddot{S}iF_2$ in the gas phase compared with other silylenes[145,146,209–211] made it a convenient object of study. It is known, that with rare exceptions[140,144,209], difluorosilylene is inert in the gas phase[4,146,209]. Because of this and because its chemistry has been frequently discussed[4,6,8,9,212], less attention is devoted to it in the present review.

1. POLYMERISATION

In the absence of active trapping agents, silylenes are polymerised with formation of polysilanes:



$$nR_3Si\ddot{S}iH \rightarrow \left(\begin{array}{c} SiR_3 \\ | \\ -Si- \\ | \\ H \end{array}\right)_n \qquad R{=}CH_3 \quad ; \qquad (46)$$

$$n\ddot{S}iX_2 \rightarrow (SiX_2)_n \quad . \qquad (47)$$

This property is characteristic of any silylene, i.e. when X = Cl,[22,44,83,139,141,142,149,167] Br,[83,135,137,149] H,[79,93,95,166] I,[27,81,82,138,149,213] CH_3,[150,154,155,162,164,190] etc.

Difluorosilylene does not form polymers in the gas phase. Its reactivity increases greatly on cocondensation with other reagents at the temperature of liquid nitrogen (−196°C).[4,146,209,212,214–221] This unusual effect may be due to the stepwise polymerisation of difluorosilylene. $\ddot{S}iX_2$ polymerises in the condensed phase with formation of biradicals of the type $\ddot{S}iF_2–(SiF_2)_n–\ddot{S}iF_2$ (where $n = 0, 1, 2, ...$) and these are in fact the reactive species[4,146,222–230]. Experiments in an argon matrix showed that polymerisation begins at approximately 35 K.[146,224]

Silicon monoxide, a very reactive silylene, polymerises rapidly even at 30 K,[130,233] forming dimers and oligomers with a bridging oxygen atom[9,130]. Owing to the causes indicated above and in contrast to other silylenes, the reactions of $\ddot{Si}F_2$ and $\ddot{Si}O$ with acceptors are investigated exclusively by the cocondensation method.

2. REACTIONS INVOLVING INSERTIONS IN SINGLE BONDS

Until recently, the ability of silylenes to form products of insertion in Si–H, E–X (E = Si, P, B, or C and X = halogen), Si–O, and Si–N bonds only were believed to be reliably established[2,76,229]. The research on insertion reactions has recently developed on a large scale, which has tended to extend current ideas about the synthetic possibilities of silylenes. Together with a description of the familiar general reactions of silylenes, we have therefore devoted much attention in the present section to new data on their properties.

The Insertion of Silylenes in Si–X Bonds (X = Halogen or OCH_3)

The formation of perhalogenopolysilanes as products of the thermal interaction of tetrahalogenosilanes with silicon [reaction (1)] involving the formation of dihalogenosilylenes which is evidently followed by their insertion in the Si–X (X = halogen) bond, has been known for a long time:

$$(n-1)\ddot{Si}X_2 + SiX_4 \rightarrow Si_nX_{2n+2} \quad . \tag{48}$$

These reactions occur in gas[25,35,44] and liquid[5,6] phases and have been thoroughly investigated; a number of perhalogenopolysilanes with n = 2–6 for X = Cl [136,139] and n = 2–5 for X = Br [136] have been obtained on their basis. The reactions of organosilylenes with alkoxypolysilanes have also been thoroughly investigated[2,158,160]. The formation of products of the $CH_3O[Si(CH_3)_2]_nOCH_3$ series in the thermolysis of *sym*-dimethoxytetramethyldisilane can be accounted for by the insertion of dimethylsilylene in the Si–O bond and not the Si–Si bond[3,161,162]. The dimethylsilylene obtained by photolysis is likewise not inserted in the Si–Si bond of 1,2-diethyltetramethyldisilane[193].

Although the possibility of the insertion of $\ddot{Si}H_2$ in the Si–Si bond has been postulated in certain recently published studies[95,100,198], nevertheless convincing confirmation of such behaviour has not been obtained for other silylenes. It is interesting that the insertion of organic silylenes (obtained by the thermolysis of alkoxypolysilanes) in the Si–O bond of an alkoxymonosilane does not compete with the analogous insertion into an alkoxypolysilane[161]. However, the absence of alkoxypolysilanes, the reaction of photolytically generated $\ddot{Si}(CH_3)_2$ with dimethyldimethoxysilane[190] proceeds with formation (in a high yield) of products resulting from insertion in the Si–O bond:

$$\ddot{Si}(CH_3)_2 + (CH_3O)_2Si(CH_3)_2 \rightarrow CH_3O\,[Si(CH_3)_2]_nOCH_3 \; ; \quad n = 2.3 \quad . \tag{49}$$

Insertion in the Si–O bond has also been postulated in the cocondensation of difluorosilylene with trimethylmethoxysilane, but the initial reaction product $(CH_3)_3.SiSiF_2OCH_3$ was not isolated, apparently owing to its further transformations[228].

Thus, although insertion in the Si–X bond (X = halogen or O) is a fairly general reaction for all silylenes, usually accompanying their formation, its further investigation is required in order to explain the different reactivities of such bonds.

Insertion in E–X Bonds (E = B, P, or C and X = F or Cl)

One of the first reactions of silylenes investigated, the interaction of SiF_2 with boron trifluoride[209,222,224,231], belongs to this type. It was established that the reaction does not occur in the gas phase, while in the condensed phase (with consecutive condensation initially of boron trifluoride and then of difluorosilylene) a number of compounds $SiF_3(SiF_2)_nBF_2$ (n = 1–4) are formed with an overall yield of 10–20%. The simplest member with n = 1 was not detected for a long time among the perfluoroborosilanes formed. Difluoro(trifluorosilyl)borane was isolated quite recently with simultaneous condensation of the reactants[232]:

$$\ddot{Si}F_2 + BF_3 \xrightarrow{\text{cocondensation}} SiF_3BF_2 \tag{50}$$

the yield being higher when $\ddot{Si}F_2$ is obtained by passing SiF_4 over silicon carbide at 1850°C. It is suggested that short-lived species (possibly an excited form of $\ddot{Si}F_2$) are formed together with the long-lived $\ddot{Si}F_2$ species.

The interaction of $\ddot{Si}Cl_2$, obtained by the reaction of silicon and silicon tetrachloride [reaction (28)], with E–Cl bonds (E = B, P, or C) [141,142] has been suggested as a general method for the synthesis of compounds with an E–SiCl linkage[234–236], for example:

$$\ddot{Si}Cl_2 + BCl_3 \xrightarrow{\text{cocondensation}} Cl_3SiBCl_2 \quad . \tag{51}$$

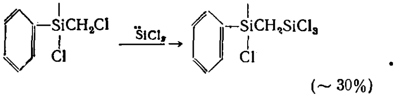
In all the experiments of this kind, the yield has been fairly low (approximately 10%). The analogous interaction of $\ddot{Si}Br_2$ with BF_3 is complicated by the exchange of halogens[2].

The gas-phase reactions of dichlorosilylene with the C–Cl bond of organic halides are of considerable preparative interest:

$$\ddot{Si}Cl_2 + CH_3Cl \rightarrow CH_3SiCl_3^{85,92} \quad ; \tag{52}$$

$$ArCH_2Cl \xrightarrow{\ddot{Si}Cl_2} ArCH_2SiCl_3^{68,92} \; (30\text{—}35\%) \quad , \tag{53}$$

Ar = phenyl or naphthyl



(54)

(~ 30%)

At first sight the interaction of $\ddot{Si}F_2$ with trifluoroiodomethane[237–239] also leads to the product resulting from insertion in the C–F bond (the main product is the compound with n = 1):

$$CF_3I + \ddot{Si}F_2 \xrightarrow{\text{cocondensation}} CF_3(SiF_2)_nI \quad . \tag{55}$$

However the additional formation of further two types of compounds suggests a more complex mechanism with formation in the first stage of the radical $\dot{Si}F_2I$ and its subsequent reactions.

The results of a study of the reaction of silicon monoxide with 1-bromo- or 1-chloro-butane and bromo- or chlorobenzene suggested that the main reaction involves insertion in the C–halogen bond[9]:

$$C_4H_9Cl \xrightarrow{\ddot{Si}O} C_4H_9(SiO)_6Cl \quad . \tag{56}$$

However, the product of the reaction of monomeric silicon monoxide was not detected. The possibility of the occurrence of the above reaction for difluorosilylene may be demonstrated by the interaction with fluoro-derivatives of benzene[216] and alkenes[217,218]:

$$\ddot{Si}F_2 + C_6F_6 \xrightarrow{\text{cocondensation}} C_6F_5SiF_3 + C_6F_4(SiF_3)_2, \tag{57}$$

$$\ddot{Si}F_2 + n\text{-}C_6H_4F_2 \xrightarrow{\text{cocondensation}} n\text{-}FC_6H_4SiF_3 \tag{58}$$

$$\ddot{S}iF_2 + H_2C{=}CF(CH_3) \xrightarrow{\text{cocondensation}} H_2C{=}C(CH_3)SiF_3 + H_2C{=}C(CH_3)Si_2F_5 \quad . \tag{59}$$

It is suggested that the attacking species is monomeric difluorosilylene. Thus, when the compounds contain the C–F bond, the latter is evidently attacked more readily than the C=C bond by monomeric $\ddot{S}iF_2$ with formation of the SiF_3 group.

Insertion in Halogen, Hydrogen Chloride, and Hydrogen Molecules

Silylenes are easily inserted in halogen–halogen bonds[76]:

$$\ddot{S}iCl_2 + X_2 \xrightarrow{\Delta} X_2SiCl_2, \tag{60}$$

where X = I, Br,[35] or Cl.[24];

$$\ddot{S}iF_2 + X_2 \xrightarrow{\Delta} F_2SiX_2 \text{ (yield up to 70\%)}, \tag{61}$$

where X = Br, Cl,[144] or I.[144,240] It must be emphasised that the reaction with halogens [reaction (61)] is so far the only example of a gas-phase reaction of difluorosilylene, which is apparently involved in the monomeric form.

Insertion in the H–Cl bond was postulated as early as 1953 [44] and was subsequently confirmed[34,46]:

$$\ddot{S}iCl_2 + HCl \rightarrow HSiCl_3 \quad . \tag{62}$$

The reaction of photolytically generated dimethylsilylene is typical[191]:

$$\ddot{S}i(Me_2) + HCl \xrightarrow{h\nu} (CH_3)_2SiHCl \text{ (yield 72\%).} \quad . \tag{63}$$

The intermediate $\ddot{S}iCl_2$ may be inserted in the H–H bond[44]:

$$\ddot{S}iCl_2 + H_2 \xrightarrow{\Delta} H_2SiCl_2 \quad . \tag{64}$$

Insertion in E–H Bonds (E = Si, Ge, O, N, or S)

The insertion of silylenes in the Si–H bond, first observed by Skell and Goldstein[150,151],

$$\underset{}{\ddot{S}i(CH_3)_2 + (CH_3)_3SiH \xrightarrow{260^\circ} \underset{(\sim 30\%)}{(CH_3)_3SiSi(CH_3)_2H}} \quad , \tag{65}$$

has been widely used both to demonstrate the intermediate formation of various silylenes and to obtain new compounds with the Si–Si bond[8,75,79,94–100,241], for example:

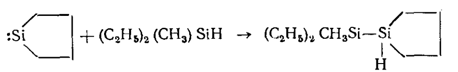
$$CH_3\ddot{S}iH + CH_3SiH_3 \xrightarrow{\Delta} CH_3SiH_2SiH_2CH_3 \quad ; \tag{66}$$

$$\ddot{S}iH_2 + Si_3H_8 \xrightarrow{\Delta} \text{n- and iso-}Si_4H_{10}; \tag{67}$$

$$H\ddot{S}iSiH_3 + Si_3H_8 \xrightarrow{\Delta} \text{n- and iso-}Si_5H_{12}. \tag{68}$$

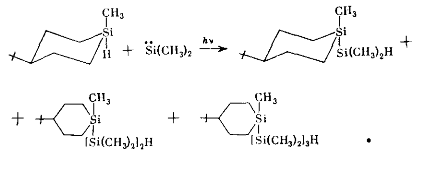
Organic silylenes obtained photochemically are also readily inserted in the Si–H bond[183–186,189,190,192–194]:

$$\ddot{S}i(CH_3)_2 + (C_2H_5)_2(CH_3)SiH \rightarrow (C_2H_5)_2CH_3Si{-}Si(CH_3)_2H \quad ; \tag{69}$$



. (70)

It has been shown by NMR [242] that the insertion of dimethylsilylene in the Si–H bond of *cis*- or *trans*-4-t-butyl-1-methyl-1-silacyclohexane proceeds *cis*-stereospecifically, as for dichlorocarbene[243]:



(71)

The observed conservation of configuration in the insertion reaction (71) is undoubtedly associated with a three-centre mechanism involving direct electrophilic attack by dimethylsilylene on the Si–H bond.

The silicon atoms obtained by thermal evaporation [see reaction (26)] are inserted in the Si–H bond with formation of silylenes[102,104–106]:

$$\cdot\dot{\underset{\cdot}{S}}i\cdot + \cdot R_3SiH \rightarrow R_3Si{-}\ddot{S}iH \quad , \tag{72}$$

which involves a further insertion in its turn:

$$R_3Si{-}\ddot{S}iH + R_3SiH \rightarrow R_3SiSiH_2SiR_3 \quad . \tag{73}$$

Similarly ^{31}Si Atoms [see reaction (43)] form silylenes which are subsequently involved in a secondary process with formation of radioactive disilane[196,197] and trisilane[198]:

$${}^{31}\ddot{S}iH_2 + SiH_4 \rightarrow H_3{}^{31}Si{-}SiH_3 \quad ; \tag{74}$$

$${}^{31}\ddot{S}iH_2 + H_3SiSiH_3 \rightarrow H_3{}^{31}SiSiH_2SiH_3 \quad . \tag{75}$$

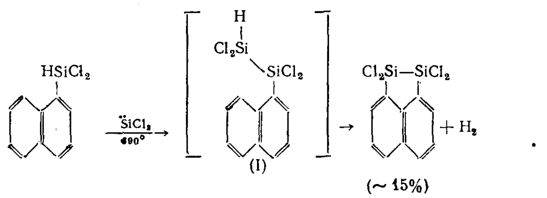
The ratio of trisilane and disilane occurring in this process enabled the authors to postulate the competing insertion of silylene in the Si–Si bond[198]. A similar hypothesis has been put forward also in studies of the pyrolysis of disilane[25] and trisilane[100]. The available data concerning the different bond strengths in disilane and silane[244] suggest the need for further research in order to account for the observation.

The reactions involving the insertion of silylene $\ddot{S}iH_2$ in the Si–H bond have been most fully investigated. Thus experiments on the joint pyrolysis of disilane and all methylsilanes have shown that $\ddot{S}iH_2$ is undoubtedly inserted exclusively in the Si–H bond of the reactant[95]. Measurements of the relative rates of insertion of $\ddot{S}iH_2$ in the E–H bonds (E = Si, Ge, or P) at 350°C have shown that the reactivity per E–H bond decreases in the following sequence[100]:

$$(CH_3)_3SiH > Si_2H_6 > (CH_3)_2SiH_2 > CH_3SiH_3 > SiH_4 > CH_3GeH_3 \quad .$$

The differences between the rates of insertion can be explained from the standpoint of the hydride nature of the E–H bond (i.e. they are correlated with the negative charge on the attacking hydrogen atom). This is particularly evident in the reaction with methylphosphine, where the hydrogen atom has a positive charge and the insertion of silylene is not observed[100,241].

The formation of a heterocyclic compound with an Si–Si bond, namely 1,1,2,2-tetrachloro-1,2-disila-acenaphthene, by the pyrolysis of trichlorosilane or hexachlorodisilane with dichloro-α-naphthylsilane, probably proceeds via a mechanism involving intramolecular dehydrocyclisation of compound (I)—the primary product of the insertion of dichlorosilylene in the Si–H bond[63]:



. (76)

The interaction of difluorosilylene with germane led to the formation of products of the type $GeH_3(SiF_2)_nH$, where $n = 1$–3.[215] The main product with $n = 1$ may be regarded as the product of the insertion of monomeric $\ddot{S}iF_2$ in the Ge–H bond:

$$\ddot{S}iF_2 + GeH_4 \xrightarrow{\text{cocondensation}} GeH_3SiF_2H \quad . \tag{77}$$

At the same time, it was suggested that germane attacks the silylene chains in $\dot{\mathrm{Si}}F_2(SiF_2)_nSiF_2$, abstracting fragments containing 1, 2, and 3 silicon atoms.

The reactions of silylenes with E–H bonds, where E = O, N, or S, have been less thoroughly investigated. Several investigations have dealt with the interaction of silylenes with alcohols[9,161,245] and water[9].

$$\ddot{\mathrm{Si}}(OCH_3)_2 + CH_3OH \xrightarrow{\Delta} HSi(OCH_3)_3 \;; \qquad (78)$$

$$4\ddot{\mathrm{Si}}O + C_2H_5OH \xrightarrow{\text{cocondensation}} (C_2H_5O)H(SiO)_4 \;. \qquad (79)$$

The reaction of difluorosilylene with methanol proceeds in a much more complex manner[245]. It is suggested that it involves monomeric $\ddot{\mathrm{Si}}F_2$, which is inserted in the O–H bond, but the product formed reacts further with the excess of alcohol, forming difluorodimethoxysilane. The most likely pathway of the reaction with water appears to be insertion of monomeric $\ddot{\mathrm{Si}}F_2$ with subsequent condensation of the product:

$$\ddot{\mathrm{Si}}F_2 + H_2O \xrightarrow{\text{cocondensation}} HF_2SiOH \;; \qquad (80)$$

$$2HF_2SiOH \rightarrow HF_2SiOSiF_2H + H_2O \;. \qquad (81)$$

As in the reaction of $\ddot{\mathrm{Si}}F_2$ with oxygen[4,222,246], polymeric oxides are not formed in this case and the biradicals are not therefore involved in the reaction mechanism.

The interaction of silicon monoxide with ammonia[9] led to the formation of a new compound having the approximate composition $NH_3(SiO)_4$.

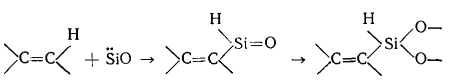
The insertion of $\ddot{\mathrm{Si}}F_2$ in the S–H bond of hydrogen sulphide was reported earlier[2]:

$$\ddot{\mathrm{Si}}F_2 + H_2S \xrightarrow{\text{cocondensation}} HF_2SiSH \;. \qquad (82)$$

Later detailed studies[219,238] showed that the process does not proceed in a single stage and evidence concerning the validity of the exclusion of the dimerisation stage was not obtained.

New Silylene Insertion Reactions

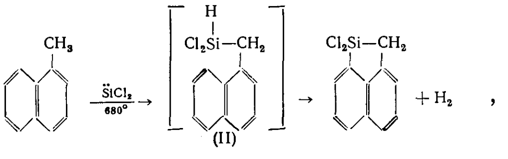
The results of studies demonstrating the ability of dichlorosilylene[68,90,92,247–249] and silicon monoxide[9,130] to interact with a wide variety of carbon–hydrogen bonds are perhaps the most interesting. It should be noted that these processes, which are the most characteristic reactions of carbenes, were completely unknown for silylenes until recently. Alkanes, anthracene, and benzene have been used in the reactions with silicon monoxide. The structure of the compounds obtained corresponds in all cases to the products resulting from insertion in the C–H bond. Furthermore, it was found that, apart from adding to multiple bonds, silicon monoxide is also "inserted" in the C–H bonds of alkenes and alkynes:



(83)

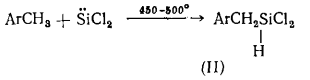
The products contain 2–3 moles of silicon monoxide per mole of alkene. Thus polymerisation evidently competes with the reaction involving the alkene, as in other cases.

The study of the gas-phase reaction of dichlorosilylene with C–H bonds[68,90,92] elucidated several important factors. After the first investigations indicating the ability of $\ddot{\mathrm{Si}}Cl_2$ to form products resulting from insertion in the C_{alk}–H bond of α-methylnaphthalene[65],



(84)

it was found that this reaction is common to all methylsubstituted aromatic hydrocarbons and heterocycles[91,92,247–249]

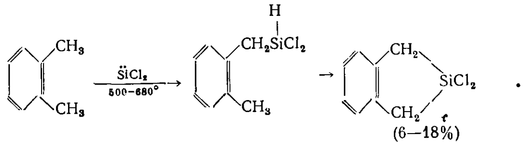


$$ArCH_3 + \ddot{\mathrm{Si}}Cl_2 \xrightarrow{450-500^\circ} \underset{(II)}{ArCH_2SiCl_2H} \;, \qquad (85)$$

where Ar = phenyl, *o*- and *p*-tolyl, *p*-biphenylyl, α- and β-naphthyl, 2- and 3-thienyl, etc.

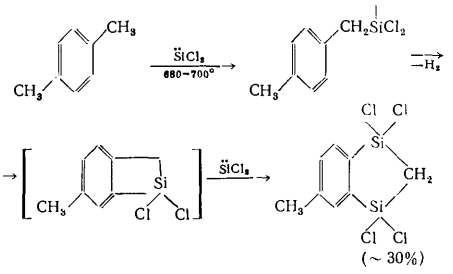
The absence of primary $\ddot{\mathrm{Si}}Cl_2$ insertion products [compounds of type (II)] in the experiments carried out at 680°C and the low yield under the conditions of reaction (85) are due to the increased tendency of these compounds to undergo radical reactions[92].

In the presence of the given substituent in the *ortho*-positions of the initial compounds, the interaction of dichlorosilylene with the C–H bond may be accompanied by subsequent intramolecular cyclisation[91,92]:



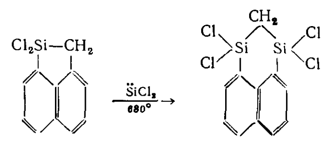
(86)

Another feature of dichlorosilylene observed in these reactions, which is of great preparative importance, is its ability to be "inserted" in the C_{ar}–C_{alk} bond of strained rings[90,92], i.e. the reaction on which the synthesis of heterocyclic compounds with two silylene groups is based[248,249]:



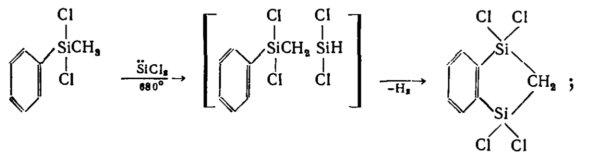
(87)

The available literature data concerning the unusual strength of the Si–C bond in pyrolytic syntheses serves as a basis for this mechanism[250]. Furthermore, pyrolysis of the primary insertion products [of the type of compound (II)] in the presence of a dichlorosilylene donor leads to the same heterocycles[92]. It is noteworthy that a reaction of this type, expansion of a five-membered ring to a six-membered ring as a result of the formal insertion of $\ddot{\mathrm{Si}}Cl_2$ in the C_{ar}–C_{alk} bond, has been observed also in another instance[68,92]:

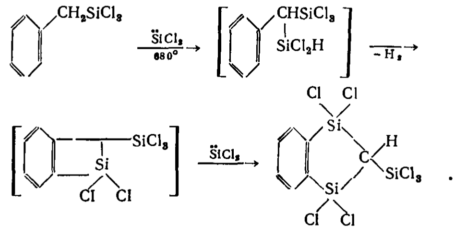


(88)

Studies on the interactions of dichlorosilylenes with other C–H bonds are only just beginning. In particular, the ability of $\ddot{\mathrm{Si}}Cl_2$ to be "inserted" in the C–H bond involving the α-carbon atom attached to the silicon atom has been confirmed by the formation of the corresponding heterocycle as a result of gas-phase reactions[92,249]:

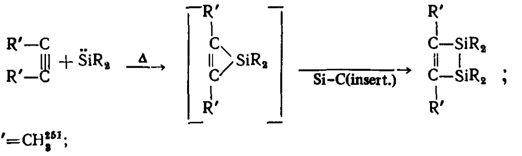


(89)



(90)

Among the latest communications, those presenting data suggesting the insertion of dimethylsilylene[251] and dichlorosilylene[92] in the Si–C bond of a silicon-containing heterocycle are of greatest interest. This hypothesis was put forward on the basis of a study of the products of the reactions of silylenes with substituted acetylenes. One of the possible mechanisms of the formation of the observed four-membered heterocycle with an Si–Si bond, put forward by analogy with dichlorocarbene[252,253], is the insertion of $\ddot{\mathrm{Si}}(\mathrm{CH_3})_2$ and $\ddot{\mathrm{Si}}\mathrm{Cl_2}$ in the Si–C bond of silacyclopropene formed as an intermediate in the first stage of the reaction (see below):



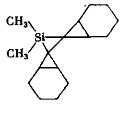
(91)

(a) $R=R'=CH_3$[251];
(b) $R=Cl$, $R'=C_6H_5$[92] .

Summarising the foregoing findings, one may conclude that the insertion reactions investigated are at present at the stage of rapid development. In this sense, the gas-phase method must be regarded as one of the most promising procedures, the wide-scale employment of which will lead to the discovery of hitherto unknown properties of silylenes.

3. THE ADDITION OF SILYLENES TO MULTIPLE BONDS

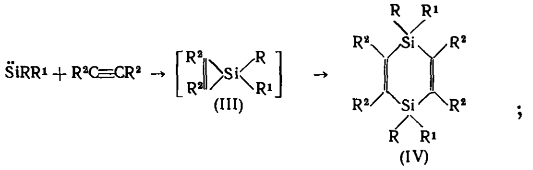
The interaction with unsaturated compounds is one of the most characteristic reactions of silylenes. Unsaturated compounds are of particular interest as trapping agents for silylenes, since they make it possible to approach the synthesis of hitherto unknown silacyclopropanes and silacyclopropenes. All the attempts to isolate three-membered heterocycles with a silicon atom in the ring, which are evidently extremely labile, have been unsuccessful[154,164,254]. Such cyclic systems can probably be stabilised by increasing the degree of substitution at the ring carbon atoms. This is confirmed satisfactorily by the synthesis of the first relatively stable silacyclopropanes by the organometallic method[255], for example:



.

Interaction with Alkynes

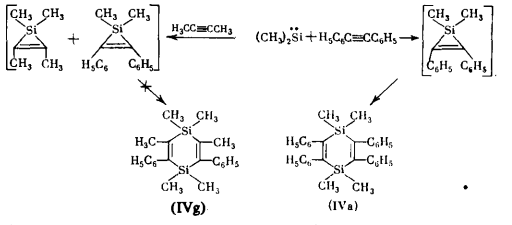
Among the large number of unsaturated "trapping agents" for silylenes which have been investigated, alkynes are the most effective. The formation of silacyclopropene in the reaction of dimethylsilylene with diphenylacetylene was reported in 1961.[152,153] Subsequent studies on this reaction[256–260] showed that the product has a dimeric structure and is tetraphenyldisilacyclohexa-2,5-diene (IVa). Since then research on the reactions of a wide variety of silylenes with alkynes has developed on a wide scale and the reaction is now used to obtain chemical proof of the formation of silylenes:



(92)

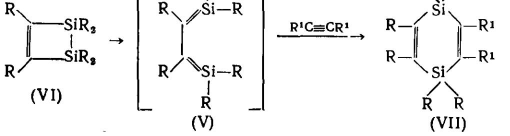
(a) $R=R^1=CH_3$, $R^2=C_6H_5$[1,152,153,155,158–160];
(b) $R=CH_3$, $R^1=OCH_3$, $R^2=C_6H_5$[160,261];
(c) $R=CH_3$, $R^1=OCH_3$, $R^2=CH_3$[2,261];
(d) $R=CH_3$, $R^1=OCH_3$, $R^2=H$[2,261,262] ;
(e) $R=R^1=Cl$, $R^2=H$[89–92,263,288] ;
(f) $R=R^1=Cl$, $R^2=C_6H_5$[89–92,263,288] .

The mechanism of this reaction is still obscure. Existing views can be summarised as follows. The majority of investigators believe that the primary step is the addition of silylene to the triple bond of the alkyne with formation of compound (III), but its subsequent fate is represented in different ways. The studies by Atwell and Weyenberg[159] of the reaction of dimethylsilylene with a mixture of diphenylacetylene and but-2-yne, which did not yield 3,5-diphenyldisilacyclohexadiene (IVg), made it possible to exclude from further consideration the previously proposed mechanism involving the π-dimerisation of compound (III). We examined the possibility of the mechanism involving a kind of dimerisation of silacyclopropene (III) with dissociation of the Si–C bond:



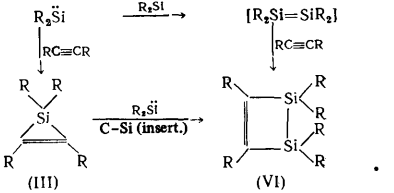
(93)

A mechanism for the formation of disilacyclohexadienes, including compound (VII), via the Diels-Alder addition of acetylene to 1,4-disilabuta-1,3-diene (V) has been proposed recently[264]:



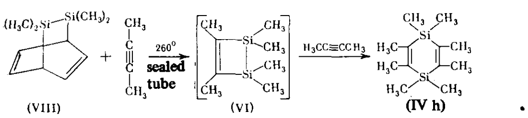
(94)

It is suggested that the diene (V) is formed from 1,2-disilacyclobutene (VI) and the authors believe that in the case where $R \neq R^1$ this explains the absence of the isomer (IVg) in the experiment with mixed actylenes. Compound (VI) can be formed in several ways: (1) by the insertion of silylene, discussed above, in the Si–C bond of the intermediate silacyclopropene; (2) by the dimerisation of silylene accompanied by the addition of the resulting disilylene to acetylene:



(95)

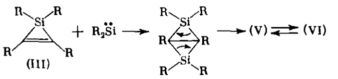
The latter mechanism is supported by the formation of disilacyclohexadiene (IVh) in 20% yield in the reaction between the donor $[(CH_3)_2Si{=}Si(CH_3)_2]$ [265] (VIII) and but-2-yne:



(96)

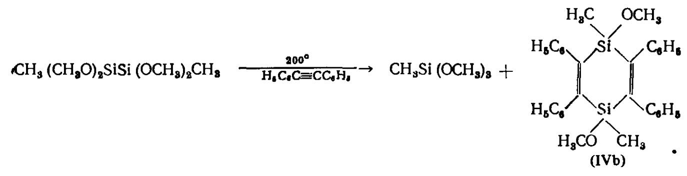
If, however, the reaction of compound (VIII) with but-2-yne in the gas phase does not lead to the formation of disilyacyclohexadiene (IVh), which may indicate different contributions of this mechanism to the reaction of silylenes with alkynes depending on its conditions. At any rate, the thermolysis of compound (VI) in the presence of but-2-yne (sealed tube, 225°C, 18 h) does indeed lead to compound (IVh) in 31% yield.

Finally Barton and Kilgour[264] also believe that the addition of silylene to the double bond of silacyclopropene with subsequent thermal rearrangement of the molecule to compound (V) is likely:



(97)

Among the studies of the above reaction, one must distinguish those which have led to the formation of disilacyclohexadienes with functional groups at the silicon atom[89–92,160,261–263]. The first example is the synthesis of the tetraphenyl-substituted 1,4-dimethoxy-1,4-dimethyl-1,4-disilacyclohexa-2,5-diene (IVb) in 50% yield[160,261]:



(98)

However, the corresponding tetramethoxy-derivatives could not be obtained by a similar procedure from diphenylacetylene and hexamethoxydisilane[159,160].

The most promising procedure involves carrying out the above reactions in the gas phase[89–92,261–263]. The yield of methoxymethyldisilacyclohexadiene (IVd) under the conditions of reaction (92) at 400°C was 60%.[261–262] The use of hexachlorodisilane and octachlorotrisilane in the reaction with alkynes (at 500–550°C) made it possible to obtain tetrachlorodisilacyclohexadiene (IVe) in yields up to 30% and its tetraphenyl derivative (IVf) in a yield of approximately 10%, which is of preparative interest for the synthesis of the previously inaccessible tetrafunctional derivatives of disilacyclohexa-2,5-diene. The stability of all the heterocycles (IV) synthesised on heating to the melting point is noteworthy. Furthermore, tetrachlorodisilacyclohexadiene (IVe) undergoes various reactions characteristic of the Si–Cl bond: methylation, and substitution of chlorine atoms by hydrogen and fluorine atoms with retention of the cyclic skeleton of the molecule. Timms' data[5] concerning the instability above 0°C of tetrachlorodisilacyclohexadiene, which he obtained by the reaction of dichlorosilylene with acetylene by the cocondensation method, must therefore be regarded as unreliable.

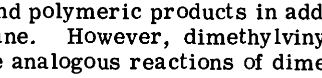
A low yield of tetrachlorotetraphenyldisilacyclohexadiene (IVf) may be associated with the insertion of $\ddot{Si}Cl_2$ in the Si–C bond of the intermediate diphenylsilacyclopropene (III) (see subsection 2 of Section III). It is interesting to note that, in the analogous reactions of acetylene and its derivatives with difluorosilylene, the formation of silacyclopropene derivatives has not been observed and the reactive species with respect to alkynes are the diradicals $\cdot(SiF_2)_2^{\cdot}$.[266–272]

A study of the interaction of silicon monoxide with alkynes[9] demonstrated the competition between two reactions: addition to the triple bond and insertion of $\ddot{Si}O$ in the C–H bond. The approximate composition of the solid product formed by the reaction with acetylene is $C_2H_2(SiO)_3$. The reaction with diphenylacetylene evidently results in the formation of the expected compounds $C_{14}H_{10}(SiO)_2$ having the disilacyclohexadiene structure.

Interaction with Alkenes

Various mixtures of products formed in the interaction of silylenes with ethylene in the gas or condensed phases have been reported in a number of studies[2,154,164,254]. The addition of dimethylsilylene to ethylene accompanied by the formation of dimethylvinylsilane has been achieved in the gas phase[254].

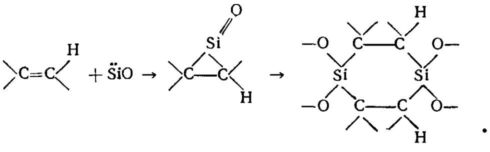
The addition of silylene (${}^{31}\ddot{Si}H_2$), obtained by the reaction of ${}^{31}Si$ atoms with phosphine, to silylene has been described[197] (see subsection 2 of Section II):



(99)

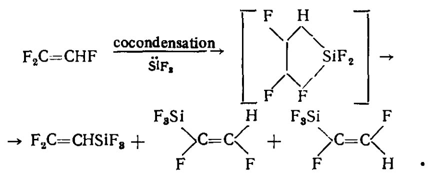
(100)

These results of the interaction of dimethylsilylene with ethylene in the liquid phase are interpreted in different ways. According to Atwell and Weyenberg[2], dimethylsilylene, obtained by the thermolysis of 7-silanorbornadiene [see reaction (33)], reacts with ethylene, forming cyclic and polymeric products in addition to dimethylvinylsilane. However, dimethylvinylsilane is not formed in the analogous reactions of dimethylsilylene formed by the reduction of dichlorodimethylsilane with lithium[154] or by the pyrolysis of the polymers $[Si(CH_3)_2]_n$ [164] see above). The possibility of error is associated with the low yield of volatile products in this reaction (overall yield less than 10%). The formation of cyclic products was postulated in the analogous experiments with silicon monoxide[9]:



(101)

In contrast to the reaction of difluorosilylene with ethylene, the cyclic products of which indicate the involvement of the polymeric species $\cdot(SiF_2)_n^{\cdot}$, the reactions with fluorinated derivatives of ethylene yield monosilanes[217,218], the formation of which is explained either by the insertion of $\ddot{S}iF_2$ in the C–F bond (see subsection 2 of Section III) or by the isomerisation of the intermediate silacyclopropane[4,218]:

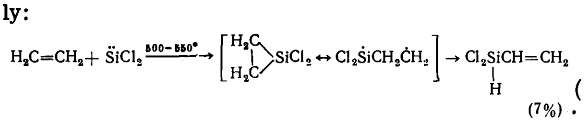


(102)

It has been reported recently[5,6] that the cocondensation of dichlorosilylene with propene (at –196°C) leads to the formation of the corresponding disilacyclohexane derivatives; the authors claim that, owing to the ease of insertion of $\ddot{S}iCl_2$ in the Si–Cl bond, it is difficult to avoid the formation of 1-trichlorosilyl-1,2-disilacyclohexane. However, attempts to demonstrate unambiguously the structure of the compounds obtained were not made.

In the light of these data, the results of studies on the gas-phase reactions of dichlorosilylene are of considerable interest. The joint pyrolysis of perchloropolysilanes and ethylene, which does not lead to the formation of cyclic compounds, is typical[92]. However, silicon-containing products are formed in an overall yield of approximately 70% in this case also.

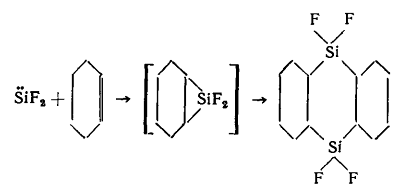
As in the instances described above, the mechanism involving the addition of dichlorosilylene to ethylene with formation of a labile adduct, the structural isomerism of which leads to dichlorovinylsilane, appears to be most likely:



(103)

The remaining organosilicon compounds [$Cl_3SiCH{=}CH_2$ (18%), $Cl_3SiC_2H_5$ (16%), $(H_2C{=}CH)Cl_2SiC_2H_5$ (20%), and $(C_2H_5)_2SiCl_2$ (10%)] are most probably the products of secondary reactions of the adduct of $\ddot{S}iCl_2$ and ethylene.

The addition of monomeric $\ddot{S}iF_2$ to cyclohexene[2] with subsequent dimerisation of silacyclopropane has been reported in a preliminary communication, but is not quoted in later reviews on the chemistry of difluorosilylene:



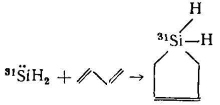
(104)

Reactions with Dienes and Polyenes

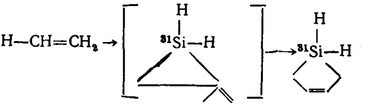
Conjugated dienes are the most reactive "trapping agents" for silylenes. Furthermore, the information in the review of Atwell and Weyenberg[2] about the addition of organic silylenes, generated by the thermolysis of alkoxydisilanes, to 2,3-dimethylbuta-1,3-diene can now be supplemented by the following new findings. These reactions proceed quite well also in the gas phase[161], where side reactions involving the dimerisation of the diene proceed to a negligible extent, and the yield of the main products is very high (approximately 60%).

It has been stated that monomeric $[^{31}Si]$ difluorosilylene, obtained by a nuclear reaction (see above), also reacts with butadiene to form 1,1-difluoro-1-$[^{31}Si]$silacyclopent-3-ene[203].

The first study on the addition of the silylene $^{31}\ddot{S}iH_2$ to buta-1,3-diene[199] showed that 80% of the silylene obtained by the nuclear reaction (43) is in the triplet state and 20% is in the singlet state[202]. The proposed mechanism for the formation of $[^{31}Si]$silacyclopent-3-ene presupposes the 1,4-addition of the triplet silylene and the 1,2-addition of the singlet silylene:

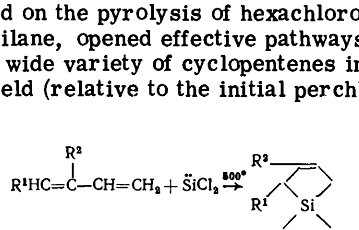


(105)



(106)

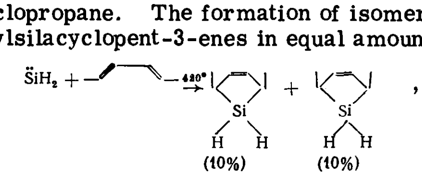
The syntheses of various mono- and bi-functional silacyclopentenes via intermediate silylenes such as $\ddot{S}i(CH_3)Cl$, $\ddot{S}i(CH_3)F$, and $\ddot{S}iCl_2$ have been described in the patent literature[274]. The method of synthesis of dichlorosilylene, based on the pyrolysis of hexachlorodisilane or octachlorotrisilane, opened effective pathways to the synthesis of a wide variety of cyclopentenes in almost quantitative yield (relative to the initial perchloropolysilane)[89-92,263]:



(107)

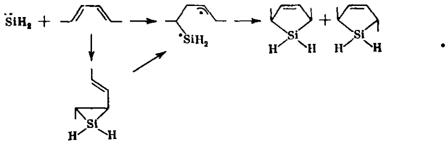
where R^1 = H or CH_3 and R^2 = H, CH_3, or Cl. It is noteworthy that the insertion of the dichlorosilylene in the C–Cl, C–H, and Si–Cl bond is observed in this case.

The silacyclopentenes obtained by reaction (107) are formally products of the 1,4-addition of dichlorosilylene, but one cannot rule out the possibility that dichlorosilylene initially attacks one of the double bonds of the diene with subsequent isomerisation of the intermediate vinylsilacyclopropane. The formation of isomeric 2,5-dimethylsilacyclopent-3-enes in equal amounts,



(108)

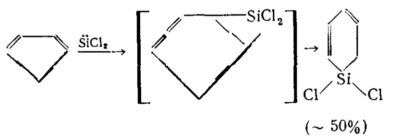
makes it possible to rule out the concerted 1,4-addition of silylene ($\ddot{S}iH_2$) to *trans*-2-*trans*-4-hexadiene[233], which should have led to the *cis*-product exclusively. This factor served as basis for the hypothesis of a biradical mechanism. The biradical can be obtained both as the primary adduct or as a result of the opening of the vinylsilacyclopropane ring[2,8]:



(109)

Reactions via the mechanism discussed above are evidently impossible for difluorosilylene[275] and silicon monoxide[9], the interaction of which with dienes in the condensed phase is accompanied by the formation of cyclic compounds containing Si_2F_4 and $(SiC)_2$ units. It is believed that the latter are the products of the 1,4-addition of dimeric biradicals.

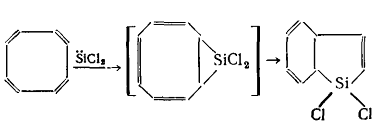
An interesting version of the reaction involves the addition of $\ddot{S}iCl_2$ to a cyclic diene (cyclopentadiene)[89-92,263]. This reaction probably proceeds via the addition of $\ddot{S}iCl_2$ to the double bond, the resulting intermediate adduct undergoing rearrangement in the next stage:



(110)

It is noteworthy that the synthesis of 1,1-dichloro-1-silacyclohexa-2,4-diene by other procedures is difficult, since these are mainly multistage syntheses with low yields producing an admixture of isomers which are difficult to separate[276].

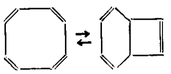
A non-conjugated cyclic polyene system such as cyclo-octatetraene is an interesting object of investigation[92]. The interaction of hexachlorodisilane with this compound at 500–550°C led to the formation of the heterocyclic compounds (IX)–(XI) with an overall yield of about 45%. The addition of dichlorosilylene tentatively proceeds via the following mechanism:



IX

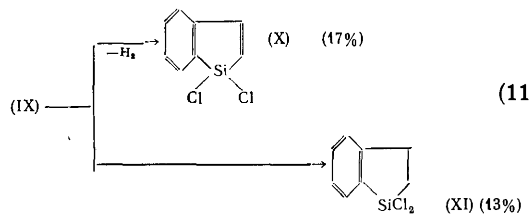
(111)

The isomerisation of the cyclo-octatetraene skeleton to the conjugated form (B) prior to the addition step is equally possible:



(A) (B)

1,1-Dichloro-8,9-dihydro-1-silaindene (IX) is fairly unstable at high temperatures and is dehydrogenated with formation of 1,1-dichloro-1-silaindene (X). The isomerisation of compound (IX) with formation of 1,1-dichloro-1-silaindan (XI) also proceeds to some extent:

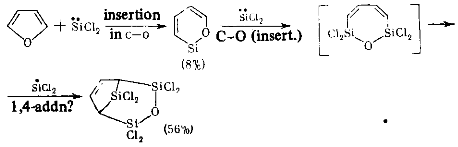


(112)

Benzene and its derivatives are known to be unreactive as trapping agents in relation to organic silylenes[2] and they should probably also exhibit a low reactivity in relation to other silylenes in the singlet state. Nevertheless one should note that biradical difluorosilylene polymers[216] as well as the less thoroughly investigated silicon monoxide react with aromatic hydrocarbons, forming cyclohexa-1,4-dienes[5,9]. The product of the reaction of silicon monoxide with benzene exhibits a high thermal stability[6].

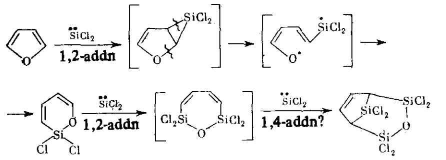
Reactions with Furan and Its Derivatives

The products of the gas-phase reaction of dichlorosilylenes with furan were unexpected[89-92]. The sequence of reaction steps can be represented in this instance by the following mechanism:



(113)

However, one cannot rule out another mechanism of the reaction, for example the addition of dichlorosilylene to the double bond of furan combined with a complex intramolecular rearrangement of the intermediate adduct:



(114)

The reaction with sylvan proceeds in the same way. The study of the interaction of perchloropolysilanes with this compound at 500–570°C showed that dichlorosilylene does not attack the methyl group; all the products detected were analogous to those isolated in the reaction with furan, the yield of the methyl-substituted bicyclic compound also being high (50%).

The examples discussed above demonstrate the enormous synthetic possibilities of the silicon analogues of carbenes (silylenes), the chemistry of which has been used in the solution of practical problems as a result of the efforts of many investigators. Summarising the foregoing, one may conclude that the chemistry of silylenes is in a state of vigorous development. This is demonstrated by the recent publications on the mechanism of the addition of phenylmethylsilylene to cyclohexene[277,278] and 2,3-dimethylbuta-1,3-diene[279] and of the addition of dimethylsilylene to cyclohexa-1,2-diene[280], which has provided evidence for the formation of intermediate silacyclopropanes. Methods for the generation of silylenes are also being improved, in particular the existing methods have been supplemented by a new procedure whereby dimethylsilylene is obtained under the mild conditions of the thermolysis of hexamethylsiliran, which until recently was completely inaccessible[281]. The above trends have been reflected also in certain recent publications[282-299], which appeared during the preparation of the review for the press. All these factors give rise to the hope for a rapid improvement of the existing methods for the synthesis and investigation of silylenes, which will undoubtedly help to predict, in a broad outline, the mode of reactions in systems which have not so far been investigated.

Some Aspects of the Theory of Gel Formation in Reactions of Polyfunctional Compounds

K.A.Andrianov and V.N.Emel'yanov

Various theories of gel formation by three-dimensional polymers derived from polyfunctional monomeric and oligomeric compounds, ranging from the theory of Carothers and Flory to the modern theories of Gordon, Kilb, Frisch, Bruneau, and Stepto, are discussed. The role of kinetic, thermodynamic, and structural factors in processes leading to the development of the gel fraction are analysed. The reactions involving polyfunctional compounds are classified, and the fundamental scheme of the three-dimensional reaction leading to gel polymers is described taking into account the altered ideas and the new criteria which have been established. The conclusions reached at a symposium on gel formation processes in polymers held in England in 1974 are examined.
The bibliography includes 149 references.

I. CLASSICAL CONCEPTS AND LAWS OF FUNCTIONALITY

The ability of a polymeric system to be converted irreversibly into an infusible and insoluble state, i.e. to promote gel formation[†], has been used for a long time in various branches of industry. It is not therefore surprising that, ever since the first steps were taken in polymer chemistry, numerous applied and theoretical studies have been devoted to the phenomenon of gel formation in three-dimensional polycondensation and polymerisation and to its interpretation and characteristics.

The role of the functionality of compounds (i.e. the number of functional groups per monomer molecule) was noted and analysed before all other factors exerting the most marked influence on the development of the gel formation process in polymers during three-dimensional polycondensation. In 1932 Bozza[1] characterised for the first time the dependence of the degree of reaction of Glyptal polymers, including the degree of condensation at the instant of gel formation (the gel formation point), as a function of the functionality of the system.

This study stimulated the development of ideas about gel formation in polymers. It had a definite influence on Carothers, who presented evidence in his 1935 paper "Polymers and Functionality"[2] that the dependence of the degree of reaction on functionality in gel formation by polymers is of a general type. Carothers' initial postulates (1) that the onset of gel formation is due to the formation of infinite three-dimensional (spatial) networks and (2) that the importance of the intramolecular cyclisation of the initial compounds is negligible determined for a long time, together with subsequent studies by Flory, a unilateral development of the theory of gel formation. Perhaps the most complete and at the same time briefest assessment of Carothers' "classical" ideas is given in the monograph of Cotter and Matzner[3]: "It is interesting to speculate whether Carothers' work, being so basic and all-encompassing, served to inhibit subsequent creativity in synthetic polymer chemistry. Frequently, when rapid, broad studies are made in a field of scientific endeavour, they can serve as unintentional barriers to further advances... The wide scope that is only now emerging for ring-forming polymerisations of polyfunctional monomers to linear polymers is indeed remarkable. Its appearance may well have been delayed by the functionality laws of polymer science".

The derivation of the system of Carothers' fundamental equations, subsequently called the "law of functionality", is based on a simplified analysis of the formation of a polymer molecule from N_0 monomer molecules with an arithmetical mean functionality f'. In the absence of intramolecular reactions, the combination of each two monomer molecules by a single covalent bond (i.e. as a result of the disappearance of two functional groups) corresponds to an overall decrease in the number of molecules equal to $2(N_0-N)$, where N is the number of molecules in the system after the attainment of a particular degree of reaction. Having referred the number of groups which have reacted to their initial number, Carothers arrives at the degree of conversion at any polycondensation stage before the attainment of the gel formation point:

$$P=2(N_0-N)/N_0f. \qquad (1)$$

[†] In the present review the terms "gel formation", "micro- and macro-gels", "the point of gel formation", "the theory of gel formation", "the gel formation period", "the sol fraction", etc. refer to the description of the formation of polymers with a three-dimensional macromolecular structure produced only as a result of covalent bonds on condensation or polymerisation of polyfunctional compounds.

Putting $N_0/N = X$ (the number-average degree of polymerisation), we obtain

$$P=2/f-2/Xf, \tag{2}$$

whence

$$X=\frac{1}{1-Pf/2}. \tag{3}$$

Assuming that $X = \infty$ at the gel formation point, Carothers defines the conversion at this point in the following way:

$$P_{cr}=2/f. \tag{4}$$

Analysis of the above equations shows that their application is rigorously limited by the following condition: none of the functional groups of the monomer or the polymer molecule is involved in the formation of any cyclic groups or fragments. The unreality of this condition was noted already in the course of the first discussion after Carothers' report on this subject. Using the model of a three-dimensional process illustrated in Fig. 1, Houwink[4] showed that Eqns. (1) and (2) are invalid. According to Houwink, when a polymer molecule A with functional groups X has reacted with another molecule B as a result of the interaction between groups *1* and *4*, then, following the further development of their process, for example on interaction between groups *2* and *5* or between groups *3* and *6*, there is no increase in the degree of polymerisation $X = N_0/N$, since the number of molecules N does not decrease. Consequently the degree of conversion actually increases, while according to Eqns. (1) and (2) it should have remained constant. Furthermore, Eqn. (3) loses its physical significance for conversions in excess of $2/f$, when the number-average degree of polymerisation becomes negative.

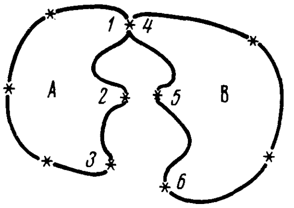

Figure 1. Houwink's model of the intramolecular cyclisation process[4].

Later it was shown[5] that the number-average degree of polymerisation at the gel formation point is extremely low, as a result of which Eqn. (4) is also contradictory.

The specific nature of the initial postulates of Carothers' theory has now also become evident. Various causes and mechanisms of gel formation in polymers, according to which the formation of an infinite three-dimensional macromolecular network is by no means a necessary criterion of this phenomenon, will be examined below. As regards the second postulate, neglect of intramolecular cyclisation processes in the macromolecular system was not only unjustified, as stated above, but actually became a definite obstacle to the development of theoretical ideas.

A more fundamental mathematical approach to the analysis of gel formation in polymers was achieved a few years later in Flory's studies[6-9], where the statistical theory of probability was first applied to three-dimensional polycondensation. It is striking that, like Carothers, Flory believes that the onset of gel formation is caused by the generation of "infinite" spatial polymeric structures. For the statistical analysis and derivation of fundamental relations, Flory employed the diagram describing the formation of a three-dimensional macromolecule illustrated in Fig. 2*a*. The same model has been frequently used by other investigators in the form of modifications 2*b* and 2*c*. Considering the probability that any chain selected at random from the polymer mixture, for example the chain in sphere *1* in Fig. 2*a*, is part of an infinite three-dimensional molecule, Flory bases his treatment on two hypotheses which he adopted *a priori*. The first is that all processes leading to the formation of cyclic groups or fragments are unlikely and are therefore disregarded. The second hypothesis is that all the reactive groups have the same reactivity throughout the process regardless of their position. Thus having placed at the head of his theory the same postulates as in Carothers' treatment, Flory actually examined one of the specific instances of three-dimensional polycondensation, namely the instance where only statistical relations and not chemical relations are dominant.

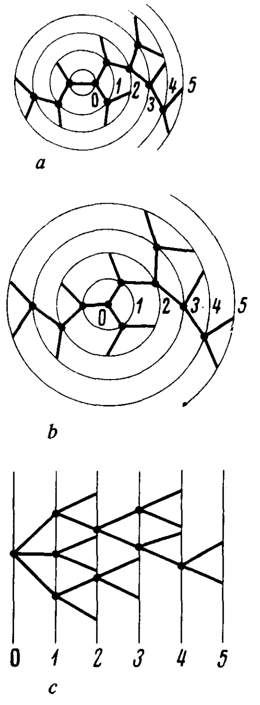

Figure 2. A topological scheme of the development of a three-dimensional polymerisation reaction: *a*) Flory's model[6]; *b*) the "growing tree" model[36]; *c*) the cascade process model[36]. The numerals represent the generations.

One of the most important parameters of Flory's theory is the branching coefficient α, which he defined as the probability that one branching component (the monomer with $f > 2$) becomes bound as a result of the reaction with another branching component. The author identified the onset of gel formation in polymers or the gel formation point with the critical conditions for explosion in certain gas-phase reactions, having shown that the overall critical value of α can be represented thus:

$$\alpha_{cr} = \frac{1}{f-1}, \tag{5}$$

where f is the arithmetical mean functionality of the branching components only [for example f for a mixture of two moles of glycerol, one mole of pentaerythritol, and give moles of dicarboxylic acid is $(2 \times 3 + 1 \times 4)/3 = 3.33$]. On the other hand, the statistical method leads to a dependence of α on the degree of condensation P:

$$\alpha = rP_A\rho/[1 - rP_A^2(1-\rho)] = P_B^2\rho/[r - P_B^2(1-\rho)], \tag{6}$$

where r is the ratio of the total number of groups A to the total number of groups B in the system, ρ is the ratio of the number of groups A belonging to polyfunctional monomers to the number of groups A in the system, and P_A and P_B are the degrees of conversion with respect to either groups A or B [Eqns.(5) and (6) were derived by Billmeyer[5]]. Evidently in the calculation of α_{cr} it is necessary to know only the functionality of the reactants. Using Eqn.(6), it is easy to calculate the degree of conversion in the reaction at the gel formation point of the polymers when α_{cr} is known.

It was found that Flory's theoretical ideas made it possible to describe the onset and development of gel formation in any polycondensation system without resorting to experiment. This appeared to be very promising, particularly from the standpoint of the practical application of the theory.

Table 1. The degree of conversion P, the branching coefficient α, and the functionality f in systems of polyfunctional monomers (according to Flory[6-9] and Carothers[2]).

Monomer system*	According to Flory			According to Carothers	
	f	α_{cr} from Eqn.(5)	P_{cr} from Eqn.(6)	f	P_{cr} from Eqn.(4)
$2A_3 + 3B_2$	3.00	0.50	70.71	2.40	83.33
$A_3 + B_3$	3.00	0.50	50.00	3.00	66.66
$A_4 + 2B_2$	4.00	0.33	57.73	2.66	75.00
$3A_4 + 4B_3$	3.42	0.41	41.17	3.42	58.33
$A_4 + B_4$	4.00	0.33	33.33	4.00	50.00

*The subscripts correspond to the number of groups per molecule.

Emphasising the generality of the relations obtained, Flory also noted that the conversion in the reaction at the gel formation point P_{cr} is independent of process conditions such as temperature, catalyst, reactant concentrations, etc.[6] Table 1 presents the characteristics, in terms of the Flory and Carothers theories, of a number of heterofunctional condensations in which the ratio of the interacting functional groups A, and B is 1 : 1, i.e. $r = 1$ in Eqn.(6). It follows from the data in Table 1 that the degree of conversion at the gel formation point, calculated from the Carothers theory, is greater than the value calculated from the Flory theory, which is due to the incorrect estimate of X in Eqn.(2), as a result of which the second term assumes a value close to zero and Eqn.(2) assumes the form of Eqn.(4).

Flory compared his theoretical treatment with the comparatively few available experimental data. The scant experimental material at that time and possibly also pure chance led to the adoption of polyesters as a practical model. Comparison shows (Table 2) that the discrepancies between theory and experiment are comparatively small, but exceed the permissible deviations in theoretical studies[6-9]. Although the author attributes the observed discrepancies to neglect of intramolecular cyclisation reactions in the calculations, he excludes them from the first phase of polycondensation (before the instant of the gel formation), evidently because they are inconvenient for mathematical treatment, and transfers them wholly to the second stage—beyond the gel formation point. This is illustrated by the course of the analysis itself and by the working scheme (Fig. 2). According to the initial postulate of the Flory theory, gel formation is a process involving the growth in the reaction mixture of giant macromolecules with a three-dimensional structure. The latter are none other than a statistical set of cyclic fragments linked in space. As can be seen from Fig. 2, Flory analyses the probability of the formation of an infinitely large branched (but not cross-linked) polymer, which suddently begins to undergo three-dimensional cyclisation only at the gel formation point, and not the probability of the formation of such polycyclic *macro-ensemble*.

Table 2. The experimental and calculated degrees of condensation and the branching coefficients at the gel formation point (according to Flory) for systems comprising tricarballylic acid, diethylene glycol, and dicarboxylic acids.

No. of expt.	P_{cr}		α_{cr}		No. of expt.	P_{cr}		α_{cr}	
	expt.	calc.	expt.	calc.		expt.	calc.	expt.	calc.
1	0.911	0.879	0.59	0.50	3	0.894	0.843	0.62	0.50
2	0.939	0.916	0.59	0.50	4	0.990	0.995	0.58	0.50

Stockmayer and Weil[10] subsequently attempted to test experimentally this artificial subdivision—into a polymer branching process alone in the first stage and mainly the formation of a three-dimensional macromolecular network structure in the second. In their attempts to refine the fundamental equations of the Flory theory, Stockmayer and Weil[10] and subsequently Weil[11] diluted the reaction mixtures with inert solvents. This method made it possible to take into account quantitatively the specific contribution of the intramolecular cyclisation reactions. Having determined the gel formation point in highly dilute mixed solutions of adipic acid and pentaerythritol, where intramolecular cyclisation should have played a significant role, Stockmayer subsequently proceeded to more concentrated solutions. Having observed that the graphical relation between P_{cr} and the volume of the reaction mixture is a straight line, he extrapolated it to zero volume and obtained values of P_{cr} in good agreement with those calculated by Eqn.(6).

Numerous cyclisation reactions of various monomers not only in dilute solutions but also in reaction media without solvents are now known[12]. In the light of the accumulated experience, the relation which Stockmayer obtained by extrapolation is characteristic of the given specific instance only.

Summarising the initial period of the establishment of a theory of gel formation in polymers, we may note that, as a result of the development of the first theoretical ideas based on the few experimental data available at the time, a number of characteristic relations, illustrated graphically in Figs. 3–5, became generally adopted in 1940 to 1945.

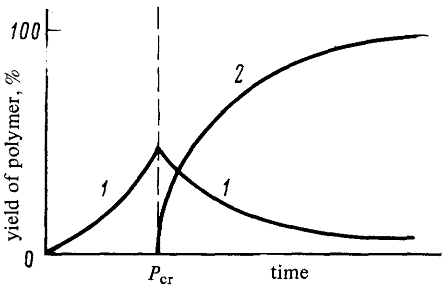

Figure 3. The yield of soluble polymeric products (curve *1*) and of the gel fraction (curve *2*) in the three-dimensional condensation of polyfunctional compounds.

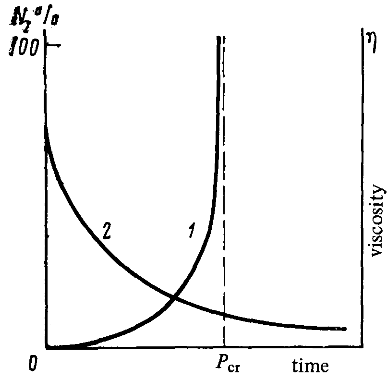

Figure 4. Variation of the viscosity of the products η (curve *1*) and of the content of functional groups in the system N (curve *2*) during condensation.

It follows from the graphs that the gel formation point of a polymer was adopted as the turning point in the reaction, dividing the process into two stages. The formation of oligomeric products is characteristic of the first stage. Their interaction with one another and with the initial monomers is responsible for the appearance of branched macromolecules, whose yield increases during the condensation, reaching a maximum at the gel formation point (Fig. 3, curve *1*). A gradual decrease of the sol fraction because of the involvement of the polymer molecules in the formation of the spatial network, i.e. the increase of the content of the gel fraction in the reaction system, is characteristic of the second stage of the condensation (Fig. 3, curve *2*).

It follows from the data in Fig. 4 that only a slight increase of the viscosity of the products is typical for the first reaction stage, but, as the reaction approaches the gel formation point, the tendency towards a sharp rise in the kinetic viscosity curve is observed (curve *1*). Diffusional factors play an increasing role at this stage and the curve describing the consumption of functional groups becomes less steep and approaches an asymptote (curve *2*).

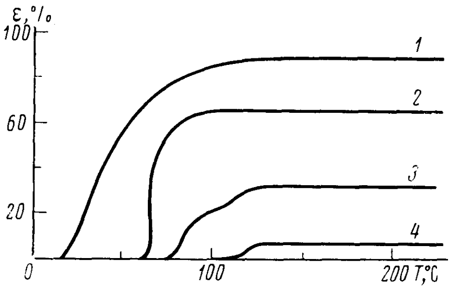

Figure 5. Variation of the thermomechanical properties of polymers beyond the gel formation point with increase of the density of cross links (a higher number of the curve corresponds to a higher density of cross links); ϵ—modulus of elasticity.

Beyond the gel formation point, it is more difficult to follow the conversion in the reaction on the basis of the content of functional groups. However, the change of the physicomechanical characteristics of the gel fraction makes it possible to infer a further development of the process. Thus an increase of the modulus of elasticity and an increase of the glass point (Fig. 5) as well as changes in other characteristics correspond to an increase of the density of cross links in the growing network owing to the continuing polycondensation within the gel particles. However, even for high degrees of conversion of the polymeric system into a gel, it is possible to extract from the latter a soluble fraction (the sol fraction), the molecular weight of which is low.

The above mechanism of the three-dimensional polymer formation process, whose arose as a result of the period of "classical" studies and ideas, was used subsequently by many investigators as the fundamental model. The main component of this model, the gel formation theory, was elaborated and adjusted. However, as long as the ideas and postulates underlying it remained unchanged, further progress was bound to be limited.

II. THE ROLE OF APPLIED MATHEMATICAL METHODS IN THE FURTHER DEVELOPMENT OF THE THEORY

A characteristic feature of the subsequent development of the theory was a comprehensive analysis of the known relations governing the process in conjunction with various mathematical methods. The mathematical procedures and approaches would merit only a simple enumeration if they did not reveal at the same time "latent" relations and characteristics in the formation of macromolecules with a three-dimensional structure, demonstrating thereby the primitive nature of the "classical" gel formation mechanism as well as the importance of a wide variety of factors which had been neglected previously.

In the course of the study of the mathematical models of three-dimensional polycondensation, the complexity and many-sided nature of this process, the role of the activity of functional groups and their distribution in the molecule, the importance of various characteristic macrochains, the structural forms of oligomers and polymers, etc., became increasingly clear. At the same time there was a growth of the complexity of the mathematical expressions describing particular characteristics.

However, instead of carrying out specific chemical tests of the relations obtained, investigators moved further into the region of purely mathematical manipulations. Thus Flory[6] described gel formation in terms of the model of a branching process (based on Semenov's theory[13] developed in the 1930s and describing the critical conditions in the explosion in certain gas-phase reactions) in combination with a statistical method of calculation. Stockmayer employed another analytical method[15-17] adopted from the theory of non-ideal gases[14]. Applying this method, he used the analogy between the phase transition from gases to liquids and the transition from the liquid soluble polymer at the gel formation point to the insoluble and infusible macrogel. The method yielded more general expressions for the fundamental characteristics of three-dimensional processes and made it possible to consider cases which Flory was unable to solve[15-17]. In particular, Stockmayer analysed the copolymerisation of vinyl and divinyl monomers, requiring a special approach, and found a general expression for the description of the "critical state" of the system. He also attempted to take into account the erroneous assumptions of the "classical" theory, namely to determine the contribution of the processes involving the formation of cyclic fragments in the molecular chains before the gel formation point[10].

Gordon[18] and Good[19,20], who applied the methods used for the description of cascade processes[21,22], found a greater scope for the mathematical analysis of polymerisation processes. The cascade theory or the theory of stochastic processes was a more advanced and convenient instrument compared with previous theories. The relation which Good found between the number-average degree of polymerisation DQ_w and the branching coefficient α has the following simple form:

$$DQ_w = \frac{4-\alpha-\sqrt{4\alpha-3\alpha^2}}{3\alpha-4+3\sqrt{4\alpha-3\alpha^2}}.$$

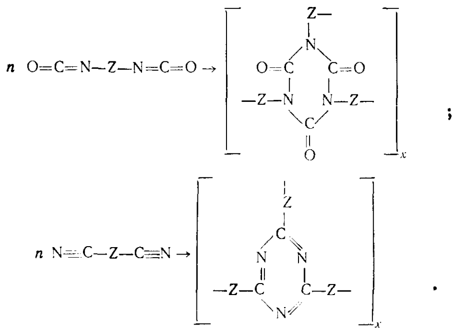
Furthermore, Good tabulated the calculated values of DQ and α for monomer systems with a tetrafunctional branching unit.

Thus the studies of Gordon and Good permitted an advance in the methods of mathematical analysis in this field. The cascade method was developed further a few years later in Whittle's studies[23,24]. Having examined the problems of the formation of bonds between reacting species with functional groups having different reactivities as well as the probability of their aggregation, Whittle extended the analytical method to more realistic but also more complex cases of the aggregation of macromolecular species with groups having different reactivities. His mathematical expressions were not, unfortunately, sufficiently simple and complete for practical applications.

Studies by Case[25-28] and Giacomo[29] played a major role in the progress in the physicochemical description of the gel formation process. Bearing in mind the primitive nature of Flory's mechanical model of the monomer, as an indefinite particle with functional groups, these workers took the first step on the way to the analysis of a monomer model with a definite structure, attempting to take into account the influence of the symmetry of the disposition of the functional groups in the molecule. This was the first attempt at a mathematical approach to the true behaviour of real compounds in three-dimensional processes. Despite the fact that Giacomo and Case took into account only one of the numerous characteristics of monomeric compounds influencing the gel formation process, namely the asymmetry of the distribution of the functional groups in the molecule manifesting different reactivities, they noted significant differences in the behaviour of these more realistic models compared with Flory's model.

Improvement of the mathematical procedures in the analysis of three-dimensional polycondensation led in its turn to the consideration of more complex and realistic models. Erlander and Fench[30], Tang Au-Chin[31], and Allen[32] achieved a mathematical description of the three-dimensional polycondensation of monomers whose molecules contain various functional groups or identical groups with different reactivities.

The studies of Fukui and Yamabe[33-35], devoted to the mathematical analysis and description of at first sight seemingly highly specific instances of three-dimensional processes, were published in 1960–1964. In the development of the synthesis of thermoreactive resins, the authors considered and analysed the formation of a three-dimensional polymer from polyisocyanates, polynitriles, and certain other monomers:



Apart from the isocyanuric and triazine cyclic *macroensembles* illustrated above, the polycyclic hexadihydrotriazine, boron oxide, and other polymers have similar structures.

It follows from the reaction equations that a branched cyclic structure is formed from the very beginning in such processes, and is converted in the course of further development into a three-dimensional structure. The formation of rings is the main process in this case and must be described by the main equation and not with the aid of average corrections, as has been done previously by Stockmayer, Case, and others. Using the old statistical methods, Fukui and Yamabe arrived at an expression describing the critical state in such systems:

$$\alpha_{cr} = \frac{1}{2(f-1)}.$$

Unfortunately due attention was not subsequently devoted to the mathematical analysis of polycondensation occurring with simultaneous and regular cyclisation and branching in the macromolecular chains.

The specific features of the formation of various chemical bonds, intermolecular and intramolecular, as well as the characteristics of the macromolecular structure generated were analysed some years later by Bruneau[36-40]. His studies were, as it were, a logical continuation, but at a higher mathematical level, of the research of Fukui and Yamabe. Bruneau examined the changes in a polyfunctional system during the reaction from two standpoints—structural and stochastic. The structural or topological aspect revealed an *ensemble* of the possible conformations of the intermediate products in the form of a Konig graph[41], while the stochastic approach made it possible to describe the chemical reaction at each instant in the form of a statistical distribution of the chemical bonds formed between the reactive molecule. The stochastic analysis led to the isolation of two types of systems of polyfunctional compounds, the real existence of which is evident: (1) the homogamous system in which a bond is formed between any pair of species (molecules) and (2) the heterogamous system where chemical bonds are formed in a specific manner. Bruneau did not insist categorically on the universality of the relations obtained, bearing in mind apparently the wide variety of factors which are difficult to take into account and which have different effects (depending on the type of reactants) on the critical parameters of gel formation. In concluding one of his communications[40], he emphasises that one can determine with the aid of his equations the critical parameters of gel formation only subject to the condition "that the mechanism of the reaction of polyfunctional monomers is known, that the formation of the three-dimensional structure satisfies the conditions of the theoretical method, and that the technique of the determination of the sol-gel transition is sufficiently sensitive and accurate".

Claiming that the gel formation theory is at the half-wave point between physics, chemistry, and biology, on the one hand, and mathematics, on the other, the author[36] endeavoured to demonstrate to workers in the former field the importance of the graph theory in the determination of the statistical structure of macromolecular compounds and to stimulate workers in the latter field to turn their attention to a particular branch of chemistry, with its topological possibilities in the study of the structure of polymers, which is exceptionally important in practice.

Apart from the above aspects of the study of the phenomena of gel formation by means of various mathematical approaches, it is also necessary to consider specifically the kinetic method of treating the problem. A number of workers supporting the kinetic approach in this field believe that the foundations of the statistical methods have been by no means adequately investigated and that this precludes *a priori* inferences about the possibility of applying it to calculations on processes of any specific type[42,43]. In contrast to the statistical method, based on the determination of the probability of the formation of macromolecules of a particular size and structure, the kinetic analytical method makes it possible to discover relatively general procedures for the calculation of the fundamental statistical characteristics of the distribution and to establish relations which determine the conditions governing the onset of gel formation in polymers.

Gordon and Scantlebury[44], who, among others, pioneered the kinetic approach to the study of gel formation in polyfunctional systems, used the statistical kinetic method to describe the condensation of adipic acid with pentaerythritol and tri(hydroxymethyl)ethane. In their assessment of the non-kinetic Whittle[23,24] and Bruneau[36] methods, these authors describe them as highly unrealistic statistical procedures, because they are not based on configuration statistics. Gordon and Scantlebury justified the proposed model for the gel formation process by solving equations involving functions of the ratio of carboxy- and hydroxy-groups. They found that at the beginning of gel formation about 10% of all the ester linkages formed are intramolecular. Such a high percentage contribution of the intramolecular cyclisation reactions threw doubt on the validity of models of the Carothers–Flory type (see Fig. 2), although the authors themselves did not discuss problems of this kind.

A very detailed mathematical description of the kinetics of the condensation of polyfunctional monomers was achieved recently by Pis'men and Kuchanov[42,45,46]. Using the reaction of glycerol with dicarboxylic acids as an example, they carried out calculations on the kinetics of the polycondensation of monomers containing reaction centres of different activities and obtained an analytical solution to the kinetic equation relating the molecular weight distribution of the products in the general case. These investigators also proposed for aromatic monomers a kinetic polycondensation mechanism in which the activity of the functional groups changes in the course of the reaction and showed that such instances cannot be described by a statistical method. The solution of the differential equations proposed[42] for the generating functions is, however, fairly difficult in most cases[47]. The application of this type of method to the description of condensation is further limited by the instant of gel formation.

In order to simplify the kinetic analytical method and the final equation, Irzhak[47] proposed a combinatorial method combining the familiar procedures and the criteria of the statistical method. In those cases where the detailed mechanism of the condensation process is known, he introduces the time characteristics of the reaction taking place. However, together with the statistical approach, the author introduced into his treatment the earlier assumptions of the statistical theory.

Summarising in 1968 the progress achieved in the mathematical description of polymerisation processes accompanied by gel formation, Gordon and Scantlebury noted[48] in the first place the importance of employing kinetic factors in the analysis (including the so called substitution effect[49], which determines the change in the rate of formation or dissociation of bonds during the reaction) and, in the second place, the greater attention paid by mathematicians to the problem of intramolecular cyclisation[50-52]. The analytical description of this simultaneous process still constitutes an unsolved problem[43,56], despite the continuing elaboration of the method[53-55].

In connection with the improvement of the mathematical procedures for the analysis, one can also expect much interest in other secondary reactions, which are no less important than intramolecular cyclisation. The influence of secondary reactions on the fundamental gel formation parameters and the properties of polymers has been frequently noted for many known classes of polymers[57]. The role of such processes is particularly important in the synthesis of elastomers[58], where the contribution of secondary reactions depends to a large extent on the conditions and increases with the degree of conversion of the monomer. One of the simplest cases of the analysis of secondary reactions—chain termination in the development of three-dimensional structure—has been examined in a study[59] where use was made of the theory of branching processes[18-21]. The mathematical description of three-dimensional polycondensation with simultaneous allowance for at least two similar factors, for example of chain transfer and cyclisation reactions, has not so far been achieved.

The characteristics of the development of the sol fraction in structured systems still require a mathematical treatment; certain variants of the analysis of its formation in conjunction with the series of assumptions and simplifications used previously have been examined[60-63]. The models of the development of the sol fraction in the studies quoted above differed little or not at all from the models proposed previously by Carothers[2] and Flory[6-9] (Fig. 2). For this reason, the studies concerned with the statistical mechanics of polymers with the star structure[64-66] adjoin this field in the mathematical analysis of three-dimensional processes.

The updating of the mathematical procedures for the investigation of three-dimensional polycondensation together with the development of synthetic methods had a further positive aspect, namely it helped to discover the error of certain assumptions and the final equations of the statistical method forming part of the procedures inherited from the 1930s. Andrianov and Emel'yanov[67,68], Pis'men and Kuchanov[42], and Raspopova et al.[43] showed that the logical and mathematical errors have been caused by the invalid application of certain procedures of the statistical method, which are in essence inapplicable to the description of chemical processes of this kind.

The latter may be illustrated by the studies of Bruneau[38,39] and certain other investigators[69-73] who demonstrated the formal contradictions arising from the "classical" theory of gel formation in a system of polyfunctional compounds. Whiteway et al.[69-71] noted with astonishment that the errors made by Flory in his first studies dealing with three-dimensional polycondensation have been frequently repeated by other investigators in the course of several decades.

III. THE GEL FRACTION AND DEVELOPMENT OF THE STRUCTURAL AND THERMODYNAMIC ASPECTS OF THE GEL FORMATION THEORY

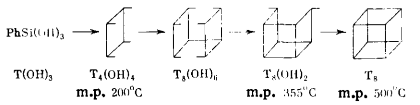
The concept of the "gel formation point" in a system of reacting polyfunctional compounds as the instant of the appearance in the reaction mixture of infinite polymeric three-dimensional structural networks (more correctly networks bounded by the walls of the reaction apparatus) was first introduced by Carothers[74] in 1931. Several years later, Staudinger[75-77] and then Flory[6] completed the formulation by defining a necessary condition for gel formation—the infinite growth of macromolecules in three directions. Thus, at the start of the development of polymer chemistry, three of the greatest authorities closely related the concept of the "gel" or the gel fraction to two factors: (1) the three-dimensional or spatial structure of macromolecules and (2) the "infinite" molecular weight.

Whereas the structural factor, which determines the most characteristic properties of the gel formation—its infusibility and insolubility in all solvents (not causing the dissociation of covalent linkages)—has not so far aroused any doubts, it was subsequently discovered that the necessity for the second factor does not by any means apply to all types of three-dimensional polymers.

The obligatory requirement of the formation of infinitely large gel macromolecules, in fact of a single macromolecule, was justified initially by the idea that a three-dimensional gel can be formed either by the cross-linking of macromolecules with a linear structure formed beforehand or via the family tree [multifunctional branching] mechanism proposed by Flory[6] (Fig. 2). Polymeric gels synthesised in accordance with the first variant did indeed correspond to all the factors mentioned above. This pathway is characteristic of the synthesis of elastomers and rubbers—polymeric materials subjected to some type of treatment in the last stage of their synthesis, for example by irradiation. A mathematical analysis of polymer-analogue reactions of this kind has been carried out by a number of investigators[78-81].

The ideas concerning the development of the process via the family tree mechanism with conversion of the branched macromolecules at the gel formation point into a three-dimensionally cross-linked polymer changed appreciably following the accumulation of experimental data. These changes were a consequence of advances in the synthetic methods of polymer chemistry and were determined primarily by the development of ideas concerning the three-dimensional processes proceeding via the microgel formation stage.

Despite the fact that studies devoted to the "embryonic" development of microgel molecules in processes of the above type are at present in the initial stage of their development, fairly thoroughly investigated pathways to the synthesis of a number of polycyclic homologues, which to a certain extent can serve as a model of developing three-dimensional structures, have already been described in the chemistry of polyorganosiloxanes for example. Thus the homocondensation of trihydroxyphenylsilane yields, apart from other polycyclophenylsiloxanes[82], a series of molecules with increasingly complex structures[83,84] (T denotes the trifunctional phenylsiloxane unit):



In the series of homologues illustrated, the solubility decreases and the melting point increases as the three-dimensional structure is formed and becomes more complex.

The influence of factors such as the flexibility of the molecular chain between the units of the polymer network on the capacity of the system for gel formation has been investigated in a number of studies by Andrianov and Emel'yanov[85-88] in relation to the three-dimensional polycondensation of tetrafunctional acid esters with tri- and tetra-hydric alcohols, various glycols, and diamines. The gel formation parameters determined in the reaction of oligomeric compounds (the critical degree of reaction and the critical branching coefficient) showed that, with increase of the length of the chain between the units of the polymer network, the instant of the appearance of the gel fraction is displaced towards increasing degrees of reaction, i.e. in the direction of the formation of more complex molecular structures. A similar relation was observed with increase of the flexibility of the chains between the units of the polymer network owing to another factor—the chemical nature of the macromolecules[67,68].

Among other structural factors directly responsible for the onset of the development of gel formation, the appearance of an additional number of units in the polymer network owing to the intertwining of the chains (entanglement) is important[89]. Despite the complexity of the analysis of this type of problem, the formation of hooking units can be followed, for example, by analogy with the method of Gartsman and Gorelik[90] or other workers[91].

A characteristic feature of molecules with a three-dimensional structure, namely the dependence of the melting point on the flexibity (elasticity) of the three-dimensional skeleton, has been traced also in another homologous series (polyphenylsilsesquioxanes)[84]:

T_8, mol. wt.1052
m.p. 500°C

T_{10}, mol. wt.1290
m.p. 418°C

T_{12}, mol. wt.1548
m.p. 385°C

Here the melting point decreases from T_8 to T_{12}, i.e. with increase of the elasticity of the lattice owing to the increase of the dimensions of the component rings.

Despite the logical incompleteness of the homologous series illustrated (the lack of the simplest model species which is built up to give a more complex three-dimensional lattice and which loses in this process both its fusibility and solubility in all solvents), certain purely structural characteristics can be traced in these instances: (1) the increase in the complexity of the molecular structure of the product during the reaction from dimeric to trimeric with its subsequent development is responsible for the gradual loss of solubility by the reaction products and for the increase of the melting point. (2) The loosening of the three-dimensional structure, i.e. the decrease of the number of bonds per unit volume and the consequent increase of the flexibility of the lattice, leads to the reverse effect—the increase of the solubility of such macromolecules and the decrease of their melting point.

In their study on the development of a theory of gel formation in the chemistry of alkyd resins, Bobalek et al.[92] proposed in 1964 a model for the process different from that of Flory (Fig. 6). This model differed in the first place by the fact that it actually altered the earlier concept of the gel formation point as the "critical instant resembling explosion in certain gas-phase reactions". It follows from Fig. 6 that the author distinguished two gel formation points. The first corresponds theoretically to the instant of the appearance in the reaction mixture of the first particles with a three-dimensional structure characterised by infusibility and insolubility. At this moment, the system is virtually homogeneous (there are only a few macromolecules with a three-dimensional structure) and, according to classical ideas, is not in a critical state. The second gel formation point corresponds to a much later reaction stage—the conversion of the fluid reaction mixture into an elastic polymer. In the author's terminology, this "physical" instant of gel formation is identical in terms of some of its characteristics to the established concept of the "classical" gel formation point (the loss of fluidity, fusibility, and solubility), but at the same time it exhibits fundamental differences—the gel particles appear and develop in the reaction mixture much earlier. Thus the hitherto clear-cut term "gel formation point" was transformed into the indefinite "gel formation period".

Studies by the Soviet polymer school later demonstrated, in relation to polyurethanes, the desirability of replacing the concept of the "gel formation point" by the more realistic "gel formation region"[93]. Electron microscope, molecular weight, and molecular probe studies by Lipatova, Lipatov, Zubko, and others in the course of the formation of polyurethanes with a three-dimensional structure[94-99] made it possible to demonstrate the appearance, already in the early stages, of globular formations with a greater or lesser degree of order in the supermolecular structures as a function of the number and positions of hydrogen bonds, the length and chemical nature of the chain in the initial compound, the reaction coditions, etc. The development of gel formation has then the properties of interglobular cross-linking and cross-linking within the globular structures. The two processes are interrelated and each may be dominant under certain conditions. The formation of the first sections of the microgel in the early stages does not in fact have any appreciable influence on the properties of the system (the latter remains fusible and fluid) but, as the microgel particles accumulate, there is a gradual transition from homogeneous to microheterogeneous conditions and then to macroheterogeneous conditions[100].

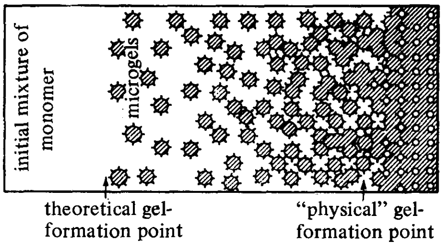


Figure 6. Schematic illustration of the formation of Glyptal polymers according to Bobalek et al.[92]

As in the study of Bobalek et al.[92] quoted above, two gel formation periods may be distinguished in the formation of polyurethanes. In the first stage network microgel particles are generated and their number increases. In the next stage, the main process involves the ~~linking~~ of the microgel particles as a result of which the system loses its fluidity and fusibility[98]. The indeterminate and diffuse nature of the boundaries of individual stages (homogeneity–microheterogeneity and microheterogeneity–macroheterogeneity) did indeed expand the "classical" definition of the gel formation point to the gel formation region or period.

The tendency to study the problems of gel formation in a number of investigations during 1960–1970[101,102] promoted a more detailed description of polymerisation processes, including transitional stages in microheterogeneous states. There was an increase in the publication of experimental data in the periodical literature, showing that macromolecules, oligomers, or monomers do not exist in an isolated state even in dilute solutions. According to the investigations of Lipatova and Proshlyakova[103], Kargin, Fakirov, and Bakeev[104,105], as well as other workers[106], the primary associated species, in the form of packets or aggregates combined in definite supermolecular structures, constitute the initial forms of the future microgel particles[107]. The involvement of the microgel particle formation stage in the three-dimensional processes was demstrated during these years for various types of polymers: polyacrylates[107-108], polyesters[92,109], polyurethanes[93-100], polyepoxides[110,111], etc. Ultimately it became evident that the specific contribution of the three-dimensional processes leading to spatial polymers via the microgel formation stage is no less significant than the contribution of the three-dimensional processes involving the formation of linear and branched macromolecular structures. In this sense, the model of a three-dimensional process proposed by Bobalek et al. becomes general.

The new mechanism has not been examined theoeretically in conjunction with a mathematical description.

The application of various physical methods to the study of three-dimensional reactions at the stages corresponding to the transition from homogeneous to microheterogeneous conditions made it possible to determine in many instances the size of the microgel particles[93,109,110].

The radius of the average globular formations in structured polyurethanes varies between 85 and 500 Å according to Lipatova's data[93]. With decrease of the molecular weight of the initial oligomer or with increase of the reaction temperature, the size of the nuclear gel particles then decreases, other conditions being equal.

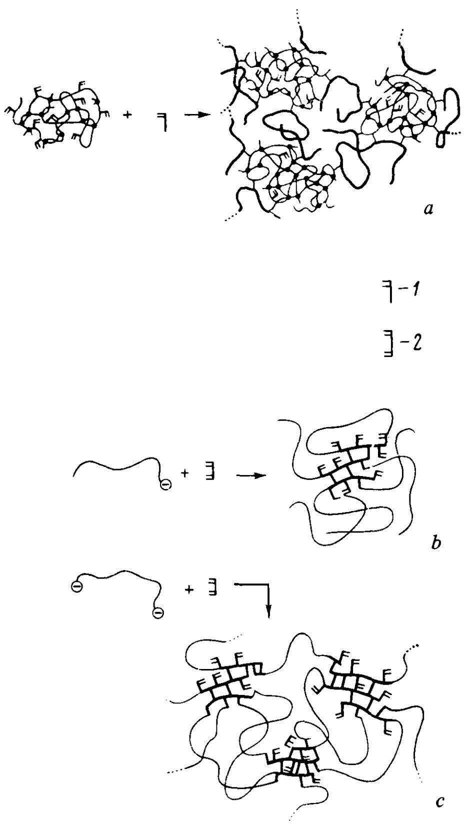

Figure 7. Schematic illustration of the directed "microgel" synthesis of three-dimensional polymers according to Funke[112] and Rempp[113]: *a*) reaction with participation of the microgel as the cross-linking agent in a three-dimensional process; *b*) synthesis of a polymer with a "star" structure containing a microgel nucleus; *c*) synthesis of a three-dimensional polymer with a porous structure; 1) vinyl monomer; 2) divinyl monomer.

Then, depending on the nature and properties of the microgel particles formed (the density of cross-linking within the microgel, the size and shape of the particle, the number of functional groups on the surface, etc.), the final product of the three-dimensional reaction is characterised to some extent by the inhomogeneity of its supermolecular structure. According to Funke[112], the homogeneity of the supermolecular structure of cross-linked polymers is an exception rather than the rule; on the other hand, the inhomogeneity of the structure of polymers can be regulated during the synthesis and it can assume organised forms. In his study of the general cases of the synthesis of three-dimensional polymers with inhomogeneous supermolecular structure, Funke put forward fundamental schemes for the synthesis of products with a predetermined structural heterogeneity (Fig. 7). It follows from Fig. 7*a* that the particles of the microgel formed beforehand can play the role of polyfunctional centres (cross-linking via the functional groups on the surface of the microgel), while the formation of linear chains between the centres can be achieved by the polymerisation of monovinyl compounds. Using the divinyl monomer and "live" poly(methyl methacrylate) chains, it is possible to synthesise either a polymer with a dense microgel nucleus and long side branches (Fig. 7*b*) or a cross-linked polymer with a supermolecular structure of a different type (Fig. 7*c*).[113]

Table 3. The development and products of polymerisation processes involving polyfunctional monomers.

Type of reaction	Development of reaction	Reaction products	References
I. Linear polycylisation	Two-dimensional development	Macromolecules with ladder or cycloladder structures	3,12,114, 117,119
II. Cyclotrimerisation with branching	Three-dimensional development of a polycyclic structure

	(b) analogous process under associative conditions;		
	(c) statistical mean development of the same processes	Macrogel (with or without preliminary microgel formation) (see Fig.6)	92-100

The new trends in the synthesis of polymers, which developed as a result of the study and utilisation of polycyclisation reactions[3,12], altered radically the concept of the functionality of the monomer as the sole factor determining the possibility or impossibility of gel formation in polymers. To illustrate this fact, it is sufficient to compare Carothers' "law of functionality"[2,74] (the monomer system is incapable of forming a three-dimensional structure for $f \leq 2$ and a three-dimensional macrogel is necessarily formed for $f > 2$) with the development of only three types of polymerisation reactions, where the average functionality of the initial monomer mixture is $f > 2$ (Table 3).

The data in Table 3 show that the range of polymerisation processes in which polyfunctional compounds are used is limited, on the one hand, by reaction of type I and IIIa leading to soluble and fusible linear and polycyclic compounds and, on the other hand, by reactions responsible for the formation of three-dimensional macrogel products (type IIIc). Within the limits of this range, one can evidently expect a wide variety of combinations of the above types.

The role and importance of various factors in the development of gel formation in systems with a high functionality have been investigated in two-, three-, and six-component mixtures of organosilicon monomers. The results showed that, under certain conditions, the reaction can be directed towards the formation of soluble polycyclic systems. Such directing factors may be the nature of the solvent[118], the nature of the organic group[120], the pH of the medium[121], and others[122].

The high functionality of the initial compound thus frequently cannot serve as a criterion of the capacity of the system for the formation of three-dimensional polymers. Furthermore, when a polyfunctional monomer exhibits an enhanced tendency towards cyclisation, an increase in the tendency of the reaction products towards the formation of polymers with a three-dimensional macromolecular structure can be achieved by reducing the overall functionality of the system. In the manufacture of organosilicon polymers, an analogous operation is achieved in the synthesis of varnish and enamel binders of type KO (the introduction of a bifunctional compound into the reaction with a trifunctional compound). Characteristics of a similar type have been investigated in relation to the condensation of a tetrafunctional monomer whose capacity for the formation of three-dimensional structures appeared only following a decrease of the overall functionality of the system as a result of the introduction of a bifunctional compound, which interferes with the intramolecular cyclisation process[123]. Similar phenomena were observed also in multicomponent systems with a high average functionality[124].

Secondary processes such as rearrangement or chain-transfer reactions can also play a decisive role in controlling the development of the three-dimensional process. Thus, in a study of the polymerisation of bicyclic siloxanes ($f = 4$), Andrianov and Zachernyuk[125] established that, under certain conditions, the yield of the three-dimensional polymer passes through a maximum and then begins to decrease owing to the increasing importance of the rearrangement process, leading ultimately to completely soluble polycyclic systems.

The probability, degree, and causes of cyclisation in three-dimensional polymerisation processes constituted an urgent problem for both mathematicians and physical chemists from the very beginning of the theory of gel formation. As the problem became more complex and many-sided, the approaches to its solution also altered. The updating of the analysis of cyclisation proceeded along these lines gradually from the study of the influence of the dilution effect[11,51,52] to the study of the conformational statistics[36,116] of polymeric and oligomeric molecules and the discovery of more general relations.

Various methods have been proposed in recent years for the quantitative estimation of the degree of polycyclisation. A number of studies by Karyakin and coworkers[126-128] were characterised by attempts at a thermodynamic approach to the analysis of polyheterocyclic polymers with a linear structure, while kinetic solutions of problems of this kind were considered by Jacobson and coworkers[129,130]. However, the above analytical procedures were far from being universal[56].

The study and description of the laws governing the formation and development of three-dimensional cyclic structures, resembling, for example, the cubic polyphenylsilsesquioxanes, microgel structures of different types, and the conversion of the latter into macrogel forms undoubtedly constitute an even more difficult problem.

Thermodynamic and kinetic factors have evidently played a decisive role in the general characteristics of the properties of structured systems. In the kinetic and thermodynamic interpretation of gel formation in a system of polyfunctional monomers, two tendencies have been noted. The characteristic feature of one tendency is analysis of the early stages of the process[43,93,115,116]: (1) of the generation of a swarm of complexes and globular aggregates via physical interaction forces; (2) of intraglobular processes before the appearance of the first microgel particles; (3) of the conditions and causes of macro- and micro-gel formation. In terms of the mechanism of Bobalek and coworkers (see Fig. 6), these studies include the stage of the three-dimensional process up to and including the theoretical gel formation point.

The principal aim in the second trend is to study the relations governing the syneresis phenomenon in the polymer–solvent system, i.e. the phenomenon of the separation of the gel and sol fractions. The region beyond the theoretical gel formation point in Fig. 6, including the instant of "physical gel formation" (syneresis), corresponds to studies of this kind[109,131-135].

In the study of the development of the three-dimensional process in polyurethane systems, one of the principal causes of the involvement of the microgel formation stage in the reaction—the large energy of the intermolecular interactions in the initial system of components—was discovered[93]. In the assessment of the vigorous intramolecular cyclisation reaction in the synthesis of three-dimensional polymers, a number of investigators suggested that the cause of the anomalous process be sought by abandoning the model of intertwined macromolecular coils in solution[43,115].

In the course of the conformational analysis of polymer chains in concentrated systems, it was shown that the free energy of the system is determined not only by the free energy of the given chain but depends also on the nature and energetic state of other macrochains in the system. According to the results obtained, the fixation of the conformation of the molecules via physical forces in the first stage of the interaction is then completed by the cyclisation reaction occurring within a much more tightly coiled polymer compared with the θ-conformation and leading to a large number of cross links within the microgel particle.

A series of studies by Dusek[131-135] were devoted in recent years to the thermodynamic investigation of syneresis in three-dimensional processes. The author's approach to the analysis of the phenomenon is characterised by a distinction being drawn as a function of the type of conversion into a three-dimensional structure, which proceeds either via microgel or macrogel formation[131]. Assuming the employment of a solvent (or the initial monomer as the reaction solvent) to be the cause of the thermodynamic instability of the system during the reaction and also the cause of the inhomogeneity of the final polymer, Dusek calculated two critical parameters of syneresis. He considered a system of polymers where syneresis is determined by the increasing density of cross-linking in the macromolecule and the gel and sol fractions are separated after the attainment of the critical number of cross links ν per unit volume of the gel. In this case, when the separation of the system is due to polymer–solvent interaction forces, syneresis occurs following the breakdown of equilibrium and the attainment of the critical value by the interaction parameter χ. A combination of critical conditions with respect to ν and χ is evidently characteristic of the majority of three-dimensional processes. For the simplest version of a binary system, a formula has been found, whose solution leads to the determination of the parameters, i.e.

$$(\Delta\mu_i)_{\text{mix}} + (\Delta\mu_i)_{\text{network}} = \ln(1-\Phi_p^0) + \Phi_p^0 + \chi(\Phi_p^0)^2 + \nu\bar{V}\Phi_p^0/2 = 0,$$

where μ_i is the chemical potential of a given component in the mixture or in the three-dimensional network, Φ_p^0 the degree of swelling of the three-dimensional product in the given solvent, and $\bar{V}$ the partial molar volume of the solvent.

Evidently, among the multiplicity of objective factors responsible for the syneresis of the system, account was actually taken of only three and the observed relation governing the syneresis conditions in a polymer system constitutes therefore a convenient mathematical model rather than a universal equation. In an experimental test of the equation, a satisfactory agreement of the observed and calculated values was noted in the case of macro-syneresis. The calculations on microgel formation processes agreed with experiment less satisfactorily.

The state of the theory of gel formation in polymers and its present problems were considered at the April 1974 symposium in England devoted to gel formation processes and gels of all four types as defined by Flory[136]. The greatest attention in studies concerned with the formation of covalently linked three-dimensional polymer networks was devoted to the problems of inter- and intramolecular reactions, the aim being to create a single general theory.

In our view, Flory's introductory report[136] constituted a disturbing factor in this respect. Together with the likely usefulness of the statistical method in the theory of gel formation, he emphasised the legitimacy of arbitrary assumptions concerning the insignificant contribution of cyclisation reactions and the constancy of the reactivity of the functional groups in the course of condensation, i.e. the assumptions introduced into the analysis of gel formation as early as the 1930s.

The possibility of the development of the three-dimensional polycondensation process virtually without cyclisation up to the gel formation point, i.e. the possibility that the reaction proceeds via the family tree mechanism, was examined by Peniche-Covas et al.[137] in relation to the system of decamethylene glycol and benzenetriacetic acid. However, the only fundamental argument quoted by the authors in support of the cascade mechanism of the development of the reaction is the possibility of highly efficient extraction of strongly branched macromolecules with molecular weights up to 10^8 from the polymer system beyond the gel formation point (the system contained between 1 and 5% of the gel fraction). They did not confirm experimentally their conclusion that the "newly generated" gel should be virtually free of cyclic structures; furthermore, they did not take into account the kinetic features of the development of the process, in particular the change in the probability of the involvement in the reaction of each of the three carboxy-groups, after the first, second, etc. group have reacted.

The opposite view concerning the importance of cyclisation reactions in three-dimensional polycondensation was reflected in a number of studies by other participants in the symposium. Referring to the considerable percentage contribution of the intramolecular cyclisation reaction even in the absence of a solvent[138], Stepto[139] examined the validity of the employment of the Kilb and Frisch theories on the basis of the available literature data (for polyesters and polyurethanes). In contrast to Flory, who excluded from consideration intramolecular cyclisation processes, both Kilb[140] and Frisch[141] described the gel formation point by the equation

$$\alpha_{\text{cr}} = \frac{1}{(f-1)(1-\lambda)},$$

where λ is a parameter absent from Flory's theory and characterising the degree of intramolecular reactions. The two authors treat λ to a certain extent differently, as a function of the concentration of the functional groups in the system at different reaction stages.

Having noted that the analogous equations proposed recently by Gordon and Scantlebury[44], Gordon and Temple[142,143], and Stamford[144] suffer from the same defect—the failure to take into account the details of the three-dimensional process (as a result of which their agreement with experiment was observed only for low degrees of conversion in the condensation reaction), Stepto proposed, on the basis of the analysis carried out, a combinatorial equation describing the critical conditions:

$$\lambda = \frac{\alpha_{\text{cr}}(f-1)-1}{(1-\alpha_{\text{cr}})\,\alpha_{\text{cr}}(f-1)} = \left(\frac{3}{2}\pi\nu b^2\right)^{\frac{3}{2}} K/N_A c_{\text{int}},$$

where c_{int} is the concentration of functional groups which have been involved in the intramolecular cyclisation reaction, ν the number of bonds in the smallest ring, b the effective bond length in the smallest ring, N_A the Avogadro number, and K a constant. The agreement between the equation and the experimental data for polyesters and polyurethanes is satisfactory in the case of polyesters according to the author.

Apart from Stepto's study dealing with the analysis of the Frisch and Kilb theories and describing the dependence of the gel formation point on the molecular structure of the components (the length and nature of the chain) as well as the reaction conditions (dilution, component ratio), a number of reports at the symposium confirmed the finding that the time has come for an experimental test of theoretical ideas and the search for and analysis of real model polymer systems.

New methods for the synthesis of model three-dimensional polymers, which permit an exact control of the number of intermolecular bonds and make it possible to guarantee a specific topology of the macromolecules, have been proposed[145,146]. According to Beinert et al.[145], model systems can be synthesised by the interaction of previously obtained linear macromolecules containing amino-groups along the entire chain with a similar polymer containing isocyanato-groups along its chain.

It has been suggested that three-dimensional macromolecules with the chain length between the network nodes specified beforehand be obtained[146] from "live" polystyrene, polyisoprene, and polyvinylpyridine macromolecules with a narrow molecular weight distribution and from branching agents—divinylbenzene or tri(allyloxy)triazine. The influence of network defects on physicomechanical properties was investigated on the models obtained and it was established that the number of "entanglements" (intertwined parts of the chain) is independent of the frequency of cross-links. According to Beinert et al.[145], the concept of the gel formation point in a three-dimensional process has lost its initial significance.

The attempts at a mathematical analysis of the dependence of the capacity of the polymer for the formation of three-dimensional structures on the chain transfer reaction in the course of the synthesis of vinyl macromolecules were described at the symposium[147]. The methods of cascade theory were used for the purpose. However, the region of applicability of the analytical expressions obtained is restricted to the reaction stages with low conversions with respect to the monomer.

The mathematical approach to the description of the dynamic behaviour of a growing three-dimensional macromolecule was used by Edwards[148]. Assuming the macroscopic behaviour of the polymer to be a consequence of the set of properties of the microscopic components, the author examined the influence of the increasing number of branching nodes in the macromolecule (intra- and intermolecular bonds, intertwined parts of the chains) on the changes in the properties of the polymer when the latter passes from the viscofluid state to the elastic state. He states that the creation of a complete dynamic theory of such systems is a more difficult problem. The problems of the study of gel formation with the aid of the new technique have been described by Wun et al.[149]

IV. CONCLUSION

In assessing the advances achieved in recent years in the development of a theory of gel formation in covalently linked three-dimensional polymers, one must note in the first place the considerable progress in the study of intramolecular interactions and cyclisation reactions of polyfunctional compounds. The solution of a number of fundamental problems of cyclisation in three-dimensional processes made it necessary to revise not only "classical" but also more modern theories of gel formation in polymers (the Gordon, Kilb, Frisch, Bruneau, etc. theories).

New experimental data showing that the functionality of the initial monomers is not a decisive factor extended the limits of the region of three-dimensional processes. In this sense, the classification of polymeric reactions involving highly functional compounds on the basis of structural features in the properties of final products can be represented as follows.

1. Reactions leading to fusible and soluble polycyclic products with a three-dimensional structure.
2. Reactions leading to polymer systems with ladder and cycloladder macromolecular structures (without gel formation).
3. Reactions proceeding in a more complex manner with simultaneous branching and cyclisation, which result in the formation of a macrogel or microgel polymer: (a) processes with insignificant degrees of cyclisation, the nature of the development of which resembles the "family tree" mechanism and which are responsible for the "homogeneous" (in the terminology of Flory[136] and other workers) formation of macrogels (the number of such reactions is evidently small); (b) processes with a fairly high degree of cyclisation proceeding via the microgel formation stage to macrogel formation; (c) processes with a high degree of intramolecular reactions leading to microgel polymers only.

The advances in the study of the early stages of the formation of three-dimensional polymers made it possible to differentiate the phenomena of micro- and macrosyneresis in a polymer–solvent system (or a polymer–low-molecular-weight reaction products system) from the phenomena involving the generation and development of three-dimensional gel particles. Taking into account these factors and also the modified concepts concerning the critical state of the system (including the "gel formation point") and the establishment of new criteria, it became possible to devise a fundamental mechanism of the process leading to covalently linked micro- and macro-gel polymers. This mechanism can include the following stages.

1. The formation of a swarm of complexes, aggregates, or globular structures via intermolecular interaction forces in solution or in the melt of polyfunctional monomers or oligomers.
2. The development of the reaction preferentially within the primary formations, or intermolecularly, or via a mixed mechanism: competing inter- and intra-molecular interactions.
3. The formation of the first microgel or macrogel particles without the manifestation of syneresis phenomena (an intermediate equilibrium state of the system containing sol and gel fractions).
4. The manifestation of micro- or macro-syneresis in the system following the breakdown of thermodynamic equilibrium.

The wide variety of the real factors associated with the physical and chemical characteristics of the initial monomers and intermediates and with the reaction conditions may lead to appreciable changes in the development of a specific process compared with the fundamental mechanism described above, for example: (a) to the coincidence of stages 3 and 4; (b) to a change in the sequence of stages—stage 4 first and stage 3 second; (c) to the absence of stage 4; (d) to the specificity of a particular stage, etc.

The development of gel formation in systems of previously obtained macromolecules can proceed via pathways different from those described and may not fit within the framework of the above mechanism. This is why the description of three-dimensional polymerisation reactions in terms of unique mathematical relations has not so far been achieved in practice. The procedures for the creation of a general theory of the formation of polymers with network and three-dimensional macromolecular structures probably require a differential investigation and description of various types of reactions of polyfunctional compounds.

Preparation and Properties of Oligo- and Poly-phenylenes with Functional Groups

V.A.Sergeev, V.K.Shitikov, and L.G.Grigor'eva

Methods of preparing oligo- and poly-phenylenes containing various functional groups are surveyed, together with several field of application. A list of 120 references is included.

CONTENTS

I. INTRODUCTION

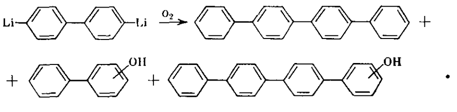
Intensive research has been undertaken during the past decade on polymers having aromatic rings in the chain and on materials based on them. Such materials are resistant not only to heat but also to various corrosive agents, including oxidants. In this respect polymers containing benzene rings in the main chain are of the greatest interest, primarily polyphenylenes, whose preparation has been reviewed several times[1-4]. However, current methods of preparation yield mainly infusible and insoluble polymers, which greatly hinders their processing and thus restricts their application.

This disadvantage might be overcome by obtaining oligophenylenes and polyphenylenes containing various functional groups. Thus polyphenylenes containing hydroxy- or carboxy-groups dissolve well in organic solvents and readily react with hydroxymethylated phenols, phenol-formaldehyde resins, oligoepoxides, metal salts, etc. to form heat-resistant, infusible cross-linked polymers[5]. The present Review surveys methods of preparation, properties, and applications of oligophenylenes and polyphenylenes containing various functional groups.

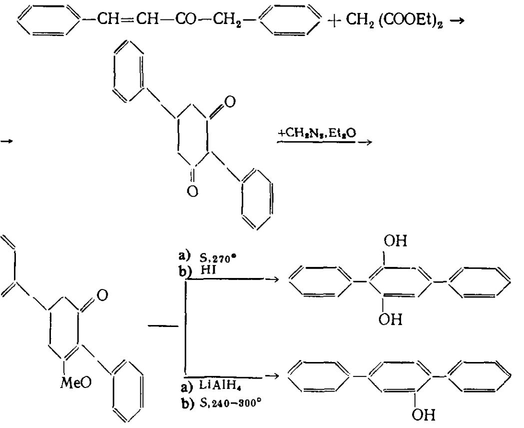
II. METHODS OF PREPARATION OF OLIGO- AND POLY-PHENYLENES WITH FUNCTIONAL GROUPS

1. Hydroxylated Oligo- and Poly-phenylenes

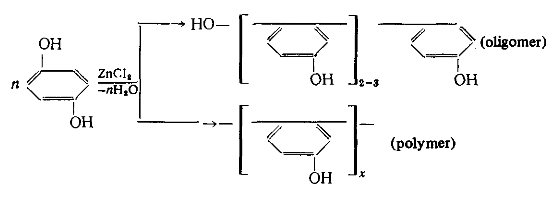
Among investigations on the preparation of hydroxylated lower oligophenylenes Pacevitz and Gilman[6] obtained *p*-phenylphenol in low yield by the oxidation with dry air of phenyl-lithium in benzene solution (at 10-15° C for 10 h). Similarly, quaterphenyl and linear oligophenylenes containing hydroxy-groups have been obtained[7] by the air oxidation of 4,4′-dilithiumbiphenyl:



The condensation of 1,4-diphenylbut-3-en-2-one with malonic ester gave[8] 2,5-diphenylcyclohexane-1,3-dione (yield ~ 80%)—the initial compound for the synthesis of *p*-terphenyl-2^5-ol (m.p. 192-193° C, yield 45%) and *p*-terphenyl-$2^{2,5}$-diol (m.p. 206-207° C, yield 35%):



Hydroxylated oligophenylenes and polyphenylenes were first obtained by Paushkin and his coworkers[9,10] by heating benzene-diols and -triols in the presence of zinc chloride (at 200-350° C for 6 h). On the basis of the infrared spectra these products were regarded as *o*-polyphenylenes (by analogy with Ref. 11):



However, the suggested reaction scheme and structure of the products can only be crude approximations, since the high-temperature oxidising polycondensation of hydroxy-derivatives of benzene in the presence of a large quantity of zinc chloride may involve formation of phenyl and phenoxyl radicals, so that the structure of the products will be determined by the subsequent reactions of these radicals. Polyphenylenepolyols were obtained that were either soluble or insoluble in the usual organic solvents depending on the conditions of dehydration. Table 1 gives yields and molecular masses ($\overline{M}_n$) of soluble fractions of polyphenylenepolyols obtained from quinol, resorcinol, and pyrogallol. The yield, solubility, and molecular mass of the polymer had their maximum values in the last case. Increase in molecular mass of fractions obtained from quinol is accompanied by a sharp rise in melting point (Table 2),[9] and the polymer having $\bar{M}_n = 2020$ does not melt below 550°C.

Table 1. Molecular masses and yields of hydroxylated polyphenylenes[9].

Initial diol	Yield of polymer, %		$\bar{M}_n$ of soluble fraction
	soluble fraction	insoluble fraction	
Quinol	30.6	54.4	1730
Resorcinol	67.0	9.3	1450
Pyrogallol	87.0	нет	1840

Table 2. Some characteristics of hydroxylated oligophenylene fractions from quinol[9].

Fraction	$\bar{M}_n$	Hydroxyl No., %	M.p., °C	Structure
1	330	22.8	160—180	2	460	21.3	360—380	3	2020	19.6	>550	
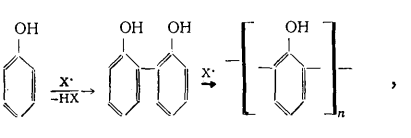
Paushkin et al. also suggested[12] polycondensation itself for the preparation of hydroxylated polyphenylenes. When phenol was heated in the presence of an equimolecular quantity of bromoform in an autoclave (at 250°C for 6 h), soluble products were obtained according to the hypothetical scheme



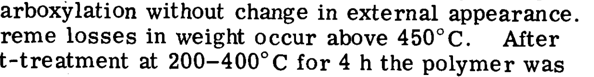
where $n = 4-15$ and X represents radicals formed by the thermal breakdown of bromoform. Fractionation of the polyhydroxyphenylene led to the isolation of oligomers having $n = 4-7$ (soluble in methanol) and $n \leqslant 15$ (soluble in dimethylformamide); the softening point rose from 110 to 250°C with increase in molecular mass. From the thermal stability and the composition of the hydrolysis products it was concluded[13] that the polymers had a linear structure. Polyhydroxyphenylenes soluble in alcohol, acetone, dimethylformamide, and aqueous alkalis were obtained[13] by the radical polymerisation of *p*-benzoquinone:

Heating phenol in the presence of iron(III) chloride at 40–90°C gave[14] poly-2-hydroxy-1,4-phenylene ("polyphenol"), an infusible dark-coloured product with $\bar{M}_n$ = 1400 (determined viscometrically), soluble only in dimethylformamide. Thermogravimetric data (ΔT = 2.5 deg min^{-1}) indicate that in an atmosphere of nitrogen the polymer begins to lose weight at 350°C, and at 900°C the losses amount to 25%. It was supposed from nuclear magnetic resonance and infrared spectroscopy together with chemical investigations that the polymer contained not only hydroxyphenylene but also cyclohexadienone groups.

2. Carboxy-containing Oligophenylenes

Berlin and his coworkers[15-21] used the Sandmeyer decomposition of bisdiazo-compounds by copper(I) salts to obtain aromatic polymers. The presence of diazo-radicals $C_6H_4.N_2^{\cdot}$ accompanying the "purely" hydrocarbon radicals leads to partial incorporation of azo-groups into the polymer chain.

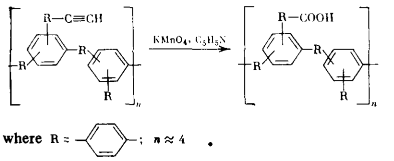
The decomposition of diazonium benzidine-3,3′-dicarboxylates[18] yielded a yellowish-brown polymer of molecular mass ~3000, which contained according to elementary analysis 1 azo-group per 6–10 benzene rings and 2 chlorine atoms per 5–16 benzene rings. Furthermore, every benzene ring contained a carboxy-group. Infrared spectroscopy suggested linear or slightly branched polymers[20], with either chlorine or peroxy as terminal groups. The structure of the products was therefore represented by the formula[18]



However, the general formula given is extremely arbitrary, and may not correspond to the true structure of the polymer molecule, since not only the structure of the blocks but also the alternation of azo-groups in the chain may be represented in other ways.

When heated in argon at 400°C for 1 h or at 250–400°C for 4 h, carboxylated oligophenylenes undergo complete decarboxylation without change in external appearance. Extreme losses in weight occur above 450°C. After heat-treatment at 200–400°C for 4 h the polymer was insoluble both in dimethylformamide and in aqueous alkalis[17].

Oligophenylenecarboxylic acids have been obtained[22,23] by oxidising oligophenylenes containing various carbon–carbon multiple bonds. Fractions having $\bar{M}_n$ = 1000–2200, obtained by the polycyclotrimerisation of a mixture of *p*-diethynylbenzene at phenylacetylene in the presence of various catalysts[24-26]—$TiCl_4.Al(iso\text{-}C_4H_9)_3$, $NiCl_2.2P(C_6H_5)_3 \times 2NaBH_4$, $Ni(C_5H_7O_2)_2.P(C_6H_5)_3$, and $[(C_2H_5O)_3P]_4CoBr$—and soluble in benzene and pyridine but insoluble in alcohol, were chosen for oxidation. Potassium permanganate was used[23] to oxidise the oligophenylenes (e.g. containing terminal ethynyl groups) by heating in pyridine solution:



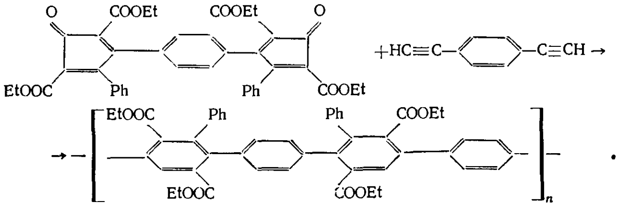
The resulting oligophenylenecarboxylic acids were light grey powders, soluble in pyridine, dioxan, oxolan, etc. Depending on the structure of the initial oligomer they had melting points of 130–280°C and acid numbers of 63–80. When the oligomeric acids were heated in argon they underwent decarboxylation, whose rate became appreciable only at 220–230°C. The resulting oligophenylenes were readily soluble in benzene, their molecular masses were closely similar to those of the original oligomers before oxidation, and they contained no carboxyls. Differential thermal analysis in helium ($\Delta T = 4.5$ deg min^{-1}) indicated that the oligomeric acids began to lose weight at ~ 230°C, vigorous decomposition occurred from 350–370 to 650°C, and the yield of the carbon residue at 900°C was 55% of the original weight of the specimen.

Oligophenylenecarboxylic acids obtained by oxidising oligophenylenes containing multiple bonds can be used as starting materials for the preparation of polyethers, polyesters, and polyamides.

3. Alkoxycarbonylated Oligo- and Poly-phenylenes

Methyl oligophenylenecarboxylates of molecular mass 1800, containing ~ 4 methoxycarbonyl groups in the oligomeric molecule, were obtained by treating the oligomeric acids with a solution of diazomethane in toluene[28]. They were grey powders, readily soluble in benzene, dioxan, chloroform, etc.

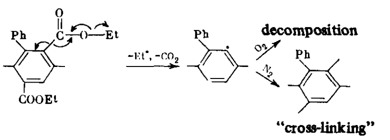
Harris and Reinhardt[27] synthesised ethoxycarbonylated oligo- and poly-phenylenes by the Diels–Alder reaction from ethoxycarbonylated biscyclopentadienones and aromatic diynes. Thus treatment of diethyl 2-oxo-4,5-diphenylcyclopentadiene-1,3-dicarboxylate with *p*-diethynylbenzene in benzene gave an approximately 97% yield of tetraethyl $1^1,1^6,3^3,3^4$-tetraphenyl-*p*-terphenyl-$1^2,1^5,3^2,3^5$-tetracarboxylate (a white powder melting at 223–224°C and readily soluble in chlorinated hydrocarbons). Similarly, ethyl carboxylates of polyphenylenes have been obtained by reaction between tetraethyl *p*-phenylenebis-4-(2-oxo-5-phenylcyclopentadiene-1,3-dicarboxylate) and *p*-diethynylbenzene in 1,1,2,2-tetrachloroethane solution:



The equation arbitrarily shows formation of a substituted poly-*p*-phenylene, although the conditions of the Diels–Alder reaction indicate the formation of both *meta*-linked and *para*-linked aromatic rings. The products had $\eta_{\log} \simeq 3.0$ (determined at a polyphenylene concentration of 0.25 g dl^{-1} in 1,1,2,2-tetrachloroethane solution at 30°C), and formed colourless, transparent films, whose infrared spectra coincided with those of model compounds.

Differential thermal analysis showed that ethoxycarbonylated polyphenylenes begin to lose weight in the air only at 370°C, and are completely decomposed when heated to 520°C. In nitrogen intense loss of weight occurs above 370°C, and at 800°C the yield of carbon residue is 55%. Infrared spectroscopy indicated[27] that the losses in weight at 370–450°C are due to decarboxylation. Under isothermal conditions films undergo decarboxylation in nitrogen even below 300°C, with the formation of insoluble products.

The above facts were explained[27] on the hypothesis of a free-radical mechanism for decarboxylation:



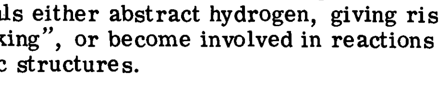
Radicals formed in the polyphenylene chain evidently undergo rapid oxidation in air. In an atmosphere of nitrogen free radicals either abstract hydrogen, giving rise to "cross-linking", or become involved in reactions leading to graphitic structures.

4. Methoxylated Oligophenylenes

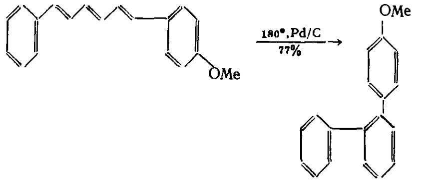
Methoxylated oligophenylenes are readily formed under the conditions of the Ullmann reaction. Thus 3,3′,5,5′-tetramethoxybiphenyl (m.p. 208°C) was obtained by heating 4-iodo-2,6-dimethoxybenzene in the presence of copper powder at 220–260°C.[28] When 4-iodo-4′-methoxybiphenyl was heated in the presence of copper bronze at 280°C for 1 h, $1^4,4^4$-dimethoxy-*p*-quaterphenyl (m.p. 338–340°C) was formed[29]:

(A)

Under conditions of oxidising dimerisation the yield of (A) is far lower[29]:



Pyrolysis of 1-*p*-methoxyphenyl-6-phenylhexa-1,3,5-triene in the presence of a palladium–carbon catalyst (10% by weight) *in vacuo* at 180°C gave *p*-methoxy-*o*-terphenyl (a colourless oil boiling at 153°C under 0.2 mmHg)[30]:



Several methoxylated *p*-oligophenylenes—from biphenyl to octophenyl—were synthesised by Kern et al.[28] from cyclic ketones and lithium aryls via intermediate hydroaromatic compounds:

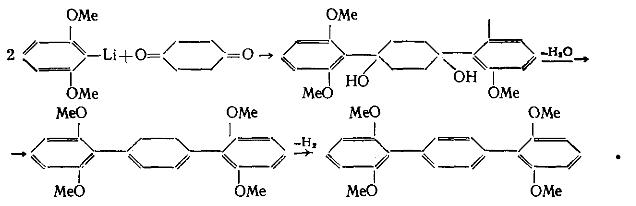


Table 3 gives the properties of the products with for comparison those of their unsubstituted analogues. It is evident that in all cases a methoxy-derivative melts at a lower temperature and dissolves better in toluene than the corresponding unsubstituted *p*-oligophenylene.

5. Halogenated Oligo- and Poly-phenylenes

Halogenated biphenyls are formed by the high-temperature treatment of halogenobenzenes: e.g. [31]

Chlorobiphenyls were found[32] among products of the pyrolysis of a mixture of *p*-nitrotoluene and chlorobenzene (at 600°C for 20 s).

Table 3. Melting points and solubilities in toluene (at 20°C) of methoxylated *p*-oligophenylenes [28].

Formula	M.p., °C	Solubility, g litre^{-1}

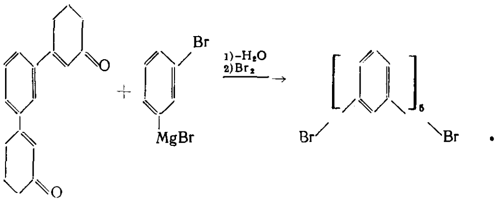
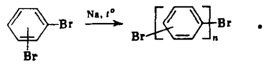
	545	—
	253	0.5
	277	0.2

An interesting method[33] was used to obtain *m*-oligophenylenes containing bromine at the ends of the polymer chain:

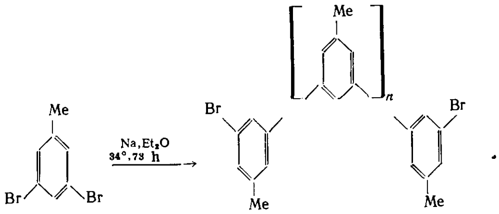


Reaction of *m*-dicyclohexenylbenzene-3′,3″-dione with *m*-bromophenylmagnesium bromide followed by dehydration and aromatisation gave a 9% yield of $1^3,5^3$-dibromo-*m*-quinquephenyl, a yellow–orange powder of m.p. 104–106°C (from alcohol). $1^3,3^3$-Dibromo-*m*-terphenyl (an uncrystallisable oil) and $1^3,6^3$-dibromo-*m*-sexiphenyl (melting at 143–145°C) were synthesised by similar methods. A multistage process is involved, and the yield of the desired product does not exceed 10%.[33]

The Wurtz–Fittig reaction has been successfully applied to the synthesis of halogenated oligophenylenes. As early as 1886 Goldschmiedt[34] obtained amorphous yellow powders, melting over the ranges 200–250 and 245–300°C, by heating *m*- and *p*-dibromobenzenes respectively with metallic sodium in ether. The reaction can be represented by the scheme (n = 8–13)



A mixture of oligomeric products having n = 2–4 and 6, containing *meta*-substituted groups, was obtained by the polycondensation of 3,5-dibromotoluene under the influence of metallic sodium[35]:



The polycondensation of *p*-dichlorobenzene in the presence of metallic sodium or a sodium–potassium alloy gives a reddish-brown powder soluble in aromatic hydrocarbons and not melting below 550°C.[36,37] Elementary analysis indicates that the polymer molecule contains ~ 5 chlorine atoms. The structure is assumed to contain not only *p*-phenylene but also *p*-quinoid groups.

A patent[38] describes the synthesis of *αω*-dibromo-*p*-polyphenylenes from *p*-dibromobenzene in a dioxan–xylene medium under the influence of metallic sodium.

Kovačic and his coworkers[39–42] undertook the oxidative dehydropolycondensation of benzene in various organic solvents—carbon disulphide, benzene, dichlorobenzene, etc.—in the presence of the $AlCl_3$–$CuCl_2$ catalytic system, and obtained polyphenylenes containing chlorine. When the reaction was accomplished in the presence of iron(III) chloride[43,44], small quantities of lower products, e.g. chlorobenzene, 4,4′-dichlorobiphenyl, etc., were also formed. This work showed that the thermo-oxidative stability of *p*-polyphenylenes increases with the chlorine content of the polymer (Table 4). When benzene underwent oxidative dehydropolycondensation in the presence of antimony(V) chloride, the polyphenylenes contained up to 31% of chlorine[40,45].

Table 4. Losses in weight of chlorinated poly-*p*-phenylenes in air (ΔT = 8 deg min^{-1}).[43,44]

Temp., °C	Loss (%) for Cl content		Temp., °C	Loss (%) for Cl content	
	6.0%	23.6%		6.0%	23.6%
350	0.49	0.35	500	55.50	15.55
400	0.99	0.94	550	97.00	73.0
450	16.15	2.70	600	100	99.9

Some Japanese investigators[46–48] obtained polyphenylenes by decomposing biphenyl-4,4′-bisdiazonium dichloride in aqueous solution in the presence of copper(I) and iron(II) chlorides at 50–80°C. In the polymer having $\bar{M}_n$ = 10 000 one chlorine atom was present per 3–4 benzene rings. The polymer dissolved in benzene, oxolan, dioxan, and chloroform[49]. Examination of fractions of molecular mass 3000–5000 showed the presence of 5–8 azo-groups per molecule[47]. A radical mechanism was assumed for the formation of polyphenylenes[50].

Detailed information on the preparation and properties of fluorinated oligophenylenes and polyphenylenes has recently been surveyed[51].

6. Alkylated Oligo- and Poly-phenylenes

Among the first syntheses of methylated oligophenylenes was that of $1^4,4^4$-dimethyl-*p*-quaterphenyl (m.p. 340°C) by heating 4-iodo-4′-methylbiphenyl in the presence of copper bronze[52]:

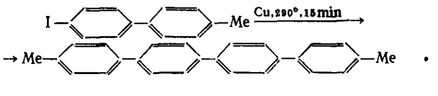


Table 5. Melting points and solubilities in toluene of methylated *p*-oligophenylenes[53–55].

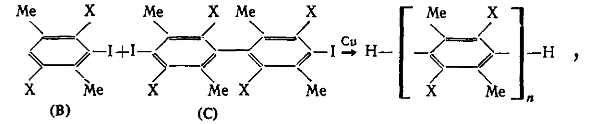
No.	Formula	M.p., °C	Solubility, g litre⁻¹
1		84	500
2		96	470
3		139	110
4		340	0.2
5		320	0.13
6		146	42
7		150	51
8		231	1.3
9		186	11
10		200	9.5
11		261	1.1

Wirth et al.[53] used the Ullmann reaction in the presence of copper powder at 230–260°C to prepare a series of methylated *p*-oligophenylenes (yield 40–50%)[53–55]. Some properties of the resulting oligomers are given in Table 5. These workers showed that the introduction of methyl groups into the $1^4,4^4$-positions of *p*-quaterphenyl (No. 5 in Table 5) has hardly any effect on the melting point or the solubility in toluene; the introduction of methyl groups into the *ortho*- and *meta*-positions lowers the melting point of the products and improves significantly their solubility in toluene. Increase in the number of methyl groups in the *p*-quinquephenyl molecule lowers the melting point and enhances the solubility in toluene (No. 8 and 9). Yet increasing the number of unsubstituted benzene rings in methylated oligophenylenes raises the melting point and lowers the solubility (No. 6–8 and 9–11). Thus methylated *p*-oligophenylenes have lower melting points and better solubility than have their unsubstituted analogues, and the solubility is better the greater the number of methylated benzene rings.

Table 6. Melting points and solubilities in toluene of *p*-oligophenylenes containing di- and tetra-methylbenzene rings[56].

No.	Formula	Degree of condensation n	M.p., °C	Solubility, g litre⁻¹
1		2	71	430.0
		3	215	7.4
		4	320	0.13
		5	395	0.005
2		2	54	700.0
		3	183	28.0
		4	266	1.1
		5	309	0.24
3		2	137	365.0
		3	272	24.0
		4	272	3.4

Oligophenylenes comprising *p*-xylene and *p*-durene units were obtained by the Ullmann reaction[56]:

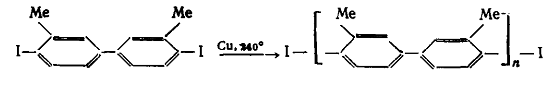


where n = 2–5 and X = H, CH_3. The highest yield (50%) of such oligophenylenes is obtained with reactants B and C in the molar proportions 10 : 1. Table 6 shows that the melting points of both unsubstituted (No. 1) and di- and tetra-methylated *p*-oligophenylenes (No. 2 and 3) rise and the solubilities in toluene diminish with increase in the degree of condensation.

Table 7. Molecular masses and melting points of fractions of methylated polyphenylene obtained by the Ullmann reaction[57].

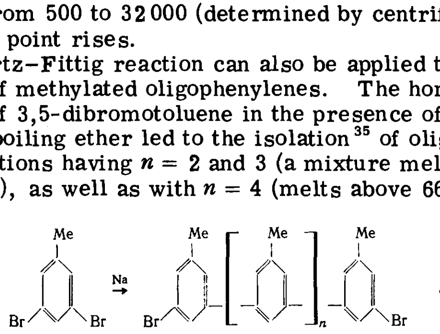
Fraction	M.p., °C	$\bar{M}_w$
1	290–310	32 000
2	225–245	3 700
3	120–140	500

The Ullmann reaction was used also for the synthesis of *p*-oligophenylenes containing a methyl group in every benzene ring[57]. The soluble methylated polyphenylenes obtained by the reaction



were fractionated by centrifugation and osmometry, when a fraction of molecular mass 300 000 was isolated. The cryoscopic method gave anomalous values of the number-average molecular mass. It was concluded[57] from viscosity, sedimentation, and diffusion results that under the given reaction conditions the polymeric molecules probably had not a linear but a branched structure, with *m*-phenylene groups in the main chain. Table 7 shows that with increase in the weight-average molecular mass of the fractions from 500 to 32 000 (determined by centrifugation) the melting point rises.

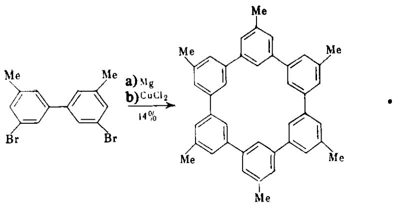
The Wurtz–Fittig reaction can also be applied to the synthesis of methylated oligophenylenes. The homocondensation of 3,5-dibromotoluene in the presence of metallic sodium in boiling ether led to the isolation[35] of oligophenylene fractions having $n = 2$ and 3 (a mixture melting below 60°C), as well as with $n = 4$ (melts above 66°C) and $n = 6$:



Each of these fractions is an amorphous yellow powder soluble in benzene and ether.

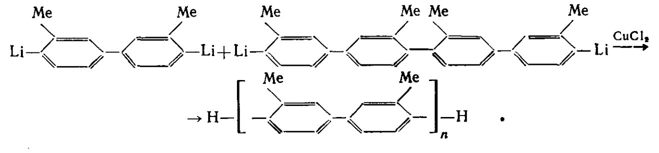
The synthesis of a methylated *p*-oligophenylene by the reaction of 4,4′-di-iodo-3,3′-dimethylbiphenyl with metallic sodium in boiling toluene was reported[58]. The resulting polymer was soluble in benzene, and melted at 150–180°C.

Organomagnesium compounds can also be used for the preparation of methylated oligophenylenes from halogenated aromatic compounds. Thus Kern et al.[59] obtained an oligophenylene by treating 4,4′-di-iodo-3,3′-dimethylbiphenyl with magnesium at 20°C. They noted that linear oligophenylenes were not formed, and concluded that the Grignard reaction, despite the milder conditions, is less suitable than the Ullmann reaction for obtaining oligophenylenes of regular structure. Bräunling et al.[60] used the Grignard reaction to synthesise methylated cyclic *m*-oligophenylenes. Thus hexamethylhexa-*m*-phenylene (m.p. 452–453°C) was obtained from 3,3′-dibromo-5,5′-dimethylbiphenyl:



3,3′-Dibromo-6,6′-dimethylbiphenyl gave a low yield of octamethylocta-*m*-phenylene (m.p. 489°C).

Furthermore, the oxidative dimerisation of dilithium derivatives of methylated aromatic compounds yields methylated oligophenylenes[61]. When a mixture of 4,4′-dilithium-3,3′-dimethylbiphenyl and $1^4,4^4$-dilithium-$1^2,2^2,3^2,4^3$-tetramethyl-*p*-quaterphenyl is treated with copper(II) chloride, methylated *p*-oligophenylenes having $n = 4$ and 6 are formed:



Similarly, $1^2,2^3,3^2,4^3,5^2,6^3,7^2,8^3$-octamethyl-*p*-octophenyl (m.p. 273°C) was obtained, together with small quantities of products having $n > 8$, from 1^4-lithium-$1^2,2^3,3^2,4^3$-tetramethyl-*p*-quaterphenyl.

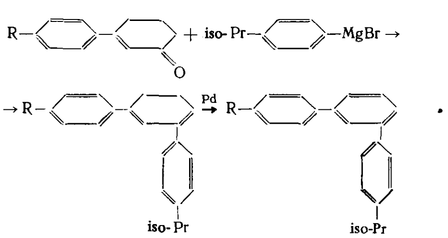
Reduction of 4-acetyl-4′-ethylbiphenyl on zinc amalgam in an acid medium gave 4,4′-diethylbiphenyl[62], which after recrystallisation from ethanol melted at 81°C.

Methylated oligophenylenes can be obtained from aromatic compounds not only by the above condensation methods but also by processes involving the formation of new benzene rings by the aromatisation of C_6 cyclic systems, as well as cycloaddition and cyclisation.

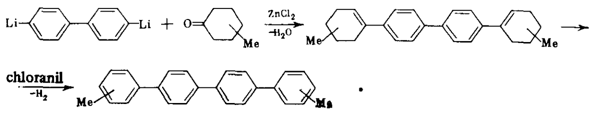
Table 8. Melting points and solubilities of methylated *p*-quaterphenyls[64].

No.	Positions of methyl	M.p., °C	Solubility, g litre^{-1}	No.	Positions of methyl	M.p., °C	Solubility, g litre^{-1}
1	1^2-	172—173	26.0	5	1^3, 4^3-	214—215	6.3
2	1^3-	244—245	3.0	6	1^4, 4^4-	338—340	0.2
3	1^4-	328—330	1.2	7	unsubst.	320	0.1
4	1^2, 4^2-	150—151	36.0				

Reaction of phenylcyclohexenone with *p*-isopropylphenylmagnesium bromide gave a diarylcyclohexadiene, whose dehydrogenation over palladium yielded an isopropyl-*m*-terphenyl[63]:



Organolithium compounds have been especially widely used in the synthesis of methylated oligophenylenes from cyclic ketones. Thus the condensation of 2-, 3-, and 4-methylcyclohexanones with 4-lithium-*p*-terphenyl or with 4,4′-dilithiumbiphenyl gave products from which the corresponding 1-methyl- and 1,4-dimethyl-*p*-quaterphenyls (Table 8) were obtained by dehydration in the presence of zinc chloride and dehydrogenation by means of chloranil in boiling xylene[64]:



Introduction of a 4-methyl group into *p*-quaterphenyl somewhat raises the melting point (cf. No. 6 and 3 with No. 7 in Table 8). Introduction of a methyl group at position 3 and especially at position 2 (cf. No. 2 and 5; 1 and 4 with No. 7) improves the solubility in toluene and lowers the melting point of the products. These effects are still more strongly developed in dimethyl-*p*-quaterphenyls substituted at the 2 or 3 positions (No. 4 and 5).

Methylated derivatives of *p*-terphenyl, *p*-quaterphenyl, *p*-quinquephenyl, *p*-sexiphenyl[55], and *p*-octophenyl[7] were obtained from cyclic diketones (cyclohexa-1,4-dione and bicyclohexyl-4,4′-dione) and lithium aryls via intermediate hydroaromatic compounds.

Somewhat later it was shown[53,54] that the increased solubility of methylated *p*-oligophenylenes obtained by the Ullmann reaction is explained by breakdown of symmetry of the compounds due to the combined effects of substitution and rotation, the latter associated with diminished symmetry resulting from internal molecular mobility (rotation of rings).

p-Oligophenylenes with $n \leqslant 14$ and containing one or two unsubstituted *m*-phenylene units in the main chain were synthesised[65]:

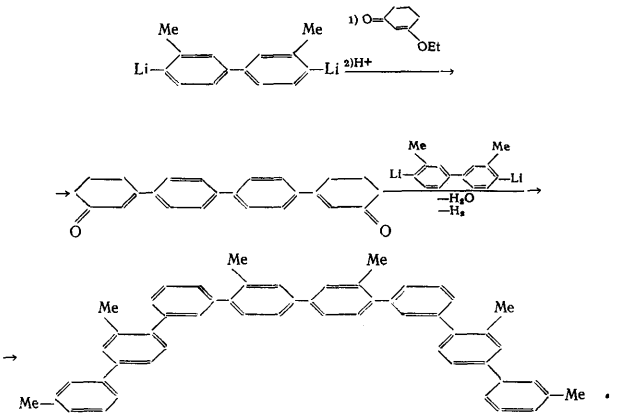


Table 9. Melting points and solubilities in toluene (at 20°C) of methylated oligophenylenes[65].

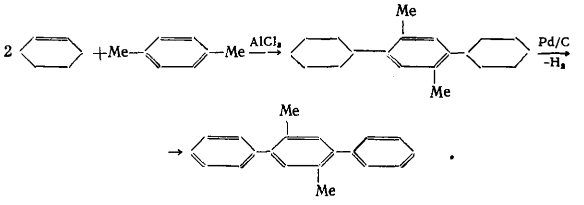
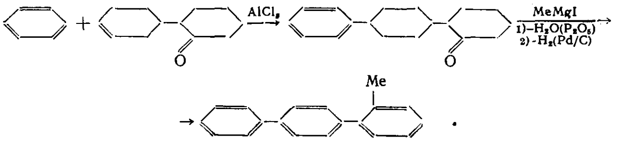
No.	Formula	M.p., °C	Solubility, g litre-1
1.		202—203	12
2.		170—171	73
3.		221—222	12
4		218—220	10

Table 9 gives the melting points and solubilities in toluene of several methylated oligomers of this type. Their infrared spectra are identical with those of *p*-oligophenylenes, whereas the ultraviolet spectra differ appreciably; the melting points are lower and the solubilities better than for the corresponding *p*-oligophenylenes.

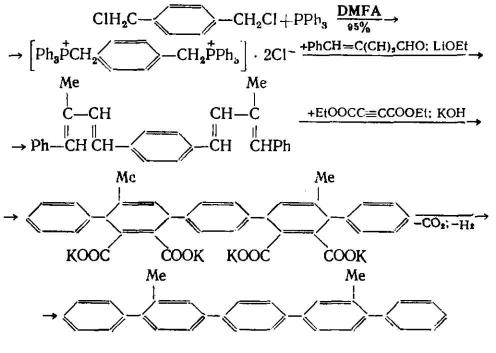
Methylated *p*-terphenyls have been obtained also by the Friedel–Crafts reaction. Deuschel[66] condensed cyclohexene with *p*-xylene in carbon disulphide in the presence of aluminium trichloride to give 2,5-dicyclohexyl-*p*-xylene, which was then dehydrogenated over a palladium–carbon catalyst to $2^2,2^5$-dimethyl-*p*-terphenyl:



1^2-Methyl-*p*-terphenyl (m.p. 91–92°C) was obtained[67] from products of the condensation of 2-cyclohex-3′-enylcyclohexanone with benzene in the presence of aluminium chloride:

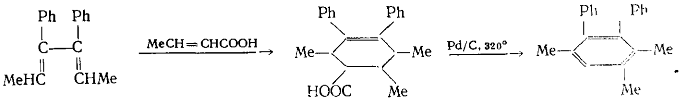


Campbell and McDonald[68] synthesised dimethyl-*p*-quinquephenyls, using cyclisation to introduce the methylated rings. Thus the reaction of *p*-xylenebistriphenylphosphonium dichloride with α-methylcinnamaldehyde gave *p*-bis-3-methyl-4-phenylbutadienylbenzene, which on the cycloaddition of diethyl acetylenedicarboxylate in the presence of potassium hydroxide formed potassium tetrahydro-$2^2,4^3$-dimethylquinquephenyltetracarboxylate, whose dehydrogenation and decarboxylation yielded $2^2,4^3$-dimethyl-*p*-quinquephenyl (m.p. 217–218°C):

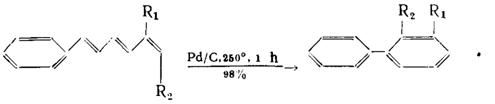


When *p*-methylcinnamaldehyde was used as initial compound, $1^4,5^4$-dimethyl-*p*-quinquephenyl (m.p. 400°C) was obtained.

Langer and Wessely[69] synthesised several methylated *o*-, *m*-, and *p*-terphenyls by the dehydrogenation over a palladium–carbon catalyst of substituted cyclohexenes—products of the cycloaddition of e.g. an acrylic acid to a buta-1,3-diene:

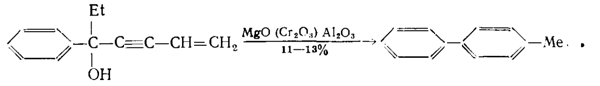


Methylated biphenyls may be formed by the high-temperature cyclisation of the side-chains of various aromatic compounds. Thus mono- and di-methylbiphenyls were obtained[30] by heating phenylalkatrienes in the presence of a palladium–carbon catalyst in a vacuum to 250°C:

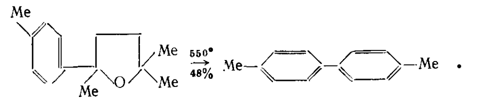


R_1=H or Me; R_2=Me

Substituted biphenyls were obtained from benzene derivatives containing at least six carbon atoms in the side-chain[70–73] (e.g. unsaturated compounds—1-ethyl-1-phenylpent-4-en-2-ynol, 1,4,4-trimethyl-1-phenylbutynediol, etc.) in the presence of a chromium–alumina catalyst:



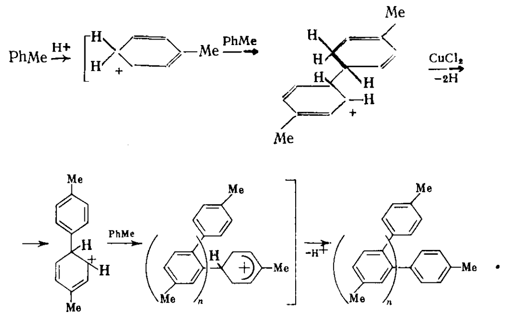
The pyrolysis of 2,2,5-trimethyl-5-*p*-tolyloxolan at 550°C yields 4,4′-dimethylbiphenyl (m.p. 121°C)[74]:



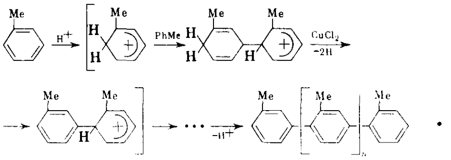
Oxidative dehydropolycondensation is currently among the best known and simplest methods for synthesising polymers having aromatic groups in the main chain. First developed by Kovačic and his coworkers in 1962,[75] it enables polyphenylenes to be obtained by the single-stage conversion of aromatic compounds in the presence of catalysts such as Lewis acids and oxidising agents at 30–37°C[39,41,42,75,76]. Several investigations have shown[43,77,78] that the oxidative dehydropolycondensation of benzene usually gives polymers that are infusible and insoluble in organic solvents. Mixtures of benzene with various aromatic hydrocarbons—e.g. naphthalene, biphenyl, terphenyl, toluene, xylenes, etc.—were proposed[79–87] for the production of fusible and soluble polyphenylenes. The properties of the resulting polymers were found to depend mainly on the process conditions (proportions and concentrations of initial monomers, catalyst concentrations, type of solvent, temperature, etc.).

Oxidative dehydropolycondensation is catalysed most effectively[41–43,77] by the aluminium(III)–copper(II) chloride system. In its presence toluene yielded oligophenylenes of mean degree of polymerisation n = 10–20, soluble in aromatic hydrocarbons (benzene, toluene) and having m.p. ≃ 250°C. Nuclear magnetic resonance, infrared, and ultraviolet spectroscopy together with elementary analysis of the oligophenylenes and of products formed under conditions of oxidative degradation showed that the main oligomer chain consisted of *ortho*-linked aromatic rings containing *p*-methyl groups. A certain number of *para*-linked phenylene units were also present in the chain. From this Kovačic and Ramsey[87] suggested that the mechanism of the formation of *o*-oligophenylenes from toluene (the ring bonds are delocalised) was

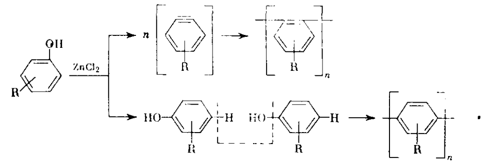
$$H_2O + AlCl_3 \rightleftarrows H_2O \ldots AlCl_3 \rightleftarrows H^+[AlCl_3(OH)]^-;$$



When a benzonium ion protonated *ortho* to the methyl group appears, growth of the oligomeric molecule leads to formation of a methylated *p*-oligophenylene:



Alkylated polyphenylenes were obtained by Paushkin et al.[9,88] by oxidative polycondensation of the corresponding phenols. Thus phenol and its homologues (*m*-cresol, *p*-t-butylphenol, etc.) in the presence of zinc chloride (at 250–350°C for 6 h) gave polymers partly soluble in dimethylformamide, phenol, pyridine, dioxan, and concentrated sulphuric acid. The solubility of the polymers diminished with rise in temperature and increase in duration of the reaction. The mechanism was regarded as involving dehydration and polymerisation of an intermediate dehydrobenzene or as polycondensation:



The former was regarded as the more probable, since polymers with *ortho*-linked benzene rings were mainly formed. However, the suggested mechanism can hardly be regarded as soundly based, since intermediate formation of dehydrobenzene is unlikely in the high-temperature conversion of phenols in the presence of catalysts. Processes involving phenoxy-radicals and their subsequent conversion products probably also take place under these conditions.

The unsubstituted or alkylated *o*-phenylenes (yield ⩽ 32%) obtained from phenol, *m*-cresol, and *p*-t-butylphenol respectively contained 9.8–19.6% of soluble fractions having $\overline{M}_n$ = 950–1050. The presence of a small quantity of oxygen in the polymer is evidently due to terminal hydroxyls[88].

7. Nitro-substituted Oligo- and Poly-phenylenes

Several nitro-*p*-quaterphenyls were synthesised in order to ascertain the influence of nitration on the solubility of oligophenylenes. Thus $1^4,4^4$-dinitro-*p*-quaterphenyl, obtained from 4-iodo-4′-nitrobiphenyl by the Ullmann reaction[29]

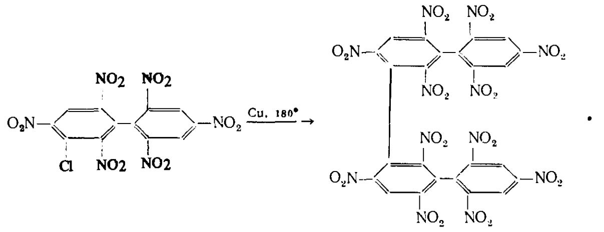
was isolated as yellow crystals of m.p. 317–320°C, insoluble in the majority of organic solvents.

Table 10. Solubilities in toluene (at 20°C) and melting points of nitrated and methylated *p*-quaterphenyls[89].

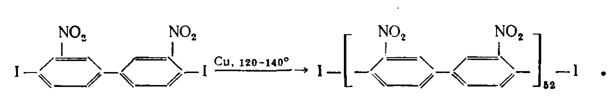
Substituted at positions	Nitro-derivative		Methyl derivative	
	solubility, g litre^{-1}	m.p., °C	solubility, g litre^{-1}	m.p., °C
2^3-	4.3	288	—	—
2^3, 3^2-	3.4	342	55	178
1^3, 4^3-	3.8	233	51	150
1^2, 2^2, 3^3, 4^2-	2.0	207	3.5	213
$1^{2,4}$, 2^3, 3^2, $4^{2,4}$-	0.85	235	470	96
	0.20	292	—	—

Comparison of the properties of methylated and nitrated *p*-quaterphenyls showed (Table 10) that the latter have rather higher melting points, but considerably lower solubilities, than their methylated analogues[89]. On the whole a nitro-group produces little enhancement of the solubility of oligophenylenes, although in polar solvents (nitrobenzene, dimethylformamide) their solubility is increased significantly.

From 3-chloro-2,2′4,4′,6,6′-hexanitrobiphenyl in dry nitrobenzene in the presence of copper bronze Dacons[90] obtained dodecanitroquaterphenyl (yield 70%), an explosive compound:

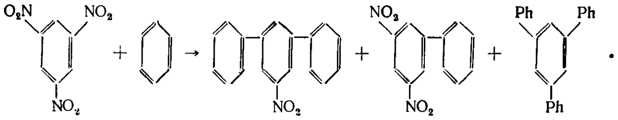


A nitro-substituted *p*-polyphenylene was obtained by the Ullmann reaction, when 4,4′-di-iodo-3,3′-dinitrobiphenyl in dimethylformamide solution in the presence of copper bronze was heated to 140°C[89]:



The polymer was a crystalline yellow powder, infusible and insoluble, which decomposed above 250°C.

As an alternative to the main method for obtaining nitrated oligophenylenes—the Ullmann reaction—the pyrolysis of aromatic compounds can be used for nitroterphenyls and nitrobiphenyls. Fields and Meyerson[32,91] studied the arylation of aromatic nitro-compounds at high temperatures. A 28% yield of 3-nitrobiphenyl was isolated from the pyrolysis of a mixture of *m*-dinitrobenzene and benzene (molar proportions 1 : 10) at 450°C. The reaction between 1,3,5-trinitrobenzene and benzene at 450–600°C gave a mixture of nitroterphenyl, dinitrobiphenyl, and triphenylbenzene:

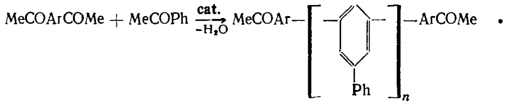


A radical mechanism is involved with intermediate formation of a phenyl radical:

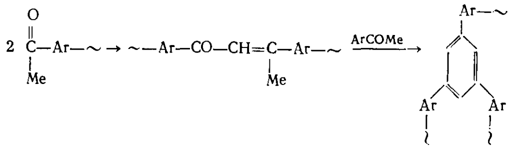
$$PhNO_2 \rightarrow Ph^{\cdot} + NO_2 \ .$$

8. Oligophenylenes containing Acetyl and Acetal Groups

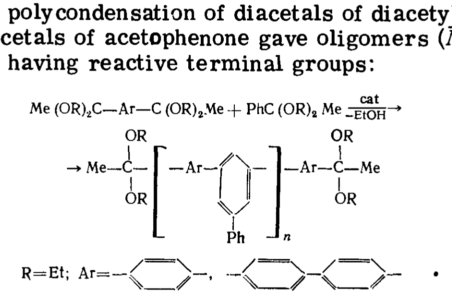
Oligophenylenes having terminal acetyl groups were first synthesised by Korshak et al.[92–94] by the polycyclocondensation of mono- and di-acetylated aromatic compounds. In the presence of an acid catalyst (hydrogen chloride, sulphuric acid, toluene-*p*-sulphonic acid) at 20°C infusible oligophenylenes, having $\bar{M}_n$ = 1500–4200, containing acetyl end-groups, and soluble in benzene, toluene, chloroform, and other organic solvents, were obtained from acetophenone with *p*-diacetylbenzene or with 4,4′-diacetylbiphenyl:



Trimerisation was shown to involve intermediate formation of a dimer containing dypnone fragments, which interacted with the acetyl group to give the 1,3,5-trisubstituted benzene rings:



The introduction of ethyl orthoformate promoted conversion of the acetyl compounds into acetals, which readily trimerised to a benzene ring. Korshak et al.[95–97] suggested that acetylated aromatic compounds should be replaced by their acetals as initial compounds, in order to diminish the significance of side-reactions in the synthesis and lower the quantity of defective structures in the polymer. The polycondensation of diacetals of diacetylarylenes with acetals of acetophenone gave oligomers ($\bar{M}_n$ = 1700–2500) having reactive terminal groups:

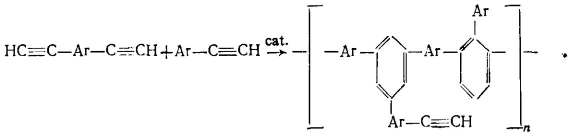


A linear structure was attributed to the resulting oligophenylenes on the basis of their elementary composition, molecular mass, and proton magnetic resonance spectra.

The oligophenylenes obtained either from acetylated aromatic compounds or from their acetals, when heated (at 400°C in the absence of a catalyst or at 300°C in the presence of toluene-*p*-sulphonic acid), set to infusible and insoluble products. Thermogravimetric results indicated that these products began to decompose at 430°C when heated in helium, and at 900°C the total losses in weight were 30%.

9. Ethynylated Oligophenylenes

The controlled synthesis of soluble aromatic polymers by the polycyclotrimerisation of a mixture of butadiyne and acetylene in an inert organic solvent, with the use of tantalum and niobium halides and oxide halides as catalysts between −30 and +200°C, was reported in the patent literature[98-100]. The chains in such polymers may terminate in ethynyl groups. Little study has been made of the properties of the products. Strongly branched oligophenylenes with terminal ethynyl groups have been obtained by the copolycyclotrimerisation of mono- and diacetylenic compounds in the presence of various catalytic systems (such as $[(AlkO)_3P]_4CoBr$,[101-103,24] $2NaBH_4.2(C_6H_5)_3P.NiCl_2$,[104] Ziegler catalysts[105], and other transition-metal complexes):



Oligophenylenes containing ethynyl groups and having molecular weights $\overline{M}_n$ = 1000–2500 (determined ebullioscopically in benzene) dissolve readily in benzene, toluene, and other organic solvents. The polymers easily set at 150–250°C to hardened products possessing high deformation heat-resistance, which increases with the number of ethynyl groups in the initial copolymer. However, the stability towards thermal oxidation of the hardened polyphenylenes diminishes with increase in the number of ethynyl groups.

Analogous soluble branched oligophenylenes having terminal ethynyl groups were obtained by Bracke[106] by the copolycyclotrimerisation of *m*-diethynylbenzene and phenylacetylene in chlorobenzene in the presence of a Fisher type of catalyst $TiCl_2.2AlCl_3$ at temperatures from −35 to +20°C. Thermogravimetry indicated that the polymer began to decompose at ~ 500°C whether in an inert gas or in air.

Furthermore, oligophenylenes having $\overline{M}_n$ = 10 000 (determined by gel-permeation chromatography), soluble in benzene and chlorinated hydrocarbons, were obtained by Chalk and Gilbert[107] by the copolycyclotrimerisation of phenylacetylene and *m*-ethynyltoluene with *m*-diethynylbenzene in the presence of a Ziegler catalyst (in toluene between −23 and +20°C). The products softened at 200–300°C depending on the molecular mass. The polymers were processed by extrusion.

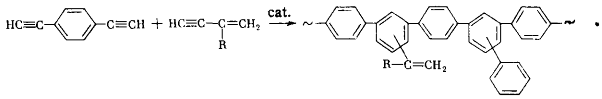
10. Alkenylated Oligophenylenes

Kern et al.[108] developed a process for obtaining 4-vinylbiphenyl and 1^4-vinyl-*p*-terphenyl by reducing 4-acetylbiphenyl and 1^4-acetyl-*p*-terphenyl with lithium tetrahydroaluminate, and subjecting the resulting α-hydroxyethyl derivatives to liquid-phase dehydration in the presence of methanesulphonyl chloride in pyridine solution:

$$ArCOMe \xrightarrow{LiAlH_4} ArCHOHMe \xrightarrow{MeSO_2Cl} ArCH{=}CH_2 \text{ .}$$

where

Branched oligophenylenes containing double bonds have been obtained[109] by the copolycyclotrimerisation of *p*-diethynylbenzene with alkenylacetylenes—butenyne or methylbutenyne—on the catalysts $[(C_2H_5O)_3P]_4CoBr$, $NiCl_2.2(C_6H_5)_3P.NaBH_4$, $(iso\text{-}C_4H_9)_3Al.TiCl_4$ (Al/Ti = 3):



The content of double bonds and the properties of the oligophenylenes depend primarily on the ratio of *p*-diethynylbenzene to alkenylacetylene in the initial mixture. Thus decrease in the ratio of the former to methylbutenyne tends to increase the solubility and the unsaturation of the oligomers and decrease their molecular mass. Completely benzene-soluble oligophenylenes were obtained at ratios of 1 : 3, when the products had $\overline{M}_n$ = 25 000 and iodine numbers of ~ 195.

Vinylated oligophenylenes obtained from *p*-diethynylbenzene and a vinylacetylene in the molar proportions 1 : 3–9 were solids only partly soluble in benzene and chloroform, probably owing to the ease of cross-linking during isolation and standing in the air. In contrast, ternary copolymers based on *p*-diethynylbenzene, butenyne, and phenylacetylene in the molar proportions 1 : 3 : 3 and 1 : 3 : 1, obtained in the presence of $(iso\text{-}C_4H_9)_3Al.TiCl_4$, dissolved completely in benzene and chloroform; their iodine numbers varied from 130 to 440.

All the alkenylated oligophenylenes were easily hardened at room temperature and on heating with the formation of infusible and insoluble products.

III. POLYMERLIKE REACTIONS OF OLIGO- AND POLYPHENYLENES

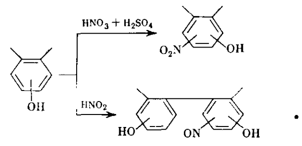
Various functional groups can be introduced into polyphenylenes by treatment with appropriate reagents, whether the polymers had been obtained by dehydrogenation of polycyclohexenes or by oxidative dehydropolycondensation of benzene. Thus Kovačic et al.[110] showed that the action of concentrated sulphuric acid on a *p*-polyphenylene yields a product in which about 60% of the aromatic rings contain sulpho-groups. Sulphonation of *p*-phenylenes with chlorosulphuric acid, oleum, or concentrated sulphuric acid gave sulphonated polymers in which the ratio of carbon to sulphur varied from 6 (one sulphur atom per aromatic ring) to 36 depending on temperature and duration of the reaction[111-113]. Specimens having ratios ≤ 9 dissolved in aqueous acetone and aqueous ethanol.

When a sulphonated polymer was fused with a mixture of sodium and potassium hydroxides 97% of the sulpho-groups were hydrolysed to hydroxy-groups[111]. The resulting hydroxylated polyphenylenes were brittle black products, soluble only in aqueous acetone and aqueous ethanol.

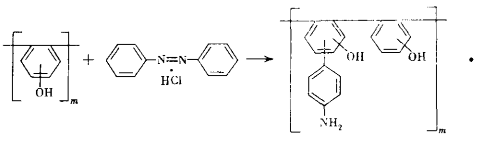
As noted earlier, the oxidative dehydropolycondensation of benzene in the presence of a Lewis acid as catalyst[39,41–44,77] will yield *p*-polyphenylenes having various degrees of halogenation. The hydrogen atoms of the aromatic ring are completely replaced by chlorine when the process is conducted in the presence of gaseous chlorine with $SnCl_2.AlCl_3$ or antimony(V) chloride as catalyst. In the presence of aluminium bromide brominated *p*-polyphenylenes are formed containing on the average ~ 3 bromine atoms per benzene ring[110].

One nitro-group can be introduced into every benzene ring by treating a *p*-polyphenylene with a nitrating mixture (nitric and sulphuric acids)[110]. Aminated polyphenylenes were obtained by reducing the nitro-polymers with hydrazine in the presence of Sn–HCl or $SnCl_2$–HCl in diethylene glycol solution, when conversion of nitro-groups into amino-groups reached 94–100%. The final products contained small quantities of nitro, azoxy, and other functional groups with incomplete reduction, and also because of the occurrence of side-reactions[110].

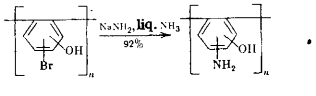
Paushkin et al.[114] used hydroxylated polyphenylenes obtained from dihydric phenols for the preparation of nitro-, nitroso-, and amino-derivatives. Thus treatment with a nitrating mixture (nitric and sulphuric acids) at temperatures not exceeding 10°C introduced a nitro-group into almost every benzene ring. Poly(hydroxynitrophenylenes) were obtained by the action of nitrous acid on a hydroxylated polyphenylene. The general trend of the nitration and nitrosation of these polymers can be represented by the scheme



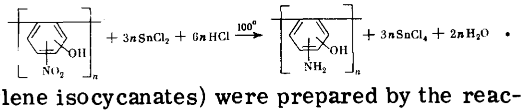
The aminophenylation of hydroxylated polyphenylenes with azobenzene hydrochloride produces polymers that are partly soluble in dimethylformamide and contain one aminophenyl group for approximately two hydroxyphenylene groups[114]:



Polymers completely soluble in dimethylformamide were obtained by the amination of poly(bromohydroxyphenylenes)[114]:



Reduction of poly(hydroxynitrophenylenes) by the action of tin(II) chloride in hydrochloric acid gave up to 70% yields of poly(aminohydroxyphenylenes):



Poly(phenylene isocycanates) were prepared by the reaction of poly(aminohydroxyphenylenes) with chloroform and alkali[114].

The above investigations have shown that the introduction of substituents into hydroxylated polyphenylenes improves their solubility but impairs their thermal stability.

IV. PRACTICAL APPLICATION OF OLIGO- AND POLYPHENYLENES CONTAINING VARIOUS FUNCTIONAL GROUPS

Much experimental information has now accumulated on the preparation and properties of oligophenylenes and polyphenylenes containing functional groups, from which conclusions can be drawn (though still preliminary) on the further development of work on these lines. Fields of practical application of the substituted oligomers and polymers, at present fairly restricted, will undoubtedly expand continuously.

When heated in a melt with alkali, polyphenylenes containing sulpho-groups form polyphenols, which are converted by treatment with formaldehyde into insoluble, infusible cross-linked products[111]. These undergo no loss in weight when heated to 400°C (in nitrogen with ΔT = 2.5 deg min^{-1}), and only at 900°C do the losses amount to 30%. The thermal stability of the products diminishes with increase in the quantity of substituents in the polymer molecule.

A heat-resistant composition was obtained also from a mixture of a chlorinated polyphenylene and a silicone grease[115].

Polyphenylenes having terminal ethynyl groups can be used as binders in polymeric antifriction materials for the production of bearings operating over the temperature range 50–320°C.[116]

Polymers obtained by treating isomeric terphenyls with benzene-*m*-disulphonyl dichloride or benzene-1,3,5-trisulphonyl trichloride at 300–350°C are used for the production of heat-resistant coatings[117]. Such coatings have been obtained also from a mixture of a soluble and a fusible polyphenylene ($\overline{M}_n$ = 500–5000), aromatic sulphonyl halides (e.g. benzene-*m*-disulphonyl dichloride), and an inorganic pigment (titanium dioxide)[118].

Thermosetting polymers of the polyphenylene type are employed as ablative coatings and for the preparation of laminates having high heat resistance[119]. Mixtures of fusible and soluble polyphenylenes were used for these purposes, with 10 wt.% of bishydroxymethylbenzenes as hardeners. $\alpha\omega$-Dibromo-*p*-polyphenylenes are used for the production of heat-resistant coatings[38].

A polymer based on *m*-dibromobenzene, containing *m*-phenylene repeating units, finds application for the manufacture of electrical insulators operating at temperatures of 23–240°C.[120] Hydroxylated *o*-polyphenylenes can be regarded as organic semiconductors[6], having conductivities of 10^{-9}–10^{-8} ohm^{-1} cm^{-1} at 50°C. Alkylated terphenyls are used as heat-transfer agents, regulators, and moderators of neutrons in atomic reactors[62]. Poly(aminohydroxy-*o*-phenylenes) have an inhibiting effect: for example, they prevent the thermal polymerisation of styrene (for up to 1.5 h at 120°C)[114].

Mass Spectrometry of Quinolizidine Alkaloids

N.S.Vul'fson and V.G.Zaikin

General and specific modes of breakdown on electron bombardment are surveyed for certain simple quinolizidine derivatives, including substances of natural origin, and many quinolizidine alkaloids of the cytisine, sparteine, and matrine series. Mass spectrometry can be used to establish the structure of this class of naturally occurring compounds. A list of 36 references is included.

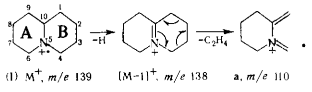
CONTENTS

I. INTRODUCTION

Alkaloids derived from quinolizidine occur widely in the vegetable kingdom. The structures of several dozen natural quinolizidine alkaloids have now been established, and several stereoisomeric compounds, not yet found in Nature, as well as derivatives possessing valuable pharmacological properties, have been prepared from them. Some steroidal alkaloids containing the quinolizidine system, as well as lycopodium alkaloids, can formally be included. However, we have considered it advisable to restrict the present Review to those quinolizidine alkaloids whose degradation on electron bombardment conforms most closely to the rules characteristic of the quinolizidine system. Lycopodium alkaloids and the corresponding steroidal alkaloids are less interesting from this point of view, since the quinolizidine part of the molecule is insufficiently specifically developed in their mass spectra (the modes of decomposition of lycopodium alkaloids on electron bombardment have been summarised in a monograph[1]). The present Review covers mass-spectrometric investigations of quinolizidine and its simple derivatives, including those of natural origin, as well as the more complicated quinolizidine alkaloids belonging to the cytisine, sparteine, and matrine groups.

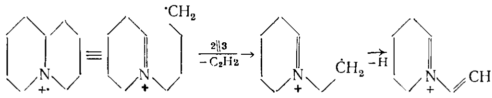
II. QUINOLIZIDINE AND ITS SIMPLE DERIVATIVES

Detailed reviews have appeared on the behaviour under electron bombardment of quinolizidine itself (I) and its deutero-analogues[2-5]. The maximum peak in the mass spectrum of (I) corresponds to the $[M-1]^+$ ion, the peak due to the molecular ion being only about half as intense[4]. Analysis of the mass spectra of the analogues labelled with deuterium at the 1,4 and 2,10 positions showed that the above ion is formed by preferential elimination of the hydrogen atom from the $C_{(10)}$ carbon atom, whereas at most 11% of the hydrogen is lost from $C_{(4)}$ and $C_{(6)}$ adjacent to the nitrogen atom[5]. Further breakdown of the $[M-1]^+$ ion, on the pattern of a retrodiene reaction (RDR), yields an ion (a) having $m/e = 110$:



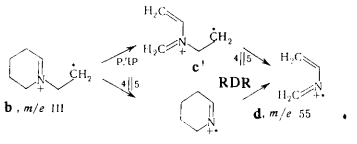
(I) $M^{+\cdot}$, m/e 139 $[M-1]^+$, m/e 138 a, m/e 110

It is supposed furthermore that this 110 ion may be formed from the molecular ion by successive rupture of the $C_{(10)}-C_{(1)}$ and $C_{(2)}-C_{(3)}$ bonds with elimination of an ethylene molecule and formation of an m/e 111 ion (b), which then loses a hydrogen atom. The 110 ion will then have the structure a'[4]:



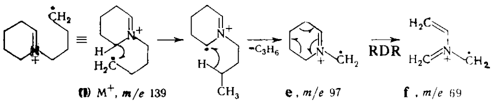
(I) M^+, m/e 139 b, m/e 111 a', m/e 110

Nor can it be excluded that (a') may be formed from the $[M-1]^+$ ion as a result of elimination of an ethylene molecule with rupture of the above two bonds accompanied by migration of a hydrogen atom from $C_{(4)}$ to $C_{(10)}$. Elimination of an ethylene molecule from ion b by rupture of $C_{(4)}-C_{(5)}$ or a retrodiene type of breakdown in ring *A* yields ions having m/e 83 (c or c'), which then lose another ethylene molecule to give the ion d with m/e 55:



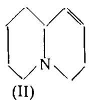
c, m/e 83

The characteristic ion e with m/e 97 is formed directly from the molecular ion (I). It was shown by means of deuterated analogues[3] that formation of this ion (e) is due to elimination of the $C_{(1)-(3)}$ atoms accompanied by countermigration of hydrogen atoms:

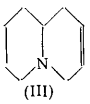


(I) M^+, m/e 139 e, m/e 97 f, m/e 69

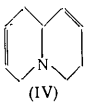
The introduction of double bonds into the quinolizidine molecule results in appreciable simplification of the mass spectrum[6]. The peaks due to molecular and $[M-1]^+$ ions are very intense in the spectra of Δ^1-, Δ^2-, and $\Delta^{1,7}$-dehydroquinolizidines



(II)



(III)



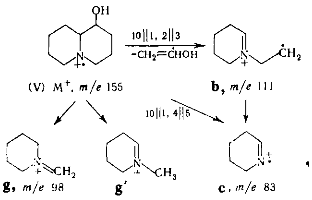
(IV)

[with (II) and (IV) the latter ions are the most intense in the spectrum]. The c ion, formed by a retrodiene type of breakdown in the B ring and then decomposing to the ion d, has the maximum intensity in the spectrum of (III).

The spectra of (II) and (IV) are characterised by unsaturated analogues of c ions with *m/e* 80 and 81. That of (II) also contains a peak due to an unsaturated analogue of the ion a′ with *m/e* 108.

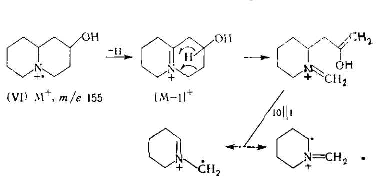
The introduction of a hydroxy-group into the quinolizidine molecule in principle leaves unchanged the modes of breakdown of the main skeleton under electron bombardment. However, the intensities with which certain processes occur depend both on the presence of such a group and on its position.

The peaks of molecular and $[M - 1]^+$ ions in the mass spectra[5] of 1-, 2-, and 3-hydroxyquinolizidines (V)-(VII) are quite intense; they are more intense with (VI) and (VII) than with (V), and in these two cases the $[M - 1]^+$ ions are more intense than the molecular ions. The main peaks in the spectra of (V) and (VII) are due to the ions c with *m/e* 83. This ion may be formed from (V) either directly from the molecular ion by rupture of $C_{(10)}-C_{(1)}$ and $C_{(4)}-C_{(5)}$ bonds or from the b ion with *m/e* 111 by loss of an ethylene molecule in the rupture of the $C_{(4)}-C_{(5)}$ bond:



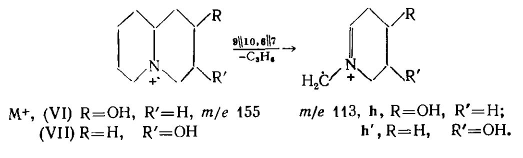
In the case of (VII) the ion c is formed only bh the first route[5].

Analysis of the mass spectra of deuterated analogues showed that the next most intense peak in the spectrum of (V) with *m/e* 98 is due to the isomeric ions g and g′, formed directly from the molecular ion by rupture of the $C_{(10)}-C_{(1)}$ and $C_{(3)}-C_{(4)}$ bonds with migration of a hydrogen atom to the charged particle. The most intense peak in the spectrum of (VI) is an ion having *m/e* 97 (e or e′):

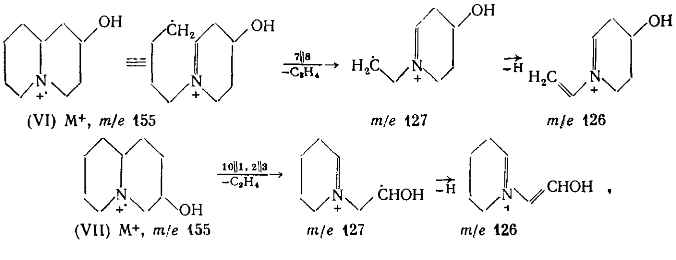


The peaks due to ions a–c are moderately intense in the spectrum of (VI). Whereas the peaks due to $[M - OH]^+$ ions are relatively weak in the spectra of (V) and (VII), the corresponding peak in the spectrum of (VI) is similar in intensity to that due to the molecular ion.

A peculiarity of the breakdown of the hydroxy-derivatives (VI) and (VII) under electron bombardment is the formation of several oxygen-containing fragments almost completely absent from the spectrum of (V). Both the former compounds are characterised by fairly intense peaks due to ions having *m/e* 113 (h and h′ respectively), resulting from rupture of $C_{(6)}-C_{(7)}$ and $C_{(9)}-C_{(10)}$ bonds with localisation of the charge on the oxygen-containing fragment:



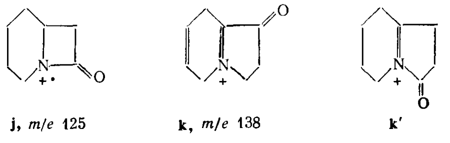
A different pattern obtains in the formation of ions with *m/e* 126 and 127, for analysis of the mass spectra of deuterated analogues of (VI) and (VII) indicates different mechanisms of formation and hence different structures:



A distinguishing feature of the mass spectrum of (VII) is the quite considerable intensity of peaks due to $[c + 1]^+$ and g ions with *m/e* 84 and 98 respectively. The spectra of all the above compounds contain not very intense peaks due to $[e - 1]^+$ ions with *m/e* 96.

Introduction of a keto-group into the quinolizidine molecule has a still more marked effect on the character of the mass spectrum. Spectra have been described for the derivatives (VIII)-(XI) with this group in positions 1-4 [4,7] and their deuterated analogues. They all differ significantly in the intensity of the peak due to the molecular ion: with (IX) and (XI) these peaks are the most intense, with (X) the intensity is ~60%, and with (VIII) only ~30%. Although a hydrogen atom is eliminated from the molecular ion in all cases, this process is less characteristic of the ketones (VIII)-(XI) than of the previous examples. The position of the keto-group has a very significant influence on the breakdown of the molecular ion, although in many cases the resulting ions have the same structure as previously. Successive elimination of a carbon monoxide molecule and a hydrogen atom with formation of ions having *m/e* 125 and 124 is most characteristic of the molecular ions of (VIII) and (X), and is confirmed by the spectra of the deuterated analogues and by the presence of the corresponding metastable peaks in the spectra[4]. In both cases different structures were ascribed to these ions, which the Reviewers regard as unsound.

Peaks due to ions with *m/e* 125 and 124 are completely absent from the mass spectrum of (IX) [4], whereas the 125 peak is present in the spectrum of (XI); according to a high-resolution mass spectrum, however, it is due to elimination of an ethylene molecule—not of carbon monoxide—and has the structure j.[7] A distinguishing feature of these ketones (IX) and (XI) is the elimination of a methyl group from the molecular ions with formation of ions having *m/e* 138 (k and k′).[4,7]



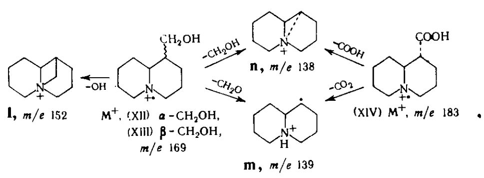
The spectra of all the ketones examined contain peaks due to ions of the previous types a and c–g; the b ion is apparent only in the spectrum of (IX). The high-resolution mass spectrum indicates that the 97 peak in the case of (X) is composite, representing not only ions e and e′ but also ions of composition C_7H_{13} and C_6H_9O.

It must be emphasised that the above ions of types a–g are in general present in the mass spectra of all quinolizidine alkaloids, their intensity varying with the type of fusion of the rings and with the nature and position of substituents.

III. QUINOLIZIDINE ALKALOIDS

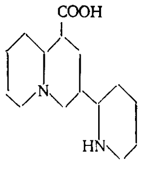
1. Simple Alkaloids

The mass spectra of the simplest quinolizidine alkaloids—lupinine (XII), isolupinine (XIII), and lupininic acid (XIV)—were described by Spiteller et al.[8] as long ago as 1964. The spectra of the epimeric alcohols (XII) and (XIII) differ little. The peaks of molecular and $[M - 1]^+$ ions are fairly intense. These compounds undergo not only the above modes of decomposition giving the ions a–g but also fragmentation of the hydroxymethyl group, with elimination of a hydroxyl radical or a formaldehyde molecule (giving the ions *l* and m with *m/e* 152 and 139 respectively), and loss of a hydroxymethyl radical yields the ion n with *m/e* 138:

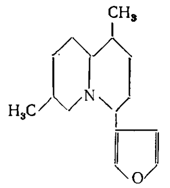


The peaks of *l* and n ions are among the most intense in the spectrum. The maximum peaks in the spectra of (XII) and (XIII) are produced by c and *l* ions respectively. The c peak predominates also in the spectrum of the acid (XIV), about threefold the intensity of the molecular ion. Loss of carboxyl and of carbon dioxide yields respectively n and m ions.

The mass spectra of α-epilupininic acid, its ethyl ester, amide, piperidide, and morpholide, and also aphyllinic acid (XV), its amide, methyl ester, and several other derivatives have been described[9]. Whereas the molecular ion of α-epilupininic acid breaks down on electron bombardment mainly similarly to (XIV), aphyllinic acid (XV) exhibits special trends resulting from the presence of a piperidine residue in its molecule. The principal feature of the spectrum of (XV) is the peak of the *m/e* 84 ion, which, though corresponding in structure to the $[c + 1]^+$ ion, is nevertheless due entirely to localisation of charge on the piperidyl residue. The remaining peaks in the spectrum of (XV) are far less intense than the 84 peak. Among fragments formed at the expense of the quinolizidine ring the most clearly evident are the a, e, and g ions. The $[M - 84]^+$ and $[M - 83]^+$ ion peaks owe their appearance to detachment of the piperidyl residue with localisation of the charge on the quinolizidine moiety. Several other peaks in the spectrum of (XV) may be explained by preliminary cyclisation of the molecular ion by elimination of a water molecule from the carboxyl and the secondary amino-group with formation of the polyheterocyclic structure of aphylline (see below).

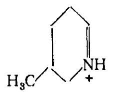


(XV)



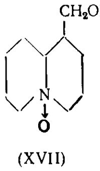
(XVI)

In the mass spectrum of deoxynupharidine (XVI)[10] the moderately intense peak due to the molecular ion is accompanied by the strongest peak at *m/e* 98, due to a homologue of the $[c + 1]^+$ ion formed by rupture of the $C_{(10)}-C_{(1)}$ and $C_{(4)}-C_{(5)}$ bonds. When the same bonds are broken but with localisation of the charge on the other moiety and migration of a hydrogen atom from the charged particle, an ion having *m/e* 136 is formed. A third, fairly intense peak at 94 is due to the oxatropylium radical-ion resulting from localisation of charge on the furan substituent.



m/e 98

m/e 94



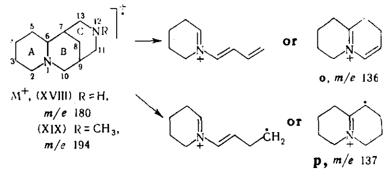
(XVII)

In concluding this subsection we must mention that mass spectra have been described also for two lupinine *N*-oxides (XVII) epimeric at the nitrogen atom[11]. Unfortunately, one of the spectra clearly corresponds to an impure compound, so that it is impossible to assess the effect of the stereochemistry on the decomposition of the molecular ions of these epimers on electric bombardment. From the spectrum of the pure epimer, however, it appears that the main path involves the successive elimination of a hydroxy-group and an oxygen atom from the molecular ion. The presence of an ion peak at 138 is probably due to elimination of a formaldehyde molecule from the $[M - OH]^+$ ion.

2. Cytisine Series

Ring *A* of the parent compound of this group of quinolizidine alkaloids (cytisine) has an α-pyridone structure, which has a significant influence on the general pattern of decomposition of this compound under electron bombardment. The successive hydrogenation and reduction of cytisine yields tetrahydrocytisine and deoxytetrahydrocytisine. The latter contains the quinolizidine structure in "pure form", so we considered it advisable to begin our survey of this group of alkaloids at this compound, and then pass to tetrahydrocytisine and cytisine, in order to trace the influence of functional groups introduced into ring *A* on the type of breakdown under conditions of mass spectrometry.

The mass spectra of deoxytetrahydrocytisine (XVIII) and its *N*-methyl derivative (XIX)[8] contain fairly intense peaks of molecular ions. The maximum peaks in the two spectra are due to g and g′ ions respectively, while the e peaks are considerably less intense. Both these ions result almost entirely from rupture of $C_{(6)}-C_{(7)}$ and $C_{(9)}-C_{(10)}$ bonds with localisation of charge on the *A* ring. This is confirmed by the constancy of the peaks on passing from (XVIII) to (XIX) and the displacement of both peaks by 2 amu in the spectrum of 2,2-dideuterated (XVIII). Among fragments noted earlier as characterising the quinolizidine system, peaks of [e − 1] ions (also formed from ring *A*) and a ions are present in the spectra of (XVIII) and (XIX). Breakdown of the molecular ion of (XVIII) involves ejection of the nitrogen atom at position 12 as amino or methylamino. With (XIX) the peak of the $[M - CH_3NH]^+$ ion with *m/e* 164 is accompanied by the $[M - (CH_3)_2N]^+$ peak at 150 and the peak of the $[M - 15]^+$ ion. The spectra of (XVIII) and (XIX) are characterised by pairs of peaks due to ions having *m/e* 136 (o) and 137 (p)



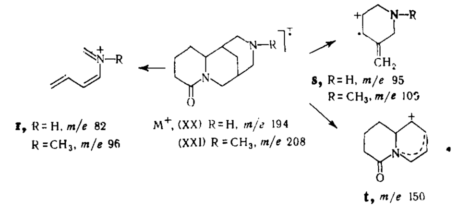
M⁺, (XVIII) R = H, *m/e* 180
(XIX) R = CH_3, *m/e* 194

o, *m/e* 136

p, *m/e* 137

for whose formation several complicated rearrangement mechanisms have been suggested[8]. As will be seen later, o and p ions are characteristic also of quinolizidine alkaloids.

The presence of the lactam carbonyl in the *A* ring of tetrahydrocytisine (XX) and its *N*-methyl derivative (XXI) has a significant influence on the type of breakdown under electron bombardment[12]. The principal peaks in their mass spectra correspond to $[M - 112]^+$ and $[M - 99]^+$ ions. They are formed by complicated rearrangements involving destruction of the polyheterocyclic system, and have been ascribed the structures r and s; elimination of the elements of ring *C* from (XX) and (XXI) yields an *m/e* 150 ion (t):



r, R = H, *m/e* 82
R = CH_3, *m/e* 96

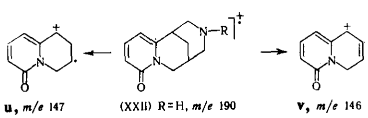
M⁺, (XX) R = H, *m/e* 194
(XXI) R = CH_3, *m/e* 208

s, R = H, *m/e* 95
R = CH_3, *m/e* 109

t, *m/e* 150

However, elimination of $CH_3NH\cdot$ and $(CH_3)_2NH\cdot$ radicals from the molecular ions of these alkaloids is not observed.

The molecular ions of cytisine (XXII) and *N*-methylcytisine (XXIII)—alkaloids containing an aromatised *A* ring—are very stable. The spectrum of (XXII) contains not only the peak due to the $[M - CH_3NH]^+$ ion but also a pair of peaks (equal in intensity to the molecular ion) having *m/e* 147 and 146, corresponding to the ions u and v formed by elimination of the elements of ring *C*:



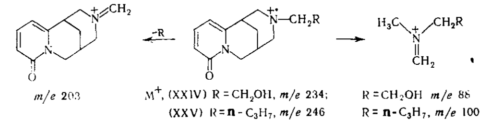
u, *m/e* 147

(XXII) R = H, *m/e* 190
(XXIII) R = CH_3, *m/e* 204

v, *m/e* 146

Unexpectedly, the spectrum of (XXIII) differs markedly from that of (XXII). Thus the u peak is almost completely absent, and the $(CH_3)_2N^+:CH_2$ ion with *m/e* 58 produces the maximum peak in the spectrum. The corresponding ion with *m/e* 44 from (XXII) is very weak. This effect is attributed to the different abilities of the $N_{(12)}$ atoms in (XXII) and (XXIII) to localise the positive charge. The spectra of (XXII) and (XXIII) also contain peaks at *m/e* 160 due to $[M - CH_3NH]^+$ and $[M - (CH_3)_2N]^+$ ions respectively.

In several cases the cytisine group of alkaloids can be distinguished from the sparteine and matridine groups simply on the basis of molecular weight, since the first group do not contain the *D* ring. Although several dimeric cytisine alkaloids and those containing substituents in the *C* ring are now known, with consequently considerably higher molecular weights, the problem can still be solved quite simply, since the substituent is easily detached on electron bombardment, yielding one of the maximum ion peaks in the spectrum, and dimeric molecules are broken "in half", so that the low-molecular regions resemble the spectra of the corresponding monomeric derivatives. For example, the main peaks in the spectra of *N*-hydroxyethylcytisine (XXIV)[13] and *N*-n-butylcytisine (XXV)[14] represent ions with *m/e* 203, corresponding to detachment of part of the $N_{(12)}$-substituent; they are accompanied by peaks peculiar to cytisine, and the 58 peak characteristic of *N*-methylcytisine is replaced by peaks displaced to *m/e* 88 and 100:

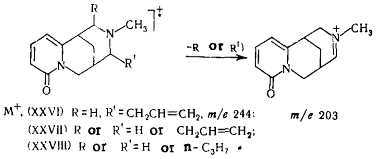


m/e 203

M⁺, (XXIV) R = CH_2OH, *m/e* 234;
(XXV) R = n-C_3H_7, *m/e* 246

R = CH_2OH *m/e* 88
R = n-C_3H_7, *m/e* 100

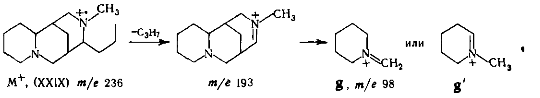
Alkyl groups located in the α-position relative to the nitrogen atom in the *C* ring of cytisine alkaloids are readily split off, so that the mass spectra of tinctorine (XXVI)[15], the perhaps identical alteramine (XXVII)[14], and also dihydroalteramine (XXVIII)[14] contain peaks of ions having *m/e* 203 together with those of ions characteristic of breakdown of the cytisine ring system:



M⁺, (XXVI) R = H, R' = $CH_2CH{=}CH_2$, *m/e* 244;
(XXVII) R or R' = H or $CH_2CH{=}CH_2$;
(XXVIII) R or R' = H or n-C_3H_7 .

m/e 203

Similarly, the most intense peak in the spectrum of hexahydroalteramine (XXIX)[14] corresponds to the $[M - n\text{-}C_3H_7]^+$ ion, which then breaks down into a g or g′ ion:



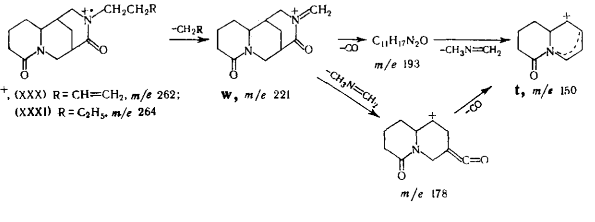
M⁺, (XXIX) *m/e* 236

m/e 193

g, *m/e* 98

g′

In tetrahydro-11-oxorhombifoline (XXX) and its dihydro-derivative (XXXI) the *C* ring contains a lactam carbonyl as well as an alkyl group[16]. Nevertheless, the maximum peak in the spectrum of (XXX) is due to an ion formed by detachment of part of the alkyl substituent. This ion with *m/e* 221 (w) then loses carbon monoxide and $CH_3N:CH_2$, being converted into ions 193 and 178, which in turn eliminate $CH_3N:CH_2$ and CO respectively to form the ion t (*m/e* 150):



M⁺, (XXX) R = $CH{=}CH_2$, *m/e* 262;
(XXXI) R = C_2H_5, *m/e* 264

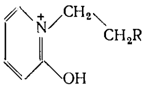
w, *m/e* 221

m/e 193

t, *m/e* 150

m/e 178

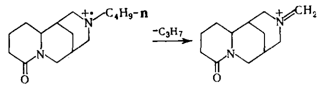
However, analysis of the mass spectrum of the 3,3-dideutero-analogue of (XXX) showed that the 150 peak is only partly displaced to 152, and is therefore composite, being due both to the t ion and to an ion t′ formed by rupture of bonds in the *B* ring with preservation of the *C* ring:



t′, R=CH=CH₂, *m/e* 150;

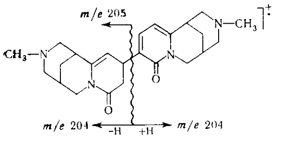
R=C₂H₅, *m/e* 152.

Breakdown of the molecular ion (XXXI) is essentially analogous to that of (XXX), differing only in containing a peak at 152 due to the t′ ion. The main peak in the mass spectrum of hexahydrorhombifoline (XXXII), briefly described in Ref. 17, is also due to the deoxy-analogue of the w ion with *m/e* 207, whose breakdown leads to ions at 138, 112, and 58:

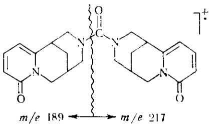


M⁺. (XXXII) *m/e* 250 *m/e* 207

The spectrum of the dimeric cytisine alkaloid—dimethamine (XXXIII) [18]—contains a very small peak of the molecular ion and intense ion peaks at 205 and 204, due to breakage of the molecule "in half" (accompanied by migration of a hydrogen atom to or from the charged particle):



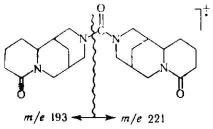
M⁺. (XXXIII) *m/e* 408



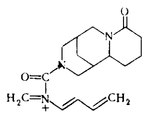
M⁺. (XXXIV) *m/e* 406

The spectrum of (XXXIII) also contains ion peaks typical of *N*-methylcytisine—at 160 [M^{+}_{cyt} − $(CH_3)_2N$], 146 (v), and the maximum at 58 $(CH_3)_2N^+$: CH_2—see above.

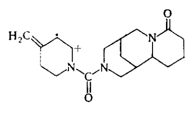
Argentine (XXXIV) belongs to a different type of dimeric cytisine alkaloids. Its mass spectrum [19,20] contains a fairly intense peak of the molecular ion and most intense peaks at 189 and 217 due to ions formed by rupture of carbon–nitrogen bonds around the central carbonyl group. Analogous breakages lead to ions with *m/e* 193 and 221, which give intense peaks in the spectrum of octahydroargentine (XXXV). [19,20] Ions at 302 and 315 are diagnostically important in the latter spectrum, for they are characteristic of the tetrahydrocytisine skeleton and are more complicated analogues of ions r and k respectively:



M⁺ (XXXV) *m/e* 414



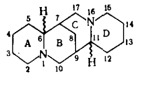
m/e 302



m/e 315

3. Sparteine Series

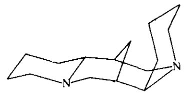
The simplest naturally occurring member of this series of alkaloids, which contains no functional group, is sparteine itself (XXXVI*a*), whose molecule is formed by two quinolizidine residues with a bridge between them



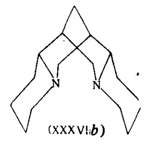
(XXXVI*a*) 6β-H, 11α-H
(XXXVI*b*) 6β-H, 11β-H
(XXXVI*c*) 6α-H, 11α-H .

Two other stereoisomers are known—α-isosparteine (XXXVI*b*) and β-isosparteine (XXXVI*c*)—as well as its *d*-enantiomer, pachycarpine (XXXVII). In principle molecular ions of these compounds break down in the same ways, although certain quantitative differences exist between the mass spectra of (XXXVI*a*) and (XXXVI*b*)[8], in particular in the ratio of the peaks of ions having *m/e* 98 and 137. The mass spectra of (XXXVI*a*) and (XXXVII) should be absolutely identical, since as optical enantiomers they have the same internal energy. Nevertheless, a difference in intensity between individual peaks (measured as percentages of the total ion current) was reported [17] between the spectra of (XXXVI*a*) and (XXXVII) obtained under the same conditions. To the Reviewers this appears strange; the attempt [17] to explain the difference by the possibility of interaction between the electric field and the molecule and by the spatial orientation of the molecule before ionisation does not stand up to criticism.

The main peaks in the mass spectra of (XXXVI*a*, *b*) and (XXXVII) [8,21] are due to the molecular, g, and p ions (the latter two with *m/e* 98 and 137 respectively); the peaks due to the ions c + 1, e, and o (84, 97, and 136) are of moderate intensity. Because of the apparent symmetry of the molecules (XXXVI*a*–*c*) it might be assumed that the ions c, c + 1, e, e − 1, g, o, and p are equally likely to be formed by rupture of bonds in ring *B* or in ring *C*, i.e. that the first five ions may contain ring *A* or *D* to equal extents, and that the last two ions may equally contain rings *A* + *B* or *C* + *D*. With sparteine (XXXVI*a*), however, in which the fusion of rings *A* and *B* is *trans*, whereas that of *C* and *D* is *cis*, only e and o ions are equally likely to contain an *A* or a *D* ring, and hence *A* + *B* or *C* + *D*, as Spiteller et al. showed [8] in experiments using a deuterium label. The ions c + 1 and g are 85–90% formed from the *A* ring, whereas p ions result from the *A* + *B* rings. The Reviewers have obtained similar results [21] from a comparison of the mass spectra of (XXXVI*a*) and its 3,3-dideutero-analogue, as well as by analysing the spectra of 13- and 14-hydroxysparteines [3,8], in which the 98 and 137 peaks have been only 85% shifted to *m/e* 114 and 153 respectively. The effect is explained by Spiteller et al. [8] firstly by the different degrees of stress in rings *B* and *C* in (XXXVI*a*) resulting from the difference in the stereochemistry of their fusion with rings *A* and *D*, and secondly by the different tendencies to migrate, resulting from the stereochemistry of the molecule, of hydrogen atoms involved in forming these rearranging ions.



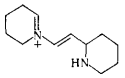
(XXXVI*a*)



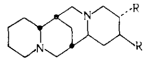
(XXXVI*b*)

The α-isosparteine molecule (XXXVI*b*), in which both *A*–*B* and *C*–*D* ring fusions are *trans*, is symmetrical, in contrast to the sparteine molecule. Therefore equally probable formation of g and p ions (*m/e* 98 and 137) may be expected from ring *A* or *D* and from *A* + *B* or *C* + *D* respectively, since in this case rings *B* and *C* are energetically equivalent. This suggestion was tested by preparing[20] the 3,4,5,6-tetradeutero-analogue of α-isosparteine, whose mass spectrum showed that the peak of the g ions was at least half displaced by 4 amu (to *m/e* 102). The p ion peak is accompanied by equally strong peaks at *m/e* 138, 139, and 140. Since the 137 ion undergoes rearrangement, and the displacement of the peak suggests that hydrogen atoms from the *A* ring are involved in its formation, it may be concluded that with α-isosparteine, in contrast to sparteine itself, the g and p ions are equally formed by charge localisation on fragments containing both *A* and *A* + *B* and *D* and *C* + *D* rings.

Analysis of the mass spectrum of the 3,3-dideutero-analogue of sparteine has shown[20,21] that formation of the ion t with *m/e* 150 is independent of the stereochemistry of *A*–*B* and *C*–*D* ring fusion and is due to the equally probable localisation of charge on fragments containing the rings *A* + *B* and *C* + *D*. The diagnostically most significant feature of the mass spectra of sparteine and its stereoisomers, enabling them to be distinguished from the isomeric matridine derivatives (see below), is the presence of fairly intense $[M - 41]^+$ ion peaks having *m/e* 193. This ion is probably formed from the molecular ion of sparteine by elimination of a cyclopropyl or an allyl radical on the rupture of bonds in rings *B* and *C*, which is supported by the mass spectra of the corresponding deutero-analogues[8,20,21]. In the view of Spiteller et al.[3] this ion has the structure x.



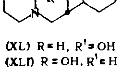
x, *m/e* 193



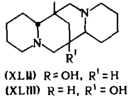
(XXXVIII) R = OH, R' = H
(XXXIX) R = H, R' = OH

The paper by these workers[3] was devoted mainly to a mass-spectrometric study of hydroxy-derivatives of sparteine. The paths along which the molecular ions of 13-hydroxysparteine (XXXVIII)[8] and its 14*e*-isomer (XXXIX)[3] decompose are analogous to those described for sparteine itself with, as already noted above, the peaks of g and p ions displaced by 16 amu owing to charge localisation on the oxygen-containing moiety. In both cases the $[M - 41]^+$ ion peaks exhibit appreciable intensity. The presence of the hydroxy-group in (XXXVIII) and (XXXIX) is shown in the spectrum of the former by the appearance of an $[M - 17]^+$ ion peak, and in that of the latter by a pair of peaks due to $[M - 17]^+$ and $[M - 18]^+$ ions.

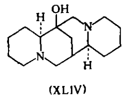
The mass spectra of 8-hydroxy- and 8-epihydroxysparteine (XL) and (XLI) differ fairly strongly from those of the preceding compounds. Thus peaks of p ions (*m/e* 137) are regularly absent, but are replaced by some of the most intense peaks of the hydroxylated analogues of p ions (*m/e* 153). The spectra also contain fairly intense peaks of o ions (136), obviously formed from these analogues by ejection of the hydroxyl radical. Among ions typical of the quinolizidine system and containing no hydroxy-group, a, e, and g are present in the spectra of (XL) and (XLI). The peaks of $[M - 41]^+$ ions have been replaced by [M – 57] ion peaks: i.e. formation of these ions involves loss of a hydroxy-group in neutral species, which provides additional conformation of the origin of the x ion (*m/e* 193) in the case of sparteine. The hydroxyl is eliminated from the molecular ions of (XL) and (XLI).



(XL) R = H, R' = OH
(XLI) R = OH, R' = H

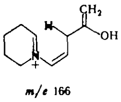


(XLII) R = OH, R' = H
(XLIII) R = H, R' = OH

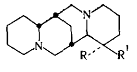


(XLIV)

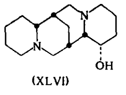
The decomposition paths of 7- and 9-hydroxysparteines (XLII) and (XLIII) and also of 7-hydroxy-β-isosparteine (XLIV) are fairly similar and somewhat recall those for (XL) and (XLI). In all cases the g ion peaks are dominant. In contrast to the preceding compounds, peaks due to o ions (*m/e* 136) are absent from (XLII)–(XLIV), but peaks appear at 166, due to ions formed by elimination of the elements of the *D* ring[3]. A peculiarity of these mass spectra is the presence of $[M - 57]^+$ together with $[M - 41]^+$ ion peaks.



m/e 166

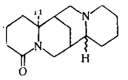


(XLV) R' = OH, R = H
(XLVa) R' = H, R = OH

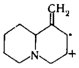


(XLVI)

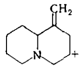
In contrast to all the above hydroxysparteines, the molecular ions of retamine (XLV), epiretamine (XLV*a*), and 12*e*-hydroxy-α-isosparteine (XLVI) are fairly easily dehydrated, with the $[M - H_2O]^+$ ion providing one of the main peaks in the spectrum of (XLV*a*). Explaining the increased intensity of the peak of the dehydration ion in the spectrum of epiretamine in comparison with that of retamine (containing respectively an equatorial and an axial hydroxyl), Spiteller et al.[3] suggest that the *D* ring in the former compound can pass into the boat form and thus ensure easier detachment of a water molecule by 1,4-diaxial elimination. The main peak in the spectra of all three compounds corresponds to the g ion, and the spectra also contain several peaks due to the decompositon of $[M - H_2O]^+$. A peculiarity of the spectra of these compounds is that the $[M - 41]^+$ have been replaced by the $[M - 43]^+$ ion peaks



(XLVII) α-H
(XLVIIa) β-H

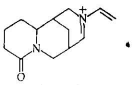


y, *m/e* 149



y + 1, *m/e* 150

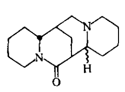
m/e 177



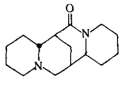
[M – 29]

In the spectra of all the oxosparteines the peaks of the molecular ions are of moderate intensity. The spectra of lupanine (XLVII)[12] and α-isolupanine (XLVII*a*)[21] are almost identical. The peaks of c + 1, e, and g ions, which retain the *D* ring, are weak; the dominating peaks are due to o ions (*m/e* 136), formed directly from the molecular ions, as indicated by the presence of the corresponding metastable peaks. The charge is localised on the fragment containing the *C* + *D* ring system. Cleavage of the *B* ring yields in both cases ions having *m/e* 149 and 150 (y and y + 1). The composition of the latter ion is supported only by a slight shift of the corresponding peak to 152 in the spectrum of the 3,3-dideutero-analogue of α-isolupanine[21]. In the range of mass numbers from *m/e* 150 to the molecular ion the spectra of both compounds contain low-intensity peaks, among which the most interesting are at 177, due to $C_{11}H_{17}N_2$ ions according to the high-resolution mass spectrum of (XLVII*a*), and also $[M - 29]^+$ ion peaks due to elimination of an ethyl radical from the *D* ring. Thus here, as with tetrahydrocytisine, the presence of a lactam carbonyl in the *A* ring does not favour charge localisation on ions containing this ring.

If the lactam carbonyl is located in the *B* ring, as in aphylline (XLVIII) and epiaphylline (XLVIII*a*)[12], the peaks of t and y ions are much less intense, while the peaks of o ions remain the most intense. The $[M - CO]^+$ ion peaks exhibit considerable intensity, and peaks appear at 191 and 192 owing to elimination of CH_3CH_2CO and CH_2CH_2CO particles from rings *B* and *C* of the molecular ions.



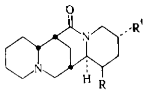
(XLVIII) α-H
(XLVIIIa) β-H



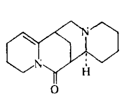
(XLIX)

In the case of 17-oxosparteine (XLIX) [12] the main peak corresponds to the e ion (*m/e* 97), and is accompanied by strongly intensified a and g peaks. The presence of a fairly intense $[M - CO]^+$ ion peak and an appreciable pair of peaks at 191 and 192 is characteristic of the spectrum of (XLIX). In contrast to lupanine, the spectra of (XLVIII), (XLVIII*a*), and (XLIX) contain y + 1 ion peaks that are considerably more intense than the y ion peaks (at 150 and 149).

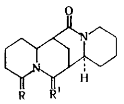
Introduction of a 14*e*-hydroxy-group into the 17-oxosparteine molecule (L) [12] hardly affects the pattern of decomposition under electron bombardment. The main peaks are still those of e and g ions, and an $[M - CO]^+$ ion peak is also observed, but ejection of the hydroxyl as a radical or a water molecule is completely absent. In the case of "17-oxoretamine" (12*a*--hydroxy-17-oxosparteine) (LI) [12] the $[M - 17]^+$, e, and g ion peaks are dominant, while peaks due to other ions are weak.



(L) R = H, R' = OH
(LI) R = OH, R' = H

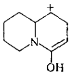


(LII)

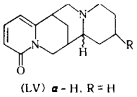


(LIII) R = O, R' = H₂
(LIV) R = H₂, R' = O

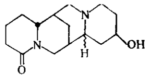
The presence of a double bond in the *A* ring of aphyllidine (LII) [12] prevents cleavage of bonds in the *B* ring, but the *C* ring opens fairly easily. The main peaks in the spectrum of (LII) are therefore due to e and g ions. In the spectrum of the dilactam—17-oxolupanine (LIII) [12]—on the other hand, the main peak is due to the t ion (*m/e* 150), which was regarded as containing *A* and *B* rings. The same peak predominates also in the spectrum of 10,17-dioxosparteine (LIV) [12], but is accompanied by an intense peak at 152, possibly due to an ion having the structure **z**.



z, *m/e* 152

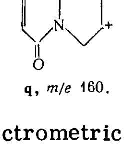


(LV) α-H, R = H
(LV*a*) β-H, R = H
(LVI) R = OH



(LVII)

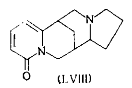
Two naturally occurring stereoisomers—anagyrine (LV) and *d*-thermopsine (LV*a*)—are sparteine alkaloids containing an aromatic ring *A*. Their mass spectra differ little [8,20,21], although peaks of individual ions may vary slightly in relative intensity. The strongest peaks in both spectra are due to g ions (*m/e* 98); they also contain peaks of o ions containing the *C* + *D* ring system, v ions, and q ions (*m/e* 136, 146, and 160 respectively).



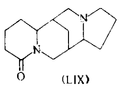
q, *m/e* 160.

Analysis of mass-spectrometric results proved that the alkaloid argentamine (LVI) [22] was a hydroxy-derivative of thermopsine. Its spectrum contained an intense peak of the molecular ion with *m/e* 260 which exceeds the molecular weight of anagyrine (LV) and *d*-thermopsine (LV*a*) by 16 amu, although the breakdown of molecular ions of all three compounds follows closely similar routes. Only the peaks of ions that in the cases of (LV) and (LV*a*) definitely contain the *D* ring move up by 16 amu on passing to the compound (LVI). Thus the peaks of g and o are displaced to *m/e* 114 and 152 respectively, whereas the peaks of v and q ions, which do not contain the *D* ring, remain fixed.

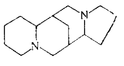
A similar situation is found on comparing the mass spectra of tetrahydroargentamine (LVII) and lupanine (XLVII) or α-isolupanine (XLVII*a*). The most intense peaks in the spectra of the latter two compounds—of o and y ions, containing *C* and *D* rings—are completely displaced by 16 amu to *m/e* 152 and 165 respectively on passing to (LVII). These results prove that the alkaloids (LVI) contains a hydroxy-group in the *D* ring, whose position at $C_{(13)}$ follows from the complete identity of the mass spectra of deoxytetrahydroargentamine and 13-hydroxysparteine (XXXVIII). [8]



(LVIII)

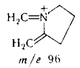


(LIX)



(LX)

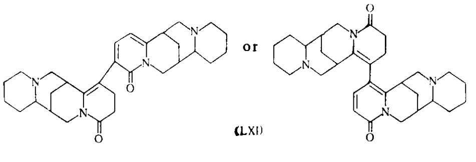
m/e 84



m/e 96

m/e 70

Interesting work was undertaken by Yunusov et al. [23] on the mass spectra of leontidine (LVIII) and its tetrahydro- and deoxytetrahydro-derivatives (LIX) and (LX), which contain a five-membered instead of a six-membered *D* ring. In the spectrum of (LVIII) the ions containing *A* and *B* rings (v and q) have the same mass numbers as in the spectrum of anagyrine (LV), whereas ions of types a and g, containing a five-membered ring, have *m/e* 96 and 84 respectively, with the latter the maximum peak in the spectrum (as with anagyrine, when it has *m/e* 98). A similar situation obtained in the spectrum of (LIX), in which the peak of the t ion (*m/e* 150) was accompanied by a peak at 136 corresponding to an analogue of the y + 1 ion with a five-membered ring. In the spectrum of deoxytetrahydroleontidine (LX) the ions with *m/e* 84, 98, and 137, containing *A* and *B* rings, correspond to c + 1, g, and p ions, whereas the ions at 96 and 70 are analogues of a and c + 1 ions resulting from a five-membered *D* ring.



(LXI)

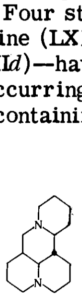
In concluding this subsection we must mention results[24] for the mass spectrum of the dimeric sparteine alkaloid diteramine (LXI), which contains a small peak of the molecular ion, a peak of an ion corresponding to the molecular ion of thermopsine with *m/e* 244, and also peaks of v and q ions. The g ion peak is the maximum, which is typical of the spectra of thermopsine and anagyrine.

4. Matrine Series.

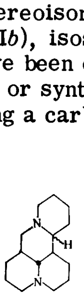
Alkaloids of this type differ from the sparteine series in the mode of fusion of the two quinolizidine systems. Unsubstituted matrine alkaloids have not yet been discovered in Nature, in contrast to the situation in the sparteine series. Isomers of sparteine in the matrine series have been obtained only artificially, by reducing carbonyl-containing compounds. Because of the special mode of fusion of the quinolizidine residues, a larger number of stereoisomers can be expected in the matrine than in the sparteine series. Four stereoisomers—matridine (LXIIa), allomatridine (LXIIb), isosophoridane (LXIIc), and sophoridane (LXIId)—have been obtained from the corresponding naturally occurring or synthetic compounds of the matrine series containing a carbonyl group in the *D* ring.

(LXIIa)

(LXIIb)

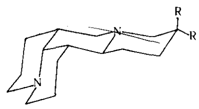


(LXIIc)

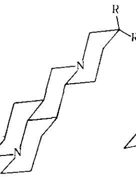


(LXIId)

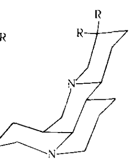
The main peaks in the mass spectra of these compounds[25] are due to c + 1, e, e − 1, g, o, and p ions. From their structures it could be supposed that these ions would be formed most efficiently by the rupture of bonds in the *C* ring. The ions p and o (*m/e* 137 and 136) would then contain the *A* + *B* ring system, the c + 1 ion (84) the *D* ring, and the e, e − 1, and g ions (97, 96, and 98) the *D* ring and the $C_{(17)}$ atom. However, incomplete data for the mass spectrum of the 15,15-dideutero-analogue of matridine[26] indicate that the *D* ring is almost completely absent from g ions, which are therefore formed by the rupture of at least three bonds in rings *A* (or *B*) and *C*. This result seemed to the Reviewers unexpected and requiring further refinement. A mass-spectrometric investigation was therefore undertaken on the 14,14-dideutero-analogues both of matridine itself (LXIIa) and of its stereoisomers (LXIIb, *c*).[25] This revealed the clear influence of the stereochemistry of these compounds on their mode of breakdown under electron bombardment.



(LXIIa) R = H
14,14-D2-matridine, R = D



(LXIIb) R = H
14,14-D2-allomatridine, R = D



(LXIIc) R = H
14,14-D2-isosophoridane, R = D

The mass spectra of the unlabelled compounds (LXIIa–*d*) are qualitatively similar, but quantitatively allomatridine (LXIIb) resembles sophoridane (LXIId), while matridine (LXIIa) resembles isosophoridane (LXIIc). The most noticeable feature of the spectra of the first two stereoisomers is predominance of peaks due to the molecular ions, whereas the peaks of the p ion (*m/e* 137) are dominant in the spectra of the second pair. The great stability of molecular ions of (LXIIb) and (LXIId) may obviously be due to the predominantly *trans*-fusion of rings in their tetracyclic system: in the former all the rings are *trans*-fused, and in the latter *A*–*B*, *A*–*C*, and *B*–*C trans*-fusion can be regarded as proved, while the type of fusion of rings *C* and *D* has not been finally proved[27,28]. Matridine (LXIIa) and isosophoridane (XLIIc), however, each contain two energetically less favourable *cis*-fused systems.

There are also other quantitative differences in the mass spectra of these stereoisomers, which cannot yet be explained owing to the absence of additional data on the elementary composition of the ions, the mechanisms of their formation, and the energetics of the molecules.

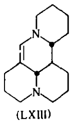
Comparison of the mass spectra of the 14,14-dideutero-analogues of matridine, allomatridine, and isosophoridane with those of the unlabelled alkaloids showed[25] that such characteristic peaks as those due to ions having *m/e* 151, 150 (y + 1), 137 (p), 136 (o), and 96 (e − 1) are not displaced by the introduction of the deuterium label at position 14: i.e. with these compounds the ions result from localisation of charge on the 1-nitrogen atom and do not contain the *D* ring. Yet the peaks of ions with *m/e* 98 and 84 (g and c + 1) differ in structure depending on the stereochemistry of the compound.

The peaks of g ions from matridine and isosophoridane are only ~24% and ~27% respectively due to ions containing the *D* ring, the majority of these ions resulting from localisation of charge on the 1-nitrogen atom and containing an *A* or *B* ring. Consequently, different mechanisms of formation of g ions can be assumed for these compounds, each involving the rupture of at least three carbon–carbon bonds. In the absence of the spectra of deuterated analogues labelled in either ring *A*, *B*, or *C*, however, it is difficult to make any definite statement. In the decomposition of allomatridine, in contrast to the above two compounds, the g ion is formed predominantly (~80%) by charge localisation on the 16-nitrogen atom and contains the *D* ring. In this case the mechanism of formation evidently involves cleavage of the $C_{(7)}$–$C_{(11)}$ and $C_{(5)}$–$C_{(17)}$ bonds with migration of a hydrogen atom to the charged particle.

The above differences in the breakdown paths of the stereoisomers of matridine can obviously be attributed to the fact that in (LXIIb) all ring fusions are *trans*, whereas in (LXIIa) the *A*–*C* and *B*–*C* fusions are *cis*, as are the *A*–*B* and *A*–*C* fusions in (LXIIc). A primary consequence may be the facilitation of bond fission in the *A*, *B*, and *C* rings of molecular ions of the latter two compounds, whereas in the first compound the bonds are equally strong in all rings, so that here the most advantageous process occurs, involving the rupture of two bonds in the *C* ring. It must also be borne in mind that the g ion can undergo rearrangement, so that its ease of formation may be influenced not only by the energy factor but also by the distance between the centres of migration.

The stereochemistry of the tetracyclic skeleton of compounds (LXIIa–*d*) influences also the decomposition routes leading to formation of the rearranging c + 1 ions. The mass spectra of the 14,14-dideuterated analogues of allomatridine and isosophoridane contain corresponding peaks displaced by 2 amu and to some extent by 1 amu: i.e. with these compounds the c + 1 ion contains predominantly the *D* ring. In the spectrum of 14,14-dideutero-matridine, however, the 1-amu displacement of the peak of this ion is only slight.

It is noteworthy that the c + 1, e, e − 1, and g ions are almost completely absent from the spectrum of 5,17-dehydroallomatridine (LXIII),[20] but an intense peak of an ion having *m/e* 95 appears.

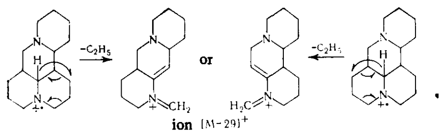


(LXIII)

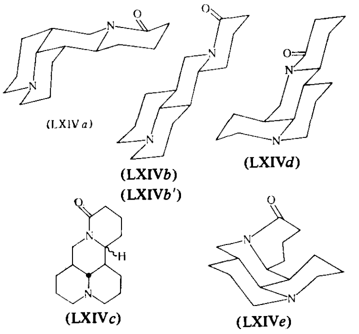
m/e 95

The mass spectra of (LXIIa) and (LXIIc) contain fairly intense ion peaks at 162, which are only small in the case of stereoisomers of sparteine. However, an ion with *m/e* 162 can hardly be diagnostically significant, since the intensity of its peak is also small in the spectrum of (LXII*b*). It is difficult to judge the origin of this ion; we know only that it contains neither the $C_{(14)}$ [26] nor the $C_{(15)}$ [25] atom, and has the composition $C_{11}H_{16}N$ according to the high-resolution mass spectrum of (LXII*c*).[21]

The spectra of (LXII*a–d*) contain also weak peaks of $[M - 43]^+$ and $[M - 29]^+$ ions but, in contrast to those of sparteine stereoisomers, no $[M - 41]$ peaks. It is supposed[21,29] that the $[M - 43]^+$ ion is formed by elimination of a propyl radical or an aziridine molecule. Formation of the $[M - 29]^+$ ion, however, is regarded as involving elimination of an ethyl radical from the *A* or *B* ring, but not from *D*, which is supported by the mass spectra of the 14,14-dideutero-analogues of the stereoisomers (LXII*a–c*) [25]:



Derivatives of (LXII*a–d*) containing a lactam carbonyl in the *D* ring are often encountered in Nature. Most thorough studies have been made of the mass spectra of matrine (LXIV*a*) [20,21,30], leontine (LXIV*b*) [31], sophoridine (LXIV*c*), the synthetic enantiomer of leontine—allomatrine (LXIV*b′*) and isosophoridine (LXIV*d*).[20,21,30]. Data have appeared[32] on the mass spectrum of darvasamine (LXIV*e*), which was regarded as the first naturally occurring *cis*-*A*–*B* stereoisomer of matrine.

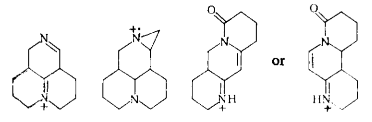


(LXIV*a*)
(LXIV*b*)
(LXIV*b′*)
(LXIV*d*)
(LXIV*c*)
(LXIV*e*)

The most characteristic feature of the mass spectra of these compounds in comparison with those of their isomers in the sparteine series (lupanine and *α*-isolupanine) comprises the exceptionally intense peaks of molecular and $[M - 1]^+$ ions, the former being rather higher in the case of matrine (LXIV*a*), with the opposite relation in the spectra of the other stereoisomers. Formation of the $[M - 1]^+$ ion is assumed to involve elimination of the 6-hydrogen atom. This may well be so, since the majority of $[M - 1]^+$ ions from quinolizidine itself (I) are formed by ejection of the hydrogen atom from the angular position 10 (Section II).[5] An attempt to relate the stability of the polycyclic system solely with the intensity of the molecular ion peaks was unsuccessful, since all these compounds (LXIV*a–d*) exhibited similar intensities of these ions measured as percentages of the total ion current[31]. Nevertheless, the sum of the intensities of molecular and $[M - 1]^+$ ion peaks was greatest with leontine (LXIV*b*), in agreement with the least stress in the completely *trans*-fused tetracyclic system. Matrine exhibits the lowest sum of the peak intensities of these ions.

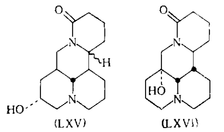
Among ions representing the quinolizidine system formed by rings *A* and *B* in the molecules (LXIV*a–d*) the peaks due to **c**, **c** + 1, **e**, and **g** are lower in their spectra than in those of oxygen-free derivatives in the cytisine, sparteine, and matridine series. In the case of compounds (LXIV*a–d*) these ions in fact result exclusively from rings *A* and *B*, which is confirmed by the unchanged position of their peaks when a deuterium label is introduced into the *D* ring.[20,21] The peaks of o and p ions are moderately intense. The presence of the corresponding metastable peak in the spectrum of matrine indicates that in this case the o ion may be formed directly from the molecular ion[20,21].

In contrast to the corresponding isomers in the sparteine series, spectra of the stereoisomers (LXIV*a–d*) contain, in the range from *m/e* 150 to the molecular ion, fairly intense peaks due mainly to cleavage of bonds in the *D* ring. The high-resolution mass spectrum of (LXIV*a*) indicated[20,21] that the ion with *m/e* 161 had the composition $C_{10}H_{11}NO$, whereas the 162 ion was due to $C_{10}H_{12}NO$ and $C_{11}H_{16}N$ ions in the proportion 55 : 45. An appreciable peak at 177, most characteristic in the spectrum of allomatrine, was due to the $C_{11}H_{17}N_2$ ion formed by elimination of the *D* ring. Elimination of part of the latter from (LXIV*a–d*) as C_3H_4O gave a comparatively stable $C_{12}H_{20}N_2$ radical-ion with *m/e* 192.[20,21,26]



m/e 177
m/e 192
m/e 205

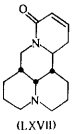
It was shown by deuterium labelling[20,21] that a propyl radical could be eliminated from ring *A* or *B*, to give an ion with *m/e* 205. It is interesting that, in contrast to oxygen-free derivatives of the sparteine and matridine series, the $[M - 29]^+$ ion peak of (LXIV*a–d*) is due to $C_{13}H_{19}N_2O$ and $C_{14}H_{23}N_3$ ions[20,21], which have therefore been formed by elimination of an ethyl radical and of (CO + H) respectively.



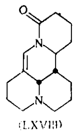
(LXV)
(LXVI)

The structure of the alkaloid 3*α*-hydroxysophoridine (LXV) was established from the rules of the breakdown of molecular ions of matrine and sophoridine[13]. The presence of the hydroxy-group in (LXV) and also in sophoranol (5*α*-hydroxymatrine) (LXVI) [20,21] is the reason for the appearance of $[M - 17]^+$ ion peaks in their mass spectra, these being the highest in that of (LXVI). The majority of peaks in this spectrum arise directly from the molecular ion, so that peaks typical of matrine (LXIV*a*) are displaced by 16 amu to larger masses, since most of these ions include *A* and *B* rings. For example, the e − 1 peak (*m/e* 96) is accompanied in the spectrum of (LXVI) by an ion peak at 112. The origin of these peaks was confirmed by analysing the mass spectrum of 6,7-dideuterosophoranol.[20,21]

Breakdown of the molecular ion of sophocarpine—13,14-dehydromatrine (LXVII) [26,30]—follows the same routes as that of matrine. Ions containing the *A–C* ring system have the same mass numbers in the two cases, whereas ions resulting from cleavage of ring *A* or *B* are 2 amu lighter from the former compound. This applies e.g. to the $[M-29]^+$ and $[M-43]^+$ ions, produced by elimination of an ethyl or a propyl radical from ring *A* or *B*.



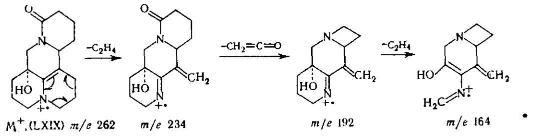
(LXVII)



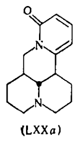
(LXVIII)

The presence of a double bond in ring *C*, as in leontalbine—5,17-dehydromatrine (LXVIII)—inhibits processes involving cleavage of this ring[26]. At the same time ring *D* may be eliminated either entirely with formation of an ion having *m/e* 175 (a dehydro-analogue of the 177 ion in the case of matrine) or partly to give the $[M - C_3H_4O]^+$ ion. The $[M-29]^+$ and $[M-43]^+$ ion peaks in the spectrum of matrine have been replaced in that of leontalbine (LXVIII) by peaks due to $[M-28]^+$ and $[M-42]^+$ ions.

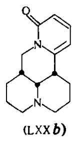
In contrast to sophoranol (LXVI), the intensity of the $[M-17]^+$ peak drops sharply in the spectrum of 6,7-dehydro-5-hydroxymatrine (LXIX) [20,21], and the molecular-ion peak is accompanied by an equal peak of the $[M-1]^+$ ion. The $[M-28]$ peak (*m/e* 234) is much more intense in the spectrum of (LXIX), but weak in all the above spectra of matrine alkaloids. Its considerable intensity is most likely due to the possibility of a retrodiene type of decomposition in ring *B*:



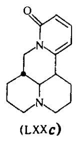
Further decomposition of the 234 ion involves either elimination of a hydroxyl radical to form a 217 ion, whose peak is among the most intense in the spectrum, or elimination of a keten molecule to give a 192 ion, which then undergoes a retrodiene breakdown with elimination of an ethylene molecule and formation of an ion with *m/e* 164. A keten molecule is eliminated also from the 217 ion, to give a 175 ion.



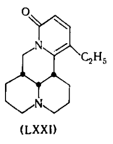
(LXX*a*)



(LXX*b*)



(LXX*c*)

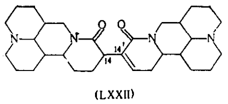


(LXXI)

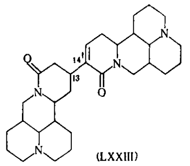
Aromatisation of the *D* ring in matrine alkaloids increases still further the difference between their mass spectra and those of the corresponding derivatives in the sparteine series (see above). As with the stereoisomers of matrine, peaks due to molecular and $[M-1]^+$ ions exhibit great (sometimes maximum) intensity in the spectra of isosophoramine (LXX*a*) [20,21,30], sophoramine (LXX*b*) [20,30], neosophoramine (LXX*c*) [33], and 12-ethylsophoramine (LXXI) [20], whereas peaks due to g ions (*m/e* 98) containing the *D* ring dominate the spectra of the corresponding sparteine derivatives (above). It is interesting that the change in the relative intensities of molecular and $[M-1]^+$ ion peaks on passing from isosophoramine (LXX*a*) to sophoramine (LXX*b*) is analogous to the change on passing from allomatrine to matrine (above). This is obviously connected with the analogy in the stereochemistry of the fusion of rings *A*, *B*, and *C* in these two pairs of compounds. The intensities of peaks due to g ions are very weak in the spectra of (LXX*a*–*c*) and (LXXI), since their formation from ring *A* or *B* requires the rupture of more than two bonds, which is obviously disadvantageous. One of the most intense peaks in the spectra of (LXX*b*), (LXX*c*)†, and (LXXI) is that of the o ion (*m/e* 136), while the peaks at 146 and 160 (v and q) typical of the spectra of anagyrine and *d*-thermopsine (above), are small and shift by 28 amu to *m/e* 174 and 188 on passing to (LXXI).

The stereochemistry of the molecules (LXX*a*–*c*) has a fairly significant quantitative influence on their spectra. Thus (LXX*a*) is characterised by high intensity of the y ion peak (*m/e* 149), while that of the o peak drops sharply. The opposite pattern is found for the spectra of (LXX*b*) and (LXX*c*), however, and with the latter compound all peaks are weak other than those of molecular, $[M-1]^+$, and o ions. According to the high-resolution mass spectrum of (LXX*a*) the not very intense peaks (around 15–25% of the maximum) of $[M-29]^+$ ions with *m/e* 215, present in the spectra of all three isomers, represent the compositions $C_{13}H_{15}N_2O$ and $C_{14}H_{19}N_2$. Hence they are formed by elimination either of an ethyl radical or of a carbonyl group together with a hydrogen atom[20,21].

The mass spectra of goebeline—the naturally occurring dimeric matrine alkaloid—and its dihydro-derivative have been given[34] to establish their structure, but with no unambiguous evidence for the suggested site (14,14′) of linking of the two moieties (LXXII). We can accept that the goebeline molecule comprises residues of matrine and sophocarpine or their stereoisomers. The mass spectrum of goebeline contains a peak due to the molecular ion together with a pair of peaks corresponding to the molecular and $[M-1]^+$ ions of sophocarpine, though the remainder of the spectrum below this pair differs quite strongly from the spectrum of sophocarpine with respect to the intensities of the peaks.

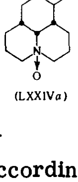


(LXXII)

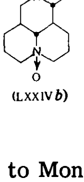


(LXXIII)

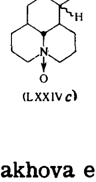
The mass spectrum of deuterated goebeline, obtained by exchange with deuteroethanol in the presence of sodium deuteroxide in oxolan, indicates the predominant incorporation of four deuterium atoms[20]. This excludes the possibility of 14,14′-linking of matrine and sophocarpine residues, since the same method of deuteration introduces two and three deuterium atoms into the former and into the latter respectively, whereas only three deuterium atoms should enter with 14,14′-linking. The Reviewers regard 13,14′-linking of matrine and sophocarpine residues (LXXIII) as most probable, although this question is by no means finally settled.



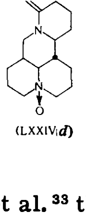
(LXXIV*a*)



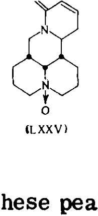
(LXXIV*b*)



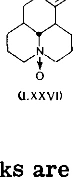
(LXXIV*c*)



(LXXIV*d*)



(LXXV)



(LXXVI)

---

† According to Monakhova et al.[33] these peaks are maxima in the spectra of (LXX*b*) and (LXX*c*), which for the former compound is inconsistent with other results[20].

In conclusion we must consider briefly a mass-spectrometric study of *N*-oxides of matrine (LXXIV*a*), allomatrine (LXXIV*b*), sophoridine (LXXIV*c*), isosophoridine (LXXIV*d*), sophocarpine (LXXV), and isosophoramine (LXXVI).[35] Their mass spectra usually contain weak peaks of the molecular ions. The $[M-16]^+$ and $[M-17]^+$ peaks are considerably more intense, and sometimes the main peaks in the spectra. The first peak in this pair is due to elimination of an oxygen atom, whereas the second peak may be due to various processes—further loss of a hydrogen atom from the $[M-16]$ ion, single-stage ejection of the *N*-oxide oxygen and a hydroxyl hydrogen atom, or elimination of an oxygen atom from the $[M-1]^+$ ion. Comparison of the ratios $I[M-17]^+/I[M-16]^+$ in the spectra of the *N*-oxides and $I[M-1]^+/I[M]^+$ in those of the corresponding unoxidised alkaloids indicates that the first of these paths is insignificant. Yet the presence of the corresponding metastable peaks in the spectra of the *N*-oxides is evidence that $[M-17]^+$ ions are formed at least partly by elimination of a hydroxyl radical from the molecular ions in a single stage. The hydrogen atom present in this radical has been eliminated from a different position from that from which the hydrogen atom is eliminated from the unoxidised alkaloids to form the $[M-1]^+$ ions.

The majority of ions produced by electron bombardment of the *N*-oxides are formed directly from $[M-17]^+$ ion. The mass spectra of the stereoisomeric *N*-oxides [LXXIV*a*–*d*) differ quantitatively among themselves mainly in the relative intensities of the $[M-16]^+$, $[M-17]^+$, $[M-18]^+$, and $[M-19]^+$ ion peaks, as well as of the peaks having m/e 148 and 150. In general the spectra of the *N*-oxides in the range of mass numbers below the $[M-17]$ peaks resemble those of the corresponding unoxidised alkaloids, but the peaks of ions characteristic of the latter are often accompanied by peaks 1 amu lower, which proves that they are due to ions containing rings *A* and *B*.

Thus all the results surveyed above provide convincing evidence that mass spectrometry can be used to assign quinolizidine alkaloids to a particular series, to determine the nature and the position of functional groups, to establish the structure of new alkaloids of this class, and in some cases also to elucidate the stereochemistry of ring fusion.

While the manuscript was being prepared for the press a more detailed study appeared[36] of the fragmentation of deoxynupharidine (XVI) and related alkaloids involving the use of high-resolution mass spectra and deuterated analogues.

Problems in Investigation of the Aroma of Foodstuffs and the Production of Imitations

R.V.Golovnya

General principles of the investigation of volatile components of foodstuffs are discussed, as well as the state of the problem of flavoured food additives. Aspects of the conferment of taste and odour on new types of food are considered. A list of 82 references is included.

CONTENTS

I. INTRODUCTION

In the majority of developed countries industrial methods for the production of food products are continually being intensified. The consequent acceleration of technical processes for the manufacture of various types of nutritional products frequently results in loss of flavour. The insufficiency of full-value protein in feeding the population (the annual world protein deficit exceeds three million tonnes[1]) has made it necessary to obtain by industrial methods new types of food based on protein concentrates, and both taste and odour must be entirely created for these products.

II. DEVELOPMENT OF THE PRODUCTION OF FOOD ADDITIVES AND FLAVOURINGS

Table 1 demonstrates the consumption of protein concentrates in the manufacture of various food products in the USA based on statistics for 1972.[2] During 1969 protein concentrates were added in almost all categories of products, especially in the manufacture of conserved meats and intermediate products. It is predicted that by 1980 a new artificial product—a milk substitute—will have appeared, and it is planned to consume another 188 million lb of protein concentrates for this purpose. A total of about a million tons of protein additives will be used in the USA foodstuffs industry in 1980. According to forecasts made in 1971 by a long-term planning service, the 1985 production of meat and poultry substitutes and of milk products in Western Europe will be respectively 2.8 and ~3.5 million tonnes[3].

Loss of flavour in food manufacture and the necessity of obtaining products from protein concentrates are the chief reasons for the sharp increase in the demand for flavourings and flavour and odour intensifiers. Demand doubled during the decade from 1955 to 1966, and continues to grow. Even the term "flavour renaissance" has now appeared (the complex of tactile, gustatory, and olfactory sensations caused by foods is denoted by the word *flavour*).

Aromatising and flavouring additives constitute 15–20% of the total cost of a foodstuff from a protein concentrate[2,4]. A vivid example of the economic advantage of the development of scientific and applied research, as well as the production of flavourings and taste and odour intensifiers, is provided by returns (Table 2) for 1971 and the forecasts for 1980 made by the American firm Frost and Sullivan Inc.[4]

Table 1. Growth of consumption of protein concentrates in the manufacture of various foodstuffs in the USA.

Product category	Planned annual increase, %	Protein additions, 10^6 lb	
		1969	1980
Baby foods	1.0	3.5	3.9
Bread and bakery products	7.5	101.0	126.1
Convenience meals	9.7	17.9	36.0
Confectionery	3.0	16.6	23.0
Cooked meats and semimanufactures	19.3	92.2	642.4
Coffee whiteners	6.0	12.0	22.8
Milk substitutes	—	—	188.2
Synthetic ice cream	5.0	3.8	6.5
Other types of milk products	1.0	98.1	109.1
Desserts	6.0	31.7	60.0
Dietetic products	2.0	8.7	105.0
Frozen foods	3.6	3.8	5.6
Macaroni and pasta products	3.0	1.5	2.1
Animal fodder	5.4	229.3	426.0
Soups	0.0	1.5	1.5
Other uses	9.3	207.3	555.0
Total quantity		828.6	$2218.5 \simeq 10^6$ tons

Table 2. Income from use of food additives (millions of dollars).

Year	Food additives	
	total	flavourings and taste intensifiers
1971	635.97	254.00
1975	804.19	326.90
1980	1108.81	476.40

Since 1958 the Flavoring Extract Manufacturers Association (FEMA) has conducted a programme aimed at establishing a statute on flavourings. All known natural and synthetic compounds employed in the food industry up to 1958 have been tested for toxicity, pharmacological effect, and metabolism in the organism both of the substance itself and of its derivatives, in six academic institutions independent of industry. A list of GRAS substances ("generally recognised as safe") has been published systematically; it includes 1121 natural and synthetic compounds, with the permissible dosage for each category of foodstuffs (drinks, ice cream, confectionery, bread and bakery products, jellies, puddings, meat, sauces, soups, milk products, pickles, seasonings, etc.)[5,6]. The number of compounds used in the food industry before 1958 that failed the test was 267, including some natural substances[7]. Of the 1121 GRAS substances 859 are used in the food industry (at a maximum dosage of 10 ppm—by volume or by weight) to flavour the foodstuff. The list of GRAS substances is extended systematically and published annually.

The modern flavourings industry is based on substances detected in the odour of natural foodstuffs, in contrast to the earlier period, when restrictions were imposed by similarity of odour and inferred toxicity. The new approach has led in several cases to qualitatively new types of imitations, indistinguishable from the natural products, since they include the key substances responsible for the odour of the latter. For example, ethyl *αβ*-epoxy-*α*-methyl-*β*-phenylpropionate has the odour of strawberries[8], 4-*p*-hydroxyphenylbutan-2-one that of raspberries[9,10], allyl phenoxyacetate pineapple[11], 2-isobutyl-3-methoxypyrazine pepper[12-14], and diallyl trisulphide garlic[15]; this last compound also possesses bactericidal properties.

III. ISOLATION AND ANALYSIS OF ODOUR COMPONENTS

Substantial difficulties arise in the investigation of the odour of natural foodstuffs. Man is able to distinguish up to 17 000 odours[16]. Since a theory of olfaction is lacking, aroma cannot be predicted from the physical and chemical properties of the molecule. The minuteness of the content of odour condensate in a specimen is responsible for the difficulties in investigating flavour. But according to Weurman the amounts of odour condensate associated with 1 kg of meat, strawberries, and bread are respectively 35, 2–8, and 8–10 mg.[17,18] The number of different substances in an odour condensate is immense—several hundreds of components belonging to various classes of organic compounds—which in practice always include acids, alcohols, esters, sulphur-containing compounds, amines, ketones, aldehydes, lactones, phenols, hydrocarbons, etc. with a wide range of boiling points, from gases to compounds boiling at 300°C.

The substances determining the character of the odour often have low threshold concentrations—of the order of 10^{-12}–10^{-14} part per unit volume or weight—undetectable by present-day analytical apparatus. The odour threshold for 2-isobutyl-3-methoxypyrazine is 10^{-12}.[14] Clearly, therefore, it is necessary to concentrate the odour in order to study it[19-21].

It must be emphasised also that analytical instruments are like a biological detector—man's olfactory organ—in being unable to estimate the quantity of odour in a complex. Moreover, there is no correlation between the sensory sensitivity of man to individual components and the sensitivity of an analytical instrument. For example, the gas chromatograph is more sensitive to acetone, whereas to vanillin the nose is more sensitive than this instrument by several powers of ten[22] (Table 3).

Table 3. Comparison between the sensitivity of the human nose and that of a chromatograph with a flame-ionisation detector[22].

Compound (in aq. soln.)*	B.p., [°C]	Limit of detection, ppm	
		chromatograph	nose
Propanal	61	0.0025	0.17
Butanal	75.7	0.12	0.07
Hexanal	131	0.3	0.03
Acetone	56	0.3	500
Methanethiol	7.6	0.013	0.002
Methyl salicylate	222	**	$0.1 \cdot 10$
Vanillin	285	**	$0.1 \cdot 10^{-9}$

---

* Analysis made on 10 ml of saturated vapour above the solution.

** Undetectable.

The investigation of odour involves mostly study of the composition of volatile components in the vapours above a foodstuff, actually in condensates of these vapours. In the scientific literature the special term "head-space analysis" has become attached to such an approach[23]. The quantity of a substance in the vapour above a food is not equivalent to its actual content in the latter. The vapour pressure P_{ia} of a substance i in the gas phase over a foodstuff is given by the formula[23]

$$P_{ia} = \gamma_i X_i P_i, \qquad (1)$$

where P_i is the saturated vapour pressure of pure i at the same temperature, X_i the mole fraction of i in the foodstuff, and γ_i its activity coefficient at this concentration.

At a constant mole fraction X_i the value of γ_i may vary by several powers of ten depending on the nature of the substance and of the medium in which it is situated[24]. In the aqueous phase of a foodstuff, for example, the activity coefficient may depend on the concentration of metal salts, their capacity for complex formation with the test substance, and also the pH. The proportions of components in the vapour over a product varies with the content of water, lipids, proteins, and other ingredients of the sample. Furthermore, several substances are present in a foodstuff in a combined state, as "precursors" from which they pass into the gas phase as a result of enzymatic or chemical reactions. Therefore samples of the same foodstuff prepared at different times from different batches of raw material may exhibit both qualitative and quantitative differences in the volatile components of the odour concentrate.

Equation (1) is valid under equilibrium conditions. On prolonged collection of volatile components the rate of diffusion from the specimen to the gas phase changes, which may distort the proportions of volatiles in the condensate in comparison with the gas phase above the specimen. For this reason volatiles are collected above the specimen only as long as the latter retains its full flavour, and the condensate has the same odour.

The influence of the above factors on the process of concentrating the aromatic components makes it almost impossible to obtain quantitative data on the total composition of odour components in a test product. However, analysis of the odour condensate enables the substances involved in forming the flavour to be studied, and their proportions in the composition to be determined. Gas-chromatographic and organoleptic investigations enable "key" components of the odour to be detected and identified. More than 2500 compounds have now been identified in the odour of various foodstuffs[25], the number increasing every year.

Separation and *identification* are necessary stages in the investigation of an odour concentrate. Gas–liquid chromatography is the only method suitable for the separation of multicomponent mixtures of volatiles of unknown composition. The detection of individual compounds and their identification can be accomplished gas-chromatographically, mass-spectrometrically, and by infrared and nuclear magnetic resonance spectroscopy. The last two methods are generally employed when components can be isolated and accumulated by preparative chromatography. Difficulties are aggravated by the fact that the majority of flavour-forming substances studied have odour thresholds in the range 10–100 pg.[23] Hence there is hardly a single present-day analytical method that can ensure reliable determination of all the organic compounds in the volatile components of natural mixtures. The absence of direct methods of analysis of the required sensitivity makes the stages of extraction and concentration of the odour components especially important. A critical approach is required to the choice of method for these stages, for treating the odour concentrate right until the specimen to be analysed is introduced into the chromatograph. Every stage requires maximum protection of the mixture from contamination and possible loss of components, with especially careful purification of solvents. Sources of error in obtaining a sample for analysis have been discussed[26]. It must also be borne in mind that if the whole of the odour concentrate undergoes gas-chromatographic analysis, it is difficult to exclude artefacts and the formation of new substances by the interaction of reactive compounds directly in the gas-chromatographic column, or even in the vaporiser under the influence of the temperature, the material of the column, and its adsorbent.

Inspection of published information has shown that special gas-chromatographic methods of identification are required for the examination of complicated natural flavouring mixtures. It is impossible to prepare a gas-chromatographic column capable of separating simultaneously diverse classes of organic compounds. Furthermore, identification by means of standard substances, in the study of mixtures containing up to 400 or more components, presents considerable difficulties, even with the use of mass-spectrometric detection.

An odour concentrate can be investigated in two ways: it can be either chromatographed as a whole or first divided into different classes of organic compounds, which are chromatographed separately. In order to diminish the artefacts and to utilise most fully the specific donor–acceptor interactions between the test substance and the adsorbent in the gas-chromatographic column it is more advisable to separate complicated odour compositions into individual classes of organic compounds having the same type of functional groups. Methods of gas-chromatrographic identification using a set of columns of differing polarity are found for each class of organic compounds[27–43].

In the separation and analysis of multicomponent mixtures the reproducibility of the gas-chromatographic results over a long period of time, which is necessary in the study of different specimens of a test material, becomes especially important. Experience of analysing the odour of natural foodstuffs has permitted comparison of the reproducibility of different gas-chromatographic characteristics[27]. The most convenient and reproducible gas-chromatographic parameter—the Kovats index—has been selected and recommended, and a theoretical justification provided for the use of an ideal series of n-alkanes in its calculation[27]. In the analysis of multicomponent mixtures it is almost impossible to place every test substance between two n-alkanes, as the Kovats formula requires[44]. I therefore propose to calculate the indices on the basis of an "ideal" series of n-alkanes constructed from three or four experimental values of the logarithms of corrected retention volumes of n-alkanes containing $n \geqslant 6$ carbon atoms, i.e. to find the coefficients in the linear equation

$$\lg V'_n = a + bn. \tag{2}$$

The legitimacy of employing an "ideal" series of straight-chain hydrocarbons for the calculation of Kovats indices was examined separately on the basis of experimental data in McReynolds' tables[45] on the retention of n-alkanes by 13 stationary phases. The accuracy of Eqn. (2) and of known non-linear equations[46,47] describing the gas-chromatographic behaviour of n-alkanes was estimated statistically on an electronic computer. It was shown that the linear approximation (2) provided quite satisfactory accuracy (0.8%) abd could be used in gas-liquid chromatography for identification purposes and for the calculation of thermodynamic functions from retention indices. Use of an "ideal" series of n-alkanes simplifies the calculation and makes the system of retention indices extremely convenient for the study of natural mixtures. It was shown also that the time required for analysis could be shortened by the use of an arithmetic retention index, which was converted by means of the "ideal" series of n-alkanes into the Kovats index[48] in order to obtain more information on the structure of the compound.

Natural mixtures can be investigated by gas chromatography either under isothermal conditions or with temperature programming. The most accurate gas-chromatographic parameters required for identification can be obtained by isothermal analysis. With linear temperature programming the only reliable retention parameter is the index I_{lin} calculated by means of the formula in Ref. 49. In order to obtain information on the structure of a compound, the dependence of this index on the experimental conditions was examined, and a correlation was found with the isometric index. A formula was deduced theoretically for the equivalent isothermal index $I_{T_0/\beta}$, so that it became possible to identify the components of an odour from an analysis with a programmed column temperature[36]. The formula enables $I_{T_0/\beta}$ to be calculated in terms of parameters characterising the experimental conditions:

$$I_{T_0/\beta} = I_{T_0} + \frac{\beta\tau_x}{2}\cdot\frac{\partial I}{\partial T},$$

where I_{T_0} is the isothermal index with T_0 the initial temperature of the analysis, β (deg min^{-1}) the rate of the programmed variation of temperature, τ_x (min) the retention time of the substance in the column, and $\partial I/\partial T$ the temperature gradient of the index.

Retention indices are convenient in being directly related to the free energy of sorption of the test substance during chromatography. Equations have been found which enable experimental indices to be used for a quantitative estimate of the gas-chromatographic sorption process based on thermodynamic functions—partial molar enthalpies, entropies, and free energies of dissolution, as well as the differences in the corresponding excess thermodynamic functions of mixing ΔH^E, ΔS^E, and ΔG^E.[50-54] The proposed set of equations, relating the indices with the thermodynamic functions of sorption, enabled optimum conditions to be selected for gas-chromatographic separation and methods of identification to be developed without the use of standard substances[27].

IV. METHODS OF IDENTIFICATION WITHOUT THE USE OF STANDARD SUBSTANCES

The name "identification without standards" is applied to a method involving the special selection, for a mixture of substances having the same type of functional groups, of a set of columns of ensure optimum conditions of separation and to permit mathematical expression of the dependence of the gas-chromatographic behaviour of a substance on its physicochemical properties. The chosen system of columns enables relative retention parameters to be used for identification, without the help of standard substances. Scheme 1 lists the set of columns recommended for the identification of various classes of organic compounds. Each system is selected to diminish the probability of errors due to the overlapping of chromatographic zones in the column.

Scheme 1

Amines

$T = 100°C$	$T = 100°C$
10% tristearin	4% Apiezon-L + 1% Na_3PO_4
5% mineral oil + 2% KOH	5% Triton X-305 + 0.5% Na_3PO_4
10% Tween-80	5% PEG-1000 + 0.5% Na_3PO_4
10% PEG-1000	3% tetrakishydroxyethylaziridine + 2% PEG-1000 + 0.5% Na_3PO_4
on Novator detergent at pH 11.5	on Chromosorb G

Monocarbonyl organic compounds

$T = 50, 125°C$	Programmed temp.
10% Apiezon-M	10% Apiezon-M
10% PEGA	10% PEGA
10% oxy-$\beta\beta'$-dipropionitrile	

Sulphur-containing compounds

$T = 60, 130°C$

10% Apiezon-M
10% Triton X-305
10% silicone OV-17
10% PEG-1000
on Chromosorb W

The set of four columns of differing polarity listed on the left of Scheme 1 was originally proposed for analysing a mixture of aliphatic amines and heterocyclic bases. The support used was Novator detergent. The donor-acceptor interaction observed between amines and phosphates[55,56] permitted the development of a practically new method for the analysis of amines[34]. The alkali was replaced by trisodium phosphate, and the detergent by Chromosorb G. The set of four columns listed on the right of Scheme 1 was proposed for the identification of amines among the components of an odour. Organic monocarbonyl compounds among the volatile components of natural materials were to be identified by the set of columns on the left (also the list on the right for analysis under isometric conditions) with temperature progamming[35-38]. A system of four stationary phases on Chromosorb W (see Scheme 1) has also been selected for the analysis of complicated mixtures containing thiols, sulphides, disulphides, and sulphur heterocycles together; this method enables substances having boiling points up to 280°C to be identified[41-43].

Table 4. Equations correlating retention indices I^* with the number of carbon atoms n in a straight-chain aliphatic amine for analysis at 100°C (Na_3PO_4)**, where m the ordinal number of the homologue.

**Temperature of analysis 100°C.

A study of 50 amines, 52 monocarbonyl compounds, and 42 sulphur-containing organic compounds has shown that the gas-chromatographic behaviour of homologues is described by a set of equations relating retention indices with numbers of carbon atoms. As an example, the equations for aliphatic amines show (Table 4) that dependence of the index I on the number of carbon atoms n in a compound is described by a set of linear and partial linear equations for each homologous series. Equations of the latter type are convenient for purposes of identification by means of an electronic computer, since they permit the coverage of a further 200 scale units of the indices, whereas linear equations are more convenient for visual interpretation of the chromatograms. Analogous equations for determining numbers of carbon atoms from gas-chromatographic data have been obtained for monocarbonyl compounds (saturated and α-unsaturated aldehydes, methyl ketones, alkadienals, and symmetrical ketones—Table 5), and also for sulphur-containing compounds (thiols, sulphides, and disulphides—Table 6).

* I^{Ap}, I^{OV}, I^{Tr}, and I^{PEG} are the retention indices on columns of Apiezon-M silicone OV-17, Triton X-305, and polyethylene glycol 1000.

Relations have also been found for all the series by means of which boiling points of homologues can be calculated from experimental values of the indices. The identity of boiling points determined from data on all the columns is a criterion of the correctness of an identification. Table 7 gives as example equations [for amines] together with boiling points derived from the indices, and shows good agreement with published boiling points. Similar sets of equations have been obtained for carbonyl compounds (Table 8). The equations set out in Scheme 2 were found (temperature of analysis 130°C) for determining the boiling points of sulphur-containing compounds from their indices on Apiezon M and OV-17 silicone columns. Table 9 lists boiling points for several sulphur-containing compounds calculated from experimental indices by means of the equations for Apiezon M.

Straight-chain and isomeric thiols, sulphides, and disulphides $$T_b = 896.3 - \frac{2.255 \cdot 10^6}{I_{130}^{\text{Ap-M}} + 2106}$$

Cyclic compounds $$T_b = 899.1 - \frac{2.255 \cdot 10^6}{I_{130}^{\text{Ap-M}} + 2106}$$

Isoalkanethiols and isoalkyl disulphides $$T_b = 872.6 - \frac{2.153 \cdot 10^6}{I_{130}^{\text{OV}} + 1998}$$

Symmetrical and unsymmetrical straight-chain sulphides $$T_{\text{K}} = 726.2 - \frac{1.359 \cdot 10^6}{I_{130}^{\text{OV}} + 1356}$$

n-Alkyl and isoalkyl disulphides $$T_b = 847.3 - \frac{1.889 \cdot 10^6}{I_{130}^{\text{OV}} + 1670}$$

The identification of a multicomponent mixture from chromatograms on three or four columns is very tiresome and time-consuming. The accumulated experimental data have been used to set up a computer programme. Fig. 1 shows the logical sequence of operations involved in deciphering an analysis. The programme was set up in computer codes in collaboration with Grigor'eva and Zhuravleva[27]. Experimental values of the indices I from all the chromatograms were fed into the computer, and for each group of organic compounds the coefficients in the equations by means of which the numbers of carbon atoms n and the boiling points were determined. The data fed into the computer and their notation are given for the analysis of amines as example.

1. Series of compounds having functional groups of the same type q, where q_1 represents primary amines, q_2 secondary amines, q_3 tertiary amines, q_4 pyridine derivatives, and q_5 other amines.

2. The sequence of processing data from the columns, with i the number of the column and j the number of the peak on the chromatogram; $i = 1$–4 represent respectively tristearin, mineral oil, Tween-80, and polyethylene glycol 1000.

3. The coefficients α, σ, B, and L for the calculation of n and T_b by means of the equations

$$n = \frac{I_{ji} - B_{q_i}}{L_{q_i}}; \quad T_b = \frac{I_{ji}}{\alpha_{q_i}} - \sigma_{q_i}.$$

4. Retention indices and their differences $I_{j,i}$ and ΔI. The permissible errors in the comparison of I, ΔI, and T_b are

$$\theta_I = \pm 5\,\text{deg}; \quad \theta_T = \pm 5\,\text{deg}; \quad \theta_{\Delta I} = \pm 20\,\text{deg}.$$

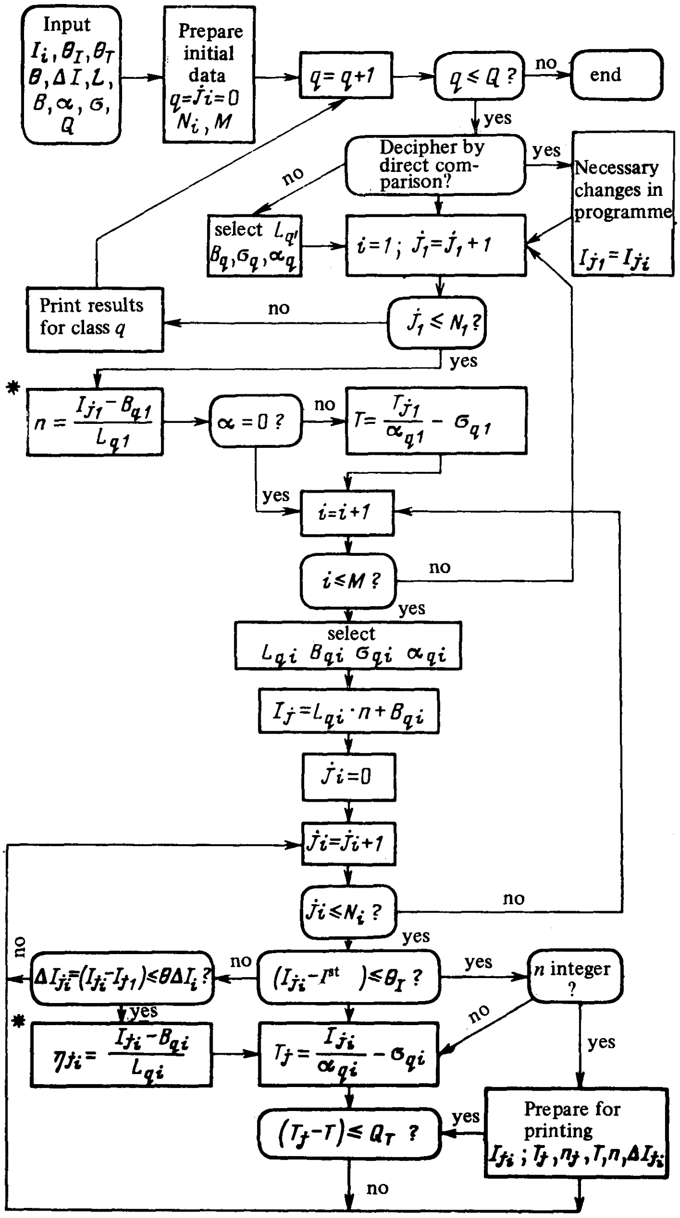

Figure 1. Block diagram of computer programme for identifying complicated mixtures from gas-chromatographic analysis without use of standard substances. For notation see text.

5. Several other parameters are also used by the computer: Q is the maximum number of series of compounds, M the maximum number of columns, and N_i the maximum number of peaks on each chromatogram. The programme permits the simultaneous processing of analytical data for a mixture of 12 types of compounds on 8 columns giving chromatograms each of which may contain up to 200 peaks[27].

The methods developed make possible the identification not only of members of the homologous series studied. In the case of unsymmetrical aliphatic and heterocyclic compounds the character of the functional group can be determined accurately, the number of carbon atoms tentatively predicted, and the boiling point of the compound estimated. The computer prints the results as a list of provisionally recognised compounds. The block scheme in Fig. 1 is of fundamental importance. It can be used to elucidate the components not only of an odour but also of other natural mixtures, e.g. hydrocarbon fractions of petroleum, essential oils, etc. The logical sequence of operations in the block diagram remains unchanged even if the gas-chromatographic behaviour of a whole series of substances on a system of columns differing in polarity is expressed in other parameters than the indices. With the accumulation of experimental information on the structural contributions to the indices the programme can be extended by calculating the indices of structures of provisionally recognised compounds. This will guide the choice of standard substance to confirm the structure of such compounds, which will facilitate identification. If the preliminary operations of calculating the indices from retention times according to previously published programmes[57] are introduced into the block diagram in Fig. 1, the task of the experimentalist is reduced to obtaining chromatograms, feeding retention times of peaks directly from the integrator into the computer, and identifying merely the peaks provisionally recognised by the computer.

V. ODOUR COMPONENTS OF CERTAIN FOODSTUFFS

Methods of identification without use of standards have been used to study the odours of several foodstuffs containing protein of animal origin—soft roe from salmon and sturgeon, salmon fillets, Russian and Dutch cheeses, volatile components of the Maillard reaction, simulating the odour of cooked meat.

The sequence of operations adopted in investigating volatile components was to obtain an odour condensate, to determine the classes of organic compounds of significance for reproducing the flavour of the product under investigation, to concentrate these classes of compounds as derivatives, to regenerate them, and then to undertake identification by gas-chromatographic analysis without the use of standard substances.

It was found that amines and monocarbonyl compounds were the most significant for the odours of sturgeon and salmon roe and of salmon fillet. The odour of cheeses is determined primarily by organic carbonyl compounds, acids, and to some extent organic bases. Sulphur-containing compounds are important in the odour of cooked meat. The results of the identification are set out in Tables 10–12.

There are several important differences in composition between the amines of sturgeon and salmon roes, and these affect their organoleptic properties. Thus the former contain more heterocyclic compounds, in particular pyridine, and the latter trimethylamine, which is characteristic of a fishy odour. It must be stressed that it has not hitherto proved possible to detect such a large number of volatile organic bases in any foodstuff. The results indicate that differences in odour between fish and fish products are probably due mainly to different quantitative relations among nitrogen bases.

Table 10. Proportions of amines in volatile components of foodstuffs expressed as relative percentages*.

Amine	Sturgeon roe	Salmon roe	Dutch cheese (4-month)	Russian cheese (4-month)	Russian cheese (10-month)
Methylamine	2.2	3.2	7.0	7.4	0.2

Unidentified amines	0.4	0.5	2.0	2.3	6.4

* Sum of areas of peaks of all amines, including those that remain unidentified, taken as 100%.

Lactic acid bacteria are widely used in the manufacture of various foodstuffs, and several of them are found in the alimentary canal. Investigation of the volatile components of the metabolism of such bacteria is therefore of especial interest. Analysis of the organic bases in volatile products of *Streptococcus lactis* shows that amines, including secondary and tertiary, accumulate during the logarithmic growth phase[58,59].

Comparison of the qualitative composition of the amines identified in various foodstuffs shows in all cases the presence of aliphatic amines, including secondary and tertiary, as well as heterocyclic compounds. Straight-chain amines are accompanied by many compounds containing isoalkyl groups. These results are of interest not only in the investigation of odour but also in the study of the carcinogenic nitrosamines contained in convenience meals or formed in the organism from precursors—amines and sodium nitrite.

Organic monocarbonyl compounds as well as amines have been studied in the odour condensates from the foodstuffs investigated. Table 11 lists the compounds found and their relative contents in the odour. With programming of the column temperature identification by means of my proposed equivalent isothermal index $I_{T_0/\beta}$ has revealed 4–9 additional compounds (indicated by an asterisk). Thus the formula for this index can be successfully applied to the analysis of a natural mixture of unknown composition with linear programming of the column temperature.

* Further identified by means of the isothermal index obtained in gas chromatography with linear programming of the column temperature.

Comparison of the quantitative proportions of various monocarbonyl compounds in the odours showed the predominance (50–70%) of alkanals in fish products, and a relatively high content of unsaturated aldehydes in salmon fillets, whereas in the odour of cheese only 13.8% of alkanals was detected, but the quantity of alkan-2-ones reached almost 70%. This represents the first observation of so many monocarbonyl compounds in the odour of such foodstuffs.

Organic sulphur compounds have been studied in the volatile components of the Maillard reaction with the odour of cooked meat[42]. Table 12 lists 25 sulphur-containing compounds identified in the odour condensate. This is probably the first case in which a large number of organosulphur compounds have been obtained from a single amino-acid (cysteine) as source of sulphur[42]. Study of the condensate of the vapour phase from the Maillard reaction is promising from the present point of view, since it permits the examination of a smaller number of components than with odour condensates from the natural product, which contains far more compounds not involved in the formation of flavour.

Table 12. Sulphur-containing compounds identified in condensate of volatile components of the Maillard reaction.

Hydrogen sulphide
Methanethiol
Ethanethiol
Propane-1-thiol
Propane-2-thiol
Butanethiol

Thiophen
2-Methylthiophen
2,5-Dimethylthiophen
Benzenethiol
2,5-Dimethyltrithiolan

* Provisionally identified.

According to the literature the odour of cooked natural meat is determined by carbonyl- and sulphur-containing organic compounds, the most significant role being assigned to thiocarbonyl derivatives[60–62]. The Reviewer's investigations have shown unambiguously that both carbonyl and thiocarbonyl compounds have only a subordinate role[42]. The presence of acids and amines is also unimportant. The odour is determined by sulphur-containing compounds.

The gas-chromatographic method of identification can be used to investigate the aroma of bread[63, 64].

VI. APPLICATION OF ODOUR ANALYSIS TO THE SOLUTION OF PRACTICAL PROBLEMS

The approach to the investigation of odour proposed and developed by the Reviewer and its application to the analysis of volatile components have enabled a simulator to be made for artificial-protein soft caviar produced in the Institute of Organoelementary Compounds of the USSR Academy of Sciences. The odour simulator was included in the technical regulations for manufacture of the caviar.

The extremely laborious investigations on the composition of the odour of natural foodstuffs can be used in solving several problems, e.g. to confer a lost flavour on products obtained by industrial methods. Thus it has been found indirectly that ethyl $\alpha\beta$-epoxy-α-methyl-β-phenylpropionate can be used in the preparation of foodstuffs smelling of strawberries. According to 1970 statistics sales in the USA were such that, if the flavouring had been natural, the size of the strawberry crop would have enabled only the demand in the single state of New Jersey to be met, although the addition of the above ester to intensify the odour was not reported to consumers[65].

Data on the composition of natural odours are used also in eliminating undesirable aftertastes with the aim of recovering valuable products for the nutrition of the population. Thus the work of Patterson in the USA revealed in 1968 the reason for the intense "smell of cats" developed in meat when stored for a long time. It was found that 0.4% of mesityl oxide contaminating the solvents for the paints previously applied to the meat-store will react with hydrogen sulphide evolved from the meat to form 4-mercapto-4-methylpentan-2-one, which has an intense "catlike" odour and a low sensitivity threshold[66,67].

Knowledge of the composition of the odour components of natural products is used in the fight against their adulteration, as well as in the manufacture of products for medical nutrition. Dietary problems in obesity and in the post-operative period can be solved by the use of flavourings and taste and odour intensifiers.

During recent years an intensive search has been made for correlations which will enable the expensive sensory assessment of the quality of foodstuffs to be replaced by objective physicochemical measurements. Such work is necessary for the establishment of objective criteria for assessing the quality of foodstuffs and for their standardisation. An example of the successful solution of this problem is provided by correlations, obtained in the Scandinavian Centre for Odour Research, for assessing the quality of canned meat from gas-chromatographic data, which required the elaboration of a verbal description of quality. Mathematical statistics was then applied to the organoleptic data, and an electronic computer used to find from these and gas-chromatographic data equations evaluating canned meat of good quality and with various defects. In this way it was shown that an objective assessment of the quality of a product can be obtained from gas-chromatographic results without the help of tasters[68-70].

Finally, data on the composition of components of the odour of natural products are required for solving the problem of flavouring new forms of food. The types of foodstuffs that supply the organism with proteins, carbohydrates, fats, vitamins, and mineral salts vary considerably and depend on the life-style, national traditions, and cultural peculiarities of each country. A unified set of foodstuffs, acceptable to all nations and peoples, cannot be envisaged in the foreseeable future. For this reason the food industry of each country is increasing its range and giving preference to forms customary in the national cuisine. The preparation of specific products of tasteless powdered protein concentrates requires both the imitation of a complex of structural and physical characteristics and a method of introducing flavourings that ensures their uniform distribution and prolonged fixation of the odour in the product.

The production of new types of food requires not only nutritional value but also a harmonious combination of texture, taste, and smell. Sour, salt, bitter, and sweet tastes can be conferred on a textured product by a combination of chemicals, e.g. common salt, citric acid, sugar, and piperine (the last isolated from pepper).

Intensifiers—natural substances minute additions of which reinforce particular taste sensations and produce a pleasant aftereffect—are used to improve taste properties. The formulae of some of them are given in Fig. 2. Since 1962 such compounds as sodium L-glutamate[71] and disodium 5'-inosinate and 5'-guanylate[72-74] have been widely used to improve the taste properties of meat and fish products, broths, vegetable courses, tomato juice, and sauces. They are able to suppress undesirable taints in the odour of foodstuffs, such as "sulphide", "greasy", "grassy", "chemical", etc. The most astonishing effect is the ability of nucleotides to create the illusion of substantiality: such sensations arise e.g. on the addition of 50–200 ppm to a broth.

Nutritionists have pointed out the unfavourable consequences of excess of carbohydrates, in particular sugar.

Addition of 15 ppm of a sweet taste intensifier—Maltol (3-hydroxy-2-methyl-4-pyrone)—enables the consumption of sugar in fruit juices and drinks to be reduced to 15%. The methyl ester of the dipeptide L-aspartyl-L-phenylalanine, which is 200 times as sweet as sugar, has also been recommended as a substitute for the latter[75].

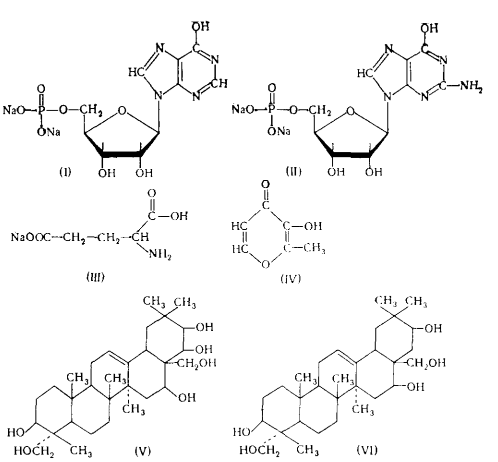

Figure 2. Some taste and odour intensifiers: (I) sodium 5'-inosinate; (II) sodium 5'-guanylate; (III) sodium glutamate; (IV) Maltol; and inhibitors: (V) gymnemagenin; (VI) gymnoestrogenin[76].

Not only taste intensifiers but also taste inhibitors have been found. For example, gymnoestrogenin[76], isolated from an African plant, suppresses a sweet taste and to some extent a bitter taste for several hours: sugar seems as tasteless as sand. The berries of the Nigerian plant *Synsepalum dilcificum* suppress a sour taste and strengthen a sweet taste (lemons taste like oranges)[77]. A thorough search is being undertaken for new inhibitors and intensifiers of taste and smell[77,78].

It is a far more complicated task to imitate the flavour of food. The creation of flavouring compositions involves deciphering the odour of natural foodstuffs. Among the several hundreds of odour components it is necessary to determine the specific, key compounds responsible for the characteristic flavour. An odour simulator for a foodstuff should be harmless and contain substances present in the flavouring composition of the natural product or obtained by reactions simulating processes occurring in the natural foodstuff (e.g. by the Maillard reaction).

The most successful examples of the conferment of odour on artificial products are provided by drinks and wines[65,79]. The reason is that flavouring compositions based on study of the odour of natural juices and wines do not change their properties on addition to aqueous and aqueous–alcoholic solutions. In this case the "texture" of the product does not appreciably affect the balance in the initial composition. Numerous attempts to impart a flavour to structured products by means of artificial compositions having a flavour closely similar to that of the natural product have given a positive result only when 95–50% of the natural product was added as foundation to the artificial product. Protein soft caviar is probably the first artificial product flavoured with an imitator without addition of the natural roe. By itself this imitation does not possess the odour of sturgeon roe, the flavour being formed in the product after introduction of the odour imitation in 2–3 h after the establishment of adsorption–desorption equilibrium[27].

The flavouring of a structurised protein usually involves a change in odour owing to disturbance of the quantitative relations among the components. Selective adsorption of the components of a flavouring mixture disturbs the quantitative proportions of the ingredients with loss of the specific odour. The selection of imitations for new forms of food may be considerably complicated by cases of synergism—the suppression or strengthening of the odour of a substance in the presence of one or more other substances—when the concentrations of the compounds may be less than the threshold values, so that each of them separately could not be perceived by man.

For two substances at concentrations x and y synergism can be expressed both as $x + y$ and as xy, and even x^y.[80] This is why the selection of flabourings cannot yet be based solely on instrumental data, but depends on the intuition and experimental skill of the chemist. Thus cases of synergism have made it extraordinarily difficult to produce a flavouring mixture for protein soft caviar, by increasing the number of variations to 200. The imitation itself does not possess the odour of roe, which appears in the culinary processing of the product and, in the opinion of tasters, imparts to protein caviar "an aromatic and gustatory character closely resembling the natural roe of fishes of sturgeon species".

A chemical imitation of an odour usually comprises 10–20 reactive compounds, which change readily not only on storage in air but also by interaction among the components. It is therefore necessary to preserve such mixtures by encapsulation or by "sealing" them into edible polymers—e.g. alginates, dextrans, polyvinyl alcohol, dextrins, etc.[81,82]—from which the components are easily displaced when required by the action of water. These powders are convenient as ingredients of products for prolonged storage. They are used also in the flavouring of fodder for cattle. In Japan, for example, special flavouring mixtures in powder form are added to improve the appetite, which promotes better anabolism of the fodder.

We may note in conclusion that the development of investigations on the odour of foodstuffs and the production of imitators are economically advantageous, despite the expensive equipment and highly qualified experts required for research on this problem. The combination of a gas-chromatographic method of separation, developed for each class of organic compounds, with mass-spectrometric detection constitutes the optimum procedure enabling maximum information to be obtained on the composition of an odour.

Theory of Complex Unimolecular Reactions

A.D.Berman

A general approach to the study of complex reacting systems, including first-order reactions, is considered. The method consists in the identification of the disposition of the characteristic vectors of the kinetic matrix for a linear system and their eigenvalues. Linear reaction pathways in the composition space correspond to non-equilibrium characteristic vectors. For an experimental determination of the kinetic constants in a complex system, it is sufficient to find all the linear reaction pathways.

The bibliography includes 56 references.

CONTENTS

I. INTRODUCTION

The theory of complex reactions deals with the general characteristics of their occurrence, i.e. the structural features of complex systems. Suppose that a system of non-linear differential equations describing the kinetics of a process has been specified:

$$\frac{da_i}{dt} = f_i(a_1 \ldots a_n); \quad i=1, \ldots n, \tag{1}$$

where a_i are the reactant concentrations and t is the time. The theory of steady-state reactions is concerned with problems of deriving kinetic equations from the steady-state condition:

$$f_i(a_1 \ldots a_n) = 0. \tag{2}$$

These problems were described in detail by Temkin, Kiperman, and Horiuti[1-5] and are not considered in the present review. Only a few general results have been obtained for the non-linear system (1). They are mainly restricted to the development of methods for the integration of the equations in specific instances and the consideration of methods for the determination of kinetic constants from experimental data—by analysing the number and stability of steady states. However, all these results are fairly specific.

Complex systems of unimolecular reactions have been investigated most fully. It is now already possible to describe in fair detail the structure of linear systems. A general method for the determination of the rate constants for individual pathways can be proposed on the basis of a theoretical analysis of experimental data. The new approach to the determination of first-order rate constants is based on finding "linear pathways" in the reaction, which will be discussed in detail below.

The present review considers mainly the general results of the theory of linear systems with a subsequent brief discussion of second-order reactions.

II. THEORY OF FIRST-ORDER REACTIONS

1. FUNDAMENTAL CONCEPTS AND NOTATION

We shall denote the ith substance in the system by A_i and its concentration by a_i. k_{ij} is defined as the rate constant for the conversion of the ith substance into the jth substance, i.e. we shall write $A_i \xrightarrow{k_{ij}} A_j$. We introduce a linear composition space, the dimensions of which are the same as the number of reactants. The elements of this space consist of vectors, whose coordinates are the same as the concentrations of the components at the outlet from the reactor: $a = \begin{pmatrix} a_1 \\ \vdots \\ a_n \end{pmatrix}$. The general system of first-order reactions can then be described by the following equation in the matrix form:

$$\frac{da}{dt} = Ka \quad , \qquad (3)$$

where K is the kinetic matrix. The form of this matrix depends on the specific reaction mechanism.

We shall attempt to answer two main questions concerning the general theory of first-order systems.

1. We shall elucidate the nature of the approach of the system to equilibrium, the possibility of decaying and non-decaying oscillations.

2. We shall attempt to devise a general method for the determination of rate constants from experimental data by studying the structure of the system.

The formulation of the first problem does not require special comment. We shall note only that the stability of the system is inferred from the sign of the real root of the characteristic equation

$$|K - \lambda E| = 0, \qquad (4)$$

where E is the unit matrix. If all the roots are real and negative, the system is stable and oscillations are impossible. If the roots are complex with a negative real component, decaying oscillations are possible.

The problem of the determination of kinetic constants will be considered in somewhat greater detail. The determination of constants for a system of complex reactions is known to involve considerable difficulties[6,7]. The constants for system (1) can be determined from the initial rates of formation of each substance. However, this entails significant errors in the determination of contact times and also errors in chemical analysis for low degrees of conversion[6]. It is possible to obtain a general solution to Eqns. (3),[8] but this hardly facilitates the determination of kinetic constants from experimental data. The point is that each kinetic curve can be described by an expression of the type

$$a_i = \sum_{i=1}^{n} c_i e^{\lambda_i t},$$

where c_i are constant and λ_i are the roots of the characteristic equation. It is therefore possible to obtain only c_i and λ_i from the experimental data. This is also not a simple problem, which has to be solved by non-linear programming methods[9]. A new method has been proposed recently for the determination of these quantities, which is apparently useful in the simplest cases[10]. The method is based on the fact that the function

$$\varphi = \sum_{i=1}^{n} a_i t \, e^{\lambda_i t}$$

has n maxima at the points $t_i = -1/\lambda_i$. It is therefore possible to find λ_i by plotting φ against t. However, it is difficult to expect the method to be applicable when $n > 3$ or 4. We shall assume that we have nevertheless succeeded in determining c_i and λ_i. The relation between the λ_i and the kinetic constants is so complex that an accurate determination of the latter is still a problem. A number of studies have been made on the analysis of the errors arising in the determination of the contact time and temperature[6,11-15]. Owing to the inaccuracy of the temperature measurements, the errors in the calculation of the rate constants are higher for larger activation energies. When the relative rate constants are determined, the error associated with the inaccurate determination of the constants diminishes, since the rate constant ratios depend less on temperature than the absolute values of the constants.

The approach to the problem of the calculation of the constants, based on the study of the structure of a system of unimolecular reactions, is of considerable interest[16]. Using this approach, it is possible to suggest a method for the determination of the relative rate constants without measuring contact times.

2. REVERSIBLE REACTIONS

We shall begin the consideration of systems of unimolecular reactions with first-order reversible reactions. The structure of such systems is simpler than the structure of systems including irreversible stages, despite the fact that a larger number of constants is required for the description of reversible reactions. The causes of this at first sight paradoxical fact will be clarified by further exposition.

In order to permit a simple geometrical interpretation of the results, we shall restrict the treatment initially to a three-component system. The following kinetic equations can be formulated:

$$\begin{aligned} \frac{da_1}{dt} &= -(k_{21}+k_{31})\,a_1 + k_{12}a_2 + k_{13}a_3, \\ \frac{da_2}{dt} &= k_{21}a_1 - (k_{12}+k_{32})\,a_2 + k_{23}a_3, \\ \frac{da_3}{dt} &= k_{31}a_1 + k_{32}a_2 - (k_{13}+k_{23})\,a_3. \end{aligned} \qquad (5)$$

In this case the matrix K can be written thus:

$$K = \begin{pmatrix} -(k_{21}+k_{31}) & k_{12} & k_{13} \\ k_{21} & -(k_{12}+k_{32}) & k_{23} \\ k_{31} & k_{32} & -(k_{13}+k_{23}) \end{pmatrix}. \qquad (6)$$

The column matrix $a = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix}$ can be imagined as a vector in a three-dimensional composition space. During the reaction, the vector a migrates in the space. The matrix

$$\frac{da}{dt} = \begin{pmatrix} \frac{da_1}{dt} \\ \frac{da_2}{dt} \\ \frac{da_3}{dt} \end{pmatrix}$$

specifies the rate of this migration. The trajectory of the end of the vector a will be called the reaction pathway.

For an n-component system, the form of the matrix K remains the same, i.e. the non-diagonal elements consist of the rate constants for the corresponding transitions. The diagonal elements consist of sums of the elements of each column with the sign reversed. The constants k_{ii} are disregarded, since they have no physical significance.

We impose two restrictions:

$$\sum_{i=1}^{n} a_i = 1; \tag{7}$$

$$a_i > 0. \tag{8}$$

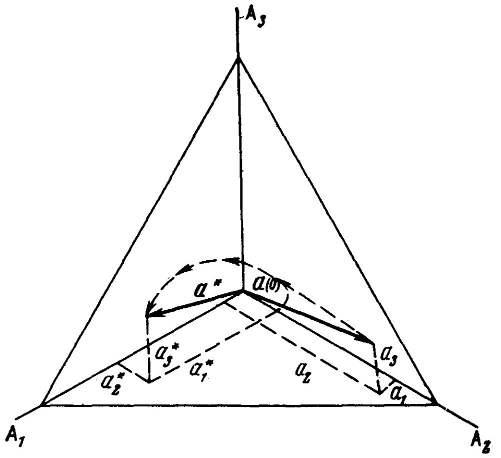

Figure 1. The composition space and the reaction triangle for a three-component system. The dashed curve represents a typical reaction pathway.

The first expresses the law of conservation of mass in the system and the second expresses the impossibility of the appearance of negative amounts of the substance.

Definition 1. The vector $a(a_1 \ldots a_n)$ is said to be positively defined if $a_i > 0$ ($i = 1, \ldots, n$); on the other hand, if $a_i \geqslant 0$ ($i = 1, \ldots, n$), then the vector a is said to be non-negatively defined. The geometrical implication of these conditions is that the end of the vector a is bounded by a plane passing through the points (1, 0, 0), (0, 1, 0), and (0, 0, 1). Furthermore, all the reaction pathways lie in the positive octant of the coordinate system (Fig. 1). During the reaction, the end of the vector $a(t)$ moves along the reaction plane in the direction towards the equilibrium point a^*. In the general case, these reactions pathways are curved.

A. Characteristic Directions

The directions in the composition space for which the condition

$$K\bar{a} = \lambda\bar{a} \tag{9}$$

is valid are called characteristic. Here a is the characteristic vector corresponding to the eigenvalue λ. It will be shown below that a linear reaction pathway corresponds to each characteristic direction.

It is known from linear algebra[17] that there can exist not more than n independent eigenvectors for an arbitrary matrix K. In terms of the coordinate system comprising eigenvectors, the matrix assumes the simplest form. If n independent eigenvectors exist (complete system), the matrix is reduced to a diagonal form. The introduction of an equivalent system of substances, each of which reacts independently of the others in the mixture, corresponds to the reduction of the kinetic matrix to the diagonal form. Evidently the calculation of constants for such a system does not present difficulties. If the eigenvectors and eigenvalues are known, it is possible to devise a transformation relating the characteristic coordinate system to the initial system. In this case, one can calculate the entire initial rate constant matrix. If the λ_i are known, then, as stated above, it is also possible to deduce the stability of the system. The study of linear reaction pathways is therefore of considerable interest for the understanding of the structure of complex systems.

The existence of a complete system of real eigenvectors for symmetrical matrices has been demonstrated in linear algebra. In the majority of instances, kinetic matrices are not symmetrical. It is therefore impossible to reach any conclusions concerning the number of eigenvectors of kinetic matrices directly on the basis of conditions (7) and (8). For reversible reactions, the kinetic matrix can be reduced to a symmetrical form. This is done using the principle of "detailed balance".

B. The Principle of Detailed Balance

This principle is important in the theory of linear systems. It states that, for each stage at equilibrium, we have

$$k_{ji}a_i^* = k_{ij}a_j^*, \tag{10}$$

and that $\varkappa_{ij} > 0$ implies that $\varkappa_{ji} > 0$.

We may note that the principle of detailed balance cannot always be obtained from the steady-state condition. For example, for the three-component system of reversible reactions considered above, one cannot obtain Eqn. (10) from the equality

$$Ka^* = 0 \tag{11}$$

without additional conditions. For $n = 2$, Eqn. (10) always follows from Eqn. (11), but for $n = 3$ this is the case only provided that the Wegsheider conditions are fulfilled[18]:

$$k_{12}k_{23}k_{31} = k_{21}k_{32}k_{13}. \tag{12}$$

For $n > 3$, analogous conditions have been obtained by other investigators[19,20]. The general conditions for which the principle of detailed balance follows from steady-state equations have been obtained by Lee[21]. For reversible reactions in closed systems, the validity of Eqn. (10) can be proved from thermodynamic considerations. However, it has been noted in the literature that, in relation to kinetics, the thermodynamic derivation of the principle of detailed balance is not always rigorous, since it is difficult to take into account multistage reaction mechanisms and deviations from ideality[22]. In the present section, we shall assume that condition (10) is valid.

C. Axiomatic Definition of a System of Unimolecular Reversible Reactions

We shall now formulate an exact definition of a system of reversible reactions and shall discuss certain mathematical results obtained from this definition.

Definition 2. A system described by the equations

$$\frac{d\boldsymbol{a}}{dt} = K\boldsymbol{a}, \quad \boldsymbol{a}(0) = \boldsymbol{a}_0, \tag{13}$$

where $\boldsymbol{a}$ is an n-dimensional composition vector and K an $n \times n$ matrix, is called a system of unimolecular reversible reactions. Furthermore, the following conditions are fulfilled:

$$\begin{gathered} a_i \geqslant 0, \\ \sum_{i=1}^{n} a_i = \text{const}, \\ k_{ij}a_j^{\bullet} = k_{\ i}a_i^{\bullet}, \end{gathered} \tag{14}$$

where a_j^* and a_i^* are equilibrium concentrations.

Theorem 1. For a system of unimolecular reversible reactions, there is a unique equilibrium point.

Theorem 2. For a system of reversible unimolecular reactions, there are n independent characteristic composition vectors, whose eigenvalues are not positive.

The proof of theorem 2 is based significantly on the principle of detailed balance [condition (14)]. The idea of the proof is as follows. Knowing the equilibrium composition, it is possible to set up the diagonal matrices

$$D^{-1/2} = \begin{vmatrix} \frac{1}{\sqrt{a_1^{\bullet}}} & & \\ & \ddots & \\ & & \frac{1}{\sqrt{a_n^{\bullet}}} \end{vmatrix}; \quad D^{1/2} = \begin{pmatrix} \sqrt{a_1^{\bullet}} & & \\ & \ddots & \\ & & \sqrt{a_n^{\bullet}} \end{pmatrix}. \tag{15}$$

These matrices are evidently non-degenerate. We now consider the trans-formation of the vector composition space in accordance with the formula $\alpha = D^{-1/2}\boldsymbol{a}$. Here we again obtain a system of reversible unimolecular reactions:

$$\frac{d\alpha}{dt} = \hat{K}\alpha, \tag{16}$$

where $\hat{K} = D^{-1/2}KD^{1/2}$. By virtue of conditions (14), the matrix $\hat{K}$ is symmetrical, as a result of which it has n independent eigenvectors. Theorem 2 is now confirmed by the similarity of matrices K and $\hat{K}$.

The non-positive nature of the eigenvalues leads to a corollary.

Corollary 1. In a system of unimolecular reversible reactions, oscillations are impossible.

The characteristic vectors of a symmetrical matrix are linked by orthogonality relations. Since these relations will be used below to find the characteristic vectors, we may also note another corollary.

Corollary 2. The characteristic vectors $X_j(x_{j1}, \ldots, x_{jn})$ of the matrix K are linked by relations of the type

$$(X_j, D^{-1} \cdot X_i) = 0, \tag{17}$$

where the brackets indicate a scalar product and the matrix D^{-1} is defined thus:

$$D^{-1} = \begin{Vmatrix} \frac{1}{a_1^{\bullet}} & & \\ & \ddots & \\ & & \frac{1}{a_n^{\bullet}} \end{Vmatrix}. \tag{18}$$

D. Solution for a First-Order Reaction System in Terms of the Concentrations of the Characteristic Substances

We saw above that there exist n characteristic composition vectors in the composition space for a system of reversible unimolecular reactions. Suppose that the unit characteristic vector in the initial coordinate system is designated by X_i. We select the unit vectors X_i as the new coordinate system. We shall refer to the system as the characteristic system or the system of equivalent substances B. Any composition vector can be written in the form

$$\alpha = \sum_{i=0}^{n-1} b_i(t)X_i. \tag{19}$$

When α is substituted in the initial equation (3), we obtain

$$\frac{d\alpha}{dt} = \sum_{i=0}^{n-1} \frac{db_i}{dt} X_i = K\alpha = \sum_{i=0}^{n-1} b_i(t) \cdot \lambda_i X_i,$$

whence

$$\frac{db_i}{dt} = \lambda_i b_i, \quad \lambda_i \leqslant 0. \tag{20}$$

The solution of Eqn. (20) presents no difficulties:

$$b_i(t) = b_i^0 e^{\lambda_i t}; \quad i = 0, \ldots n-1. \tag{21}$$

If $\lambda_i < 0$, then $b_i(t) \to 0$ when $t \to \infty$. Substitution of $b_i(t)$ defined by Eqn. (21) in Eqn. (19) yields

$$\alpha = \sum_{i=0}^{n-1} b_i^0 e^{\lambda_i t} X_i. \tag{22}$$

Since material balance must hold, then at least one eigenvalue should be zero. We shall denote it by λ_0. Then

$$\alpha = b_0^0 X_0 + \sum_{i=1}^{n-1} b_i^0 e^{\lambda_i t} X_i. \tag{23}$$

Since the sum of the concentrations of the components at any instant is unity, we obtain

$$\sum_{j=1}^{n} \alpha_j = b_0^0 \sum_{j=1}^{n} x_{0j} + \sum_{i=1}^{n-1} b_i^0 e^{\lambda_i t} \cdot \sum_{j=1}^{n} x_{ij} \equiv 1. \tag{24}$$

It follows from Eqn. (24) that $\sum_{j=1}^{n} x_{ij} = 0$ and that the following relation holds when the length X_0 is suitably chosen

$$\sum_{j=1}^{n} x_{0j} = 1. \tag{25}$$

Evidently there exists only one positively defined characteristic composition vector X_0 in the system. All other characteristic vectors contain negative elements, since otherwise the equality $\sum_{j=1}^{n} x_{ij}=0$ would have been impossible. Geometrically this condition implies that the characteristic vectors are perpendicular to the vector $I\{1, 1, 1\}$. For a three-dimensional system, the vectors $X_i (i \neq 0)$ are parallel to the plane of the reaction triangle. Since the vectors X_i contain negative coordinates, linear reaction pathways directed along these vectors cannot be observed experimentally. A significant feature of reversible reactions is that at equilibrium the system contains all the substances for which the equilibrium characteristic vector X_0 does not have zero coordinates. One can therefore always find a linear combination of X_0 and X_i such that the resultant vector is non-negatively defined.

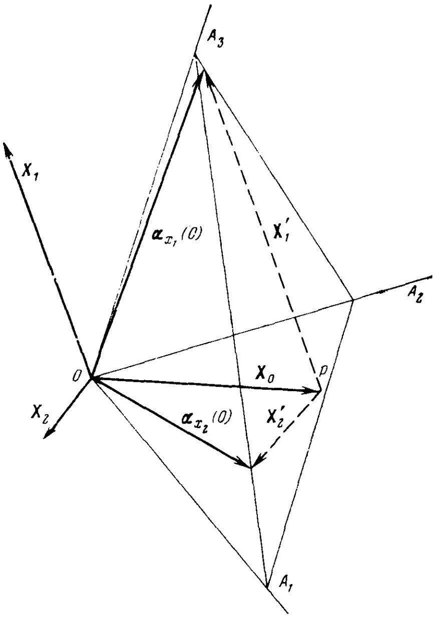

Figure 2. Disposition of the characteristic vectors for a three-component system. The dashed lines represent the characteristic vectors transferred to the equilibrium point P.

We now turn to the geometrical interpretation for a three-component system. Since the vectors X_1 and X_2 are parallel to the plane of the reaction triangle and during the reaction move to the equilibrium point P (Fig. 2) located in the plane of the reaction triangle, one may assert that the vectors X_1 and X_2 lie in this plane. We have not so far refined the lengths of the vectors X_1 and X_2 which are the unit vectors in the system B. We shall choose them in such a way that their ends are located on the sides of the reaction triangle. The vector sums

$$\alpha_{x_1}(0)=X_0+X_1 \text{ and } \alpha_{x_2}(0)=X_0+X_2 \tag{26}$$

then correspond to real compositions.

Definition 3. The characteristic vectors $X_i (i \neq 0)$ satisfy Eqn. (26), where X_0 is a positively defined vector and $\alpha_{x_1}(0)$ a non-negatively defined vector, will be called quasipositive. At least one element of each vector $\alpha_{x_i}(0)$ is zero owing to the above choice of the length of the vectors X_i, which restricts $\alpha_{x_i}(0)$ to the area bounded by the reaction triangle.

Eqns. (26) are equivalent to Eqns. (22) for $n = 3$, $b_0^0 = b_1^0 = 1$, $b_2^0 = 0$ or $b_0^0 = b_2^0 = 1$, $b_1^0 = 0$. Using Eqns. (22) and (26), we obtain equations for the migration of $\alpha_{x_1}(t)$ and $\alpha_{x_2}(t)$ towards equilibrium:

$$\alpha_{x_1}(t)=X_0+e^{\lambda_1 t}X_1, \tag{27}$$

$$\alpha_{x_2}(t)=X_0+e^{\lambda_2 t}X_2. \tag{28}$$

Eqns. (27) and (28) define linear reaction pathways in the composition space. They show that

$$X_l=\alpha_{x_l}(0)-X_0. \tag{29}$$

Thus, in order to determine the characteristic vectors, it is necessary to know the points of intersection of the linear reaction pathways with the sides of the reaction triangle and the equilibrium composition vector. The problem of the determination of the eigenvectors has been reduced to finding the linear reaction pathways. The eigenvectors are fully defined within the composition space and their determination does not require the knowledge of the reaction time.

E. Method for the Determination of Rate Constants from Experimental Data

The following method has been proposed for the experimental determination of linear pathways. We select any convenient initial composition and determine the corresponding reaction pathway. Fairly close to equilibrium, the reaction pathway is determined by the characteristic vector with the lowest eigenvalue. Linear extrapolation of the section of the pathway near equilibrium yields a new initial composition. This process is repeated until the reaction pathway becomes linear. Having eliminated the time t from Eqns. (21), we obtain

$$\ln b_i=\text{const}+\left(\frac{\lambda_i}{\lambda_j}\right)\ln b_j. \tag{30}$$

By determining the compositions along two linear sections, it is possible to find b_i and b_j and then λ_i/λ_j from the slope of the linear plot of $\ln b_i$ against $\ln b_j$. The matrix X can be set up using the coordinates of the characteristic vectors and the eigenvalues can be used to obtain the diagonal matrix Λ.

These data are sufficient to determine the relative rate constants from the relation

$$K=X\Lambda X^{-1} \quad . \tag{31}$$

The inverse of a matrix X^{-1} can be calculated as follows[16]. One evaluates initially the diagonal matrix L from the formula

$$L=X^{T}D^{-1}X, \tag{32}$$

where X^T is the transpose of a matrix. After this, the inverse of a matrix can be calculated from the equation

$$X^{-1}=L^{-1}X^{T}D^{-1}. \tag{33}$$

The graphical method, which is convenient for a three-component system, is virtually inapplicable to a system with a larger number of components. In this case, the reaction pathway can be conveniently specified in a parametric form having selected as the parameter the concentration a_j of one of the components (which varies monotonically with time). For an n-component system, there are $n-1$ equations of the type

$$a_{x_l}(t) = X_0 + e^{\lambda_l t} X_l, \tag{34}$$

corresponding to linear reaction pathways. We shall consider the linear pathway corresponding to the lth characteristic vector and shall formulate equations which follow from Eqn. (34):

$$\begin{aligned} a_1 &= x_{10} + e^{\lambda_l t} x_{1l}, \\ a_2 &= x_{20} + e^{\lambda_l t} x_{2l}, \\ &\dots\dots\dots\dots\dots \\ a_n &= x_{n0} + e^{\lambda_l t} x_{nl}. \end{aligned} \tag{35}$$

If t is eliminated with the aid of the jth equation from the remaining equations, we obtain $n-1$ equations of the type

$$a_m = \left(\overset{\bullet}{a}_m - \frac{x_{ml}}{x_{jl}} \overset{\bullet}{a}_j \right) + \frac{x_{ml}}{x_{jl}} a_j. \tag{36}$$

Thus the linear pathway in the $(n-1)$-dimensional space is converted into $n-1$ straight lines in two-dimensional spaces. The method of approximations described above for $n = 3$ can be applied also to the general case with two-dimensional representations of the reaction pathways.

For n-component systems, one must bear in mind that, after the linear pathway corresponding to the characteristic vector X_j has been found, the new initial composition used to find the vector X_{j+1} cannot be selected arbitrarily. The point is that, for certain initial compositions, the method of approximations can lead to the same linear reaction pathway. To prevent this, the initial composition is chosen in such a way that the vector $[X_0 - a(0)]$ in the system B is orthogonal with respect to X_j. The procedure will be elucidated in detail in relation to the example described below.

F. Pseudounimolecular Systems of Heterogeneous Catalytic Reactions

We considered above unimolecular reactions only. However, there exists an important class of non-linear systems for which the above results are valid. Consider a pseudounimolecular system of reactions, which will be referred to as the reaction system, where the rate of change of the amounts of various substances is expressed as first order by the law of mass action, each term of the equation being multiplied by the same function of composition and time. For example, heterogeneous first-order reactions occurring on the homogeneous catalyst surface are pseudounimolecular. For the simplest mechanism of reversible reactions A ⇌ B, one can write

$$\frac{dc_A}{dt} = -(k_1 c_A - k_2 c_B)\,\varphi(c_A, c_B), \tag{37}$$

$$\frac{dc_B}{dt} = (k_1 c_A - k_2 c_B)\,\varphi(c_A, c_B), \tag{38}$$

where

$$\varphi(c_A, c_B) = \frac{1}{1 + c_A b_A + c_B b_B}. \tag{39}$$

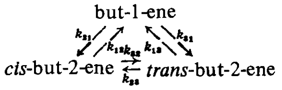
It was shown above that the matrix of the relative rate constants can be determined using only the information about the compositions and disregarding the reaction time. It is therefore possible to reduce pseudounimolecular reactions to the case analysed above by introducing a new time scale. For this purpose, we shall assume that $\varphi[c_A(t), c_B(t)]$ is a function of time and shall replace the independent variable:

$$d\tau = \varphi(t)\,dt, \tag{40}$$

which yields a system of unimolecular reactions.

G. Examples of the Determination of the Rate Constants for Reversible Unimolecular Reactions

Example 1. We shall consider initially a three-component system. The isomerisation of butenes on alumina has been investigated by Haag and Pines[23]. If it is assumed that the catalyst surface is homogeneous, the system may be regarded as pseudounimolecular. The method described above has been used[16] to calculate the rate constants. The designation of the rate constants is indicated in the scheme below:



(I)

Fig. 3 illustrates the reaction pathway obtained when pure *cis*-but-2-ene is introduced into the reactor. The dashed line represents the tangent to the curved reaction pathway drawn near the equilibrium point. The intersection of the tangent with the side of the triangle yields a new initial composition:

$$\alpha(0) = \begin{pmatrix} 0.24 \\ 0.76 \\ 0 \end{pmatrix}.$$

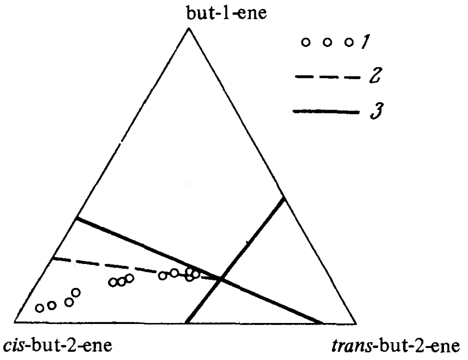


Figure 3. The study of the isomerisation of butenes in the presence of Al_2O_3: 1) reaction pathway obtained following the introduction of pure *cis*-but-2-ene into the reactor; 2) tangent to the reaction pathway; 3) linear pathways.

The sequence of components in the column matrix is

$$\begin{pmatrix} \text{but-1-ene} \\ \textit{cis}\text{-but-2-ene} \\ \textit{trans}\text{-but-2-ene} \end{pmatrix}.$$

Next, experiments were performed with the new initial composition. Table 1 presents the last twelve points forming an approximately linear section in the vicinity of equilibrium. A straight line passing through these points and the equilibrium point was fitted by the method of least squares:

$$\alpha^{*}=X_0=\begin{pmatrix}0.1436\\0.3213\\0.5351\end{pmatrix}\ .$$

Table 1. Series of compositions for the second approximation in the isomerisation of butenes.

But-1-ene	*cis*-But-2-ene	*trans*-But-2-ene	But-1-ene	*cis*-But-2-ene	*trans*-But-2-ene
0.1622	0.3604	0.4775	0.1537	0.3471	0.4992
0.1776	0.3769	0.4455	0.1571	0.3464	0.4965
0.1664	0.3595	0.4741	0.1542	0.3431	0.5027
0.1654	0.3622	0.4724	0.1521	0.3451	0.5028
0.1690	0.3671	0.4639	0.2525	0.3408	0.5067
0.1603	0.3441	0.4955	0.1532	0.3416	0.5052

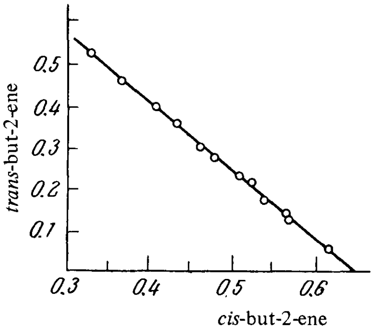

Figure 4. The linear reaction pathway in the isomerisation of butenes.

Its extrapolation to the side of the triangle yielded a new initial composition:

$$\alpha'(0)=\begin{pmatrix}0.3286\\0.6714\\0.0000\end{pmatrix}.$$

Fig. 4 presents the composition points for the reaction pathway corresponding to the last initial composition in the fourth approximation. This composition,

$$\alpha(0)=\begin{pmatrix}0.3492\\0.6508\\0.0000\end{pmatrix}$$

was used to determine the vector X_1. Using $\alpha(0)$ and X_0, we obtain

$$X_1=\alpha(0)-X_0=\begin{pmatrix}0.2056\\0.3295\\-0.5351\end{pmatrix}.$$

Calculation of the third characteristic vector. The vector X_2 may be calculated without additional measurements using the orthogonality relations (17). In our case the matrices $D^{1/2}$ and $D^{-1/2}$ are

$$D^{1/2}=\begin{pmatrix}0.3789&0&0\\0&0.5668&0\\0&0&0.7315\end{pmatrix},$$

$$D^{-1/2}=\begin{pmatrix}2.6389&0&0\\0&1.7642&0\\0&0&1.3670\end{pmatrix}\ .$$

We calculate the vectors

$$\overline{X}_0=D^{-1/2}X_0=\begin{pmatrix}0.3789\\0.5668\\0.7315\end{pmatrix}$$

$$\overline{X}_1=D^{-1/2}X_1=\begin{pmatrix}0.5426\\0.5812\\-0.7315\end{pmatrix}.$$

$\overline{X}_1$ is adjusted to unit length:

$$l_1=(\overline{X}_1,\overline{X}_1)=1.1673\ .$$

The round brackets indicate a scalar product.

$$\overline{X}_1/\sqrt{l_1}=\begin{pmatrix}0.5022\\0.5380\\-0.6771\end{pmatrix}.$$

The vector X_2 is orthogonal with respect to $\overline{X}_0$ and $\overline{X}_1$. We take initially the vector $\overline{\gamma}_1$, orthogonal with respect to X_0; this can be readily done, for example, by interchanging the first two elements of X_0, reversing the sign of one of them, and setting the third equal to zero:

$$\overline{\gamma}_1=\begin{pmatrix}-0.5668\\0.3789\\0.0000\end{pmatrix}.$$

We shall now seek $\overline{\gamma}_2$ in the form of a linear combination of $\overline{X}_1$ and $\overline{\gamma}_1$:

$$\overline{\gamma}_2=\overline{X}_1+\lambda\overline{\gamma}_1.$$

From the condition that $\overline{X}_2$ and γ_1 are perpendicular, it is easy to find that

$$\lambda=-\frac{1}{(\overline{\gamma},\overline{X}_1)};$$

$$\overline{\gamma}_2=\overline{X}_1-\frac{\overline{\gamma}}{(\overline{\gamma}_1,\overline{X}_1)}=\begin{pmatrix}-0.5262\\0.4224\\-0.0547\end{pmatrix}.$$

We now retransform $\overline{\gamma}$ so that it applies to a non-orthogonal system:

$$\gamma_2=D^{1/2}\overline{\gamma}_2=\begin{pmatrix}-0.1994\\0.2394\\-0.0400\end{pmatrix}.$$

The vectors γ_2 and X_2 are parallel. The length of X_2 is chosen so that the first coordinate of the vector $X_2+X_0=\alpha_{X_2}(0)$ is zero:

$$X_2=\begin{pmatrix}-0.1436\\0.1724\\-0.0288\end{pmatrix}.$$

We now find

$$\alpha_{x_2}=X_2+X_0=\begin{pmatrix}0.0000\\0.4937\\0.5063\end{pmatrix}.$$

On combining the vectors X_0, X_1, and X_2, we obtain the matrix

$$X=\begin{pmatrix}0.1436 & 0.2056 & -0.1436\\ 0.3219 & 0.3295 & 0.1724\\ 0.5351 & -0.5351 & -0.0288\end{pmatrix}.$$

Calculation of the inverse of a matrix. The matrix D^{-1} will be determined from the equilibrium amounts:

$$D^{-1}=\begin{pmatrix}6.9638 & 0 & 0\\ 0 & 3.1123 & 0\\ 0 & 0 & 1.8688\end{pmatrix}.$$

We calculate the matrix

$$L=X^{\mathrm{T}}D^{-1}X=\begin{pmatrix}1.000 & 0 & 0\\ 0 & 0.8566 & 0\\ 0 & 0 & 4.2077\end{pmatrix}.$$

The inverse of the matrix is found from the equation

$$X^{-1}=L^{-1}X^{\mathrm{T}}D^{-1}=\begin{pmatrix}1.000 & 1.000 & 1.000\\ 1.2265 & 0.8784 & -0.8560\\ -4.2077 & 2.2579 & -0.2269\end{pmatrix}.$$

Experimental determination of the ratios of the characteristic roots and calculation of the matrix of the relative rate constants. We now transform the reaction pathway for pure *cis*-but-2-ene so that it applies to the system B by means of the formula $\beta = X^{-1}\alpha$. The results of the recalculation are presented in Table 2.

Table 2. Isomerisation of butene.

t	$\alpha(t)$	$\beta(t)$	t	$\alpha(t)$	$\beta(t)$
t_0	0.0000 1.0000 0.0000	1.0000 0.8784 2.2579	t_3	0.1411 0.6487 0.2102	1.000 0.5629 0.8233
t_1	0.0543 0.8897 0.0560	1.0000 0.8001 1.7677	t_4	0.1620 0.5230 0.3150	1.0000 0.3883 0.4279
t_2	0.0854 0.8177 0.0969	1.000 0.7400 1.4650			

Fig. 5 illustrates the variation of $\ln b_1$ with $\ln b_2$. Evidently Eqn. (30) yields a straight line whose slope can be used to find the ratio of the characteristic roots λ_1/λ_2. Having determined $\lambda_1/\lambda_2 = 0.4769$ from the graph, we obtain the matrix:

$$\Lambda'=\begin{pmatrix}0.0000 & 0.0000 & 0.0000\\ 0.0000 & -0.4769 & 0.0000\\ 0.0000 & 0.0000 & -1.0000\end{pmatrix}.$$

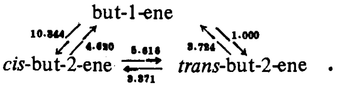
The matrix K^1 is calculated from the formula

$$K^1=X\Lambda'X^{-1}=\begin{pmatrix}-0.72 & 0.2381 & 0.0515\\ 0.5327 & -0.5273 & 0.1736\\ 0.1918 & 0.2982 & -0.2251\end{pmatrix}.$$

The matrix of the relative rate constants K can now be readily evaluated after dividing all the elements by 0.0515:

$$K=\begin{pmatrix}-14.068 & 4.623 & 1.000\\ 10.344 & -10.239 & 3.371\\ 3.724 & 5.616 & -4.371\end{pmatrix}.$$

Thus the relative rate constants are



(II)

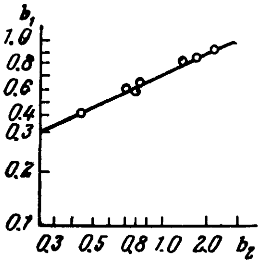


Figure 5. Variation of $\ln b_1$ with $\ln b_2$ for pure *cis*-but-2-ene as the initial species. The slope of the straight line is 0.4769.

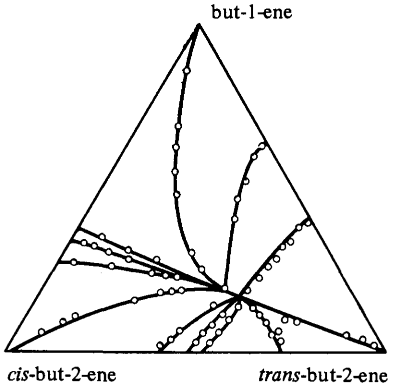

Figure 6. Comparison of the calculated reaction pathways (continuous lines) with the experimental compositions (circles) for the isomerisation of butenes.

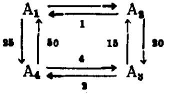
Fig. 6 illustrates the comparison of the calculated and experimental reaction pathways.

Example 2. We shall now examine a hypothetical four-component system to which the following scheme corresponds:



(III)

Subsequently "experimental" data were obtained[16] by calculation from the exact characteristic vectors and roots based on scheme (III). Errors obeying the normal distribution for the standard deviation $\sigma = 1\%$ were added to the exact compositions.

The pure substance A was used as the initial composition. Nine "experimental compositions" along the reaction pathway were used to plot a_m against a_j in Fig. 7. The equilibrium values are located on the vertical dashed line on the left-hand side. The Figure also shows the linear approximations for each curve near equilibrium. The tangents have been produced to the a_1 axis. A vertical line is drawn from the point of intersection with the a_1 axis (corresponding to the substance A_2) nearest to the origin of coordinates. The ordinates of the intercepts of the tangents with this straight line form the matrix

$$\begin{pmatrix}0.3274\\0.0000\\0.0397\\0.6329\end{pmatrix}.$$

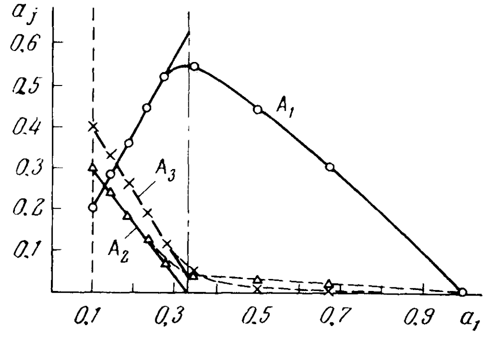


Figure 7. Method for the determination of the new initial composition in the search for a linear reaction pathway in a four-component system.

The sum of the elements of this matrix is 0.008 owing to random errors. In order to obtain a new composition, we therefore divide the matrix elements by 1.008:

$$\alpha_{x_1'}(0)=\begin{pmatrix}0.3248\\0.0000\\0.0394\\0.6279\end{pmatrix}.$$

The above procedure was then repeated until a sufficiently close agreement was obtained between successive values found on extrapolation. This yielded the matrix

$$\alpha_{x_1}(0)=\begin{pmatrix}0.3214\\0.0000\\0.0382\\0.6404\end{pmatrix}.$$

The equilibrium vector is

$$\alpha^*=X_0=\begin{pmatrix}0.1000\\0.2000\\0.4000\\0.2000\end{pmatrix}.$$

We now calculate

$$X_1=\alpha_{x_1}(0)-X_0=\begin{pmatrix}0.2214\\-0.3000\\-0.3618\\0.4404\end{pmatrix}.$$

In order to select a new composition, we use the following procedure. We calculate the vectors $\bar{X}_0$ and $\bar{X}_1$ in the coordinate system B:

$$\bar{X}_0=D^{-1/2}X_0=\begin{pmatrix}0.316228\\0.547723\\0.632456\\0.447214\end{pmatrix}.$$

After similar calculations and normalisation, we obtain

$$\bar{X}_1=\begin{pmatrix}0.484615\\-0.379123\\-0.395966\\0.681634\end{pmatrix}.$$

We now contruct a vector orthogonal with respect to X_1 and X_0 and use it to calculate the initial composition. We set up the vector

$$\bar{\gamma}_1=\begin{pmatrix}0.0000\\-0.622456\\0.547723\\0.000000\end{pmatrix}.$$

Evidently γ_1 is orthogonal with respect to $\bar{X}_1$. We calculate

$$\bar{\gamma}_2=\bar{\gamma}_1-(\bar{X}_1,\bar{\gamma}_1)=\begin{pmatrix}-0.011097\\-0.623774\\0.556790\\-0.015609\end{pmatrix}.$$

After the transformation of γ_2 so that it applies to a non-orthogonal coordinate system and a change in length, we obtain

$$X_{2'}=\begin{pmatrix}-0.003081\\-0.30000\\0.309211\\-0.006130\end{pmatrix},$$

$$\alpha(0)=X_{2'}+X_0=\begin{pmatrix}0.0969\\0.0000\\0.7092\\0.1939\end{pmatrix}.$$

After repeating the successive approximations, starting from this composition, we obtain the vector

$$X_2=\begin{pmatrix}-0.011748\\-0.300000\\0.309178\\0.002571\end{pmatrix}.$$

The vector X_3 may be calculated from the orthogonality relations. Further calculations differed in insignificant details only from the case of a three-dimensional system examined above.

The isomerisation reactions of xylenes have been investigated[24] by a similar method. The experimental linear reaction pathways have been used[25] to test the calculated rate constants.

H. The Structure of Systems of First-Order Reversible Reactions

We shall now summarise the discussion of systems of unimolecular reversible reactions. The structure of these systems is fully described by the theorems formulated above. We found that there are n characteristic vectors with non-positive eigenvalues for reversible reactions in an n-dimensional composition space. Any solution of Eqns. (3) (or the reaction pathway) is a linear combination of characteristic vectors with time-dependent coefficients. One of the characteristic vectors, with a zero eigenvalue, is a positively defined equilibrium vector. The remaining characteristic vectors contain negative elements. However, a linear combination of each non-equilibrium characteristic vector with the equilibrium vector yields a non-negatively defined vector. Therefore all non-equilibrium characteristic vectors are quasipositive. A linear reaction pathway located in the positive octant of the vector space corresponds to any quasipositive vector. All these linear pathways can be observed experimentally. The determination of $n - 1$ linear reaction pathways makes it possible to calculate the matrix of relative rate constants without measuring the reaction time. The system of reversible unimolecular reactions approaches the unique equilibrium point monotonically, oscillations in the system being impossible. Curved reaction pathways approaching the equilibrium point via a spiral curve are therefore also impossible.

3. FIRST-ORDER SYSTEMS INVOLVING REVERSIBLE AND IRREVERSIBLE REACTIONS

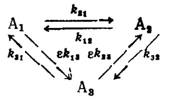
A. The Form of the Kinetic Matrix

The structure of systems containing irreversible steps is significantly more complex than the structure of reversible reactions examined above. This is associated primarily with the fact that the principle of detailed balancing does not hold for systems involving irreversible steps. On the basis of this principle, we showed above that there is a complete system of characteristic vectors for reversible reactions in an n-dimensional composition space and also that the positive octant of the vector space contains $n - 1$ linear reaction pathways. The study of these pathways actually made it possible to devise a method for the determination of the rate constants. A system of reversible reactions approaches the unique equilibrium point regardless of the chosen initial composition. When irreversible steps are present in the system, there may be an infinite number of equilibrium points, there may not be a complete system of characteristic vectors, and the linear reaction pathways may originate from the positive octant of the vector space. The study of irreversible reactions therefore requires a new approach, which will now be discussed.

We shall consider irreversible steps as the limiting cases of reversible stages, involving large changes in free energy or a large decrease in the corresponding rate constants[26]. For example, the simple scheme

(IV)

can be regarded as the limiting case of the scheme



(V)

when $\epsilon \rightarrow 0$. We shall show what information can be derived from the principle of detailed balancing in such a limiting transition. The Wegsheider condition for scheme (V) yields $k_{12}k_{23}k_{31} = k_{32}k_{21}k_{13}$. The rate constant matrix for scheme (V)

$$\begin{pmatrix} -(k_{21}+k_{31}) & k_{12} & \varepsilon k_{13} \\ k_{21} & -(k_{12}+k_{32}) & \varepsilon k_{23} \\ k_{31} & k_{32} & -\varepsilon(k_{13}+k_{23}) \end{pmatrix}$$

becomes the kinetic matrix for system (IV) when $\epsilon \rightarrow 0$:

$$\begin{pmatrix} -(k_{21}+k_{31}) & k_{12} & 0 \\ k_{21} & -(k_{12}+k_{32}) & 0 \\ k_{31} & k_{32} & 0 \end{pmatrix} . \qquad (41)$$

The equilibrium concentrations for scheme (V) are calculated from the principle of detailed balancing:

$$\begin{aligned} a_1^{*} &= \varepsilon\,(k_{13}/k_{31})\,a_3^{*}, \\ a_2^{*} &= \varepsilon\,(k_{23}/k_{32})\,a_3^{*}, \\ a_3^{*} &= a_3^{*}. \end{aligned} \qquad (42)$$

The equilibrium composition matrix D changes in the following way when $\epsilon \rightarrow 0$:

$$\begin{pmatrix} a_1^{*} & 0 & 0 \\ 0 & a_2^{*} & 0 \\ 0 & 0 & a_3^{*} \end{pmatrix} \rightarrow \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The matrix D for scheme (IV) is degenerate, so that $D^{-1/2}$ does not exist and reduction to the symmetrical form which we used above is no longer possible. However, it follows from the principle of detailed balance that the ratio of the equilibrium concentrations is independent of ϵ:

$$\frac{a_1^{*}}{a_2^{*}} = \frac{k_{13}k_{23}}{k_{31}k_{32}} = \frac{k_{12}}{k_{21}}. \qquad (43)$$

It follows from Eqn. (43) that

$$\frac{a_1^{*}}{a_1^{*}+a_2^{*}} = \frac{k_{12}}{k_{12}+k_{21}}; \quad \frac{a_2^{*}}{a_1^{*}+a_2^{*}} = \frac{k_{21}}{k_{12}+k_{21}}.$$

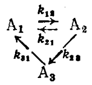
We now construct the matrix

$$D = \begin{pmatrix} \dfrac{k_{12}}{k_{12}+k_{21}} & 0 & 0 \\ 0 & \dfrac{k_{21}}{k_{12}+k_{21}} & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad (44)$$

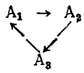
and calculate

$$D^{-1/2}KD^{1/2} = \begin{pmatrix} \begin{bmatrix} -(k_{21}+k_{31}) & (k_{12}k_{21})^{1/2} \\ (k_{12}k_{21})^{1/2} & -(k_{12}+k_{23}) \end{bmatrix} & \begin{matrix} 0 \\ 0 \end{matrix} \\ \begin{matrix} k_{13} & \qquad k_{32} \end{matrix} & 0 \end{pmatrix}. \qquad (45)$$

Evidently the submatrix enclosed in brackets is symmetrical. Thus, using the limiting form of the principle of detailed balancing, it is possible to reduce to a symmetrical form the submatrices corresponding to subsystems with reversible reactions. We shall use this fact below for the description of complex systems involving irreversible steps. However, one should note here that we shall be forced to restrict somewhat the range of subsystems considered. We shall postpone until the next section the study of systems involving cycles of irreversible reactions. For example, schemes of the type



(VI)

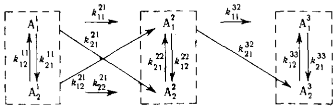


(VII)

are not analysed, because they cannot be regarded as limiting cases of the corresponding schemes for reversible reactions, since the Wegsheider condition is infringed in the limiting transition, i.e. the principle of detailed balance ceases to hold. In fact, we shall attempt to represent scheme (VI) as the limiting case of scheme (V) when the constants k_{32} and k_{13} tend to zero. Both these constants enter into the right-hand side of Eqn. (12), so that the condition defined by this equation breaks down when k_{32} and k_{13} decrease.

Below we shall formulate rigorously the class of systems to be considered. To extend the treatment from an example to the general case, we shall introduce certain concepts and symbols.

The irreversible stages in the general system can be isolated by subdividing the system into reversible subsystems linked by irreversible stages. We shall combine substances linked by reversible reactions into subsystems and shall consider the reactions between these subsystems, assuming them to be identical with fictitious simple substances. We shall consider the following scheme:



(VIII)

This system can be divided into subsystems:

$$M^1 \leftrightarrow \overset{A_1^1}{\underset{A_2^1}{\downarrow\uparrow}}\ ;\ M^2 \leftrightarrow \overset{A_1^2}{\underset{A_2^2}{\downarrow\uparrow}}\ ;\ M^3 \leftrightarrow \overset{A_1^3}{\underset{A_2^3}{\downarrow\uparrow}}\quad . \tag{IX}$$

The entire system can then be represented thus: $M^1 \rightarrow M^2 \rightarrow M^3$. In designating the substances, the superscript refers to the number of the subsystem and the subscript to the number of the substance in the subsystem. The kinetic matrix assumes the following form:

$$K=\begin{pmatrix} \begin{bmatrix} -(k_{21}^{11}+k_{11}^{21}+k_{21}^{21}) & k_{12}^{11} \\ k_{21}^{11} & -(k_{12}^{11}+k_{12}^{21}+k_{22}^{21}) \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \\ \begin{bmatrix} k_{11}^{21} & k_{12}^{21} \\ k_{21}^{21} & k_{22}^{21} \end{bmatrix} & \begin{bmatrix} -(k_{11}^{22}+k_{11}^{32}+k_{21}^{32}) & k_{12}^{22} \\ k_{21}^{22} & -k_{12}^{22} \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \\ \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} & \begin{bmatrix} k_{11}^{32} & 0 \\ k_{21}^{32} & 0 \end{bmatrix} & \begin{bmatrix} -k_{21}^{33} & k_{12}^{33} \\ k_{21}^{33} & -k_{12}^{33} \end{bmatrix} \end{pmatrix}.$$

In designating the rate constants, the superscripts again refer to the numbers of the subsystems and the subscripts to the numbers of the substances. The first subscript refers to the reaction product and the second to the starting material. Thus the rate constant for the reaction $A_5^1 \rightarrow A_4^3$ is designated by k_{45}^{31}.

If the submatrices enclosed in square brackets are designated by K^{ij}, we find that

$$K=\begin{pmatrix} K^{11} & 0 & 0 \\ K^{21} & K^{22} & 0 \\ 0 & K^{32} & K^{33} \end{pmatrix}. \tag{46}$$

Evidently the kinetic matrix in the example considered is triangular.

We shall now deal with the general case. We shall put $M^\alpha \rightarrow M^\beta$ only when there is a series of consecutive reactions leading from subsystem M^α to subsystem M^β. For example $M^\alpha \rightarrow M^\beta$ if the following sequence of reactions occurs:

$$M^\alpha \rightarrow M^{\alpha+1} \rightarrow M^\beta \quad . \tag{X}$$

We shall consider systems in which there are only three possibilities: (1) $M^\alpha \rightarrow M^\beta$; (2) $M^\beta \rightarrow M^\alpha$; (3) there is no interaction between M^α and M^β. Conditions 1 and 2 cannot be fulfilled simultaneously. It is readily seen that cycles are thus excluded from consideration. Conditions 1–3 determine the form of the kinetic matrix. We shall assign to the subsystems superscripts such that $\beta > \alpha M^\alpha \not\rightarrow M^\beta$, i.e. all the rate constants for the conversion of A_i^β into A_i^α are zero. After the introduction of such numbering of the subsystems, it is possible to formulate the kinetic matrix as follows:

$$K=\begin{pmatrix} K^{11} & \dots\dots\dots & \\ K^{21} & K^{22} & \dots\dots \\ \dots & \dots\dots & \dots \\ K^{\nu 1} & \dots\dots & K^{\nu\nu} \end{pmatrix}, \tag{47}$$

where the submatrices $K^{\beta\alpha}$ are the matrices of the rate constants for the irreversible reactions leading from M^α to M^β.

The diagonal submatrices $K^{\alpha\alpha}$ can be written as follows:

$$K^{\alpha\alpha}=K^{m\alpha}+\Sigma^{\cdot\alpha}, \tag{48}$$

where $\Sigma^{\cdot\alpha}$ is the diagonal matrix corresponding to the irreversible reactions leading from M^α. The diagonal elements of $\Sigma^{\cdot\alpha}$ are equal to the sum of the elements of the corresponding column with the sign reversed. Systems with a kinetic matrix of type (47) are considered below.

B. The Eigenvalues

We shall set up for each diagonal submatrix a matrix of equilibrium ratios D^α, as was done in the example analysed above. We define for the entire system a non-degenerate diagonal matrix $D^{1/2}$:

$$D^{1/2}=\begin{pmatrix} (D^1)^{1/2} & & & \\ & (D^2)^{1/2} & & \\ & & \ddots & \\ & & & (D^\nu)^{1/2} \end{pmatrix}, \tag{49}$$

where $(D^i)^{1/2}$ is the matrix of the equilibrium ratios for the irreversible subsystem M^i. The element with the number jj in the matrix $(D^i)^{1/2}$ is

$$[(a_j^i)^*]^{1/2}/\left[\sum_i (a_i)^*\right]^{1/2}.$$

It can be shown that the diagonal submatrices $B^{\alpha\alpha}$ of the matrix $B = D^{-1/2}KD^{1/2}$ are symmetrical. Hence follows theorem 3: The diagonal submatrices $K^{\alpha\alpha}$ of the triangular kinetic matrix K for a system involving reversible and irreversible stages possess a complete system of characteristic vectors.

It has also been shown[26] that the matrix of the characteristic vectors for the kinetic matrix K is triangular:

$$X=\begin{pmatrix} X^{11} & 0 & \dots\dots & 0 \\ X^{21} & X^{22} & \dots\dots & 0 \\ \dots & \dots & \dots\dots & \dots \\ X^{\nu 1} & \dots & \dots\dots & X^{\nu\nu} \end{pmatrix}, \tag{50}$$

where $X^{\alpha\beta}$ is the matrix of the characteristic vectors of the submatrix $K^{\alpha\beta}$. There are m relations of the type

$$K^{\alpha\alpha}X^{\alpha\alpha}=X^{\alpha\alpha}\Lambda^\alpha, \tag{51}$$

where m is the total number of reversible subsystems and Λ^{α} the matrix of the eigenvalues of the submatrix $K^{\alpha\alpha}$.

We therefore have theorem 4: all the eigenvalues of the kinetic matrix K are fully defined by the submatrices $K^{\alpha\alpha}$.

Corollary 1. All the eigenvalues of the matrix K are non-positive.

Corollary 2. Oscillations are impossible in a system involving reversible and irreversible first-order reactions with a triangular matrix K.

We found that each diagonal submatrix $K^{\alpha\alpha}$ has a complete system of characteristic vectors. However, from this it does not yet follow that the entire matrix K is a complete system of characteristic vectors. This is true only when the eigenvalues of the submatrices $K^{\alpha\alpha}$ and $K^{\beta\beta}$ are not the same. When the eigenvalues are the same, cases are possible where the kinetic matrix cannot be reduced to the diagonal form. Nevertheless, in practice the matrix K should usually have a complete system of eigenvectors. We shall prove the validity of this case and shall discuss it below.

C. Disposition of the Characteristic Vectors

We recall that a linear reaction pathway in the composition space corresponds to each characteristic vector. We are interested only in the linear pathways located in the positive octant of the space. For a system of reversible reactions, the non-equilibrium vectors were found to be quasipositive and the corresponding linear reaction pathways could be observed experimentally. We shall attempt to elucidate the disposition of the characteristic vectors in a system involving reversible and irreversible stages.

Definition 4. The subsystem M^{ν} is called finite if there are no irreversible reactions leading from this subsystem to others. A system may contain several finite subsystems. For example the subsystems M_5 and M_4 in the scheme

$$\begin{tikzcd} M_1 \arrow[r] \arrow[d] & M_2 \arrow[r] & M_3 \arrow[dl] \\ M_5 & M_4 & \end{tikzcd} \qquad \text{(XI)}$$

are finite.

In each of s finite closed subsystems, there is an equilibrium positively defined characteristic vector $X_e^{\nu\nu}$. Thus the entire system contains s characteristic vectors of the type

$$X_e^{\nu} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ X_e^{\nu\nu} \end{pmatrix}, \qquad (52)$$

where X_e^{ν} is a column vector of the matrix X. All the linear combinations of these vectors are the equilibrium points of the system involving irreversible stages and all the equilibrium points are linear combinations of the equilibrium vectors. Thus the system contains s independent positive vectors in the positive octant.

A linear combination of equilibrium and non-equilibrium characteristic vectors in the systems considered does not necessarily give rise to a positively defined vector, since the equilibrium point is located in the composition subspace. In fact a criterion for the existence of quasipositive vectors, arising from the open subsystem $M^{\alpha}\rightarrow$, readily follows from the equation for a system with a unique equilibrium point:

$$\alpha_{x_i} = X_i^{\alpha} + X_e^{\nu} = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ X_i^{\alpha\alpha} \\ X_i^{\alpha+1,\alpha} \\ \vdots \\ X_i^{\nu\alpha} \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \vdots \\ \vdots \\ 0 \\ X_e^{\nu\nu} \end{pmatrix}. \qquad (53)$$

Theorem 5. For the characteristic vector X_i^{α}, where $\alpha < \nu$, to be quasipositive, it is necessary and sufficient that all the subvectors $X_i^{\beta\alpha}$ should contain only non-negative elements.

Theorem 6[26]: The matrix $X^{\alpha\alpha}$ for the open subsystem $M^{\alpha}\rightarrow$ contains one and only one subvector $X_i^{\alpha\alpha}$, all the elements of which are non-negative. The existence of the positively defined vector follows from Wei's theorem[27], namely theorm 7: one of the following statements is valid for a system of first-order reactions including any number of components: either the equilibrium composition is non-zero or there is at least one linear pathway in the positive octant of the space.

Hence follows the conclusion that, which the system contains u open subsystems of type $M^{\alpha}\rightarrow$, there are at most u quasipositive vectors arising from these subsystems.

We shall consider yet another special case of subsystems such that there are no reactions leading from them to other open subsystems and there are only reactions leading to a finite subsystem. Subsystems of this kind are called adjacent to the finite system. Since the characteristic vector X_i^{α} for such a subsystem does not contain the subvectors $X_i^{\beta\alpha}$, where β is an open subsystem, it follows that there is always one quasipositive vector for each subsystem adjoining the finite system. If the system contains v adjacent subsystems, one can assert that there are v quasipositive vectors.

We shall also consider a pair of transitional subsystems of the type

$$\begin{tikzcd} M^{\alpha} \arrow[r] \arrow[d] & M^{\beta} \arrow[d] \\ {} & {} \end{tikzcd} . \qquad \text{(XII)}$$

It is of interest to obtain a criterion of the absence of negative elements from the subvectors $X_r^{\beta\alpha}$.

This criterion is given by therem 8: for transitional subsystems (XII), the subvector $X_r^{\beta\alpha}$, where M^{β} is an intermediate subsystem (not adjacent to the finite system) will not contain negative elements when $|\lambda_r^{\alpha}| < |\lambda_r^{\beta}|$ and will contain non-positive elements when $|\lambda_r^{\alpha}| > |\lambda_r^{\beta}|$.

We can now summarise the findings obtained from the consideration of the structure of systems involving irreversible stages. A complex system with reversible and irreversible stages can be conveniently represented by reversible subsystems linked by irreversible stages. It is possible to isolate two principal differences from systems involving reversible reactions only. The first is that the matrix K cannot always be reduced to a diagonal form. However, in practice such instances should not arise frequently. It is therefore more important that not all the characteristic vectors are quasipositive and the corresponding linear pathways cannot be observed experimentally. The following statements may be made about the disposition of the eigenvectors:

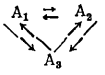
1. There exists a positively defined equilibrium characteristic vector for each finite subsystem.
2. All non-equilibrium characteristic vectors, arising from a finite subsystem, are quasipositive. The corresponding linear pathways can be observed experimentally.
3. The number q of quasipositive vectors arising from intermediate subsystems is between u (the number of all intermediate subsystems) and v (the number of subsystems adjoining the finite system).

Thus the characteristic vectors for systems involving irreversible stages are frequently not located in the positive quadrant of the composition space and it is impossible to obtain the positive vector from a linear combination of equilibrium and non-equilibrium characteristic vectors. A "projection" method has therefore been proposed[28] whereby artificial linear reaction pathways may be obtained.

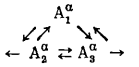
D. Artificial Linear Reaction Pathways. Projection Method

The essential feature of the method in the simplest case reduces to the consideration, instead of the open subsystem $M^{\alpha}\rightarrow$, of a closed subsystem $\hat{M}^{\alpha}$, which is obtained by adding to the subsystem the mass loss as a result of irreversible reactions away from the subsystem. Geometrically this implies the projection of the reaction pathways on the (1, 1, ..., 1) hyperplane.

Projection of the principal subvectors $X^{\alpha\alpha}$. We shall compare initially a reversible closed system M with a subsystem $M^{\alpha}\rightarrow$ in relation to three-component systems:



(XIII)



(XIV) .

In each of these systems, there is a positively defined characteristic vector. In the first case, this is an equilibrium vector X_e and in the second a vector $X_r^{\alpha\alpha}$. The equilibrium vector X_e contains the entire mass of the system M and the sum of all the elements of non-equilibrium characteristic vectors is zero. In other words, all the characteristic vectors X_i with $i \neq e$ are perpendicular to the unit vector I (1, ..., 1) and they are therefore located in the (1, 1, ..., 1) hyperplane. On the other hand, the $X_r^{\alpha\alpha}$ does not contain the mass of the entire system and the vectors $X_r^{\alpha\alpha}$ and I may not in fact be perpendicular. The disposition of the characteristic vectors is illustrated in Figs. 8 and 9. When the initial vector $a_x(0)$ of a closed system M is located in the plane of the equilibrium vector and one of the non-equilibrium characteristic vectors, the movement of the system towards equilibrium is given by the equation

$$a_x(t)=X_e+b_i(t)X_i. \tag{54}$$

Thus a natural linear reaction pathway in the (1, 1, ..., 1) hyperplane arises for each characteristic vector X_i. All the curved reaction pathways are also located in the (1, 1, ..., 1) hyperplane. For the system $M^{\alpha}\rightarrow$, the reaction pathways can no longer be located in the plane perpendicular to the vector I, since the equilibrium point which the system approaches coincides with the origin of coordinates. If the initial vector is located in the plane of the vector $X_r^{\alpha\alpha}$ and one of the other characteristic vectors $X_i^{\alpha\alpha}$, then the movement towards equilibrium can be described by the equation

$$a_x(t)=b_r^{\alpha}X_r^{\alpha\alpha}+b_i^{\alpha}(t)X_i^{\alpha\alpha}. \tag{55}$$

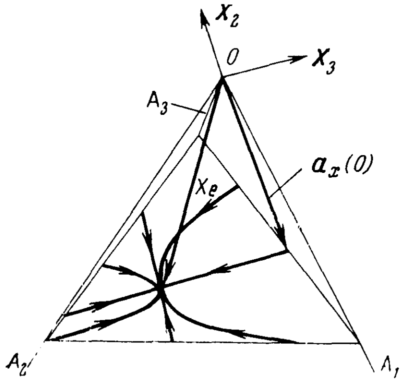


Figure 8. Reaction pathways and characteristic vectors for the system (XIII).

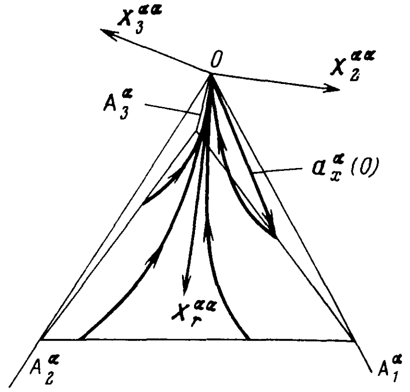

Figure 9. Reaction pathways and characteristic vectors for the system (XIV).

Since the vectors $X_r^{\alpha\alpha}$ and $X_i^{\alpha\alpha}$ are non-zero, we obtain a curved reaction pathway. The only linear reaction pathway located in the positive octant of the vector space therefore coincides with the direction of the vector $X_r^{\alpha\alpha}$. Furthermore, Eqn. (55) shows that any composition vector located in the plane of $X_r^{\alpha\alpha}$ and $X_i^{\alpha\alpha}$ for $t = 0$ remains in this plane subsequently. Thus the reaction pathway for the system $M^{\alpha}\rightarrow$ consists in the general case of a spatial curve. If this curve is projected onto the

(1, 1, ..., 1) hyperplane, it is possible to obtain an artificial linear reaction pathway. Fig. 10 illustrates a projection parallel to the vector $X_r^{\alpha\alpha}$, which yields an artificial linear reaction pathway.

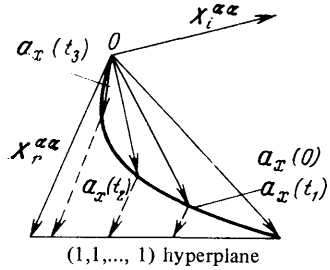

Figure 10. Projection of curved reaction pathways on the (1, 1, ..., 1) hyperplane.

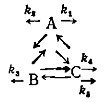
We shall consider initially the specific case of the subsystems $M^\alpha \rightarrow$, where the sum of the rate constants for the irreversible reactions involving the ith substance of the subsystem is independent of the number i. Thus, for the subsystem



(XV)

this implies that $k_1 + k_2 = k_3 = k_4 + k_5 = c =$ const. When the length of the characteristic vectors is chosen suitably, the following expression can be formulated for the reaction pathway in the subsystems considered:

$$a^\alpha(t) = e^{-ct} X_r^{\alpha\alpha} + \sum_{l=2}^{n^\alpha} b_l(t) X_l^{\alpha\alpha}, \tag{56}$$

where n^α is the dimension of the subsystem $M^\alpha \rightarrow$. The entire mass of the system is concentrated at $X_r^{\alpha\alpha}$ and the remaining characteristic vectors are perpendicular to the unit vector I = (1, 1, ..., 1). The loss of mass from the system owing to irreversible reactions is $X_r^{\alpha\alpha} - e^{-ct} X_r^{\alpha\alpha}$. Projection parallel to the direction of the vector $X_r^{\alpha\alpha}$ is equivalent to an artificial compensation for the mass lost as a result of the irreversible reactions. The artificial composition vector $\hat{a}^\alpha(t)$, arising on projection, is defined by the equation

$$\hat{a}^\alpha(t) = X_r^{\alpha\alpha} + \sum_{l=2}^{n^\alpha} b_l(t) X_l^{\alpha\alpha}. \tag{57}$$

We obtained an equation for a closed system of reversible reactions with an artificial equilibrium point $X_r^{\alpha\alpha}$.

We shall now consider the general case of subsystems $M^\alpha \rightarrow$. In the general case, it is no longer possible to assume that all the vectors $X_i^{\alpha\alpha}$ are orthogonal with respect to the unit vector I (1, 1, ..., 1). The following equation holds for the reaction pathway:

$$a^\alpha(t) = b_r^\alpha(t) X_r^{\alpha\alpha} + \sum_k b_k^\alpha(t) X_k^{\alpha\alpha} + \sum_j b_j^\alpha(t) X_j^{\alpha\alpha}, \tag{58}$$

where the vectors $X_k^{\alpha\alpha}$ are orthogonal with respect to the unit vector I, a condition which does not hold for the $X_j^{\alpha\alpha}$. The number of vectors $X_k^{\alpha\alpha}$ and $X_j^{\alpha\alpha}$ is unimportant and the only significant factor is that the total number of characteristic vectors $X_i^{\alpha\alpha}$ (for $i \neq r$) is equal to $n^\alpha - 1$. The length of the characteristic vectors orthogonal with respect to I will be chosen so that the vectors are located in the (1, 1, ..., 1) hyperplane.

We showed above that, when $M^\alpha \rightarrow$ is projected, it is converted into a closed subsystem $\hat{M}^\alpha$ with an equilibrium point $X_r^{\alpha\alpha}$. Since $X_r^{\alpha\alpha}$ contains the entire mass in the transformed subsystem $\hat{M}^\alpha$, the remaining characteristic vectors must be orthogonal to the unit vector I. Eqn. (58) can therefore be transformed in such a way that all the vectors other than $X_r^{\alpha\alpha}$ are orthogonal to the unit vector. Since the vectors $X_r^{\alpha\alpha}$ and $X_j^{\alpha\alpha}$ are located in the (1, 1, ..., 1) hyperplane, the vector $X_r^{\alpha\alpha} - X_r^{\alpha\alpha}$ must be located in a plane parallel to this hyperplane. The required transformation can therefore be obtained by adding $\Sigma b_i(t) X_r^{\alpha\alpha}$ to the first term of Eqn. (58) and by substracting it from the last term:

$$a^\alpha(t) = \left\{ b_r(t) + \sum_j b_j(t) \right\} X_r^{\alpha\alpha} + \sum_k b_k^\alpha(t) X_k^{\alpha\alpha} + \sum_j b_j^\alpha(t) (X_j^{\alpha\alpha} - X_r^{\alpha\alpha}). \tag{59}$$

We shall now consider an artificial system $\hat{M}^\alpha \rightarrow$ obtained by projecting the vector $a^\alpha(t)$ onto the (1, 1, ..., 1) hyperplane parallel to $X_r^{\alpha\alpha}$. The weight loss from the system is

$$\left[b_r^\alpha(0) + \sum_j b_j^\alpha(0) \right] X_r^{\alpha\alpha} - \left[b_r^\alpha(t) + \sum_j b_j^\alpha(t) \right] X_r^{\alpha\alpha}. \tag{60}$$

In order to obtain the artificial system, we add this amount to $a^\alpha(t)$ defined by the Eqn. (59):

$$\hat{a}^\alpha(t) = X_r^{\alpha\alpha} + \sum_k b_k^\alpha(t) X_k^{\alpha\alpha} + \sum_j b_j^\alpha(t) (X_j^{\alpha\alpha} - X_r^{\alpha\alpha}). \tag{61}$$

The last equation is valid for an artificial closed system of reversible first-order reactions with a matrix $\hat{K}_{\alpha\alpha}$. The eigenvector matrix for $\hat{K}_{\alpha\alpha}$ is

$$\hat{X}^{\alpha\alpha} = (X_r^{\alpha\alpha}, \ldots\ldots X_k^{\alpha\alpha} \ldots\ldots (X_j^{\alpha\alpha} - X_r^{\alpha\alpha})). \tag{62}$$

Projection in non-diagonal subsystems. In the previous section we considered the principal systems whose kinetic matrices are located on the diagonal of the matrix for the entire system. We shall now consider non-diagonal transitional subsystems.

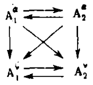
We shall analyse initially two special cases: the system

$$M^\alpha \rightarrow M^\nu \quad , \tag{XVI}$$

where M^ν is a finite subsystem and

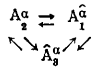
$$\underset{\downarrow}{M^\alpha} \rightarrow \underset{\downarrow}{M^\beta} \text{ when } K^{\beta\alpha} \neq 0 \ . \tag{XVII}$$

The system (XVI) is closed and all the characteristic vectors, except the equilibrium vector X_e^ν, are perpendicular to the vector I. The equilibrium vector X_e^ν is of the form $X_e^\nu = \begin{pmatrix} 0 \\ X_e^{\nu\nu} \end{pmatrix}$. The only quasipositive characteristic vector will be designated by X_e^α. The possibility of obtaining artificial reaction pathways by projection will be examined in relation to the system



(XVIII)

Fig. 11 illustrates the (1, 1, 1, 1) hyperplane for the system (XVIII). The natural linear reaction pathway X_2^α is not located in the positive octant of the vector space. The curved reaction pathway, beginning in the (X_r^α, X_i^α) plane, remains in this plane until the attainment of the equilibrium point X_e^α. By projecting the curved pathway onto the subspace (1, 1, 0, 1), one can therefore obtain an artificial linear pathway in a finite segment of the positive octant. Such projection converts the system (XVIII) into the artificial system



(XIX)

The artificial equilibrium point N for the system (XIX) coincides with the point of intersection of the line of the vector X_r^α with subspace (1, 1, 0, 1).

Returning now to the general case, the equation for the system $M^\alpha \rightarrow M^\nu$ will be written in the form

$$a(t) = X_e^\nu + b_r^\alpha(t)X_r^\alpha + \sum_{i=2}^{n^\nu} b_i^0(t)X_i^\nu + \sum_{i=2}^{n^\alpha} b_i^\alpha(t)X_i^\alpha. \tag{63}$$

We transform Eqn. (63) into the equation for a system of reversible reactions from which the component A_j^ν has been excluded. The final result is

$$\hat{a}(t) = \{X_e^\nu + CX_r^\alpha\} + \sum_{i=2}^{n^\alpha} b_i^\alpha(t)\{X_i^\alpha - \varphi_i^\alpha X_r^\alpha\} + \sum_{i=2}^{n^\nu} b_i^\nu(t)\{X_i^\nu - \varphi_i^\nu X_r^\alpha\}, \tag{64}$$

where the scalars φ_i^k ($k = \alpha$ or ν) have been chosen so that $(X_{ik} - \varphi_i^k X_{jr}) = 0$; the constant C is chosen so that

$$\hat{a}_j^\nu = X_{je}^{\nu\nu} + CX_{jr}^{\nu\alpha} = 0. \tag{65}$$

The initial composition for the artificial linear pathway is determined from the equation

$$\hat{a}(0) = \{X_e^\nu + CX_r^\alpha\} + b_i^k(0)\{X_i^k - \varphi_i^k X_r^\alpha\}, \tag{66}$$

where $k = \alpha$ or ν.

It must be emphasised that a natural linear reaction pathway is a simple linear combination of the equilibrium vector and one non-equilibrium characteristic vector. On the other hand, an artificial linear pathway is a linear combination of several characteristic vectors,

We shall now consider the open system (XVII). We shall ignore all stages after $M^\alpha \rightarrow$ and $M^\beta \rightarrow$ and shall take into account only the subspace corresponding to $M^\alpha \rightarrow$ and $M^\beta \rightarrow$. The subvectors

$$X_i^u = \begin{pmatrix} X_i^{\alpha\alpha} \\ X_i^{\beta\alpha} \end{pmatrix}, \quad X_i^\beta = \begin{pmatrix} 0 \\ X_i^{\beta\beta} \end{pmatrix} \tag{67}$$

are the characteristic vectors of the subsystem (XVII).

We shall consider two cases of interest. It was shown previously that, when $\lambda_r^\alpha < \lambda_r^\beta$, then X_r^u should be a non-negative vector. It is possible to show that X_r^u consists of positive elements only. For the scheme (XVII), one can write the following equation:

$$a^u(t) = b_r^\alpha(t) + b_r^\beta(t)X_r^\beta + \sum_{i=2}^{n^\alpha} b_i^\alpha(t)X_i^u + \sum_{i=2}^{n^\beta} b_i^\beta(t)X_i^\beta. \tag{68}$$

We shall assume, to make the treatment concrete, that none of the characteristic vectors is perpendicular to the vector I. Furthermore, the length of the characteristic vectors is chosen so that they are located in the (1,1,...,1) hyperplane.

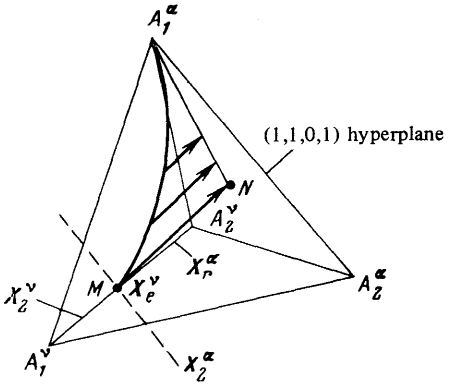


Figure 11. Parallel projection for the system (XVIII); M—equilibrium point; N—artificial equilibrium point.

Eqn. (68) can then be rewritten in the form

$$\begin{aligned} a^u(t) = {} & (b_r^\alpha(t) + b_r^\beta(t)) + \sum_{i=2}^{n^\alpha} b_i^\alpha(t) + \sum_{i=2}^{n^\beta} b_i^\beta(t)X_r^u + \\ & + b_r^\beta(t)\{X_r^\beta - X_i^u\} + \sum_{i=2}^{n^\alpha} b_i^\alpha(t)(X_i^u - X_r^u) + \sum_{i=2}^{n^\beta} b_i^\beta(t)(X_i^\beta - X_r^u). \end{aligned} \tag{69}$$

In Eqn. (69) the vectors $X_j^R - X_r^u$ ($j = i$ or r, $R = u$ or β) are perpendicular to the vector I. The entire loss of mass takes place along X_r^u. Parallel projection results in compensation for the loss of mass from the system:

$$\hat{a}^u(t) = X^u + b_r^\beta(t)\{X_r^\beta - X_i^u\} + \sum_{i=2}^{n^\alpha} b_i^\alpha(t)\{X_i^u - X_r^u\} + \sum_{i=2}^{n^\beta} b_i^\beta(t)(X_i^\beta - X_r^u). \tag{70}$$

Eqn. (70) is the equation for a closed system of reversible reactions with an artificial equilibrium point X_r^u. The initial compositions for artificial linear reaction pathways are

$$\begin{aligned} \hat{a}_x(0) &= X_r^u + b_i^\alpha(0)(X_i^u - X_r^u), \ i \neq r; \\ \hat{a}_x(0) &= X_r^u + b_i^\beta(0)(X_i^\beta - X_r^u). \end{aligned} \tag{71}$$

We shall now consider the case where $\lambda_r^\alpha > \lambda_r^\beta$. The subvector $X_r^{\beta\alpha}$ must contain negative elements and X_r^u is not located in the positive octant. In this case, the vector X_r^u can be used to transform the open system (XVII) into a closed system. By carrying out transformations similar to those described above, we obtain

$$\begin{aligned} \hat{a}^u(t) = {} & X_r^\beta + b_r^\alpha(t)\{X_r^u - X_r^\beta\} + \\ & + \sum_{i=2}^{n^\alpha} b_i^\alpha(t)\{X_i^u - X_r^\beta\} + \sum_{i=2}^{n^\beta} b_i^\beta(t)\{X_i^\beta - X_r^\beta\}. \end{aligned} \tag{72}$$

The initial composition for a linear reaction pathway is determined from

$$\hat{a}_x(0)=X_r^{\beta}+b_i^{\alpha}(0)\{X_i^{u}-X_r^{\beta}\}. \tag{73}$$

Since $X_r^{\beta} = \begin{pmatrix}0\\ X_i^{\beta\beta}\end{pmatrix}$ and X_i^{u} contains negative elements for $i \neq r$, a linear pathway located in the positive octant is obtained only when the vector X_r^{β} is used. Next, suppose that $i \neq r$. Eqn. (72) can be regarded as one describing an artificial closed system $\hat{M}^{\alpha} \rightarrow \hat{M}^{\beta}$. Using a method similar to that described above, this system can be transformed into a system of reversible reactions with the exclusion of one component. The final result is

$$\begin{aligned}\hat{\hat{a}}^{u}(t)=X_r^{\beta}+C(X_r^{u}-X_r^{\beta})+\sum_{i=1}^{n^{\alpha}} b_i^{\alpha}(t)\{X_i^{u}-X_r^{\beta}-\varphi_i^{u}(X_r^{u}-X_r^{\beta})\}+\\ +\sum_{i=1}^{n^{\beta}} b_i^{\beta}(t)\{X_i^{\beta}-X_r^{\beta}-\varphi_i^{\beta}(X_r^{u}-X_r^{\beta})\}.\end{aligned} \tag{74}$$

The initial composition for a linear pathway is given by the formula

$$\hat{\hat{a}}_x(0)=X_r^{u}+C(X_r^{u}-X_r^{\beta})+b_i^{\alpha}(0)\{X_i^{u}-X_r^{\beta}-\varphi_i^{u}(X_r^{u}-X_r^{\beta})\}. \tag{75}$$

We shall now show how these results can be used to determine the rate constants.

E. Definition of the Rate Constants

Rate Constants for Reversible Reactions. All the constants for reversible reactions are located in the diagonal submatrices $K^{\alpha\alpha}$. It was shown above that

$$K^{\alpha\alpha}=X^{\alpha\alpha}\Lambda^{\alpha}(X^{\alpha\alpha})^{-1}. \tag{76}$$

If the principal subvectors $X_i^{\alpha\alpha}$ have been found, it is possible to determine the eigenvalues λ^{α}. Then, knowing $X_i^{\alpha\alpha}$ and the matrix Λ^{α}, it is possible to calculate the rate constant matrix from Eqn. (76).

The principal subvectors $X_i^{\alpha\alpha}$ are the characteristic vectors of the system $M^{\alpha}\rightarrow$. Since such a scheme involves a zero equilibrium composition, there exists only one natural linear reaction pathway located in the positive octant of the vector space and coinciding with the directions of the vector $X_r^{\alpha\alpha}$. However, if the composition vector $a_x^{\alpha}(t)$ is located initially in the plane of the vectors $X_r^{\alpha\alpha}$ and $X_i^{\alpha\alpha}$, the movement of the system towards equilibrium is described by the equation

$$a_x^{\alpha}(t)=b_r^{\alpha}(t)X_r^{\alpha\alpha}+b_i^{\alpha}(t)X_i^{\alpha\alpha}. \tag{77}$$

When this curved pathway is projected onto the (1, 1, ..., 1) hyperplane, it is possible to obtain an artificial linear reaction pathway. Using a projection parallel to the vector $X_r^{\alpha\alpha}$, we obtain the equation for the artificial composition vector $\hat{a}(t)$:

$$\hat{a}^{\alpha}(t)=a^{\alpha}(t)+\delta(t)X_r^{\alpha\alpha}. \tag{78}$$

The scalar $\delta(t)$ is chosen so that

$$\delta(t)=1-\sum_{i=1}^{n^{\alpha}} a_i^{\alpha}(t). \tag{79}$$

The transformation of the subsystem A^{α} leads to a subsystem $\hat{M}^{\alpha}$ in which there are $n^{\alpha}-1$ artificial linear reaction pathways for each vector $X_i^{\alpha\alpha}$ with $i \neq r$. These artificial linear pathways can be found by the procedure used to find the natural linear pathways in a system of reversible reactions. Thus the following steps are necessary for the determination of the rate constants in the subsystem $M^{\alpha}\rightarrow$:

1. One must find the natural linear reaction pathway and the unique quasipositive characteristic vector $X_r^{\alpha\alpha}$. This can be done as described above when reversible reactions were considered.
2. The experimental reaction pathways are recalculated in terms of Eqns. (78) and (79), which gives rise to the artificial subsystems $\hat{M}^{\alpha}$.
3. The linear reaction pathways and the vectors $\alpha_{x_i}(0)$ must be found for the artificial subsystem $\hat{M}^{\alpha}$. This is again done by the procedure described above.
4. The vectors $X_i^{\alpha\alpha}$ with $i \neq r$ must be determined.

Since the vectors $\hat{a}_x^{\alpha}(0)$, $X_i^{\alpha\alpha}$, and $X_r^{\alpha\alpha}$ are coplanar, it is sufficient to determine the constant γ in the equation

$$X_i^{\alpha\alpha}=\hat{a}_x^{\alpha}(0)+\gamma X_r^{\alpha\alpha}. \tag{80}$$

Using the orthogonality relations, we obtain

$$\gamma=-\frac{[(X_r^{\alpha\alpha})^{T}(D^{\alpha})^{-1}a_x^{\alpha}(0)]}{[(X_r^{\alpha\alpha})^{T}(D^{\alpha})^{-1}(X_r^{\alpha\alpha})]}, \tag{81}$$

where the superscript T implies the transpose of a matrix; the matrix $(D^{\alpha})^{-1}$ is of the form

$$(D^{\alpha})^{-1}=\begin{pmatrix}1/a_1^{*} & & & & \\ & \cdot & & & \\ & & \cdot & & \\ & & & \cdot & \\ & & & & 1/a_n^{*}\end{pmatrix}, \tag{82}$$

where a_i^{*} are the equilibrium concentrations in the absence of irreversible stages.

5. The eigenvalues must be determined.

For the subvector $X_r^{\alpha\alpha}$, located in positive octant of the space A^{α}, we can observe directly the rate of movement towards zero characteristic composition:

$$\hat{a}_x^{\alpha}(t)=b_r^{\alpha}(t)X_r^{\alpha\alpha}=b_r^{\alpha}(0)\cdot e^{\lambda_r^{\alpha}t}X_r^{\alpha\alpha}. \tag{83}$$

Consequently

$$\ln\frac{b_r^{\alpha}(t)}{b_r^{\alpha}(0)}=\lambda_r^{\alpha}t. \tag{84}$$

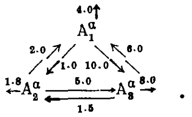
λ_r^{α} can therefore be found from the plot of $\ln[b_r^{\alpha}(t)/b_r^{\alpha}(0)]$ against t. However, this method cannot be applied to the subvectors $X_i^{\alpha\alpha}$ $(i \neq r)$, since they are not located in the positive octant of the vector space. On the other hand, we can determine the ratio $\lambda_i^{\alpha}/\lambda_r^{\alpha}$ from any curved pathway located in the plane of the vectors X_r and X_i.

The corresponding equation is

$$\frac{b_i^{\alpha}(t)}{b_r^{\alpha}(t)}=\left[\frac{b_r^{\alpha}(t)}{b_r^{\alpha}(0)}\right]^{\lambda_i^{\alpha}/\lambda_r^{\alpha}}. \tag{85}$$

Having plotted $\ln[b_i^{\alpha}(t)/b_i^{\alpha}(0)]$ against $\ln[b_r^{\alpha}(t)/b_r^{\alpha}(0)]$ we should obtain a straight line with a slope equal to $\lambda_i^{\alpha}/\lambda_r^{\alpha}$. Furthermore, Eqn. (85) provides a method for the determination of the relative rate constants from experimental composition data without the need to know λ_r^{α} and the contact time. However, if we determine only the relative characteristic numbers λ_i^{α} for each subsystem $M^{\alpha}\rightarrow$, then all the elements $K^{\alpha\alpha}$ will be referred to one of the constants within each subsystem of the reversible reactions. In order to obtain the final result, it is therefore necessary to reduce all the submatrices $K^{\alpha\alpha}$ to a single basis. The foregoing will be made clear by an example.

Example 3. Suppose that the following reaction scheme is specified:



(XX)

The rate constant matrix then assumes the following form:

$$K=\begin{pmatrix}-15.0 & 1.0 & 6.0\\ 1.0 & -8.8 & 1.5\\ 10.0 & 5.0 & -15.5\end{pmatrix}. \tag{86}$$

Table 3 presents several points along the reaction pathway, which corresponds to the initial composition

$$a^\alpha(0)=\begin{pmatrix}1\\0\\0\end{pmatrix}. \tag{87}$$

Table 3. Parallel projections for the system (XX).

t	$a^\alpha(t)$	$\sum_{i=1}^{n} a^\alpha(t)$	$\delta(t)$	$\delta(t)\,X_r^{\alpha\alpha}$	$\hat{a}^\alpha(t)$
0	$\begin{pmatrix}1\\0\\0\end{pmatrix}$	1.0	0	$\begin{pmatrix}0\\0\\0\end{pmatrix}$	$\begin{pmatrix}1\\0\\0\end{pmatrix}$
0.02	$\begin{pmatrix}0.7500\\0.0182\\0.1489\end{pmatrix}$	0.9171	0.0829	$\begin{pmatrix}0.0260\\0.0215\\0.0354\end{pmatrix}$	$\begin{pmatrix}0.7760\\0.0397\\0.1843\end{pmatrix}$
0.20	$\begin{pmatrix}0.1336\\0.0557\\0.1605\end{pmatrix}$	0.3498	0.6502	$\begin{pmatrix}0.2032\\0.1692\\0.2778\end{pmatrix}$	$\begin{pmatrix}0.3368\\0.2249\\0.4383\end{pmatrix}$

It also illustrates the course of the calculation for a parallel projection of the reaction pathway. The positively defined vector

$$X_r^{\alpha\alpha}=\begin{pmatrix}0.3126\\0.2602\\0.4272\end{pmatrix}, \tag{88}$$

to which corresponds a natural linear reaction pathway, is assumed to be known in these calculations. Fig. 12 illustrates artificial linear pathways for the system (XX). In our example, the matrix $(D^\alpha)^{-1}$ is

$$(D^\alpha)^{-1}=\begin{pmatrix}1/0.3158 & 0 & 0\\ 0 & 1/0.1579 & 0\\ 0 & 0 & 1/0.5263\end{pmatrix}. \tag{89}$$

We now determine the vector $X_2^{\alpha\alpha}$ from the initial composition for the linear section

$$\hat{a}_x^\alpha(0)=\begin{pmatrix}0.4510\\0\\0.549\end{pmatrix}. \tag{90}$$

We obtain from Eqn. (81)

$$\gamma=-\frac{0.8920}{1.0850}=-0.8221. \tag{91}$$

Eqn. (80) yields

$$X_2^{\alpha\alpha}=\begin{pmatrix}0.4510\\0\\0.5490\end{pmatrix}-0.8221\begin{pmatrix}0.3126\\0.2602\\0.4272\end{pmatrix}=\begin{pmatrix}0.1940\\-0.2139\\0.1978\end{pmatrix}. \tag{92}$$

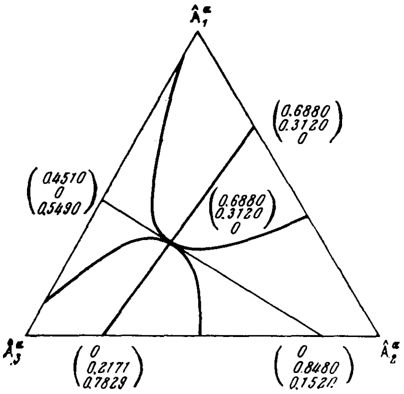


Figure 12. Artificial linear pathways for the system (XX).

The rate constant for irreversible reactions. In order to employ the above method for the determination of the individual constants for all irreversible reactions, it is necessary to determine the characteristic vectors for the systems containing both the main subvectors and the subvectors of the transitional systems. We shall consider initially two special cases: the system $M^\alpha \rightarrow M^\nu$ (where M^ν is a finite subsystem) and the open system

$$\begin{tikzcd} M^\alpha \arrow[r] \arrow[d] & M^\beta \arrow[d, "K^{\beta\alpha}\neq 0"'] \\ \text{when} & {} \end{tikzcd} \tag{XXI}$$

The system $M^\alpha \rightarrow M^\nu$ is closed and the equilibrium characteristic vector is

$$X_e^\nu=\begin{pmatrix}0\\X_e^{\nu\nu}\end{pmatrix}. \tag{93}$$

The system contains a unique natural linear reaction pathway corresponding to the vector X_r^α. We shall show below how to obtain artificial linear pathways corresponding to the vectors X_i^α $(i\neq r)$ by parallel projection. These linear pathways lie in a subspace of the composition space. We saw above that parallel projection gives rise to an artificial system $\hat{M}$ with the equilibrium vector $X_e^\alpha + CX_r^\alpha$.

The algorithm for the calculation of the rate constants for the system $M^\alpha \rightarrow M^\nu$ reduces to the following steps:

1. We find the natural linear reaction pathway and the positively defined vector X_r^α. The equilibrium vector X_e^ν is assumed to be known.

2. We consider the subsystem $M^{\alpha}\rightarrow$ and determine the subvectors $X_{i}^{\alpha\alpha}$ and the rate constants for the reversible reactions (see subsection D above).

3. We carry out a projection parallel to the vector X_{r}^{α} in accordance with the formula

$$\hat{a}(t)=a(t)+\delta(t)X_{r}^{\alpha},\tag{94}$$

where $\delta(t)$ is chosen so that the ith coordinate of the vector $\hat{a}(t)$ should be zero, i.e. $\hat{a}_{i}(t)=0$.

4. We find the equilibrium point in the artificial system $X_{e}^{\nu}+CX_{r}^{\alpha}$. The constant C is chosen on the basis of the condition that the ith coordinate of the equilibrium vector is equal to zero.

5. We find the artificial linear pathways and the vectors $\hat{a}_{i}(0)$.

6. We determine the vectors X_{i}^{α}, which requires the determination of the constants γ_1 and γ_2 in the equation

$$\begin{pmatrix}X_{i}^{\alpha\alpha}\\ X_{i}^{\nu\alpha}\end{pmatrix}=\gamma_1\begin{pmatrix}X_{r}^{\alpha\alpha}\\ X_{r}^{\nu\alpha}\end{pmatrix}+\gamma_2\left\{\begin{pmatrix}a_{x}^{\alpha}(0)\\ a_{x}^{\nu}(0)\end{pmatrix}-\begin{pmatrix}0\\ X_{e}^{\nu\nu}\end{pmatrix}-C\begin{pmatrix}X_{r}^{\alpha\alpha}\\ X_{r}^{\nu\alpha}\end{pmatrix}\right\}.\tag{95}$$

The constants γ_1 and γ_2 are determined from the vector equation

$$X_{i}^{\alpha\alpha}=\gamma_1X_{r}^{\alpha\alpha}+\gamma_2\{a_{x}^{\alpha}(0)-CX_{r}^{\alpha\alpha}\}\tag{96}$$

using the known subvectors $X_{r}^{\alpha\alpha}$ and $X_{i}^{\alpha\alpha}$.

7. The eigenvalues λ_{i}^{α} are determined in the study of the subsystem $M^{\alpha}\rightarrow$. The values of λ_{i}^{ν} are found when the subsystem M^{ν} is examined, as described in the discussion of reversible reactions.

Consider now the open system

$$\begin{tikzcd} M^{\alpha} \arrow[r] \arrow[d] & M^{\beta} \arrow[d] \\ {} & {} \end{tikzcd}\tag{XXII}$$

It was shown above that, when $|\lambda_{r}^{\alpha}|<|\lambda_{r}^{\beta}|$, the vector $X_{r}=\begin{matrix}0\\ X_{r}^{\beta\beta}\end{matrix}$ contains only positive elements. Depending on the relative eigenvalues, we should therefore project the reaction pathways parallel to X_{r}^{u} or X_{r}^{β}. Since natural linear pathways in the positive octant of the vector space correspond to positively defined vectors, the linear pathways should be found first and λ_{r}^{β} and λ_{r}^{α} should be determined. Assuming that this step has already been carried out, we shall consider two cases.

I. Let

$$|\lambda_{r}^{\alpha}|<|\lambda_{r}^{\beta}|.\tag{97}$$

(1) We set up an artificial subsystem by a projection parallel to X_{r}^{u} in accordance with the equation

$$\hat{a}^{u}(t)=a^{u}(t)+\delta(t)X_{r}^{u},\tag{98}$$

where the scalar $\delta(t)$ is chosen so that the sum of the elements $a(t)$ is unity.

(2) We determine the linear pathways in the artificial subsystems $a_{x_i}(0)$.

(3) We determine the vectors

$$X_{i}^{u}=\gamma_1\hat{a}_{x}(0)+\gamma_2X_{r}^{u}.\tag{99}$$

The constants γ_1 and γ_2 are determined from the known subvector $X_{i}^{\alpha\alpha}$, which is found beforehand by studying the subsystem $M^{\alpha}\rightarrow$.

II. Let

$$|\lambda_{r}^{\alpha}|>|\lambda_{r}^{\beta}|.$$

(1) Projection parallel to the vector X_{r}^{β} leads to the equation

$$\hat{a}^{u}(t)=a^{u}(t)+\delta_1(t)X_{r}^{\beta},\tag{100}$$

where $\delta_1(t)$ is chosen in such a way that the sum of the coordinates $\hat{a}_{i}^{u}(t)$ is unity. Such projection leads to an artificial closed system of the type $\hat{M}^{\alpha}\rightarrow\hat{M}^{\beta}$, in which there is a unique linear reaction pathway in the positive octant of the vector space and a unique characteristic vector X_{r}^{u} without negative elements.

(2) We find the linear reaction pathway and the vector $\hat{a}_{x}^{u}(0)$.

(3) We determine the vector X_2 from the equation

$$X_{2}^{u}=\begin{pmatrix}\hat{a}_{x}^{\alpha}(0)\\ \hat{a}_{x}^{\beta}(0)\end{pmatrix}+\gamma\begin{pmatrix}0\\ X_{r}^{\beta\beta}\end{pmatrix}.\tag{101}$$

The coefficient γ is determined by studying the curved pathway in the hyperplane of the vectors X_{r}^{u} and X_{r}^{β}. The reaction pathway in this hyperplane is given by the equation

$$a(t)=b_{r}^{\alpha}(t)X_{r}^{u}+b_{r}^{\beta}(t)X_{r}^{\beta}.\tag{102}$$

Using Eqn. (101), it can be shown that

$$b_{r}^{\alpha}(t)=e^{\lambda_{r}^{\alpha}t};\ b_{r}^{\beta}(t)=-\gamma e^{\lambda_{r}^{\beta}t}.\tag{103}$$

It follows from Eqns. (102) and (103) that

$$F_1=\left(\sum a_{l}^{\beta}(t)-e^{\lambda_{r}^{\alpha}t}\sum a_{x_l}^{\beta}(0)\right)=\gamma F_2=\gamma\left(e^{\lambda_{r}^{\alpha}t}-e^{\lambda_{2}^{\beta}t}\right).\tag{104}$$

Since λ_{r}^{α} and λ_{r}^{β} may be assumed to have been determined from the study of the subsystems $M^{\alpha}\rightarrow$, the constant γ a can be found from the slope of the linear plot of F_1 against F_2.

(4) In order to determine the characteristic vectors X_{i}^{u}, where $i\neq r$, it is necessary to carry out a second projection using the vector $X_{r}^{u}-X_{r}^{\beta}$ in accordance with the formula

$$\hat{\hat{a}}^{u}(t)=\hat{a}^{u}(t)+\delta_2(t)(X_{r}^{u}-X_{r}^{\beta}),\tag{105}$$

where $\delta_2(t)$ is chosen so that one of the coordinates of the vector $\hat{\hat{a}}^{u}(t)$ is zero and the others are positive.

(5) We find the characteristic vectors X_{i}^{u}. For this purpose, it is necessary to determine the three constants in the equation

$$X_{2}^{u}=\gamma_1\begin{pmatrix}\hat{\hat{a}}_{x}^{\alpha}(0)\\ \hat{\hat{a}}_{x}^{\beta}(0)\end{pmatrix}+\gamma_2\begin{pmatrix}X_{r}^{\alpha\alpha}\\ X_{r}^{\beta\alpha}\end{pmatrix}+\gamma_3\begin{pmatrix}0\\ X_{r}^{\beta\beta}\end{pmatrix}.\tag{106}$$

Since the subvector $X_{2}^{\alpha\alpha}$ may be regarded as known, a system of equations for the determination of γ_1 and γ_2 follows from the first row of Eqn. (106):

$$X_{2}^{\alpha\alpha}=\gamma_1\hat{\hat{a}}^{\alpha}(0)+\gamma_2X_{r}^{\alpha\alpha}.\tag{107}$$

The curved pathway in the subspace stretched over the three vectors X_{i}^{u}, X_{r}^{u}, and X_{r}^{β} may be used to determine γ_3:

$$a(t)=b_{i}^{\alpha}(t)X_{i}^{u}+b_{r}^{\alpha}(t)X_{r}^{u}+b_{r}^{\beta}(t)X_{r}^{\beta};\tag{108}$$

and it can be shown that in our case

$$b_{i}^{\alpha}(t)=\frac{1}{\gamma_1}e^{-\lambda_{1}^{\alpha}t},$$

$$b_{r}^{\alpha}(t)=-\frac{\gamma_2}{\gamma_1}e^{-\lambda_{r}^{\alpha}t},$$

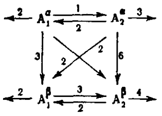
$$b_{r}^{\beta}(t)=-\frac{\gamma_3}{\gamma_1}e^{\lambda_{r}^{\beta}t}.$$

The constant γ_3 can be found from the slope of the linear plot of F_3 against F_4, where

$$F_3=\gamma_1\Big[\sum_i a_i^{\beta}(t)-e^{\lambda_i^{\alpha}t}\sum_i \hat{\hat{a}}_x^{\beta}(0)\Big]-\gamma_2[e^{\lambda_i^{\alpha}t}-e^{\lambda_r^{\alpha}t}]X_r^{\beta\alpha};$$
$$F_4=[e^{\lambda_i^{\alpha}t}-e^{\lambda_r^{\beta}t}]\cdot\sum X_{ri}^{\beta\beta}. \qquad (109)$$

The procedure for the calculation of the constants can be made clear by the following artificial example[29].

Example 4. Consider the scheme



(XXIII)

The rate constant matrix is

$$K=\begin{pmatrix}-8 & 2 & 0 & 0\\ 1 & -13 & 0 & 0\\ 3 & 2 & -5 & 2\\ 2 & 6 & 3 & -6\end{pmatrix}, \qquad (110)$$

$$\lambda_r^{\alpha}=-7.6277 \text{ and } \lambda_r^{\beta}=-3.0.$$

and the characteristic vector matrix assumes the following form:

$$X=\begin{pmatrix}-2.7446 & 8.7445 & 0 & 0\\ -0.5109 & -3.4891 & 0 & 0\\ 1.1861 & -1.6861 & 0.5 & -2\\ 3.0694 & 17.4307 & 0.5 & 3\end{pmatrix}. \qquad (111)$$

Fig. 13 illustrates the reaction pathways for the initial composition

$$\begin{pmatrix}0.5341\\0.0994\\0.3665\\0\end{pmatrix}.$$

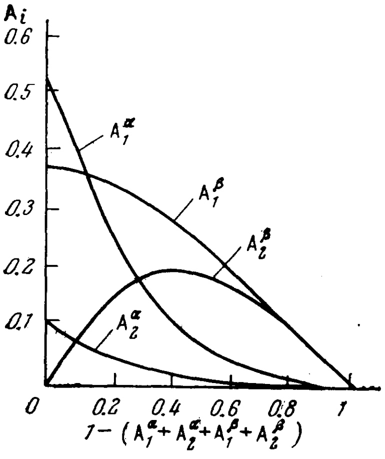


Figure 13. Reaction pathway for the system (XXIII).

Table 4 presents the calculations for a projection parallel to the vector

$$X_r^{\beta}=\begin{pmatrix}0\\X_r^{\beta\beta}\end{pmatrix}=\begin{pmatrix}0\\0\\0.5\\0.5\end{pmatrix}. \qquad (112)$$

The artificial linear reaction pathway for the initial composition

$$\begin{pmatrix}0.5341\\0.0994\\0.3665\\0\end{pmatrix}$$

is illustrated in Fig. 14.

Table 4.

t	$a^u(t)$	$\sum_i a_i^u(t)$	$\delta_1(t)$	$\delta_1(t)X_r^{\beta}$	$\hat{a}^u(t)$
0	$\begin{pmatrix}0.5341\\0.0944\\0.3665\\0\end{pmatrix}$	1.0	0	$\begin{pmatrix}0\\0\\0\\0\end{pmatrix}$	$\begin{pmatrix}0.5341\\0.0944\\0.3665\\0\end{pmatrix}$
0,05	$\begin{pmatrix}0.3644\\0.0653\\0.3561\\0.3552\end{pmatrix}$	0.8910	0.1090	$\begin{pmatrix}0\\0\\0.0545\\0.0545\end{pmatrix}$	$\begin{pmatrix}0.3644\\0.0553\\0.4106\\0.1597\end{pmatrix}$
0.10	$\begin{pmatrix}0.2488\\0.0450\\0.3342\\0.1626\end{pmatrix}$	0.7906	0.2094	$\begin{pmatrix}0\\0\\0.1047\\0.1047\end{pmatrix}$	$\begin{pmatrix}0.2488\\0.0450\\0.4389\\0.2673\end{pmatrix}$

0.35	$\begin{pmatrix}0.0369\\0.0068\\0.1923\\0.1668\end{pmatrix}$	0.4028	0.5972	$\begin{pmatrix}0\\0\\0.2986\\0.2986\end{pmatrix}$	$\begin{pmatrix}0.0369\\0.0068\\0.4909\\0.4654\end{pmatrix}$

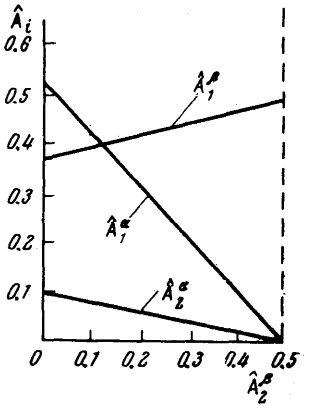

Figure 14. Artificial linear reaction pathway for the system (XXIII).

The functions F_1 and F_2 are calculated from Eqn. (104). A linear plot of F_1 against F_2 is obtained, whose slope yields $\gamma=-1.189$. We now calculate X_r^u from Eqn. (99):

$$X_r^u=\begin{pmatrix}0.5341\\0.0994\\0.3665\\0\end{pmatrix}-1.189\begin{pmatrix}0\\0\\0.5\\0.5\end{pmatrix}=\begin{pmatrix}0.5341\\0.0994\\-0.2280\\-0.5945\end{pmatrix}. \qquad (113$$

The vector X^{u}_{r} differs only by its length and sign from the first column of the matrix X [Eqn. (111)].

In order to determine X_2, we make use of a further projection, but this time the projection is parallel to the vector $X^{u}_{r} - X^{\beta}_{r}$. The course of the calculations is illustrated in Table 5.

Table 5.

t	$a^{u}(t)$	$\delta_1(t)$	$\hat{a}^{u}(t)$	$\delta_2(t)$	$\hat{\hat{a}}^{u}(t)$
0	$\begin{pmatrix}0\\0.5\\0.5\\0\end{pmatrix}$	0	$\begin{pmatrix}0\\0.5\\0.5\\0\end{pmatrix}$	0	$\begin{pmatrix}0\\0.5\\0.5\\0\end{pmatrix}$
0.06	$\begin{pmatrix}0.0321\\0.2301\\0.4199\\0.1737\end{pmatrix}$	0.1442	$\begin{pmatrix}0.0321\\0.2301\\0.4920\\0.2458\end{pmatrix}$	—0.0957	$\begin{pmatrix}0.2947\\0.2790\\0.4263\\0\end{pmatrix}$
0.20	$\begin{pmatrix}0.0259\\0.0393\\0.2832\\0.2310\end{pmatrix}$	0.4206	$\begin{pmatrix}0.0259\\0.0393\\0.4935\\0.4413\end{pmatrix}$	—0.1718	$\begin{pmatrix}0.4973\\0.1270\\0.3757\\0\end{pmatrix}$

The reaction pathway for the initial composition

$$\begin{pmatrix}0\\0.5\\0.5\\0\end{pmatrix}$$

is illustrated in Fig. 15. Fig. 16 presents an artificial linear pathway. We shall now determine the constant of the equation

$$X^{u}_{i} = \begin{pmatrix}X^{\alpha\alpha}_{i}\\X^{\beta\alpha}_{i}\end{pmatrix} = \gamma_1\begin{pmatrix}\hat{\hat{a}}^{\alpha}_{x}(0)\\\hat{\hat{a}}^{\beta}_{x}(0)\end{pmatrix} + \gamma_2\begin{pmatrix}X^{\alpha\alpha}_{r}\\X^{\beta\alpha}_{r}\end{pmatrix} + \gamma_3\begin{pmatrix}0\\X^{\beta\beta}_{r}\end{pmatrix}. \qquad (114)$$

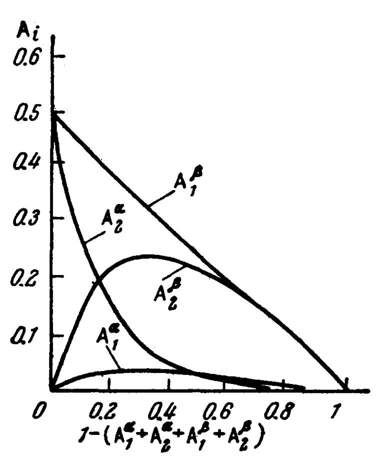

Figure 15. Reaction pathway for the system (XXIII).

Using the known subvectors $X^{\alpha\alpha}_{r}$ and $X^{\alpha\alpha}_{2}$, we obtain the following system of equations:

$$X^{\alpha\alpha}_{2} = \gamma_1\hat{\hat{a}}^{\alpha}_{x}(0) + \gamma_2 X^{\alpha\alpha}_{r} = \begin{pmatrix}-0.5931\\1.5931\end{pmatrix} + \gamma_1\begin{pmatrix}0\\0.5\end{pmatrix} + \gamma_2\begin{pmatrix}-2.7446\\-0.5109\end{pmatrix}. \qquad (115)$$

It follows from Eqn. (115) that $\gamma_1 = 3.4069$ and $\gamma_2 = 0.2161$. γ_3 is determined from the plot of F_3 against F_4. F_3 and F_4 are calculated from Eqns. (109) and $\gamma_3 = -3.691$ is found. We now determine

$$X^{u}_{2} = 3.4069\begin{pmatrix}0\\0.5000\\-0.5000\\0\end{pmatrix} + 0.21\begin{pmatrix}-2.7446\\0.5109\\1.1861\\3.0694\end{pmatrix} - 3.691\begin{pmatrix}0\\0\\0.5\\0.5\end{pmatrix} = \begin{pmatrix}-0.5931\\1.5931\\0.1142\\-1.1824\end{pmatrix}.$$

It is readily seen that X^{u}_{2} is identical with the second column of the matrix X apart from the length and sign.

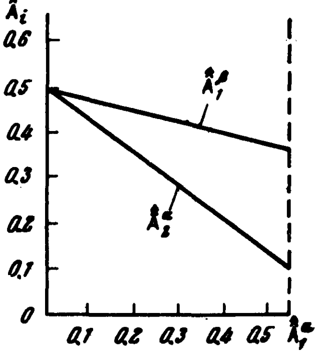

Figure 16. Artificial linear reaction pathway for the system (XXIII); initial composition.

$$\begin{pmatrix}0\\0.5\\0.5\\0\end{pmatrix}$$

4. THE GENERAL CHARACTERISTICS OF FIRST-ORDER REACTIONS

We examined above systems of reversible first-order reactions and systems involving certain irreversible stages. In both cases we employed the principle of detailed balance or its corollaries, which can be found by considering irreversible stages as the limiting cases of reversible reactions obtained on decreasing the rates of the corresponding transitions. However, there exist systems of pseudofirst order, to which the principle of detailed balance is in general inapplicable. We shall consider initially certain examples of such systems[30].

Example 5.

$$\begin{aligned}&A_1 + B_1 \rightleftarrows A_2 + B_2\ ;\\&A_2 + B_3 \rightleftarrows A_3 + B_4\ ;\\&A_3 + B_5 \rightleftarrows A_1 + B_6\ .\end{aligned} \qquad (XXIV)$$

If the reactions are carried out in a closed system, the usual thermodynamic conditions are valid. On the other hand, when the system contains an excess of substances

B, the reactions can be described by the equivalent pseudofirst order scheme:

$$A_1 \rightleftarrows A_2;\ A_2 \rightleftarrows A_3;\ A_3 \rightleftarrows A_4 \qquad \text{(XXV)}$$

One can then speak only of steady-state conditions. The Wegsheider conditions[18] may therefore not in fact hold for the matrix.

Example 6. Consider copolymerisation reactions, which can be described sometimes by first-order systems. We denote by $P_i(\nu)$ a polymer of type i with a chain length ν and by M_j a monomer of type j. The reaction mechanism can be formulated thus:

$$P_i(\nu) + M_j \to P_j(\nu + 1). \qquad (116)$$

The second-order reaction constant will be designated by k_{ij}. If the monomer concentration does not change, the process can be described by a system of unimolecular reactions with constants which depend on the monomer concentration. The diagonal elements of the kinetic matrix K then possess physical significance. The principle of detailed balance does not hold in such a system. Polymerisation kinetics have been examined in a number of studies[31-33].

Example 7. Suppose that the process takes place on a discretely inhomogeneous catalyst surface with two types of centres. A system of reactions with the kinetic matrices K_1 and K_2 takes place at each type of centres. Then the overall transformation can also be described by a first-order equation with the matrix $\lambda K_1 + (1 - \lambda)K_2$, where λ is the fraction of centres of the first type on the catalyst surface. It can be easily shown that, even if the principle of detailed balance holds for each set of centres, it may not hold for the system as a whole. In the specific instance where the matrices K_1 and K_2 have identical equilibrium vectors, the principle of detailed balance holds for the entire system. This can be readily understood, since in the latter case a thermodynamic equilibrium is established in the steady-state and the thermodynamic conditions are the same for both types of centres. On the other hand, when one is dealing with a system of pseudofirst order, there is no thermodynamic equilibrium and the steady-state conditions may be different for each type of centre. This factor is extremely important for the kinetics of complex reactions on polyfunctional catalysts[34-37].

Example 8. Consider the class of first-order reactions which have been called[30] "bound". This class includes systems containing cycles of irreversible reactions which we previously excluded from consideration. We introduce the following definitions. We call a substance A_i the descendant of A_j if a sequence of reactions $A_j \to A_k \to \ldots A_i$ with strictly positive constants exists. The system of unimolecular reactions is called bound if each substance is the descendant of another. For example, the system $A_1 \rightleftharpoons A_2 \to A_3$ is a bound system of an L-system. The system $A_1 \rightleftharpoons A_2$, $A_3 \rightleftharpoons A_4$ is not bound. A system of reversible reactions is an L-system if it cannot be subdivided into subsystems between which there is no interaction. The following two schemes do not belong to the L-class:

$$A_1 \rightleftarrows A_2 \to A_3 \rightleftarrows A_4\,; \qquad \text{(XXVI)}$$

$$\begin{tikzcd} A_1 \arrow[r] \arrow[rr, bend right] & A_2 \arrow[r] & A_3; & A_4 \arrow[r, shift left] & A_5 . \arrow[l, shift left] \end{tikzcd} \qquad \text{(XXVII)}$$

If the system can be subdivided into ν subsystems, each of which is an L-system, it belongs to the class L_ν. The following results have been obtained for L-systems.

1. All L-systems have a unique positively defined equilibrium vector.
2. A positively defined equilibrium vector exists when and only when the system of unimolecular reactions belong to the class L_ν. The multiplicity of the zeroth eigenvalue of the kinetic matrix is ν.
3. All the eigenvalues of the kinetic matrix (other than the zeroth eigenvalue) have negative real components and are located on a complex plane in a circle $|z + r| \leqslant r$, where r is the maximum modulus of the diagonal elements of the matrix K.[30] This assertion can be proved by the Perron theorem familiar in matrix theory[38].

Thus, in contrast to the systems of reversible reactions discussed above, decaying oscillations are possible in L-systems containing cycles. The introduction of non-linear stages into these systems leads to non-decaying auto-oscillations[39-41].

5. Group Kinetics

An enormous number of substances are sometimes involved simultaneously in complex systems, which precludes not only kinetic calculations on individual reactions but also even a simple chemical analysis of such mixtures. It is therefore necessary to subdivide substances into definite classes and to investigate the interactions between individual classes. For example, in the cracking of petroleum, hydrocarbons are subdivided into olefins, paraffins, naphthenes, and aromatic compounds. However, it is by no means always clear to what extent this distorts the kinetic relations and in what cases the subdivision of the reactants into groups is legitimate. An attempt has been made[42,43] to answer these questions in relation to systems of unimolecular reactions. We shall assume that conditions (14), formulated in the definition of a system of reversible reactions, have been fulfilled. We introduce a linear transformation of an n-dimensional vector composition space into an $\hat{n}$-dimensional space where $\hat{n} < n$. Such a transformation is achieved with the aid of a rectangular $\hat{n} \times n$ matrix M with the rank $\hat{n}$:

$$\hat{a} = Ma. \qquad (117)$$

In the simplest case this transformation can be represented as projection. Three substances can be divided into two classes (Fig. 17):

$$\hat{a}_1 = a_1 + a_2,$$
$$\hat{a}_2 = a_3. \qquad (118)$$

In this case, the transformation matrix M is

$$M = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \qquad (119)$$

In this transformation the same vector $\hat{a}$ corresponds to vectors a' and a'' (see Fig. 17). We now introduce certain definitions.

Definition 5. Vectors a and a' will be called equivalent if the equality

$$Ma = Ma' \qquad (120)$$

holds. In an abbreviated form, Eqn. (120) can be written in the form

$$a \simeq a'.$$

Definition 6. The system of unimolecular reactions $da/dt = Ka$ is called exactly divisible into classes if, after transforming the composition space with the matrix $M : \hat{a} = Ma$, the kinetics can be described by the equation

$$\frac{d\hat{a}}{dt} = \hat{K}\hat{a}\,, \tag{121}$$

where $\hat{K}$ is a matrix.

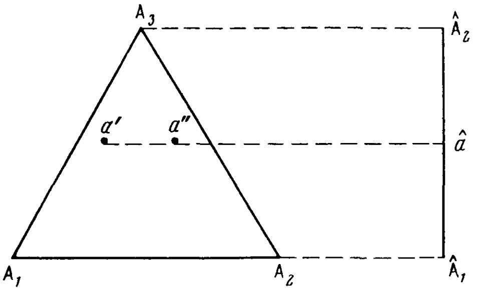

Figure 17. Transformation of the three-dimensional space specified by the matrix

$$\begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

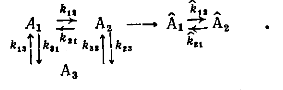
If the initial kinetic matrix has the dimensions $n \times n$, then the matrix $\hat{K}$ has the dimensions $m \times n$, where $m < n$. We shall now formulate the necessary and sufficient conditions under which the system is exactly divisible into classes.

Theorem 9. For the system to be exactly divisible into classes, the following conditions is necessary and sufficient:

$$MK = \hat{K}M, \tag{122}$$

where M is an $n \times m$ matrix. We shall make clear the significance of this condition in terms of examples. Consider a three-component system of reversible reciprocal reactions A_1, A_2, and A_3. We shall combine A_1 and A_2 in one class, while the second class will consist of A_3. This yields a two-component system:

Example 9.



(XXVIII)

The matrix M for such a subdivision into classes was quoted above [matrix (119)]. The conditions (120) are

$$k_{31} = k_{32} = k_{13} + k_{23} = \hat{k}_{21} = \hat{k}_{12}. \tag{123}$$

We shall consider yet another example.

Example 10.

(XXIX)

We combine A_1 and A_2 in the first class and A_3 and A_4 in the second class. The equivalent scheme is the same as in the previous case:

$$\hat{A}_1 \underset{\hat{k}_{21}}{\overset{\hat{k}_{12}}{\rightleftarrows}} \hat{A}_2\,.$$

The conditions (120) then become

$$\begin{gathered} k_{31} + k_{41} = k_{32} + k_{42} = \hat{k}_{21}\,; \\ k_{13} + k_{23} = k_{14} + k_{24} = \hat{k}_{12}. \end{gathered} \tag{124}$$

Thus the conditions (120) impose sufficiently rigid limitations on the rate constants.

It has been shown[37] that the composition $\hat{a}(t)$ for systems divisible into classes can be calculated both from kinetic $a(t)$ curves and from the matrix K, i.e.

$$\hat{a}(t) = Me^{-Kt}a(0) = e^{-\hat{K}t}Ma(0). \tag{125}$$

This relation yields yet another definition of systems exactly divisible into classes.

Definition 7. A system of unimolecular reactions is called exactly divisible into classes if equivalence is maintained for the reaction pathways for each pair of M-equivalent vectors $a(0)$ and $a'(0)$. In other words, it follows from $a(0) \sim a'(0)$ that $a(t) \sim a'(t)$.

A consequence of this definition is that we should obtain a single reaction pathway $\hat{a}(t)$ in the transformed three-component system in experiments with the initial compositions (1, 0, 0) and (0, 1, 0) when the substances A_1 and A_2 are combined in one class. Different reaction pathways are of course obtained in the initial composition space. This can be used for experimental tests of the possibility of the subdivision of the system into classes. Suppose that the first three components in a system of five components are combined in one class and the fourth and fifth components are combined in the second class. The experiment is carried out for the initial composition (1, 0, 0, 0, 0). We determine the kinetic relations

$$\begin{gathered} \hat{a}_1(t) = a_1(t) + a_2(t) + a_3(t), \\ \hat{a}_2(t) = a_4(t) + a_5(t). \end{gathered} \tag{126}$$

We then repeat the experiment with the initial compositions (0, 1, 0, 0, 0) and (0, 0, 1, 0, 0). If we obtain similar relations $a_1(t)$ in all three experiments, the combination of substances A_1, A_2, and A_3 in a single class is legitimate. After this, it is possible to carry out experiments with the compositions (0, 0, 0, 1, 0) and (0, 0, 0, 0, 1). If the relations $\hat{a}_2(t)$ are the same in these experiments, the substances A_4 and A_5 can be combined in a single class.

We shall now consider how the characteristic vectors vary when the dimensions of the vector space are diminished on subdivision into classes.

Theorem 10. If X_i is the eigenvector of the rate constant matrix for a system which is exactly divisible into classes, corresponding to the eigenvalue λ_i, then the vector MX_i is zero or is the eigenvector of the matrix $\hat{K}$ with the same eigenvalue λ_i.

Thus, when the matrix K has n eigenvectors, the matrix $\hat{K}$ has $\hat{n}$ eigenvectors for the same values of λ_i and the equality $MX_i = 0$ hold for $n - \hat{n}$ vectors. Thus, by studying the reaction pathways in the space A_n, it is possible to determine $\hat{n}$ eigenvectors $X_i = MX_i$ for the exact values of λ_i. The remaining eigenvectors of the initial system cannot be determined.

The subdivision of complex systems into classes taking into account diffusion has also been examined[42]. An approach has been described[43], in terms of the above definitions, to the study of unimolecular systems which cannot be exactly subdivided into classes. However, this can be done only approximately. Expressions are given whereby it is possible to estimate the errors arising in the approximate subdivision of complex systems into classes containing several substances.

In the present section, we have considered only those investigations in which an attempt has been made to approach group kinetics from the standpoint of the general theory of unimolecular reactions. Naturally, other approaches to the problem are also possible. For example, reactants can be represented by mixtures with continuous compositions[44-46]. The extensive literature on this problem cannot be discussed here.

III. AN OUTLINE OF THE STRUCTURE OF NON-LINEAR SYSTEMS

1. Canonical Forms

It is possible to find simple canonical forms for linear systems which are convenient for the solution of equations and the analysis of the structure. For non-linear systems of complex reaction, the situation is much more involved. Consider a non-linear system of complex reactions[27]:

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = \mathrm{f}^i(x^1, \ldots x^n);\ i = 1, \ldots n. \tag{127}$$

In the general case, there exists a non-linear transformation leading to the system (127) in the canonical form:

$$\begin{aligned} &\frac{\mathrm{d}y^1}{\mathrm{d}t} = g(y^1, \ldots y^n), \\ &\frac{\mathrm{d}y^i}{\mathrm{d}t} = 0;\ i = 2, \ldots n. \end{aligned} \tag{128}$$

However, there is no general method for deducing these transformations. We shall consider a system of chemical kinetic equations obtained in accordance with the Law of Mass Action. For reactions whose order is not greater than the third, one can write

$$\frac{\mathrm{d}x^i}{\mathrm{d}t} = \sum_j a^i_j x^j + \sum_{k,j} b_{jk} x^j x^k + \sum_{j,k,p} c_{jkp} x^j x^k x^p. \tag{129}$$

The first term of Eqn. (129) corresponds to first-order reactions and the second term describes second-order reactions. It can be shown[47,48] that equations of type (129) with up to sth order terms can be reduced to homogeneous sth order equations. Henceforth we shall consider only homogeneous systems having specified

$$\frac{\mathrm{d}X}{\mathrm{d}t} = P_n(X), \tag{130}$$

where $P_n(X)$ is the polynomial form of the vector X.[49] For a polylinear operator, there exist canonical forms which can be solved.

1. $P_n(X)$ is a semilinear operator:

$$\begin{gathered} P_n(X + Y) = P_n(X) + P_n(Y), \\ P_n(\alpha X) = \mathrm{f}(\alpha) P_n(X). \end{gathered} \tag{131}$$

This form arises, for example, for the scheme

$$\begin{gathered} 2\,\mathrm{A} \rightarrow \mathrm{B} \quad , \\ 3\,\mathrm{C} \rightarrow \mathrm{D} \quad . \end{gathered}$$

2. The triangular scheme:

$$2\,\mathrm{A} \rightarrow 2\,\mathrm{B} \rightarrow 2\,\mathrm{C} \quad .$$

3. The scheme

$$\begin{gathered} \mathrm{A}_1 + \mathrm{A}_2 \xrightarrow{k_1} \mathrm{A}_3 \ , \\ \mathrm{A}_1 + \mathrm{A}_3 \xrightarrow{k_2} \mathrm{A}_4 \end{gathered} \tag{XXX}$$

and the more complex scheme

$$\begin{gathered} \mathrm{A}_1 + \mathrm{A}_2 \rightarrow \mathrm{A}_3 \quad , \\ \mathrm{A}_3 + \mathrm{A}_2 \rightarrow \mathrm{A}_4 \quad , \\ \mathrm{A}_5 + \mathrm{A}_2 \rightarrow \mathrm{A}_6 \quad , \\ \mathrm{A}_6 + \mathrm{A}_2 \rightarrow \mathrm{A}_7 \end{gathered} \tag{XXXI}$$

have also been considered[50,51]. Unfortunately other canonical forms do not permit a solution of the initial system. The problem of the canonical forms of second-order equations has still been little studied.

2. Linear Reaction Pathways

For a linear system, a linear reaction pathway is specified by the formula

$$X(t) = X_e + \alpha(t) Y, \tag{132}$$

where X_e is the equilibrium vector. We shall consider a second-order homogeneous system:

$$\frac{\mathrm{d}X_i}{\mathrm{d}t} = B(X, X). \tag{133}$$

The possibility of the existence of linear reaction pathways will now be elucidated. Having substituted Eqn. (132) in Eqn. (133), we obtain

$$Y \frac{\mathrm{d}\alpha}{\mathrm{d}t} = B(X_e, X_e) + 2\alpha B(X_e, Y) + \alpha^2 B(Y, Y). \tag{134}$$

The first term is zero, since at equilibrium $\mathrm{d}\boldsymbol{X}_e/\mathrm{d}t = 0$. For Eqn. (134) to hold, it is necessary and sufficient that the following conditions should be fulfilled:

$$B(X_e, Y) = \beta Y, \tag{135}$$

$$B(Y, Y) = \lambda Y. \tag{136}$$

These conditions are rarely fulfilled, but they are valid in some cases, for example for the scheme $2\mathrm{A} \rightleftharpoons 2\mathrm{B} \rightleftharpoons 2\mathrm{C}$. For closed systems, linear pathways are rare. However, for systems with irreversible stages involving open subsystems, this is not the case.

Consider the system

$$2\,\mathrm{A} \rightarrow \mathrm{C};\ 2\mathrm{B} \rightarrow \mathrm{E};\ \mathrm{A} + \mathrm{B} \rightarrow \mathrm{D}.$$

It contains the open subsystem (A, B). When $t \rightarrow \infty$, we have $c_A \rightarrow 0$ and $c_B \rightarrow 0$. In the general case of a system with irreversible stages, the equilibrium vector is $X_e(0, 0, 0, \ldots, x_e^{n+1}, x_e^n)$. When an m-dimensional space is considered, the equilibrium point coincides with the origin of coordinates. For such subsystems, linear pathways are possible, since $B(X_e, Y) = 0$ and it is only necessary that $B(Y, Y) = \lambda Y$; for a homogeneous sth order system, condition (136) assumes the following form:

$$P_s(\alpha X) = \alpha^s P_s(X). \tag{137}$$

The following Wei theorem is valid:

Theorem 11. For chemical reactions involving any number of components, and of any homogeneous order, the equilibrium point either does not coincide with the origin of coordinates or there is at least one pathway in the positive octant of the vector space.

We shall now discuss the problem of the number of possible linear pathways. The number of such pathways is equal to the number of the roots of the equation

$$P_s(aX)=a^s\lambda X. \tag{138}$$

We found above that for linear systems there can be not more than n independent eigenvectors or that an infinite number of eigenvectors corresponds to a single eigenvalue. In the non-linear case, reliable results have been obtained mainly for a two-component system. Table 6 presents the maximum number of linear pathways as a function of the number of components and the order of the reaction.

Table 6. Number of possible linear reaction pathways.

No. of components	Reaction order				
	1	2	3	4	5
2	2	3	4	5	6
3	3	(8)	—	—	—

It is seen from these results that analysis of linear reaction pathways in non-linear systems cannot yield far-reaching results similar to those obtained for unimolecular reactions. At the same time, some of the theorems quoted above are useful also in the consideration of non-linear systems. In particular, they are useful in the analysis of stability, since Lyapunov theorems reduce the problem to the analysis of the stability of the linearised system. Thus the impossibility of non-decaying oscillations in the vicinity of thermodynamic equilibrium follows from theorem 2. A detailed proof of this assertion can be found in Zhabotinskii's book[39]. Interesting communications on the qualitative theory of chemical kinetic equations have been published very recently[52-56]. However, their discussion is outside the scope of the present review.

Ion-Molecule Reactions Initiated by the β-Decomposition of Tritium in Tritiated Compounds

G.P.Akulov

Ion-molecule reactions initiated by the β-decomposition of tritium in various compounds are examined and a systematic account is given. The theoretical and experimental foundations of the radiochemical method for the investigation of this important type of chemical interactions are described. The ion-molecule reactions investigated are combined in two groups: the reactions of the ions HeT^+ and the reactions of carbonium ions. Conclusions concerning the reactivity of the intermediate species, the mechanisms of their interaction with various substances, and the prospects for the utilisation of the radiochemical method of investigating ion-molecule reactions are reached on the basis of the experimental results presented.

CONTENTS

I. INTRODUCTION

As early as the end of the last century, the existence of molecular ions was discovered from the study of the electrical conductivities of flames and gases subjected to an electrical discharge. In 1905, Langevin[1] and subsequently also other investigators[2] attempted a theoretical development of models of the gas-phase interaction of charged species with neutral molecules. However, the first experimental study[3] specially devoted to ion-molecule reactions was not published until 1952. During the two decades elapsed since its publication, there has been a sharp growth of intensity of research in this field. In the USA alone, more than one hundred papers have been published annually during the last few years on ion-molecule reactions and the expenditure by the state on this research exceeds at the present time 2 500 000 dollars annually[4].

The interest in ion-molecule reactions is due to the fact that the knowledge of the mechanism, thermochemistry, and kinetics of these interactions is extremely important for the understanding of the processes developing under the influence of radiation and light, in the flame, in electrical discharges, in mass spectrometers, in the upper layers of Earth's atmosphere, in the atmospheres of other planets, and in heterolytic organic reactions. Thus, for example, as early as the beginning of this century, it was established that certain organic substances are capable of dissociating into molecular ions[5]. Numerous subsequent investigations by organic chemists showed that the majority (approximately 60%) of organic reactions proceed via a stage involving the formation of charged molecular species—carbonium ions. The processes accompanying the interaction of radiation or light with matter also take place with participation of ionised species. The hypothesis of the occurrence of ion-molecule reactions in radiation processes, put forward by Lind[6] as early as 1912, has now been widely adopted in radiation chemistry[7-11]. Bimolecular reactions between ions and molecules have been observed in mass spectrometry as secondary processes already in the first instruments. However, these reactions were regarded for a long time as fundamental obstacles to the development of analytical mass spectrometry[12-14]. For this reason, despite their early observation, the systematic study of these reactions did not begin until the 1960s.[3,15-17] Ion-molecule reactions also play an important role in astrochemistry. For example, Libby[18] suggested that the ion-molecule reactions developing in Jupiter's atmosphere may give rise to "petroleum rain"†.

Ion-molecule reactions are studied at present mainly by the following methods: (1) mass spectrometry; (2) ion-cyclotron resonance; (3) the method of the total elimination of charge; (4) the discharge technique; (5) the radiochemical method. With the exception of the last procedure, all these methods have been discussed in detail in numerous reviews of ion-molecule reactions[20-40] and also in a review[41] specially devoted to the experimental techniques for the investigation of these processes. The lack in the above publications of information about the radiochemical method for the investigation of ion-molecule reactions can apparently be accounted for by the fact that the first studies in this field were begun less than ten years ago[42-45]. Despite the comparatively recent introduction of the method, it has now been used successfully in more than 30 investigations.

---

† This striking picture of the atmospheric phenomena on Jupiter was described by Libby at a lecture devoted to the 50th anniversary of the National Scientific Council of Canada in 1966. The arguments presented reduced to the following. The components of Jupiter's atmosphere are known to be hydrogen and methane, which ionise under the influence of intense cosmic radiation. The H_2^+ and CH_4^+ ions generated thereby react with methane, forming the highly reactive species CH_5^+, which is capable of giving rise to the synthesis of heavy hydrocarbons[19].

The method is based on a fundamentally new procedure for the initiation of ion–molecule reactions, consisting in the generation of molecular ions by the spontaneous nuclear-chemical transformation of tritiated compounds:

$$\mathrm{RT} \xrightarrow{-\beta^-} [\mathrm{RHe^+}] \rightarrow [\mathrm{R^+He}] \rightarrow \mathrm{R^+} + \mathrm{He} \quad .$$

The use of repeatedly tritiated starting compounds made it possible to obtain labelled charged molecular species, the chemical state of which may be followed from their radioactivity.

In the present review, an attempt is made to discuss the theoretical and experimental foundations of the method and also to examine systematically the experimental results published up to May, 1974.

II. THEORETICAL AND EXPERIMENTAL FOUNDATIONS OF THE APPLICATION OF β-DECOMPOSITION PROCESSES IN THE STUDY OF ION–MOLECULE REACTIONS

The possibility of employing β-decomposition processes in the study of ion–molecule reactions is based on a series of theoretical and experimental investigations of nuclear transformations of this type and their chemical consequences.

The first result of the β-transformation of a radioactive atom is known to be the formation of a singly charged atom of a neighbouring element in the Periodic Table (the daughter atom) in accordance with the following scheme:

$${}^{A}_{z}\mathrm{M}_{A-z} \rightarrow {}^{A}_{z+1}[\mathrm{D}]^{+}_{A-z-1} + e^- + \tilde{\nu} \ ,$$

where P and D are the symbols for the parent and daughter elements, A and z are the mass number and nuclear charge of the atom of the parent element, and e^- and $\tilde{\nu}$ are the β-particle and antineutrino respectively. For the β-decomposition of the tritium atom, this scheme assumes the following form: ${}^{3}_{1}\mathrm{H}_2 \rightarrow {}^{3}_{2}\mathrm{He}^{+}_{1} + e^{-1} + \tilde{\nu}$.

The subsequent fate of the $[\mathrm{D}]^+$ ion formed depends on a number of factors, which include in the first place the shaking effect. The shaking effect, i.e. the perturbation of the electron shells in consequence of the sudden change in nuclear charge, is one of the most important causes of excitation and additional ionisation of the singly charged ion of the daughter element. Calculations of the probabilities of the excitation and additional excitation of daughter atoms have shown[46,47] that a considerable proportion of these ions (up to 80%) are in the ground electronic states and that the overall yield of multiply charged ions does not exceed 20%, most of them consisting of ions having the +2 charge.

Similar calculations for the β-decomposition of isolated tritium atoms[48] showed that 70% of the decomposition steps lead to the formation of non-excited $\mathrm{He^+}$ daughter ions, 25% give rise to daughter ions in the first excited level (40.5 eV), 2.5% yield daughter ions in levels with energies between 40.5 and 54.4 eV, and only 2.5% lead to the formation of doubly charged $\mathrm{He^{2+}}$ daughter ions. A characteristic feature of the β-decomposition of tritium atoms is the impossibility of the formation of ions of the daughter element with a charge greater than +2. The highly charged states arising in the β-decomposition of the atoms of other elements can be produced as the result of the ionisation of the inner electron shells in consequence of the shaking effect and the subsequent cascades of vacancies. In the β-decomposition of tritium, the development of vacancy cascades is impossible owing to the presence of only one electron shell.

We have discussed hitherto processes leading to the excitation and ionisation of the daughter atom formed on β-decomposition of isolated tritium atoms. We shall now consider how these effects are manifested when the atom undergoing decomposition forms part of a molecule. The electronic processes developing in the atom as a result of β-decomposition take place over a period much shorter than the period of atomic vibrations; one can therefore assume that these processes, occurring in atoms, predetermine the set of energy and charge states of the molecular ions. Since the yield of non-excited $\mathrm{He^+}$ daughter ions formed in β-transformations of isolated tritium atoms is about 70%, one may expect approximately the same yield of non-excited primary molecular ions $[\mathrm{RHe}]^+$ in the β-decomposition of tritium atoms forming part of the molecules RT.

The primary molecular ions subsequently undergo a number of transformations, which include in the first place electronic transitions, accompanied by the migration of charge, from the helium atom to other atoms in the primary molecular ions:

$$\left[\overset{\overset{e^-}{\curvearrowright}}{\mathrm{RHe}^+}\right] \longrightarrow \left[\mathrm{R^+He}\right] \quad .$$

Such a charge distribution can be accounted for by the fact that the ionisation potential of the helium atom (24.581 eV) is much higher than the ionisation potential of organic radicals (< 10 eV).

The next process undergone by the species generated is their decomposition with formation of the ion $\mathrm{R^+}$ and a helium atom. Since the energy of the C–He bond is estimated as only 0.18 eV,[49] this decomposition should occur over a period close to the period of the atomic vibrations. Subsequent spatial separation of the species produced takes place owing to the momentum acquired by the helium atom as a result of radioactive recoil.

Radioactive recoil is due to the emission of a nuclear electron and an antineutrino. The maximum recoil energy is defined by the expression[50]

$$E_{\mathrm{max}} = 536 \cdot 10^{6} E^{\beta}_{\mathrm{max}} \left(\frac{E^{\beta}_{\mathrm{max}} + 1.02}{M_{\mathrm{D}}} \right) ,$$

where E_{max} is the maximum recoil energy (MeV), E^{β}_{max} the maximum energy of the β-particle (MeV), and M_{D} the mass of the daughter atom (a.m.u.).

Since the emission energy of tritium is minimal ($E^{\beta}_{\mathrm{max}} = 0.0186$ MeV) compared with the emission energies of other β-radioactive isotopes, the recoil energy in the decomposition of tritium is small. The maximum recoil energy calculated from the above formula is only 3.35 eV.

In the β-decomposition in atomic systems, the recoil energy is generated in the form of the kinetic energy of the daughter atoms. In the general case of β-decomposition of an atom in a molecular system, part of the recoil energy can be consumed in the dissociation of the bond between the daughter atom and the remainder of the molecule. This component is determined by the rotational-vibrational coefficient $(M - M_{\mathrm{D}})/M$, i.e. depends on the ratio of the mass of the residue $M - M_{\mathrm{D}}$ and the mass of the molecule M.[51] In the decomposition of tritium forming part of various organic molecules, the rotational-vibrational coefficient is close to unity and one can therefore expect that a considerable proportion of the recoil energy will be consumed in the excitation of the molecular ion as a whole. However, owing to the virtually zero energy of the C–He bond, the helium atom in the intermediate species $[R^+He]$ can be regarded as free and the entire recoil energy is therefore generated as the kinetic energy of the helium atoms.

Thus theoretical studies of the β-decomposition processes and the accompanying transformations lead to the following conclusion important for the problem under consideration: the main chemical consequence of the β-decomposition of tritium atoms forming part of the molecule RT is the formation of non-excited singly charged molecular ions R^+.

Among the systems investigated at the present time, only one instance is known in which the above rule does not hold. This applies to the simplest tritium-containing compound—tritiated hydrogen (R = H or T). The primary molecular ions $^3HeH^+$ and $^3HeT^+$, formed in the β-decomposition of tritium forming part of the TH and T_2 molecules respectively, are extremely stable charged molecular species. The high stability of the protonated and tritonated helium species is not surprising, since their isoelectronic analogue, the $^4HeH^+$ ion, has been detected in mass spectrometers as early as the 1920s. The latter ion, which is the simplest two-electron heteronuclear particle, has been the subject of numerous theoretical calculations. Its dissociation energy, calculated by a number of workers [52-65] using different methods, is in the range between 1.46 and 2.04 eV. A value of the dissociation energy of the HHe^+ ion close to the calculated results has been obtained in the photoionisation studies of Chupka and Russell [66].

According to Cantwell's calculation [67], the major proportion of the primary molecular ions formed in the β-decomposition of tritium in the T_2 molecule are in the ground state, 11% are in the first excited level, and 4.5% are in the second excited level. Schwartz [68] estimated the fraction of primary molecular ions in the ground state as 93%. Taking these data into account as well as all that has been said previously about the excitation energy acquired by the primary molecular ions in consequence of the shaking effect and radioactive recoil, one may conclude that, in the vast majority of these ions, energy sufficient for the dissociation of the HeH bond cannot be located in the latter. For this reason, the main result of the β-decomposition of tritium in the TH and T_2 molecules is the formation of the non-excited molecular ions $^3HeH^3$ and $^3HeT^+$.

Table 1. The relative yields of ionic fragments in the β-decomposition of TH.

Ion	Yield, %		Ion	Yield, %	
	according to Ref.69	according to Ref.70		according to Ref.69	according to Ref.70
$^3HeH^+$	93±1.9	89.5±1.1	H^+	1.55±0.16	2.3±0.4
$^3He^+$	5.1±0.3	8.2±1.0	$^3He^{2+}$	0.14±0.01	—

The results of theoretical studies on the chemical consequences of the β-decomposition of tritiated compounds have been confirmed in numerous experimental investigations. Among these, one can isolate two groups of studies which differ fundamentally as regards the methods used to investigate the consequences of β-transformations. One of these groups comprises investigations where the charged fragments arising on β-decomposition of the tritium incorporated in various molecules were studied by the mass-spectrometric technique [69-78]. The other group comprises investigations devoted to the study of the same problem by radiochemical methods [42,79].

Without considering in detail the methodological problems of mass-spectrometric studies, we may note that in all cases instruments were used which made it possible to analyse the ions formed directly on β-decomposition of gaseous tritium-containing compounds. Table 1 presents the results of two independent mass-spectrometric determinations of the yields of ionic fragments arising on β-decomposition of the TH molecule [69,70].

Despite certain differences between the instruments used in these studies, the results are in good agreement. The principal characteristic feature of the latter is the high yield of the $^3HeH^+$ molecular ions.

Table 2. The relative yields of ionic fragments in the β-decomposition of T_2.

Ion	Yield, %
T^3He^+	94.5±0.6
$T^+ + {}^3He$	5.5±0.6

Wexler [70] established that the primary molecular ion $^3HeT^+$ formed on β-decomposition of the T_2 molecule is still more stable (Table 2).

The yields of fragment ions formed on β-decomposition of tritium in the CH_3T, [71] C_2H_5T, [72] n- and iso-C_3H_7T, [73] C_6H_5T, [74] $C_6H_5CH_2T$, and *o*-, *m*-, and *p*-$CH_3C_6H_4T$ [73] molecules have also been determined by the mass-spectrometric technique. As predicted by theoretical studies, the principal charged molecular species in the above instances proved to be the corresponding carbonium ions R^+. The yields of these species are compiled in Table 3.

The radiochemical method for the investigation of the chemical consequences of tritium decomposition processes in certain hydrocarbons has been used by Italian investigators [42,79]. It is important to note that these studies were carried out at the usual pressures, where the fragments arising as a result of the decomposition of the primary molecular ions were able to interact with the molecules of the initial substances and certain additives. A conclusion concerning the nature of the processes involving the primary molecular ions was reached on the basis of the nature and yields of the products of these reactions. For example, it was established [42] that the β-decomposition of one of the tritium atoms in the CT_4 molecule in a mixture containing 84% C_3H_8, 14% CT_4, and 2% O_2 is accompanied by a change in the isotope composition of methane. Together with the initial CT_4 molecules, those of CT_3H appeared, the radioactivity of the latter amounting to 74% of the total radioactivity of the primary CT_3He^+ molecular ions generated during the experiments. The formation of the triply labelled methane can be accounted for by the exothermic hydride ion transfer reaction between the labelled methyl cation and propane:

$$CT_3^+ + C_3H_8 \rightarrow CT_3H + C_3H_7^+ \quad . \qquad (1)$$

Since CT_3H is the main product of the reaction and its formation can be accounted for only in terms of reaction (1), the authors [42] concluded that the principal result of the decomposition of tritium in methane is the formation of the methyl cations CT_3^+. It is noteworthy that in the case under consideration the initial mixture was at atmospheric pressure. The similarity of the results of the mass-spectrometric studies and the studies carried out by the Italian workers permits the conclusion that the yields of the charged fragments are independent of the pressure at which they are formed.

Table 3. The yields of carbonium ions in the β-decomposition of tritium forming part of hydrocarbons.

Initial cpd.	Carbonium ion	Yield, %	References	Initial cpd.	Carbonium ion	Yield, %	References
CH_3T	CH_3^+	83	71	$2\text{-}C_3H_7T$	$2\text{-}C_3H_7^+$	41	73
C_2H_5T	$C_2H_5^+$	80	72	C_6H_5T	$C_6H_5^+$	72	74
$1\text{-}C_3H_7T$	$1\text{-}C_3H_7^+$	56	73	C_7H_7T	$C_7H_7^+$	78	73

Thus it follows from the theoretical and experimental studies discussed above that the processes involving the β-decomposition of tritium in molecular systems lead to the formation of the corresponding molecular ions. These processes in fact constitute the basis of the radiochemical method for the investigation of ion–molecule reactions.

III. FOUNDATIONS OF THE EXPERIMENTAL TECHNIQUES IN THE RADIOCHEMICAL METHOD FOR THE INVESTIGATION OF ION-MOLECULE REACTIONS

In order to investigate the reactions of 1-propyl and 2-propyl cations, the ions must be generated from [1-T]propane in the former case:

$$CH_3CH_2CH_2T \xrightarrow{-\beta^-} CH_3CH_2CH_2^+ + He$$

and from [2-T]propane in the latter case:

$$CH_3CHTCH_3 \xrightarrow{-\beta^-} CH_3C^+HCH_3 + He \quad .$$

For ion–molecule reactions, such labelled compounds are then introduced into a medium containing the substances involved in the reaction of the propyl cations to be investigated and the resulting mixture is kept until the products of the ion–molecule interactions accumulate.

In order to identify the products formed on interaction of the small number of ions arising in the β-decomposition during a time interval suitable for the experiment and to determine their yields, it is necessary to employ polytritiated compounds[80], i.e. compounds containing at least two tritium atoms. In this case the β-decomposition of one of the radioactive atoms leads to the formation of a molecular ion and the presence of another tritium atom ("the label") in the ion makes it possible to investigate the products of the ion–molecule reactions. For example, in the case considered here one must employ [1-T_2]propane {or [1-T_3]propane} and [2-T_2]propane. The interaction of the labelled ion obtained as a result of the reactions

$$CH_3CH_2CT_3 \xrightarrow{-\beta^-} CH_3CH_2CT_2^+ + He \quad , \tag{2}$$

$$CH_3CT_2CH_3 \xrightarrow{-\beta^-} CH_3C^+TCH_3 + He \tag{3}$$

with the molecules of the surrounding medium leads to the formation of radioactive products. They are analysed by the usual methods employed for labelled compounds.

Thus the experimental method for the investigation of ion–molecule reactions initiated by the β-decomposition of tritiated compounds include three main stages:

1. the synthesis of a suitable polytritiated source of molecular ions;
2. the preparation of the reaction mixture and accumulation of the products of the ion–molecule reactions;
3. analysis of the reaction products.

1. Synthesis of the Initial Polytritiated Compound

The simplest and most readily available tritium-containing compound which may be used as the source of HeT^+ ions is molecular tritium, which is used by the isotope industry in large amounts and is very pure (up to 99%).

Other polytritiated compounds are not manufactured on an industrial scale and are synthesised under laboratory conditions. Such syntheses involve considerable experimental difficulties[81,82]. Several tens of syntheses of polylabelled compounds have now been described, most of the products being tritiated derivatives[83-89].

2. Preparation of the Reaction Mixture and Accumulation of the Products of the Ion–Molecule Reactions

By virtue of the characteristics of the nuclear-chemical processes mentioned above, the radiochemical method for the investigation of ion–molecule reactions permits the study of the interaction of molecular ions with both individual substances and with their mixtures in any state of aggregation. In the preparation of the reaction mixture, the choice of the optimum specific radioactivity is important. The use of a low specific activity of the mixture leads to an increase of the duration of the experiment. The accumulation of a sufficient amount of products for detection at a low specific activity requires a long exposure time. For example, the molecular ions CT_3^+ formed in one month as a result of the decomposition of tritium in CT_4 have an overall activity of only about 1% of the total activity of the source of these ions, i.e. CT_4.

On the other hand, the employment of a high specific activity involves the possibility of undesirable radiolytic processes, because, as a result of the β-decomposition, the reaction system is exposed not only to molecular ions but also to β-particles with an average energy of 5.6 keV. The latter can decompose a definite fraction of the initial tritiated compound, which leads to the formation of labelled products indistinguishable from the products of the ion-molecule reactions investigated. In order to prevent these secondary processes, it is necessary to prepare reaction mixtures with a fairly low level of specific activity. Calculations based on the G factors and estimates of the dose received by the system have shown, for example, that the rate of formation of tritiated radiolysis products in alkanes is negligibly small for a specific activity less than 0.5 mc $mmole^{-1}$ [42].

This conclusion was confirmed experimentally by the so called "blank" experiments involving the employment of singly labelled compounds with the same specific activity as the corresponding polylabelled compounds[42,79]. Since the decomposition of monotritiated molecules leads to the formation of ions without a radioactive label, the detection in such experiments of any tritiated products different from the initial compound indicates the occurrence of radiolytic processes. "Blank" experiments carried out for a number of systems have shown that the radiation-induced decomposition of the specimens is not a significant source of tritiated products if the system has a specific activity less than 0.5 mc mmole^{-1}.

In order to suppress the radiolytic processes, suitable diluents are added to the specimens until the attainment of the required specific activity. Italian investigators[42,79] used for this purpose suitable carriers, while the experiments carried out at Leningrad University[140-146] involved the employment of noble gases (argon or xenon). In contrast to carriers, the inert gases suppress radiolytic processes but do not take part in the reactions with the molecular ions formed and do not therefore complicate the ion–molecule interactions investigated.

The mixture of the initial polytritiated compound and the substrate, diluted until the attainment of a specific activity of several tenths of mc mmole^{-1}, is sealed in tubes with a volume of several milli-metres and is maintained until the accumulation of the products of the ion–molecule reactions. The accumulation time, which depends on the specific activity of the mixture and the sensitivity of the analytical method, varies from several days to several months.

3. Analysis of the Products of the Ion–Molecule Reactions

The relatively low radioactivity of the molecular ions formed during the experiment and consequently the low radioactivity of the products of their interaction as well as the fact that the latter are always analysed in the presence of a large amount of the undecomposed polytritiated starting compound necessitates the employment of a sensitive and effective analytical technique. The most convenient methods for the qualitative and quantitative analysis of the labelled products of ion–molecule interactions are chromatographic procedures and particularly the gas radiochromatographic method‡.

Apart from the qualitative and quantitative analyses of the products, the determination of the intermolecular distribution of tritium in such products is extremely interesting. The available information about the intramolecular distribution of the label throws light on the mechanisms of the processes leading to the formation of such products. The study of the distribution of tritium within the molecule is usually based on the change of the specific activity of the compound when a hydrogen atom in a given position (or a whole group of atoms) is substituted by a suitable inactive group. Such analysis has been carried out, for example, in the study of the products of the interaction of HeT$^+$ ions with toluene[95,96].

It is noteworthy that, in order to investigate the processes involving the neutralisation of the molecular ions formed on β-decomposition of tritiated compounds, the method proposed by Lloyd and coworkers[97,98] is extremely promising. In this method, the products of the neutralisation of the molecular ions (radicals) are investigated by electron spin resonance.

IV. ION–MOLECULE REACTIONS INITIATED BY THE β-DECOMPOSITION OF MOLECULAR TRITIUM

As already mentioned, the β-decomposition processes involving molecular tritium can be used to generate ionised molecules of tritiated helium (HeT$^+$) and to investigate a wide variety of reactions of these species.

The possibility of ion–molecule reactions with participation of HeT$^+$ ions was first reported by Wilzbach[99]. Subsequently this study constituted the basis of a new and extremely promising method for synthesising tritiated compounds, which has now been called the "Wilzbach method": a mixture of organic substances is prepared with an amount of gaseous tritium such that the radioactivity of the mixture is equal to several curies and the system is allowed to stand for several days. The nuclear-chemical processes developing in the system lead to the formation of a wide variety of labelled compounds.

The bulk of the studies employing this method involved its preparative aspect. However, there have been several investigations whose subject was the mechanisms of the formation of tritiated compounds. For example, Yang and Gant carried out a series of studies[100-103] designed to elucidate the role of various pathways to the formation of tritiated products from ethane, ethylene, cyclopropane, and propane containing gaseous tritium. The principal conclusion derived from these investigations is that labelled compounds are formed via two types of reaction: the reactions initiated by HeT$^+$ ions and the reactions initiated by β-particles.

In conformity with the point of view adopted at the present time[104], the formation of labelled compounds by the Wilzbach method involves mainly radiation processes. For this reason, studies on the introduction of a label into organic compounds by the Wilzbach method yield only limited information about the reaction of HeT$^+$ ions. On the other hand, the radiochemical method for the investigation of ion–molecule reactions examined here is free from this disadvantage.

1. The Reactions of HeT$^+$ Ions with Alkanes and Cycloalkanes

The reactions of the molecular ions HeT$^+$, formed on β-decomposition of molecular tritium, with methane, ethane, propane, butane, and isobutane as well as cycloalkanes ranging from C_3 to C_6 have been the subject of detailed studies by a group of workers at Rome University[105-107]. Tables 4 and 5 list the yields of the labelled products of the interaction of HeT$^+$ ions with alkanes and cycloalkanes respectively.

Table 4. The products of the interaction of HeT$^+$ ions with alkanes.

Alkane	Yields of products, %						Overall yield
	CH_3T	C_2H_5T	C_2H_3T	C_3H_7T	n-C_4H_9T	iso-C_5H_9T	
CH_4	40	2	13	—	—	—	55
C_2H_6	14	34	—	—	—	—	48
C_3H_8	12.8	5.1	—	12.3	—	—	30.2
n-C_4H_{10}	15.2	6.2	2.5	2.3	15.3	—	41.5
iso-C_4H_{10}	23.4	1.7	3.5	3.2	—	17.9	49.7

The following main conclusions can be drawn from the tabulated results: (a) the overall yield of the tritiated hydrocarbons is relatively low (from 25 to 55%); the

---

‡ In order to become acquainted with the method of gas radiochromatography, the reader may be recommended to consult Refs. 90–94.

authors suggest that the remaining activity corresponds to HT §; (b) in all the systems investigated, the labelled initial hydrocarbon is formed in a high yield; (c) the reactions of HeT^+ ions with alkanes are not accompanied by isomerisation processes; (d) when HeT^+ ions react with cycloalkanes, high yields of the corresponding labelled cyclic hydrocarbons are formed, which indicates the retention of the cyclic structure of the intermediate species.

Table 5. The products of the interaction of HeT^+ ions with cycloalkanes.

Cycloalkane	Yields of products, %						
	HT	CH_3T	C_2H_5T	C_2H_3T	C_3H_7T	C_3H_5T	initial [T] cycloalkane
Cyclopropane	~35	23.0	3.7	12.1	2.2	6.7	19.2
Cyclobutane	~45	1.3	6.1	11.1	—	8.4	6.9
Cyclopentane	~65	—	2.6	4.1	4.6	3.4	11.1
Cyclohexane	75	—	1.2	1.6	2.7	3.0	9.7

In their discussion of the results of studies on the reactions of HeT^+ ions with alkanes, Cacace and coworkers[105,106] assumed that the first stage in these reactions is the protonation (or more precisely tritonation) of the initial hydrocarbons in accordance with the following general mechanism:

$$C_nH_{2n+2} + HeT^+ \rightarrow [C_nH_{2n+2}T]^+ + He \quad . \qquad (4)$$

Reaction (4) is analogous to the gas-phase protonation of the simplest hydrocarbons, for example methane by H_3^+, D_3^+, CHO^+, CH_5^+, and CH_4^+ ions[108-117], ethane by CH_5^+, H_3^+, D_3^+, and CHO^+ ions[108,111,115], and deuteriated propane by CH_5^+ ions[118], which is well known in mass spectrometry.

The $[C_nH_{2n+2}T]^+$ carbonium ions formed as a result of reaction (4) are in an excited state and their excitation energy increases with increase of n. Some of these excited molecular ions are stabilised on collisions with the molecules of the surrounding medium:

$$[C_nH_{2n+2}T]^+_{exc} + S \rightarrow [C_nH_{2n+2}T]^+ + S_{exc} \qquad (5)$$

while some undergo monomolecular decomposition via various energetically allowed pathways, the most probable and general of which for all the systems investigated are the following fragmentation reactions:

$$[C_nH_{2n+2}T]^+_{exc} \begin{cases} \nearrow [C_nH_{2n+1}]^+ + HT & (6a) \\ \searrow [C_nH_{2n}T]^+ + H_2 \quad . & (6b) \end{cases}$$

The stabilised tritonated hydrocarbons then undergo neutral thermal reactions with the inactive substrate molecules, involving proton transfer and reforming the initial labelled hydrocarbons¶:

$$[C_nH_{2n+2}T]^+ + C_nH_{2n+2} \rightarrow C_nH_{2n+1}T + [C_nH_{2n+3}]^+ \quad . \qquad (7)$$

Thus the consecutive processes (4), (5), and (7) explain the formation of the labelled initial compound—one of the principal products of the reactions of HeT^+ ions with alkanes, while the decrease of the stability of the $[C_nH_{2n+2}T]^+$ carbonium ions with increase of the number of carbon atoms explains the decrease of the yield of the corresponding tritiated hydrocarbons on passing from methane to butane.

As already mentioned, one of the characteristics of the reactions of HeT^+ ions with alkanes is the comparatively low overall yield of tritiated hydrocarbons. Although Cacace and coworkers did not determine the yield of hydrogen tritide, one can be certain that the remaining fraction of radioactivity corresponds to this compound. This hypothesis is supported by the high yield of HT in the reactions of HeT^+ ions with cycloalkanes (Table 5).

According to the general mechanisms of the first stages of the ionic processes quoted above, the formation of labelled hydrogen can be accounted for by the fragmentation of a considerable proportion of the excited $[C_nH_{2n+2}T]^+$ carbonium ions via reaction (6a). However, if it is supposed that all the hydrogen atoms in the excited tritiated hydrocarbon are equivalent, then, as a result of the statistical distribution of tritium atoms, the ratio of the activity of hydrogen (A_{HT}) and that of the corresponding carbonium cation ($A_{C_nH_{2n}T^+}$) is $2/(2n + 1)$ and this in turn implies that the overall yield of the tritiated hydrocarbons, formed mainly in the successive interactions of the $[C_nH_{2n}T]^+$ carbonium ions, should be much higher than the yield of HT. For example, in the interaction between HeT^+ and butane about 80% of the radioactivity should pass to the hydrocarbons. Similar considerations have served as a basis for the hypothesis that the HeT^+ molecular ions not only manifest powerful protonating properties but also the properties of Lewis acids, i.e. these species are capable of abstracting a hydride ion from hydrocarbons, forming HT as the single tritium-containing product:

$$C_nH_{2n+2} + HeT^+ \rightarrow C_nH^+_{2n+1} + HT + He \quad .$$

This hypothesis explains the low yield of labelled hydrocarbons.

The present authors believe that, while attributing to the HeT^+ ions the properties of Lewis acids in the reaction of these species with alkanes ranging from C_2 to C_4, Cacace and coworkers[105,106] unjustifiably failed to mention the possibility of reactions involving the abstraction of a hydride ion in the T_2–CH_4 system. Indeed, if HeT^+ reacted solely as a Brønsted acid via reactions (4)–(7), the yield of labelled hydrocarbons should be much higher than that obtained by the authors. According to Aquilanti and Volpi[111], about 50% of the methyl carbonium ions should be stabilised and should then give rise to tritiated methane via reaction (7). The remaining 50% of ions decompose via reaction (6), forming 20% HT and 30% CH_3T in accordance with the formula quoted above. Thus the overall radioactivity of the hydrocarbons should be 80%, which is much higher than the experimental value.

The formation of the remaining products of the interaction of HeT^+ ions with alkanes can be explained by the subsequent reactions of the $[C_nH_{2n}T]^+$ carbonium ions formed via reaction (6b) with substrate molecules and also via other pathways involving the fragmentation of the excited $[C_nH_{2n+2}T]^+$ carbonium ions. For example, it has been suggested[106] that CH_3T, found in high yields in all the systems investigated, is formed as a result of the following monomolecular decomposition of tritonated hydrocarbons:

$$[C_nH_{2n+2}T]^+_{exc} \rightarrow [C_{n-1}H_{2n-1}]^+ + CH_3T \quad . \qquad (8)$$

---

§ Unfortunately the authors of the studies quoted here did not carry out an analysis for hydrogen tritide in the reactions between HeT^+ ions and alkanes.

¶ Similar reactions are well known in mass spectrometry[111].

The results of studies on the reactions of HeT⁺ ions with cycloalkanes can be explained similarly (Table 5). It is interesting to note that, with increase of the molecular weight of the initial cyclic hydrocarbons, the yield of HT rises from 35% for cyclopropane to 75% for cyclohexane. The authors explain this behaviour by the fact that, when there is competition between triton transfer

$$\text{cyclo-}C_nH_{2n} + HeT^+ \rightarrow [C_nH_{2n}T]^+_{exc} + He \qquad (9)$$

and the abstraction of a hydride ion

$$\text{cyclo-}C_nH_{2n} + HeT^+ \rightarrow [\text{cyclo-}C_nH_{2n-1}]^+ + HT + He \qquad (10)$$

reaction (10) becomes dominant on passing from cyclopropane to cyclohexane.

The detection of labelled cyclic hydrocarbons among the products of the ion–molecule interactions shows that the carbonium ions formed by reaction (9) also have a cyclic structure. These results constitute direct proof of the formation of gas-phase cycloalkyl carbonium ions, the existence of which has been postulated for a long time but has not been demonstrated experimentally†.

2. The Reactions of HeT⁺ Ions with Aromatic Hydrocarbons

The gas-phase ion–molecule reaction initiated by the β-decomposition of T_2 in aromatic hydrocarbons (toluene, anisole, fluoro-, chloro-, and bromo-benzenes, and $\alpha\alpha\alpha$-trifluorotoluene) have been reported[121–124]. We shall begin the discussion of these results from three standpoints: the mechanisms of the formation of the products, the intramolecular distribution of tritium in the products, and the relative reactivities of the aromatic compounds.

Table 6. The products of the interaction of HeT⁺ ions with aromatic compounds.

Aromatic cpd.	Yields of products, %		
	initial [T] cpd.	[T] benzene	other products
$C_6H_5CH_3$	60±8	3.8±0.5	[T] methane (about 8%)
$C_6D_5CD_3$	60±8	3.6±0.5	[T] methane (about 6%)
$C_6H_5C_4H_9$	65±10	25±4	[T] toluene (0.9 ± 0.1%), [T] ethylbenzene, and [T] xylenes (3.6 ± 0.4%)
$C_6H_5OCH_3$	49±10	2.0±0.2	—
C_6H_5F	67±10	<0.2	—
C_6H_5Cl	76±10	3.7±0.8	—
C_6H_5Br	69±10	8±1	—
$C_6H_5CF_3$	81±10	2.9±0.3	—

Table 6 presents the yields of the identified products of the reactions considered. Evidently the main products in all the systems investigated are the labelled initial compounds and benzene, the overall yield of the tritium-containing hydrocarbons being much higher than in reactions of HeT⁺ ions with alkanes and cycloalkanes. These data led to the hypothesis that the higher stability of the protonated arenes, formed via the extremely exothermic (–100 kcal mole⁻¹) reaction

$$ArX + HeT^+ \rightarrow [ArXT]^+_{exc} + He \qquad (11)$$

enables a considerable proportion of these ions to become stabilised on collision with the molecules of the aromatic hydrocarbon ArX (X = CH_3, C_4H_9, OCH_3, F, Cl, Br, or CF_3). The stabilised tritiated ion then transfers a proton to the substrate molecule in accordance with the neutral thermal reaction

$$[ArXT]^+ + ArX \rightarrow \overline{ArX} + [ArXH]^+ \quad , \qquad (12)$$

where $\overline{ArX}$ denotes a labelled compound.

Thus reactions (11) and (12) lead to the formation of the main products of the reactions investigated—the tritiated initial aromatic hydrocarbons.

Some of the excited tritonated molecules which have not been stabilised undergo monomolecular fragmentation:

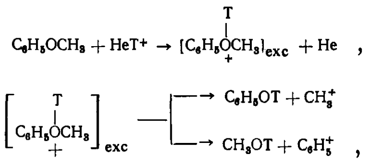
$$[ArXT]^+_{exc} \rightarrow ArT + X^+ \quad .$$

As already mentioned, the overall radioactivity of the products identified was lower than the radioactivity of the HeT⁺ ions generated during the experiment. Cacace and coworkers do not explain this radioactivity deficit in most instances[121,122] and sometimes[123] assume that part of the radioactivity is lost on the walls of the reaction vessel or is contained in products, undetected under the given conditions of analysis, which are formed in the reaction between HeT⁺ and nucleophilic impurities present in the reaction mixture in trace amounts. We believe that a more logical and more consistent hypothesis, in the light of previous investigations, would be that, as in the reactions with alkanes and cycloalkanes, in the reactions considered here HeT⁺ ions possess not only protonating properties but also the properties of Lewis acids, i.e. they react with aromatic compounds as follows:

$$C_6H_5X + HeT^+ \rightarrow C_6H_4X^+ + HT + He$$

forming HT, whose yield was not unfortunately determined.

Furthermore, there is no doubt that in the reactions with aromatic compounds having substituents with lone electron pairs ($C_6H_5OCH_3$, C_6H_5Cl, C_6H_5Br, C_6H_5F), some of the HeT⁺ ions interact with the electron pairs, forming the corresponding oxonium and halogenonium ions. The monomolecular fragmentation of subsequent bimolecular reactions of these ions lead to the formation of labelled alcohols or hydrogen halides. For example, the reactions



$$C_6H_5OCH_3 + HeT^+ \rightarrow [C_6H_5\overset{T}{\underset{+}{O}}CH_3]_{exc} + He \quad ,$$

$$\left[C_6H_5\overset{T}{\underset{+}{O}}CH_3\right]_{exc} \rightarrow \begin{cases} C_6H_5OT + CH_3^+ \\ CH_3OT + C_6H_5^+ \end{cases} ,$$

which compete with those determined previously, can account for the relatively low yield (51%) of labelled products found by Cacace et al.[123] It is regrettable that the authors did not attempt to detect among the reaction products labelled compounds formed as a result of the electrophilic attack by HeT⁺ ions on the heteroatoms of the substituents.

Extremely important information about the ion–molecule processes developing in the system and about the nature of the intermediate protonated arenes may be obtained by studying the intramolecular distribution of tritium in the final reaction products. Here one can assume that the distribution of the label in the final products reflects the selectivity of the initial interactions of the HeT⁺ ions with various positions of the reacting molecule.

---

†There have been numerous reports of the formation of such ions in solution[119,120].

The intramolecular distribution of tritium in the products of the reaction of HeT^+ ions with toluene, anisole, $\alpha\alpha\alpha$-trifluorotoluene, and halogenobenzenes has been investigated[121-124]. The results of these studies, illustrated in Fig. 1, lead to the following general conclusion. In their gas-phase interaction with the π electrons of the aromatic ring, HeT^+ ions exhibit an appreciable selectivity, although the latter is not high. The fact that the selectivity of the protonation reaction is low is satisfactorily consistent with the general rule familiar for electrophilic substitution in solutions, according to which an increase of the reactivity of the electrophilic species entails a decrease of the positional selectivity[125]. Among the known Brønsted acids, the gaseous non-solvated HeT^+ ion is one of the most reactive species. It is therefore not surprising that it exhibits a low selectivity in the reactions investigated.

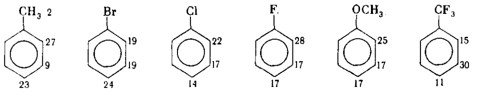


Figure 1. The intramolecular distribution of tritium in the products of the interaction of HeT^+ ions with aromatic hydrocarbons. The numerals denote the relative proportions of radioactivity (%) belonging to each position.

Table 7 presents data obtained in a study of the selectivity of aromatic compounds in reactions of HeT^+ ions (competing reactions). These data show that the reactivity of all the substances investigated, with the exception of $\alpha\alpha\alpha$-trifluorotoluene, in relation to HeT^+ ions is higher than the reactivity of benzene. One should note that the reactivity of aromatic compounds in reactions with HeT^+ ions is low. These results can also be explained by the high electrophilic reactivity of tritonated helium.

Table 7. The relative reactivities of aromatic compounds in the reaction with HeT^+ ions.

Aromatic cpd.	Reactivity in relation to benzene
ααα-Trifluorotoluene	0.8
Benzene	1.0
Fluorobenzene	1.2
Toluene	1.5
Chlorobenzene	1.6
Bromobenzene	2.0
Benzonitrile	2.2
Anisole	3.0

The results of studies on the reactions of the close analogue of tritonated helium, namely the D_2T^+ ion, with gaseous aromatic hydrocarbons (at a pressure of 750 mmHg and room temperature) are in good agreement with the results of the studies discussed above[126,127].

In conclusion of this section, we may note that the β-decomposition of molecular tritium in systems containing noble gases (Y) makes it possible to investigate the reactions of the tritiated ions YT^+ of the noble gases[128]. The radiochemical method for the generation of the tritiated ions of noble gases is based on the exothermic reaction

$$HeT^+ + Y \rightarrow He + YT^+ .$$

The only study on these lines was devoted to the investigation of the reactions of NeT^+ and XeT^+ ions with methane[128]. It was established that these reactions are analogous to those of HeT^+ ions with methane discussed previously.

The further employment of the radiochemical method for the study of the reactions of protonated noble gases will undoubtedly supplement the available information obtained in mass-spectrometric[129-134], radiation[135], and theoretical[65] studies on these interesting, reactive species.

V. ION-MOLECULE REACTIONS INITIATED BY THE β-DECOMPOSITION OF TRITIATED HYDROCARBONS

1. Reactions of Carbonium Ions with Alkanes and Cycloalkanes

Most of the studies on the reactions of carbonium ions generated in the β-decomposition of tritiated hydrocarbons are concerned with the bimolecular interaction of these species with non-radioactive sources of the corresponding ions. For example, studies have been made on the reactions of methyl cations with methane[42], of ethyl cations with methane[45,79], of propyl cations with propane[86], and of cyclopentyl cations with cyclopentane[87]. The results of these investigations are presented in Tables 8-11.

Table 8. The products of the interaction of methyl cations CT_3^+ with methane.

Product	Yield, %
CHT_3	<5.0
HT	28.7
Ethylene	10.9
Ethane	1.0
Propane	0.8
Propene	<0.02
n-Butane	0.3

Table 9. The products of the interaction of ethyl cations $C_2H_4T^+$ with ethane.

Product	Yield, %
Hydrogen	11.6±0.10
Methane	3.0±0.10
Ethylene	5.5±0.03
Propane	1.6±0.50
Butane	2.7±0.20
Propene	—

It is noteworthy that the experimental technique used in these investigations did not enable the authors to determine the yields of the products of the very important reaction involving the abstraction of an H^- ion from the reacting molecules by carbonium ions (with the exception of the methyl cation). Such hydride ion transfer reactions result in the formation of the molecules of the initial hydrocarbons but with one tritium atom less. For example, processes of this kind developing in the $C_2H_4T_2$–C_2H_6 system,

$$C_2H_4T_2 \xrightarrow{-\beta^-} C_2H_4T^+ + He \quad , \tag{13}$$

$$C_2H_4T^+ + C_2H_6 \rightarrow C_2H_5T + C_2H_5^+ \quad , \tag{14}$$

lead to the formation of monotritiated ethane, the yield of which cannot be determined against the background of the large amount of the initial doubly tritiated ethane‡. However, despite the fact that direct experimental proof of the occurrence of processes analogous to reactions (13) and (14) has not been obtained for the ethyl, propyl and cyclopentyl cations, the low yield of the identified products (ranging from 23 to 7%) suggests that such processes play a significant role.

Table 10. The products of the interaction of propyl cations $C_3H_6T^+$ with propane.

Product	Yield, %
Hydrogen	9.3
Methane	7.9
Ethane	1.9
Ethylene	4.9
Acetylene	0.7
Propane	6.0
Methylacetylene + allene	~4.9

Table 11. The products of the interaction of cyclopentyl cations $C_5H_8T^+$ with cyclopentane.

Products	Yield, %
Methane	1.6
Ethane	0.4
Propane	0.5
Butane	0.7
Pentene	3.5

Making this assumption and taking into account the decrease of the yield of the detected tritiated products with increase of the molecular weight of the ion, one may conclude that the transfer of a hydride ion from the hydrocarbon molecule to the carbonium ion is more characteristic of heavy ions. There have been numerous mass-spectrometric studies in which it has been shown that the hydride ion transfer reaction is characteristic of all the lower alkanes[113,115,116,138].

Another characteristic reaction of carbonium ions is known to be the condensation reaction[139]

$$[C_nH_{2n+1}]^+ + C_nH_{2n+2} \rightarrow [C_{2n}H_{4n+1}]^+ + H_2 \quad .$$

Such reactions lead to the formation of new carbonium ions. Their subsequent involvement in the hydride ion transfer reaction is responsible for the formation of heavier hydrocarbons. Thus condensation of the methyl cation and methane leads to the formation of a labelled ethyl cation. The latter does not react with methane, but, in the presence of even a small amount of propane, it is rapidly involved in the hydride ion abstraction reaction, forming labelled ethane (Table 8). It is also possible that similar processes take place in the $C_2H_4T_2$–C_2H_6 system. In this case the condensation reactions give rise to labelled butane.

Having examined the two main types of reactions of carbonium ions generated by the β-decomposition of tritiated hydrocarbons (with alkanes and cycloalkanes), we shall not discuss in detail the mechanism of the processes involving the formation of all the remaining products detected and we shall only note that the secondary ions produced by the fragmentation of the excited primary molecular ions are involved in such processes. A more detailed discussion of this problem can be found in the original papers quoted previously.

Table 12. The products of the interaction of methyl cations CT_3^+ with benzene and toluene.

o-Xylene	—	—	49±3	16±1	24±3	11±1

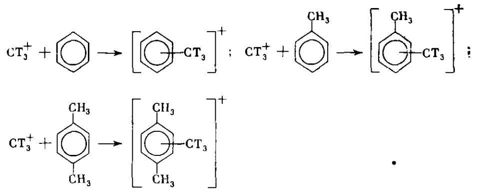
2. The Reactions of Carbonium Ions with Aromatic Compounds

The radiochemical method for the investigation of ion–molecule reactions has been used to investigate the gas-phase interactions of free methyl cations with benzene, toluene, and *m*-, *o*-, and *p*-xylenes[140] and also of the liquid-phase reactions of phenyl cations with benzene[89]. Tables 12 and 13, which list the relative yields of the labelled products of the interaction of methyl cations with benzene, toluene, and the isomeric xylenes, show that tritiated aromatic hydrocarbons having the same structures as the initial compounds as well as the products of the methylation of the latter are mainly formed.

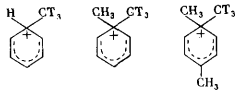
---

‡ A gas-chromatographic method of isotope analysis is available only for methane[136,137].

When methyl cations interact with aromatic hydrocarbons, the free *p*-orbital of the carbonium atom overlaps with the π orbitals of the aromatic ring, which results in the formation of the corresponding π complexes:

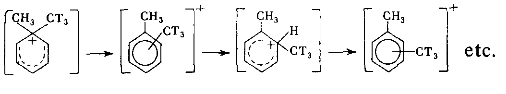


Such π complexes are known to be capable of isomerising to σ structures of the type



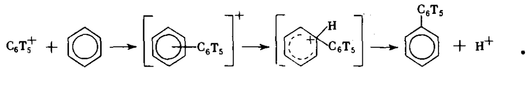
The further reactions of these σ complexes can proceed via two mechanisms. The first involves unimolecular decomposition with reformation of the molecules of the initial compounds§. The formation of labelled substrates by this mechanism is demonstrated by the discovery of labelled xylenes having the same structure as the initial compounds among the products of the interaction of methyl cations with xylenes.

The second mechanism of the reaction of the intermediate σ complexes involves their deprotonation. The deprotonation processes lead to the formation of labelled products of the methylation of the initial aromatic compounds. It is interesting to note that, as a result of such processes, labelled *m*-xylene is formed in the CT_4–toluene system in a yield exceeding those of *o*- and *p*-xylenes. These results are inconsistent with the familiar directing rule for electrophilic substitution reactions in solution. This discrepancy can probably be accounted for by a rearrangement in the corresponding phenonium ions¶:



The monomolecular deprotonation reactions of the intermediate phenonium ions are endothermic ($\Delta Q \simeq 100$ kcal mole^{-1}) and therefore occur only on collisions between ions and molecules capable of combining with a proton (in the present case toluene molecules are species of this kind). The interval between the collisions of the species in the reaction system is about 10^{-9} s. The time of the rearrangements is probably close to the period of the atomic vibrations (10^{-13} s). Thus rearrangements associated with the migration of methyl groups can occur several times before the phenonium ion loses a proton in a bimolecular collision with the surrounding molecules. The rearrangements of phenonium ions are proved convincingly by the results of experiments designed to investigate the interaction of methyl cations with xylene isomers. Regardless of the isomers used as the starting material, all three possible trimethylbenzene isomers were formed.

The study of the reactions of phenyl cations, generated in the β-decomposition of tritium in fully tritiated benzene, with non-radioactive benzene molecules showed that the only product of such reactions is labelled biphenyl[89]. Its formation can be accounted for by the same processes as in the formation of the methylation products in the reactions of methyl cations with aromatic compounds. These processes can be represented schematically as follows:



Together with labelled biphenyl, [T_5] benzene can also be formed. This product may be obtained via the reaction involving the abstraction of hydride ions, which is well known for carbonium ions:

$$C_6T_5^+ + C_6H_6 \rightarrow C_6T_5H + C_6H_5^+ \quad .$$

Unfortunately the method used in the above investigation[89] to analyse the products did not allow the isotope analysis of the tritiated benzene molecules.

3. The Reactions of Carbonium Ions with Compounds Containing Atoms having Lone Electron Pairs

In order to investigate this group of ion–molecule reactions, the starting materials used were inorganic and organic oxygen (water, alcohols, and ethers)[44,142-144], halogen (hydrogen and ethyl halides)[145], and nitrogen (amines)[146] compounds.

(a) **Reactions of carbonium ions with oxygen compounds.** Tables 14 and 15 present the results of the analysis of the products of the interaction of methyl cations with water, alcohols, and ethers. Evidently the main product of the interaction of methyl cations with water and alcohols is tritiated methanol and the products of the interaction of methyl cations with ethers are the corresponding labelled methyl-containing ethers.

Table 14. The products of the interaction of methyl cations CT_3^+ with water and alcohols.

Starting material	Yields, %					
	H_2O	CH_3OH	C_2H_5OH	C_3H_7OH	C_4H_9OH	$C_5H_{11}OH$
H_2O	11±1	89±1	—	—	—	—
CH_3OH	4±1	86±2	10±1	—	—	—
C_2H_5OH	2±1	80±2	—	18±1	—	—
n-C_3H_7OH	—	85±2	—	—	15±1	—
iso-C_3H_7OH	—	100	—	—	—	—
n-C_4H_9OH	—	94±1	—	—	—	6±1
s-C_4H_9OH	—	100	—	—	—	—
iso-C_4H_9OH	—	100	—	—	—	—

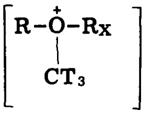
To facilitate the consideration of these results, the initial oxygen-containing substances will be designated by ROR_X (where R and R_X = H or organic group). By virtue of the electrophilic nature of carbonium ions, the most characteristic processes in the interaction of methyl cations with compounds of the type considered involve the addition of these species to atoms with lone electron pairs

---

§The high yield of tritiated benzene in the CT_4–C_6H_6 system is probably associated with the isotope exchange between the tritium and protium atoms in the intermediate phenonium ions.

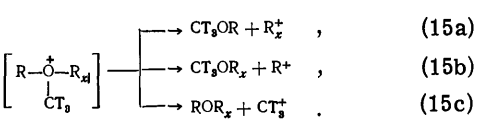
¶Such processes occur, for example, in the isomerisation of xylenes in the presence of acid catalysts[141].

(in the present instance oxygen atoms). Such addition results in the formation of excited† oxonium ions:



$$\left[R-\overset{+}{O}(CT_3)-R_X \right] .$$

Such ionium ions are known to exist in both gas and liquid phases[111,113,147]. Since the collision frequency of the species at atmospheric pressure is lower by 2–3 orders of magnitude than the bond vibration frequency, sufficient time elapses before the collision of the oxonium ion formed with any other species for the redistribution of the excitation energy throughout the ion. If part of the energy localised at the O–organic group bond exceeds the activation energy for the decomposition of the oxonium ion at this bond, the latter is ruptured under these conditions. The possible modes of fragmentation of the oxonium ion are represented below:



$$\left[R-\overset{+}{O}(CT_3)-R_x \right] \rightarrow CT_3OR + R_x^+ \quad , \qquad (15a)$$

$$\rightarrow CT_3OR_x + R^+ \quad , \qquad (15b)$$

$$\rightarrow ROR_x + CT_3^+ \quad . \qquad (15c)$$

Table 15. The products of the interaction of methyl cations CT_3^+ with ethers.

* Q is the yield of reaction products.
** I is the ionisation potential.

One of the most important factors on which the probability of the decomposition of the ion via a particular channel depends is the stability of the products formed and in the first place the stability of the charged fragments[149]. It follows from Eqn. (15) that such charged fragments are the carbonium ions CT_3^+, R^+, and R_X^+. The ionisation potentials of the corresponding radicals can serve as a measure of the stability of the carbonium ions[150]. The ions which may be regarded as products of the ionisation of the radical with the lowest ionisation potential are the most stable.

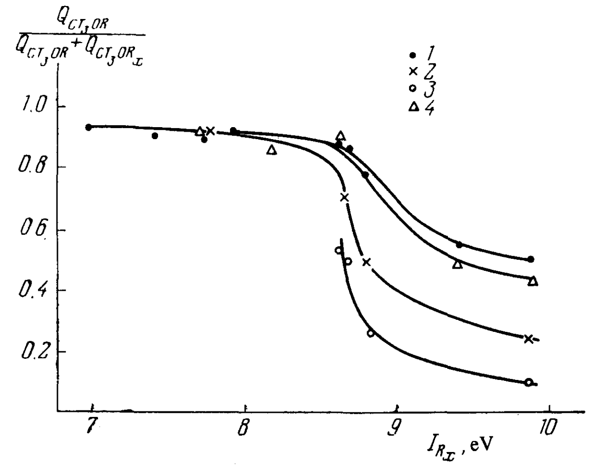

Figure 2. Dependence of the relative yields of the products of the interaction of methyl cations with the ethers ROR_X on the ionisation potentials of R_X: 1) CH_3OR_X; 2) $C_2H_5OR_X$; 3) $C_3H_7OR_X$; 4) $C_6H_5OR_X$.

Within the limits of each of the series of ethers ROR_X investigated, reactions (15b) and (15c) lead to the formation of the same charged fragments (CT_3^+ and R^+). Different R_X^+ ions are formed only in reaction (15a) for different initial ethers. It might have been expected that the stability of these ions will largely determine the mode of fragmentation of the intermediate oxonium ion. Indeed, it is seen from Table 15 that, when methyl cations interact with the ethers ROR_X, the relative yields of the ethers CT_3OR vary in parallel with the ionisation potentials of the groups R_X. Fig. 2 presents a graphical representation of the variation of these quantities for the reaction of methyl cations with ethers. Evidently the yields of the ethers $ROCT_3$ vary in accordance with a nearly exponential law up to a certain value of I_{R_X} (above 8.6 eV) and then remain virtually constant as the ionisation potentials are varied further. In order to account for the absence of a dependence of the yield of products on the ionisation potentials of the radicals when $I < 8.6$ eV, one can make the following assumption. The β-decomposition of tritium in CT_4 may lead to the formation of a certain amount of methyl cations. These cations react with the ethers and give rise to highly excited oxonium ions whose fragmentation proceeds via different pathways having equal probabilities.

---

† The excitation energy of the transition complex is determined by the excitation energy of the carbonium ion and its affinity for the ether molecule. The latter exceeds 100 kcal mole^{-1} for the majority of the reactions investigated[148].

The absence of labelled ethers among the products of the interaction of methyl cations with alcohols shows that the monomolecular abstraction of the thermodynamically relatively unstable H^+ ion from the intermediate hydrodialkyloxonium ion  $CT_3-\overset{\overset{\displaystyle H}{|}}{\underset{+}{O}}-R_X$ is an unlikely process compared with the abstraction of the much more stable R_X^+ ion. In the reactions of methyl cations with aromatic ethers, account must be taken of the possibility of the alkylation of the aromatic ring. These processes will be discussed in greater detail below.

(b) The reactions of carbonium ions with halogen compounds. The results of a study[145] of the ion–molecule reactions of methyl cations with halogen halides (HCl, HBr, and HI) and ethyl halides (C_2H_5Cl, C_2H_5Br, and C_2H_5I) are presented in Table 16.

Table 16. The products of the interaction of methyl cations CT_3^+ with hydrogen halides and ethyl halides.

C_2H_5Br	37±1	43±2	20±3	—
C_2H_5I	100	—	—	—

It is seen from the data in Table 16 that the reactions of methyl cations with hydrogen halides lead to the formation of the corresponding labelled methyl halides, while the reactions of these species with ethyl halides give rise to methyl, ethyl, and propyl halides.

There is no doubt that the first stage in these reactions is the interaction of the free *p* orbital of the carbonium ion with the lone electron pairs of the halogen atoms. The interaction results in the formation of the corresponding halogenonium ions $[CT_3XR]^+$. The monomolecular decomposition of the complex $[CT_3XR]^+$ can proceed via two pathways. The first pathway involves the reaction which is the reverse of the process investigated. On the other hand, the transformation of the complex via the second pathway

$$[CT_3XR]^+ \begin{array}{l} \overset{1}{\nearrow} RX + CT_3^+ \\ \underset{2}{\rightarrow} CT_3X + R^+ \end{array}$$

leads to the formation of the corresponding labelled methyl halide. This mechanism of the formation of tritium-containing methyl halide may be adopted only for the reactions of methyl cations with ethyl halides. On the other hand, the heat of reaction of CT_3^+ with hydrogen halides,

$$CT_3^+ + HX \rightarrow CT_3X + H^+$$

is approximately 100 kcal $mole^{-1}$, which implies that the transformation of the 'onium ion proceeds monomolecularly. In order to account for the mechanism of the formation of labelled methyl halides, one could resort to processes involving bimolecular fragmentation of the intermediate ions:

$$CT_3\overset{+}{X}H + HX \rightarrow CT_3X + H\overset{+}{X}H \quad .$$

However, comparison of the proton affinities of hydrogen halides and the corresponding methyl halides showed that this reaction is also energetically unfavourable. Indeed, the proton affinities of HCl, HBr, and HI are 140, 141, and 145 kcal $mole^{-1}$,[151] while the affinities of CH_3Cl, CH_3Br, and CH_3I are 160, 163, and 170 kcal $mole^{-1}$ respectively[152]. The mechanism of the formation of methyl halides in the gas-phase interaction of methyl cations with hydrogen halides therefore still remains obscure.

(c) Reactions of carbonium ions with nitrogen compounds. Only one study has been published so far[146] in which gas-phase reactions of free carbonium ions with the given class of compounds were investigated. These are the reactions of methyl cations with diethylamine (Table 17).

Table 17. The products of the interaction of methyl cations CT_3^+ with diethylamine.

Product	Yield, %	Product	Yield, %
Diethylamine	26±1	Ethylpropylamine	10±1
Diethylmethylamine	55±1	Ethylisopropylamine	9±1

The main products of the reaction of methyl cations with diethylamine are labelled diethylamine, diethylmethylamine, ethylpropylamine, and isopropylamine. The formation of these products cannot be accounted for in terms of the mechanisms which we invoked in the discussion of the reactions of carbonium ions with other classes of compounds. This can probably be explained by the fact that, in contrast to the other substances investigated, the amines are characterised by the highest proton affinities (> 215 kcal $mole^{-1}$).[153] By virtue of this feature and also by virtue of the relatively low proton affinity of the methylene group (120 kcal $mole^{-1}$),[153] the most characteristic reaction in this case is apparently the exothermic proton transfer from the methyl cation to the amine molecule and not the formation of the intermediate ammonium ion:

$$CT_3^+ + (C_2H_5)_2NH \rightarrow CT_2 + [(C_2H_5)_2NTH]^+ \quad .$$

The subsequent reactions of the tritium-containing methylene group and the diethylammonium ion make it possible to explain the formation of all the products detected. Thus the isotope exchange reaction

$$(C_2H_5)_2NTH^+ + (C_2H_5)_2NH - (C_2H_5)_2NT + (C_2H_5)_2\overset{+}{N}H_2$$

leads to the formation of the labelled initial diethylamine, while the reactions involving the insertion of methylene groups in various bonds of the amine molecule‡ give rise to the other products detected.

4. Reactions of Carbonium Ions with Compounds whose Molecules Contain Several Nucleophilic Centres

In the study of ion–molecule reactions of this type, methyl cations were used as the molecular ions and the starting materials consisted of a number of organic compounds whose molecules contained an aromatic ring and

---

‡ Similar reactions are well known in the chemistry of carbenes[154,155].

atoms with lone electron pairs. Such substances include bromobenzene[156], nitrobenzene[157], and alkyl phenyl and alkyl benzyl ethers[144].

The results obtained in the above studies show that the interaction of methyl cations with compounds of the given group leads to the formation of two types of products. One type comprises products resulting from the alkylation of the aromatic ring and the other comprises compounds whose formation involves attack by methyl cations on the lone electron pair. Thus, in the ion–molecule reactions considered here, there is competition between the interactions of methyl cations with the π electrons of the aromatic ring and with the free electron pairs of the substituent atoms.

Table 18 lists the intramolecular competition factors f_{comp}, which are defined as the ratios of the yields of the products of the interaction of methyl cations with the lone electron pairs (Q_p) to the yields of the products of the interaction with the π electrons of the aromatic ring (Q_π). It follows from Table 18 that, in the interactions of free methyl cations with the compounds investigated, the lone electron pairs of the substituent atoms are more reactive than the π electrons of the aromatic ring. The reactivities of the free electron pairs of bromine atoms, the nitro-group, and ether oxygen in alkyl benzyl ethers are similar, but much lower than the reactivities of the lone electron pairs of the oxygen atoms in alkyl phenyl ethers.

Table 18. The relative yields of the products of competing reactions and competition factors.

Starting material	Q_p, %	Q_π, %	f_{comp}
C_6H_5Br	65	35	1.86
$C_6H_5NO_2$	65	35	1.86
$CH_3OCH_2C_6H_5$	58	42	1.38
$C_2H_5OCH_2C_6H_5$	64	36	1.78
$CH_3OC_6H_5$	80	20	4.00
$C_4H_9OC_6H_5$	82	18	4.55
iso- $C_5H_{11}OC_6H_5$	88	12	7.34

Presumably the observed changes in the competition factor are associated with the changes in the ratio of the basicities of the nucleophilic centres in these compounds. However, one should note that studies on the relative basicities of the nucleophilic centres in a single molecule have not been made. We believe that extremely valuable information in this field of theoretical chemistry can be obtained with the aid of the radiochemical method considered here for the investigation of ion–molecule reactions.

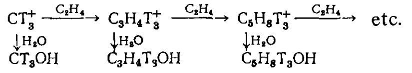
5. Competitive Reactions of Carbonium Ions

The possibility of using the radiochemical method for the study of competitive intermolecular reactions may be demonstrated by the results of a recent study of the gas-phase reactions of methyl cations with ethylene–water mixtures for different molar ratios of the components, namely $[C_2H_4]:[H_2O] = 1:1,\ 2:1,\ 3:1,\ 4:1$, and $5:1$.[158] It was established that the main products of these reactions are aliphatic alcohols.

The carbonium ions generated in unsaturated hydrocarbons are known[159] to initiate cationic polymerisation reactions. When methyl cations are generated in ethylene, these reactions can be represented by the equation

$$CT_3^+ + CH_2{=}CH_2 \rightarrow CT_3CH_2CH_2^+ \xrightarrow{C_2H_4} CT_3(CH_2)_3CH_2^+ \text{ etc.} \qquad (16)$$

For a reaction mixture containing water molecules, two competing processes will occur: the polymerisation reaction (16) and the reactions with water of all the varieties of the carbonium ions produced, leading to the formation of alcohols:



$$\begin{array}{llll} CT_3^+ \xrightarrow{C_2H_4} & C_3H_4T_3^+ \xrightarrow{C_2H_4} & C_5H_8T_3^+ \xrightarrow{C_2H_4} & \text{etc.} \\ \downarrow{\scriptstyle H_2O} & \downarrow{\scriptstyle H_2O} & \downarrow{\scriptstyle H_2O} & \\ CT_3OH & C_3H_4T_3OH & C_5H_8T_3OH & \end{array} \qquad (17)$$

With increase of the concentration of ethylene, an increase of the contribution of reaction (16) may be expected and hence an increase of the yield of alcohols with a larger number of carbon atoms. Experimental data confirm this hypothesis.

It is noteworthy that straight-chain alcohols were not detected among the products of the reactions of the intermediate carbonium ions, although the formation of such alcohols might have been expected bearing in mind the position of the carbonium centre at the instant of formation of these ions. This experimental finding permits the conclusion that there is sufficient time for the cations formed in reaction (16) to isomerise to thermodynamically more stable structures. Similar isomerisation reactions of carbonium ions are well known in organic chemistry.

It is also interesting that, for all the $[C_2H_4]:[H_2O]$ ratios, the yield of labelled methanol exceeds the value which might have been expected for a statistical mechanism of reactions (17). For example, for an equimolar ethylene : water ratio, a 50% yield of methanol could have been expected. The experimental yield (82.5%) greatly exceeds this value. The data obtained make it possible to estimate the competition factor for the reaction of methyl cations with methylene and water: $f_{\text{comp}} \simeq 4$. The higher reactivity of methyl cations in relation to water molecules compared with their reactivity in relation to ethylene molecules is due to the higher affinity of the CH_3^+ ions for H_2O (82 kcal mole^{-1})[148] compared with their affinity for C_2H_4 (69.5 kcal mole^{-1}).[160]

Analogous studies on the competitive reactions involving a wider range of substances will make it possible, in our view, not only to determine the competition factors in such reactions but also to supplement the nucleophilicity scale for substances, the construction of which is based on the equation $\lg(k_P/k_{H_2O}) = Sn$, where k_P/k_{H_2O} is the competition factor for the reactions of the carbonium ion with a base P and water, n is the nucleophilicity constant, and S the constant characterising the substrate[161].

VI. PROSPECTS FOR THE USE OF THE RADIOCHEMICAL METHOD OF INVESTIGATING ION–MOLECULE REACTIONS

On the basis of the theoretical considerations discussed previously and the experimental results published at the present time, one may reach certain conclusions about the scope of the radiochemical method for the investigation of ion–molecule reactions and about the prospects for its application in studies on the chemistry of molecular ions.

One of the most important features of this method is the possibility of obtaining molecular ions having the desired composition, structure, and initial location of the charge.

The composition and structure of molecular ions are determined by the composition and structure of the initial tritiated compounds and the initial location of the charge depends on the position of the tritium atom in these compounds.

The employment of the covalent tritides of certain elements as the initial compounds makes it possible to obtain the isosteric molecular ions of these elements (with a sextet of outer electrons), which are analogues of carbonium ions. As an example, we shall quote certain mechanisms for the formation of nitrogen-, oxygen-, and silicon-containing analogues of carbonium ions:

$$NT_3 \xrightarrow{-\beta^-} \bar{N}T_2^+ + He \quad ,$$
$$T_2O \xrightarrow{-\beta^-} TO^+ + He \quad ,$$
$$SiT_4 \xrightarrow{-\beta^-} SiT_3^+ + He \quad .$$

It should be noted that tritium-containing compounds, behaving as radiochemical sources of molecular ions, are characterised by a constant and prolonged action. They can be used for several years.

The radiochemical method leads to considerable possibilities not only for the generation of unique charged molecular species but also for the investigation of their chemical behaviour under a wide variety of conditions. This method makes it possible to investigate the reactions of molecular ions both with any individual substances and with their mixtures. A characteristic feature of the method is also the possibility of carrying out ion–molecule reactions in any state of aggregation.

The ion–molecule reactions initiated by the β-decomposition of tritiated compounds can be used to solve many important chemical problems. Such reactions can be applied in the experimental study of the relative basicities of substances (intermolecular competing reactions). Labelled electrophilic species constitute a kind of detector of electron densities in the molecule (intramolecular competing reactions).

Furthermore, ion–molecule reactions can be used to study processes where the involvement of molecular ions is postulated and also to study the individual stages of cationic polymerisation reactions.

The reactions of tritium-containing molecular ions have found application in the synthesis of a wide variety of tritiated compounds[162].

Intermolecular Photochemical Reduction of Aromatic Nitro-compounds

A.N.Frolov, N.A.Kuznetsova, and A.V.El'tsov

The current data on the intermolecular photochemical reduction of aromatic nitro-compounds under various conditions are considered and the mechanism of the primary stage of the photoprocess in neutral, acid, and basic media is discussed. The dependence of the photochemical reactivity of nitro-compounds on the characteristics of the structure of their excited state is examined.

The bibliography includes 113 references.

CONTENTS

I. INTRODUCTION

The present review considers data on the intermolecular photochemical reduction of aromatic nitro-compounds (aliphatic nitro-compounds and intramolecular photochemical reduction of aromatic nitro-compounds have already been reviewed[1,2]).

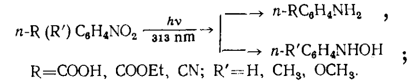
The results of the first systematic studies on the photochemical reduction of nitro-compounds were published in the middle 1960s,[3-6] although isolated studies had been published before that[7-9]. Photochemical reduction of nitro-compounds is briefly considered in Morrison's review[1]. Numerous studies concerned with the synthetic aspects and mechanism of photochemical reduction have now been made and are discussed in the present paper.

It follows from the published data that the composition and yield of the products of the photochemical reduction of many nitro-compounds depend on the reaction conditions. These differences are associated with changes in the photochemical reduction mechanism. In Morrison's review[1], the mechanism of the photochemical reduction of nitro-compounds is treated as one involving the homolytic abstraction of a hydrogen atom from a solvent molecule excited by a molecule of the nitro-compound. However, this mechanism probably operates only in neutral alcoholic and ethereal solutions. There is reason to believe that in acid and alkaline media the process proceeds via a two-stage heterolytic mechanism with initial electron transfer followed by proton transfer. In the present review, it is shown how ideas have developed about the mechanism of the photochemical reduction of nitro-compounds in neutral, acid, and alkaline media.

II. PHOTOCHEMICAL REDUCTION OF NITRO-COMPOUNDS BY HYDROGEN DONORS (PHOTOCHEMICAL DEHYDROGENATION)

It has been established that aromatic nitro-compounds give rise to amino- and hydroxylamino-compounds on irradiation in protic solvents. When nitrobenzene is irradiated in 2-propanol by light at a wavelength of 366 nm, it is reduced to phenylhydroxylamine[3] with a quantum yield of 1.14×10^{-2}. As a result of the subsequent dark oxidation reactions and condensation with the reformed nitrobenzene, the final product is azoxybenzene. α-Nitrosonaphthalene is unreactive under these conditions[10], but is reduced on irradiation with light at a wavelength of 366 nm in benzene in the presence of a hydrogen donor stronger than 2-propanol, namely tri-n-butyltin[11]. The photochemical reaction product, α-naphthylamine, was identified from its fluorescence spectrum. In contrast to α-nitronaphthalene, the β-isomer is reduced in 2-propanol and β-naphthylhydroxylamine is formed with a quantum yield of 0.037.[12]

Nitrobenzoate esters are reduced to amines on irradiation in ethanol[13] and esterification and transesterification are observed; the yield of the amines is 13–40%. Other *p*- and *m*-derivatives of nitrobenzene undergo similar reactions[14,15]:



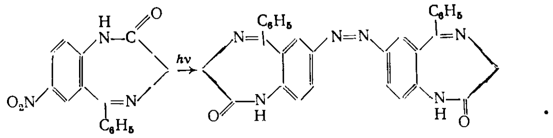
$$n\text{-R(R}')\text{C}_6\text{H}_4\text{NO}_2 \xrightarrow[313\ \text{nm}]{h\nu} \left[\begin{array}{l} \longrightarrow n\text{-RC}_6\text{H}_4\text{NH}_2\ , \\ \longrightarrow n\text{-R}'\text{C}_6\text{H}_4\text{NHOH}\ ; \end{array}\right.$$

R=COOH, COOEt, CN; R'=H, CH_3, OCH_3.

The photolysis was carried out in 2-propanol in an atmosphere of nitrogen at room temperature. The quantum yield of the reaction, determined spectrophotometrically from the decrease in the amount of the initial nitro-compound, is 0.12–0.45 for electron-accepting substituents (R) and 0.02–0.03 for electron-donating substituents (R'). *p*-Nitrophenol and *p*-nitroaniline are not reduced under these conditions[15]; however, photochemical reduction does occur when the amino-group is acylated[15,16]. It has been shown[14,15] that the quantum yield in the photochemical reduction of substituted nitrobenzenes in 2-propanol is satisfactorily correlated with the Hammett σ constants.

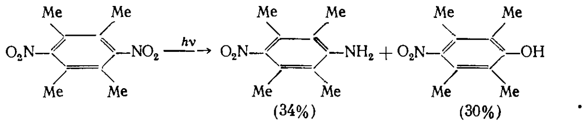
m-Dinitrobenzene and 1,3,5-trinitrobenzene are reduced photochemically in ethanol, the yield of the corresponding azoxy-derivatives not exceeding 2 %.[4] A similar process takes place in tetrahydrofuran. The final products were isolated by thin-layer chromatography. It has been established that ethanol is then oxidised to acetaldehyde[4].

On irradiation with light filtered through Pyrex glass in tetrahydrofuran, 7-nitro-5-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepin-2-one gives a 10% yield of an azo-compound[16]:

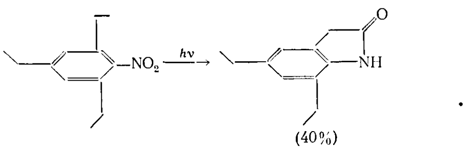


The reaction product was identified by its elemental composition and infrared, ultraviolet and mass spectra.

It is of interest that the photolysis in isopropyl alcohol of *p*-nitroacetophenone gives rise to a product resulting from the reduction of the nitro-group and not the keto-group, namely 4,4-diacetylazoxybenzene, in 31% yield[17]. The photochemical reduction of the sterically shielded nitro-group in 2-propanol has been investigated[18] and it has been shown that, together with the reduction process, the nitro-group is substituted by the hydroxy-group:



If the alkyl substituent in the *ortho*-position with respect to the nitro-group has a *β*-carbon atom, the photochemical reduction probably proceeds intramolecularly, for example[18]:



It has been reported[6] that 1,2,3,4-tetramethyl-5,6-dinitrobenzene is reduced photochemically in anhydrous ether to 1,2,3,4-tetramethyl-5-nitroaniline in 25% yield. The reaction was carried out with irradiation by the light of a 450 W mercury lamp at 2–6°C with stirring by a stream of nitrogen. The products were isolated by thin-layer chromatography and identified by ^{1}H NMR and from the elemental composition and mass spectra.

On irradiation with light filtered through Pyrex glass in ether, *p*-nitroanisole is reduced to *p*-anisidine (30%) and 4,4′-dimethoxyazoxybenzene (12%).[19] Under these conditions, nitrobenzene yields 44% of aniline, 2% of azobenzene, and 1% of 2-hydroxyazobenzene[19].

Heterocyclic compounds behave on photolysis similarly to nitro-compounds of the benzene series. It has been shown[5,20–22] that 4-nitropyridine *N*-oxide is converted quantitatively into the corresponding hydroxylamine on irradiation in absolute ethanol. Similar results were obtained for 4-nitro-derivatives of the *N*-oxides of *α*-picoline and 2,6-lutidine[5]. The experiments were performed in an atmosphere of nitrogen; after irradiation in the presence of oxygen, unidentified products having a different composition are formed.

Thus the photochemical reduction of nitro-compounds in a series of protic solvents proceeds comparatively readily. t-Butyl alcohol does not promote the occurrence of the reaction[13,19].

Qualitative aspects of the photochemical reduction by hydrogen donors have been considered in the studies described above. We shall now examine the available data concerning the nature of their reactive excited state and the mechanism of photochemical dehydrogenation.

1. The Multiplicity of the Excited State in the Photochemical Dehydrogenation Reaction

A characteristic feature of nitro-compounds is the comparative ease of the transition from the singlet to the triplet excited state and vice versa. The quantum yield in the formation of triplets is 0.6–0.8,[10,23] regardless of the configuration of the triplet state (n, π^* or π, π^*). Bearing in mind the longer lifetime of the triplet state compared with the singlet state, nitro-compounds in the triplet state are presumably involved in photochemical reduction.

This conclusion, based on the work of Brown and Williams[24], was reached in Morrison's review[1]. The evidence available at present for the involvement of the triplet state (T) in the photochemical reduction of nitro-compounds can be divided into two groups. They are based on (1) information about the chemical reactivity of nitro-compounds in the T state according to flash photolysis data[25] and (2) a comparison of data for the sensitisation or inhibition of the formation of the T state (from ESR [24] and phosphorescence spectra[26]) and the photochemical reduction reaction; in a number of studies the conclusions concerning the involvement of the T state in the reaction is based on experiments designed to investigate the influence of the donors and acceptors of the energy of triplet excitation on the quantum (chemical) yield of the reaction[3,12,19].

(1) The triplet–triplet absorption spectra of *α*- and *β*-nitronaphthalenes have been described[25,27,28]. Capellos and Porter[25] determined by the method of laser photolysis the rate constant for the abstraction of hydrogen from ethanol by *α*-nitronaphthalene (10^4 M^{-1} s^{-1}) and nitrobenzene (10^6 M^{-1} s^{-1}) in the T state. The photochemical dehydrogenation rate constant for nitrobenzene in the excited state[10], found from the dependence of the photochemical reduction quantum yield on the concentration of the alcohol (2-propanol), is 0.8×10^6 M^{-1} s^{-1}. The agreement between the constants determined by different methods is satisfactory and is consistent with the conclusion[10] concerning the triplet nature of the reactive state in photochemical reduction.

(2) Perfluoronaphthalene, the singlet level of which is higher and the triplet level (E_T = 56 kcal mole^{-1}) is lower than for nitrobenzene (E_T = 60 kcal mole^{-1}), has been used as an inhibitor of the photochemical reduction of nitrobenzene[24]. The irradiation was carried out with light at a wavelength >330 nm, which is not absorbed by perfluoronaphthalene, in degassed tetrahydrofuran solutions at room temperature. Following irradiation in the absence of inhibitors, the authors observed an ESR spectrum, which they attributed to the radical $C_6H_5N\dot{O}_2H$. In the presence of 0.1 M perfluoronaphthalene, the photochemical reduction of nitrobenzene did not occur. Under these conditions, the solution in tetrahydrofuran at –160°C gives rise to the ESR spectrum resulting from the formation of perfluoronaphthalene in the triplet state.

It has been shown[26] that 4-nitropyridine *N*-oxide (E_T = 52 kcal mole^{-1}) quenches the phosphorescence of diacetyl (E_T = 56.3 kcal mole^{-1}) in degassed solutions in ethanol and 2-propanol at room temperature. When a mixture of diacetyl and 4-nitropyridine *N*-oxide in alcohol is irradiated with light at a wavelength exceeding 400 nm, which is absorbed by diacetyl alone, the product is 4-hydroxyaminopyridine *N*-oxide. The results of the above studies[24,26] can be explained within the framework of the hypothesis of the triplet energy transfer leading to the T state of the nitro-compounds.

It has been concluded in a number of investigations that oxygen influences the photochemical reduction of nitro-compounds. Thus the quantum yield for the formation of phenylhydroxylamine by the reduction of nitro-benzene in 2-propanol is 1.14×10^{-2} in degassed solutions and 0.87×10^{-2} in air-saturated solutions[3]. The photochemical reduction of β-nitronaphthalene is also suppressed in the presence of oxygen[12].

According to Barltrop and Bunce's data[19], the yield of aniline in the photolysis of nitrobenzene (E_T = 60 kcal mole^{-1}) in ether in the presence of a fourfold excess of benzophenone (E_T = 69 kcal mole^{-1}), with almost complete absorption of the incident light by benzophenone, increases by a factor of six. Diacetyl and octafluoronaphthalene inhibit the photochemical reduction reaction[19]. Similar inhibition occurs also in the reduction of β-nitronaphthalene in the presence of cyclohexa-1,3-diene[12].

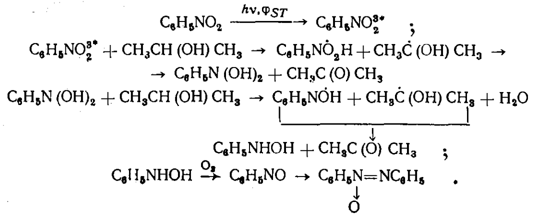
In the discussion of data based on the inhibition and sensitisation of a chemical process, one must bear in mind the multistep mechanism of the photochemical reduction (see below) and hence the possible influence of organic excitation energy acceptors or oxygen not only on the triplet state deactivation stage but also on the secondary thermal processes involving radical species. The above investigations did not yield unambiguous evidence showing that the sensitisation of the photochemical reduction reaction is in fact due to the triplet–triplet energy transfer. The conclusions concerning the triplet nature of the reactive state of nitro-compounds in photochemical dehydrogenation reactions, based on the above results[3,12,19], are therefore tentative.

2. The Photochemical Dehydrogenation Mechanism

Yet another feature is characteristic of nitro-compounds in the n, π^* excited triplet state. The structure of the nitro-group in this state is such that its chemical properties resemble those of a "biradical"[1], like the carbonyl group in the triplet state of ketones[29]. It has been shown for ketones[30,31], that the properties of the reacting triplet state and of the t-butoxy-radical vary in parallel in hydrogen abstraction reactions.

The mechanism of photochemical reduction in protic solvents, including as a primary step the abstraction of a hydrogen atom from the alcohol by the nitrogen-compound in the excited triplet state n, π^*, has been considered[1,3] in conformity with the foregoing considerations:

Scheme 1



$$C_6H_5NO_2 \xrightarrow{h\nu, \varphi_{ST}} C_6H_5NO_2^{3*} \quad ;$$
$$C_6H_5NO_2^{3*} + CH_3CH(OH)CH_3 \rightarrow C_6H_5N\dot{O}_2H + CH_3\dot{C}(OH)CH_3 \rightarrow$$
$$\rightarrow C_6H_5N(OH)_2 + CH_3C(O)CH_3$$
$$C_6H_5N(OH)_2 + CH_3CH(OH)CH_3 \rightarrow \underbrace{C_6H_5N\dot{O}H + CH_3\dot{C}(OH)CH_3}_{\downarrow} + H_2O$$
$$C_6H_5NHOH + CH_3C(O)CH_3 \quad ;$$
$$C_6H_5NHOH \xrightarrow{O_2} C_6H_5NO \rightarrow \underset{\underset{O}{\downarrow}}{C_6H_5N{=}NC_6H_5} \quad .$$

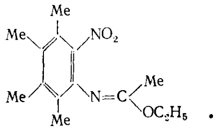
According to Scheme 1, phenylhydroxylamine is formed without a stage involving the formation of nitrosobenzene, which is believed[3] to be produced by the oxidation of phenylhydroxylamine by the dissolved oxygen.

It has been shown[19] that the photolysis of phenylhydroxylamine in ether leads to the formation of aniline in 42% yield. When an ethereal solution of nitrobenzene is irradiated with light filtered through Pyrex glass, aniline is again formed, but under these conditions nitrosobenzene is converted into azoxybenzene[19]. A similar result was obtained in the photolysis of nitrosobenzene in methanol[32]. These results lead to the conclusion, in agreement with Scheme 1, that nitrosobenzene does not constitute an intermediate stage in the photochemical reduction of nitrobenzene to phenylhydroxylamine.

However, it has been established recently that, when deoxygenated dilute (10^{-3}–10^{-5} M) solutions of nitrosobenzene in 2-propanol are irradiated, phenylhydroxylamine is formed with a quantum yield of 0.047.[33] The photolysis of concentrated nitrobenzene solution gave azoxybenzene. The latter process has probably been observed in earlier investigations[19,32]. In the light of these data, Scheme 1 may not reflect quite accurately the sequence of reactions involving the formation of the intermediates in the photochemical reduction.

We shall now consider data confirming qualitatively certain details of Scheme 1. The abstraction of a hydrogen atom from the solvent by an excited molecule of the nitroso-compound is indicated by the dependence of the quantum yield of the photochemical reduction of p-nitrobenzonitrile on the C–H bond energy of the reducing agent: the quantum yield of this reaction decreases on passing from 2-propanol to ethanol and hexane[15]. Similar data have been published for m-dinitrobenzene[34]. It has been established[34] that the efficiency of the photochemical reduction of p-dinitrobenzene decreases on passing from CH_3OH to CD_3OD, the isotope effect being $K_H/K_D \simeq 2.6$.

The photolysis of 1,2,3,4-tetramethyl-5,6-dinitrobenzene in ether yielded[6] compound (I), which is a product of the recombination of the radicals formed in the photochemical dehydrogenation of ether by the nitro-compound:



(I)

The structure of compound (I) was confirmed by infrared spectroscopy, ^1H NMR, and elemental analysis. Its formation is consistent with the radical mechanism for the primary step of the photochemical reduction in protic media.

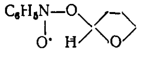
The formation of phenyl nitroxide $C_6H_5N\!\left\langle\begin{matrix}H\\ O^{\cdot}\end{matrix}\right.$ (Scheme 1) in the photolysis of nitrobenzene in secondary alcohols and tetrahydrofuran follows from a number of data[35-37]. When photolysed in the cavity of a microwave spectrometer, the ESR spectrum is identical to that of phenyl nitroxide obtained in the photolysis of nitrosobenzene[35]. When nitrobenzene is irradiated in primary alcohols, the product is the radical $C_6H_5N(\dot{O})R$, while in secondary alcohols (in 2-propanol) $C_6H_5N\dot{O}H$ is formed. The radical $C_6H_5N(\dot{O})C(OH)(CH_3)_2$ was detected in a later investigation[37] involving the irradiation of nitrobenzene in 2-propanol.

The detection of the primary photochemical reduction product, the $ArN\dot{O}_2H$ radical, would constitute direct confirmation of Scheme 1. Such confirmation has been obtained for the photochemical reduction of ketones. When benzophenone was irradiated with ultraviolet light in ethanol in the ESR spectrometer cavity, the simultaneous appearance of diphenyl hydroxymethyl and hydroxyethyl radicals was observed[38]:

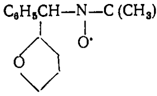
$$(C_6H_5)_2CO^{3*} + CH_3CH_2OH \rightarrow (C_6H_5)_2\dot{C}OH + CH_3\dot{C}HOH \quad .$$

However, the analogous radical $C_6H_5N(\dot{O})OH$ derived from nitrobenzene has not yet been detected experimentally.

Ward[39] attributed the ESR signal obtained in the photolysis of nitrobenzene in tetrahydrofuran to the $C_6H_5N(\dot{O})OH$ radical. However, later studies[37,40] established that this signal is due to the $C_6H_5N\dot{O}_2R$ radical (II), which is formed when the tetrahydrofuryl radical reacts with nitrobenzene:



(II)



(III)

When the tetrahydrofuryl radical is removed from the system with the aid of a spin trap (t-butyl phenyl nitrone), the characteristic spectrum of radical (III) appears instead of the ESR spectrum obtained by Ward.

A radical of the $ArNO_2R$ type has been detected[41] following the irradiation of 2-nitrofuran in triethylsilane:

The attempts to obtain the $C_6H_5N\dot{O}_2H$ radical by the photolysis of nitrobenzene in the presence of other effective hydrogen donors were unsuccessful[35,40]. However, the $ArN\dot{O}_2H$ radical has been detected in the reaction of atomic hydrogen with solid nitrobenzene[42] and also in the low-temperature radiolysis of nitrobenzene[43]. Evidently it is rapidly destroyed under the photolytic conditions.

It has been suggested[37] that a radical of type $ArN\dot{O}_2R$ undergoes monomolecular decomposition:

$$ArN(\dot{O})OR \rightarrow ArNO + R\dot{O}$$

leading, as with the $ArN\dot{O}_2H$ radical, to the formation of the final reaction products.

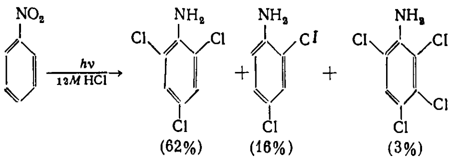
Thus the mechanism of the photochemical reduction, involving the abstraction of hydrogen from solvent molecules by the nitro-compound in the n, π^* triplet state, may be regarded as generally accepted.

The abstraction of hydrogen from alcohol molecules by nitro-compounds in the π, π^* triplet state was not observed until recently[1]. According to the latest data, 2-nitronaphthalene[12] and 4-nitropyridine Λ-oxide[26], which have the lowest π, π^* triplet level, are reduced on irradiation in 2-propanol. The quantum yield in the photochemical reduction of 2-nitronaphthalene is 0.037. Nitrobenzene in the n, π^* triplet state is reduced under these conditions with a quantum yield of 0.0114.[3] It is believed[12] that the rate of abstraction of hydrogen by 2-nitronaphthalene in the triplet state is lower by 3–4 orders of magnitude than for nitrobenzene, but the longer lifetime of the 2-nitronaphthalene triplets compensates the lower rate and leads to a comparatively high quantum yield in the photochemical reduction. Furthermore, one must bear in mind that the quantum yield is for the formation of the triplet states of 2-nitronaphthalene (0.83) is higher than for nitrobenzene (0.67).[10,23]

The low quantum yield in the conversion of nitrobenzene in 2-propanol into arylhydroxylamine [bearing in mind that the quantum yield in the transition of nitrobenzene to the excited state is 0.67 (Hurley and Testa[10]) and that the degree of conversion of $C_6H_5N(\dot{O})(OH)$ into C_6H_5NHOH is 100%] is evidently due to the fact that the deactivation of triplets predominates over the abstraction of hydrogen from the solvent. Thus it has been reported[11] that the lowest triplet state of nitrobenzene is of the n, π^* type and that the rate of abstraction of hydrogen atoms is high $(0.8 \times 10^6\ \mathrm{mole^{-1}\ s^{-1}})$.[10] The low quantum yield in the photochemical reduction of nitrobenzene is therefore associated, according to the authors[10], with the high rate of deactivation of the triplet state $(\sim 10^9\ \mathrm{s^{-1}})$.

III. PHOTOCHEMICAL REDUCTION OF NITRO-COMPOUNDS IN AN ACID MEDIUM

Studies of the photochemical reduction of nitro-compounds in alcohols showed that the process proceeds more effectively when hydrochloric acid is added[44,45]. Thus the quantum yield in 50% aqueous isopropyl alcohol in an atmosphere of nitrogen increases from 1.14×10^{-2} in the absence of acid to 0.3 in the presence of 12 M HCl.[44] The initial product of the reduction of nitrobenzene in isopropyl alcohol in the presence of HCl is phenylhydroxylamine, which was determined polarographically[45]: the final products are aniline (40%), *p*-chloroaniline, and *p*-aminophenol. When nitrobenzene is irradiated in the presence of 12 M HCl but in the absence of alcohol, the reduction of the nitro-group is accompanied by the substitution of the hydrogen atoms in the benzene ring by chlorine[46]:



Similar results were obtained for *o*-, *m*-, and *p*-substituted nitrobenzenes[47]. The quantum yield in the photochemical reduction of nitrobenzene derivatives in water in the presence of 12 M HCl (determined from the decrease in the amount of the nitro-compound) depends only slightly on the electron-accepting properties of the substituent and decreases following the introduction of an electron-donating group into the ring[47].

On irradiation with light at a wavelength of 335 nm[48] in a hydrochloric acid–2-propanol mixture, α-nitronaphthalene is converted into α-naphthylamine in 70% yield. It has been shown[49] that the primary product of the photochemical reduction of α-nitronaphthalene under these conditions is α-naphthylhydroxylamine, which is converted in the presence of HCl into 4-chloro-1-naphthylamine. The latter is dechlorinated photochemically and yields α-naphthylamine. The quantum yield in the formation of 4-chloro-1-naphthylamine, identified from ultraviolet, infrared, and fluorescence spectra, increases in proportion to the concentration of HCl.[50] The maximum quantum yield was 1.28×10^{-2} for 6 M HCl in 50% aqueous 2-propanol solution, while in the alcohol in the absence of acid an appreciable photochemical reaction is not observed.

On irradiation in alcohol in the presence of HCl, 4-nitropyridine is converted into 4-hydroxyaminopyridine and 4,4′-azopyridine[51]. The quantum yield for the decrease in the amount of 4-nitropyridine rises to 0.94 with increase of HCl concentration[29,51]. According to the results of Cu and Testa[52], the limiting quantum yield in the photochemical reduction of 4-nitropyridine in 2-propanol in the presence of HCl is somewhat smaller, amounting to 0.65. The discrepancy between the quantum yields has been explained[52] by the difference between the two analytical methods used to determine the degree of conversion of the starting material (spectrophotometry[29] and polarography[52]).

Irradiation of 5-nitroquinoline in aqueous 2-propanol in the presence of HCl leads to the formation of 5-amino-6,8-dichloroquinoline[53]; the maximum quantum yield in the photochemical reduction is 5.44×10^{-2} at an HCl concentration $\geqslant 1$ M.

The linear dependence of the quantum yield in the photochemical reduction of α-nitronaphthalene on the HCl concentration led[50,51] to a mechanism for the photochemical reduction of nitro-compounds by isopropyl alcohol in an acid medium (Scheme 2), including a stage in which the excited triplet state is protonated (aromatic nitro-compounds in the ground state are weak bases):

Scheme 2

$$\mathrm{ArNO_2} \xrightarrow{h\nu,\varphi_{ST}} \mathrm{ArNO_2^{3*}} \quad ;$$

$$\mathrm{ArNO_2^{3*}} + \mathrm{H^+} \rightleftarrows \mathrm{Ar\overset{+}{N}O_2H^{3*}} \quad ;$$

$$\mathrm{ArNO_2^{3*}} \rightarrow \mathrm{ArNO_2} \quad ;$$

$$\mathrm{Ar\overset{+}{N}O_2H^{3*}} + \mathrm{(CH_3)_2CHOH} \rightarrow \underset{\substack{\downarrow \\ \text{reaction products.}}}{\mathrm{Ar\dot{N}O_2H}} + \mathrm{(CH_3)_2\dot{C}OH} + \mathrm{H}^{\cdot\cdot}$$

The quantum yield in the photochemical reduction of nitrobenzene is independent of HCl concentration up to 3 M, after which it increases linearly. Evidently the protonation of nitrobenzene in the *T* state begins to an appreciable extent only at HCl concentrations exceeding 3 M.[44]

Using the method of pulsed laser photolysis, Capellos and Porter[25] determined the rate constants for the protonation of α-nitronaphthalene (1.85×10^7 M^{-1} s^{-1}) and nitrobenzene (4.4×10^7 M^{-1} s^{-1}) in the *T* state, the values obtained being much greater than the dehydrogenation rate constants (10^4 and 10^6 M^{-1} s^{-1} for α-nitronaphthalene and nitrobenzene respectively[25]). These results agree indirectly with Scheme 2).

The completion of the photochemical reduction of the protonated triplet state should include an electron transfer stage. This process is probably unlikely, since alcohols, the ionisation potentials of which are 11–12 eV, are weak electron donors[54]. Data which cannot be accounted for by the mechanism of acid catalysis (Scheme 2) have been published recently. It has been shown[53,55,56] that catalysis is observed in the presence of HCl but not H_2SO_4. Since the hydrogen sulphate anion undergoes one-electron oxidation with greater difficulty than the chloride anion, the authors[55] suggested that the protonation in the presence of HCl is preceded by electron transfer from the chloride anion to the excited triplet state of the nitro-compound (Scheme 3):

Scheme 3

$$\mathrm{ArNO_2} \xrightarrow{h\nu,\varphi_{ST}} \mathrm{ArNO_2^{3*}} \quad ;$$

$$\mathrm{ArNO_2^{3*}} + \mathrm{Cl^-} \rightarrow [\mathrm{ArNO_2^{\dot{-}}} \ldots \mathrm{Cl^{\cdot}}] \quad ;$$

$$[\mathrm{ArNO_2^{\dot{-}}} \ldots \mathrm{Cl^{\cdot}}] + \mathrm{H^+} \rightarrow [\mathrm{Ar\dot{N}O_2H} \ldots \mathrm{Cl^{\cdot}}] \quad ;$$

$$[\mathrm{Ar\dot{N}O_2H} \ldots \mathrm{Cl^{\cdot}}] + \mathrm{CH_3CH(OH)CH_3} \rightarrow \underset{\substack{\downarrow \\ \text{reaction products.}}}{\mathrm{Ar\dot{N}O_2H}} + \mathrm{HCl} + \mathrm{CH_3\dot{C}(OH)CH_3}$$

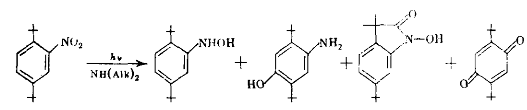
The conversion of the $\mathrm{Ar\dot{N}O_2H}$ radical into the final products can be described within the framework of Scheme 1.

An absorption spectrum with a maximum in the region of 440 nm has been obtained in the flash photolysis of degassed nitrobenzene solutions in aqueous 2-propanol in the presence of 6 M HCl. The authors attribute it[56] to the $\mathrm{C_6H_5\dot{N}O_2H}$ radical formed on protonation of the radical-anion. A similar result was obtained for 4-nitropyridine[56]. The authors[56] are inclined to favour a photochemical reduction mechanism resembling Scheme 3, although they were unable to measure the spectrum of the pair [$\mathrm{ArNO_2^{\dot{-}}}$ .. Cl] or the radical-anion $\mathrm{ArNO_2^{\dot{-}}}$ in acid media. The reason for this is probably the high rate of protonation of the radical-anion (for example, the rate constant for the protonation of the α-nitronaphthalene radical-anion is approximately 10^{10} M^{-1} s^{-1}).[25] On the other hand, there are literature data[57] demonstrating one-electron transfer from the chloride anion of the nitro-compound in the ground state (m-dinitrobenzene and trinitrobenzene), resulting in the formation of radical-anions. Similar data for the reaction in the excited state are lacking.

IV. PHOTOCHEMICAL REDUCTION OF NITRO-COMPOUNDS IN AN ALKALINE MEDIUM

A series of studies on the photochemical reduction in alakaline media has shown that the composition of the reaction products and the kinetics are different from those in the photochemical reduction in neutral media. In alkaline media, the reduction process proceeds more effectively and the yield of products is higher than for the photochemical reduction in alcohols and ethers; instead of hydroxylamines and amines, final condensation products are obtained—azo- and azoxy-compounds. The yield of the azo-compound in the photolysis of 7-nitro-5-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepin-2-one in diethylamine is higher than in tetrahydrofuran (40% and 10% respectively)[16].

There are data showing that, on irradiation in neutral solutions, 1-t-butyl-2-nitrobenzenes give rise to intramolecular products only, namely indolinones (VII),[58-61] while in solutions in aliphatic amines products of the intermolecular reduction of the nitro-group are formed, i.e. hydroxylamines (V) and amines (VI):[59-62]



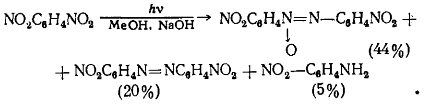
(IV) (V) (VI) (VII) (VIII) .

In the latter case, indolines (VII) and quinones (VIII) are formed as side products. The hydroxylamines (V) are converted into azoxy- and azo-compounds[59-61] and can also condense with amine oxidation products[62].

The photochemical reduction of a series of mononitro-compounds in alkylamines has been investigated[19] and it has been shown that the composition of the reaction products is more varied than in photochemical reduction in neutral media: the yield of arylamines varies from 6 to 22%, that of azo-compounds from 2 to 20%, that of azoxy-compounds from 5 to 35%, and that of o-hydroxyazo-compounds from 10 to 30%.

Aromatic amines may be used as reducing agents[63]. When m-chloronitrobenzene is irradiated in a benzene solution of N-methylaniline in an atmosphere of nitrogen, 37% of m-chloroaniline is formed; in the presence of NN-dimethylaniline, the yield of m-chloroaniline is 25%. Under these conditions, α-nitronaphthalene is converted into α-naphthylamine (37%) [63] and arylamines are oxidised, N-methylformanilide (34%) and N-methylaniline (56%) being fromed from NN-dimethylaniline.

An increase of the yield of the reduction products compared with alcoholic media is also observed in an alkaline alcoholic medium. The photolysis of m-dinitrobenzene in ethanol yields not more than 2% of an azoxy-compound[4], while irradiation in 50% aqueous methanol in the presence of 0.05 M NaOH gives a yield of reduction products up to 69%:[64,65]



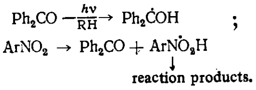
$$NO_2C_6H_4NO_2 \xrightarrow[\text{MeOH, NaOH}]{h\nu} \underset{\underset{O}{\downarrow}}{NO_2C_6H_4N}{=}N{-}C_6H_4NO_2 + \;(44\%)$$
$$+ \underset{(20\%)}{NO_2C_6H_4N{=}NC_6H_4NO_2} + \underset{(5\%)}{NO_2{-}C_6H_4NH_2} \quad .$$

A number of other mono- and di-nitro-compounds of the benzene and naphthalene series are also reduced under these conditions[65]. The photolysis of 5-nitro- and 8-nitro-anthraquinone-1-sulphonic acids in alkaline aqueous alcoholic solutions gives an approximately 3% yield of amino-anthraquinonesulphonic acids[66].

The sequence in which the photochemical reduction products are formed in an alkaline medium has been described[19]. It has been shown that irradiation with light at a wavelength ≤290 nm leads to the formation of anilines, while irradiation with light at a wavelength ≥290 nm results in the formation of azoxy- and azo-products. The experiments were carried out in the presence of oxygen, since it has an insignificant influence on the yield of the final product[19]. The irradiation of azo- and azoxy-benzenes under the experimental conditions leads to the formation of hydrazobenzene[67] and 2-hydroxyazobenzene[68] respectively. Aniline is also formed in small amounts under these conditions[19], but the process is much slower than the formation of anilines from hydroxylamines. The authors[19] therefore believe that anilines are formed on photochemical reduction mainly from the corresponding arylhydroxylamines and not from azo- and azoxy-derivatives. It has also been suggested that a nitroso-compound is formed as an intermediate before the hydroxylamine formation stage. Arylhydroxylamines and nitroso-compounds are unstable in alkaline media and condense with formation of azo- and azoxy-compounds, which has been established by special dark experiments[19,65].

Indirect data consistent with the involvement of nitro-compounds in the triplet state in photochemical reduction in alkaline media have been published[65,69]. A study has been made of the sensitisation of the photochemical reduction of 4,4′-dinitrobiphenyl (E_T = 58 kcal mole^{-1}) by naphthalene (E_T = 61 kcal mole^{-1}) and benzophenone (E_T = 69 kcal mole^{-1}).[65] The relative singlet levels in these pairs is not known accurately but, judging from the long-wavelength limit of the absorption spectra, the energy of the singlet state, at least in naphthalene, is higher than in 4,4′-dinitrobiphenyl. Irradiation was carried out with light at a wavelength of 254 nm, the ratio of the donor and acceptor concentrations being such that the main bulk of the exciting light (≥90%) is absorbed by benzophenone or naphthalene. Under these conditions, the quantum yield of the reaction, found from the decrease in the amount of the nitro-compound, is 0.056 in the absence of the sensitiser and 0.03 and 0.16 in the presence of naphthalene and benzophenone respectively.

The quantum yield and the photochemical reduction of 4-*NN*-diethylamino-4′-nitroazobenzene in butylamine increases from 4.2×10^{-4} to 0.14 when 0.27 M benzophenone is introduced[69]. These data can probably be accounted for by energy transfer via triplet levels. However, results have been published showing[69] that the sensitisation of the photochemical reduction of nitro-compounds by benzophenone may be to some extent also "chemical" sensitisation (for the description of its mechanism, see Monroe and Wamser[70]):



$$Ph_2CO \xrightarrow[RH]{h\nu} Ph_2\dot{C}OH \quad ;$$
$$Ph_2\dot{C}OH + ArNO_2 \rightarrow Ph_2CO + \underset{\underset{\text{reaction products.}}{\downarrow}}{ArN\dot{O}_2H}$$

It has been suggested[19,63] that photochemical reduction in both amines and alcohols proceeds via a mechanism involving the dehydrogenation of the amine by the nitro-compound in the triplet state, which leads to the formation of the $ArN\dot{O}_2H$ radical. However, this hypothesis is inconsistent with the results of other studies[10,19,63], where it has been shown that α-nitronaphthalene is not reduced in alcohol[10] but is reduced in amines[19,63].

α-Nitronaphthalene is known to have a π, π* lowest triplet state, which is relatively unreactive in hydrogen abstraction reactions[23,71]. Possibly the reduction of the π, π* triplets of nitro-compounds in alkaline media is facilitated by the occurrence of the process via a mechanism different from that of photochemical dehydrogenation. In this respect, the photochemical reduction of nitro-compounds in alkaline media resembles the photochemical reduction of ketones. Electron transfer with subsequent proton transfer in secondary processes has been suggested as the first stage in the reduction by alkylamines of excited states of ketones, which are unreactive in hydrogen abstraction reactions[72]. This is indicated by the chemical polarisation of electrons[73], observed on irradiation of the benzophenone–triethylamine system, and also by the decrease in the rate of photochemical reduction with increase in the ionisation potential of the amine[72].

Pacifici et al.[69] were the first to suggest that the reduction of nitro-compounds in amines proceeds via electron transfer from the solvent to the nitro-compound in the triplet state. The authors observed that the direction of the photochemical reaction of 4-*NN*-diethylamino-4′-nitroazobenzene in amines is different from that in alcohols. A hydrazo-compound (resulting from the reduction of the azo-group) is formed in alcohols, while in butylamine the reduction involves the nitro-group, the product—4-*NN*-diethylamino-4′-hydroxyaminoazobenzene—having been identified from the ultraviolet spectrum and its conversion into an azoxy-compound. The following reaction mechanism was proposed:

$$ArNO_2 \xrightarrow[\varphi_{ST}]{h\nu} ArNO_2^{3*} \quad ;$$

$$ArNO_2^{3*} + RNH_2 \rightarrow ArNO_2^{\dot{-}} + RNH_2^{\dot{+}} \quad .$$

The radical-anion of the nitro-compound abstracts a proton from the radical-cation of the amine:

$$ArNO_2^{\dot{-}} + RNH_2^{\dot{+}} \rightarrow ArN\dot{O}_2H + R\dot{N}H \quad .$$

The $ArN\dot{O}_2H$ radical is subsequently converted into the final products.

A similar mechanism has been proposed in another investigation[62], the difference being that the radical-anion of the nitro-compound and the radical-cation of the amine are believed by the authors to exist in the form of an ion pair, where proton transfer takes place.

There are data showing that photochemical reduction in alkaline alcoholic media also proceeds with electron transfer in the primary step[65]. It has been established that the quantum yield of the photochemical reduction of nitro-compounds in absolute alcohol in the presence of sodium alkoxide and in alkaline aqueous alcoholic media increases with increased concentration of the alkoxide ion[34,65]. According to ESR data, there is a simultaneous increase in the steady-state concentration of the radical-anions of the nitro-compounds[74]. These results have been explained by the participation of the alkoxide ion in the photochemical reduction, which involves one-electron transfer from the anion to the nitro-compound in the excited triplet state (Scheme 4):

Scheme 4

$$\mathrm{ArNO_2} \xrightarrow[\varphi_{ST}]{h\nu} \mathrm{ArNO_2^{3*}} \quad ;$$

$$\mathrm{ArNO_2^{3*}} + \mathrm{CH_3\overline{O}} \rightarrow [\mathrm{ArNO_2^{\dot{-}}} \ldots \mathrm{CH_3\dot{O}}] \quad ;$$

$$[\mathrm{ArNO_2^{\dot{-}}} \ldots \mathrm{CH_3\dot{O}}] \rightarrow \underset{\substack{\downarrow \\ \text{reaction products.}}}{\mathrm{ArN\overline{O}_2H}} + \mathrm{CH_2O}\ (\text{or}\quad \mathrm{ArN\dot{O}_2H} + e + \mathrm{CH_2O})$$

The radicals formed as a result of electron transfer are probably enclosed in a solvent cage, where hydrogen transfer takes place[65,74]. Hydrogen transfer may be promoted by the formation of the $\mathrm{CH_3\dot{O}}$ radical in a non-equilibrium state, which has excess vibrational energy. This scheme is consistent with the absence of an isotope effect in the photochemical reduction by $\mathrm{CH_3O^-}$ and $\mathrm{CD_3O^-}$ ions[34,74]. In contrast to photochemical dehydrogenation, where the ratio $K_H/K_D = 2.6$ for *p*-dinitrobenzene, in photochemical reduction in an alkaline medium $K_H/K_D = 1$ for *m*-dinitrobenzene and 1.4 for *p*-dinitrobenzene[34,74]. In the reduction by the alkoxide ion, the C–H bond energy in the reducing agent probably plays a secondary role. This conclusion can be explained on the hypothesis that the rate of reaction of the excited state of the nitro-compound with the alkoxide ion is diffusion-controlled and reduces to electron transfer in the primary step; the transfer of a hydrogen atom (proton) takes place in subsequent stages of the reaction, which are not kinetically controlled[34].

Data demonstrating the formation of radical-anions when the charge of a strong base is accepted by the nitro-compound provide a qualitative confirmation of Scheme 4 for the photochemical reduction of nitro-compounds in alkaline media[75–77]. On irradiation, the probability of electron transfer increases markedly[78,79]. According to data obtained by ESR, alkylamines[69] and alkali metal alkoxides[74,79] can play the role of reducing agents in electron phototransfer[74,79].

It has been noted[65] that nitro-compounds are reduced by the formate anion as well as alkoxide ions. The limiting quantum yield in the photochemical reduction of *m*-dinitrobenzene by sodium formate in water is 0.01.[34] *m*-Dinitrobenzene is not reduced by sodium acetate in water[65]. The authors explain this by the fact that, in contrast to acetate anions, alkoxide and formate anions behave as hydride ion donors. The transfer of a hydride ion can in principle proceed in stages, and may include electron transfer followed by the transfer of a hydrogen atom.

V. INTERMOLECULAR PHOTOCHEMICAL DEOXYGENATION AS A VARIETY OF PHOTOCHEMICAL REDUCTION

Intermolecular photochemical deoxygenation can be regarded as a kind of photochemical reduction process in which the reduction products are formed via the abstraction by the reducing agent of an oxygen atom from the nitro-group in the excited nitro-compound. The photochemical deoxygenation of nitro-derivatives by triethyl phosphite has been described[80].

It has been observed recently that nitrobenzene and some of its derivatives react with the cyanide ion under the influence of ultraviolet light and are converted into nitroso-compounds[81–83]:

$$\mathrm{ArNO_2} + \mathrm{CN^-} \xrightarrow{h\nu} \mathrm{ArNO} + \mathrm{OCN^-} \quad .$$

The reaction proceeds stoichiometrically and the quantum yield increases as the cyanide concentration rises to 1 M. Evidently nitrosobenzene is formed in the reaction of excited nitrobenzene with $\mathrm{CN^-}$.[83]

The photochemical deoxygenation occurring when the nitrobenzene–$\mathrm{BCl_3}$ complex is irradiated in cyclohexane has been described[84]; the quantum yield is 3.9×10^{-3}. The authors believe that electronic excitation leads to a weakening of the N–O bond of nitrobenzene and a strengthening of the O–B bond in the complex. The transfer of an oxygen atom from nitrobenzene to $\mathrm{BCl_3}$ is accompanied by the liberation of a chlorine atom, which gives rise to a chain process resulting in the formation of chlorocyclohexane and $\mathrm{H_3BO_3}$.

VI. SIDE REACTIONS ACCOMPANYING PHOTOCHEMICAL REDUCTION

The photochemical reduction of nitro-compounds is frequently complicated by side reactions, which may compete with the reduction process and sometimes become fully dominant. The photochemical reactions involving substituents in the nitro-compound (photochemical dehalogenation, photochemical rearrangement of benzoate esters, hydrolysis of the nitrile group, etc.) are not considered here. Under the conditions of "reducing photolysis", the nitro-group itself can undergo photochemical denitration, or photochemical substitution, or can be converted into a nitrite. These processes sometimes completely suppress the photochemical reduction of the nitro-group.

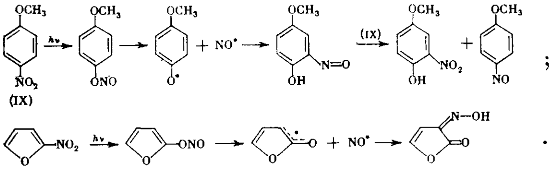
Photochemical denitration of nitro-compounds has been observed in the photolysis of isomeric chloro- and bromo-nitrobenzenes in an aqueous alcoholic solution of sodium nitrite[85]. Taking into account the results of El'tsov et al.[86], the nitro-group is presumably reduced under photolysis conditions to an amino-group, the latter is diazotised, and the diazo-group formed is substituted by hydrogen. Photochemical denitration by sodium tetrahydroborate has been observed in the photochemical reduction of certain nitro-compounds: *α*-nitronaphthalene 4-methoxy-1-nitronaphthalene, and 1-nitropyrene[82].

Certain aromatic nitro-compounds can not only reduce the nitro-group but can also participate in the photochemical substitution of the nitro-group by cyano-, methoxy-, hydroxy-groups, etc. Thus *α*-nitronaphthalene and *p*-nitroanisole are reduced to the amines on irradiation in aliphatic amines[19], while in the presence of $\mathrm{CN^-}$, $\mathrm{CH_3O^-}$, and $\mathrm{OH^-}$ ions they are involved in nucleophilic photochemical substitution reactions[81,87,88]. In the presence of HCl, 1-nitronaphthalene, 1,5-dinitronaphthalene, and 1,8-dinitronaphthalene in chloroalkanes are converted by the photochemical substitution of the nitro-groups by chlorine into the corresponding chloronaphthalenes[89]. At a concentration of 0.1 M in ethanol, 4-nitropyridine *N*-oxide is reduced to hydroxylamine[20]. Under the same conditions, at a concentration of the initial nitro-compound of 0.001 M, the nitro-group is replaced by a hydroxy-group; at moderate concentrations, the two photochemical reactions compete[20,90]. In the presence of piperidine, the substitution leads to the formation of 4-piperidinopyridine *N*-oxide[91]. The nitro-group in α-nitroazulene is readily substituted photochemically[87,92]. The photochemical substitution of the nitro-groups in certain nitrocompounds by hydroxy-groups has been discussed in a review[93].

It has been suggested that photochemical substitution takes place with participation of the triplet state[92]. This hypothesis is based on the results of experiments on the sensitisation by benzophenone of the photochemical substitution of the nitro-group in *p*-nitroanisole[94] and 2,6- and 1,7-dinitronaphthalenes[95]. The quenching of the *T* state of α-nitronaphthalene by hydroxide ions has been reported[25]; the quenching rate constant, determined from the triplet–triplet absorption spectra in degassed ethanol solutions, is 1.73×10^8 M^{-1} s^{-1}. (The quantity is equal to the sum of the rate constants for the quenching of the *T* state by hydroxide and ethoxide ions, since in ethanol solutions hydroxide ions are in equilibrium with ethoxide ions[34].)

The photochemical conversion of the nitro-group into a hydroxy-group can proceed intramolecularly via the intermediate formation of a nitrite group (the nitro–nitrite rearrangement). The nitro–nitrite rearrangement was first postulated by Chapman et al.[96] to account for the formation of anthraquinone and 10,10′-bianthrone in the photolysis of 9-nitroanthracene. They believe that the rearrangement is promoted by steric hindrance, which displaces the nitro-group from the plane of the aromatic ring. The overlap (in the excited state) of the *p*-orbital of the oxygen in the nitro-group with the *p*-orbital of the aromatic system leads to the formation of an oxaziridine ring, which is converted by a thermal reaction into a nitrite group. Other data[18,58] are consistent with this hypothesis. The hydrolysis of nitrites leads to the formation of hydroxy-derivatives, which are usually the final products of the photochemical reaction.

There are data indicating the intermediate formation of nitrites on irradiation of nitro-compounds which are not subjected to steric hindrance in the ground state. In this case, the displacement of the nitro-group from the plane of the aromatic ring is probably caused by the transition to the excited state. Thus the formation of 4-methoxy-2-nitrophenol and 3-hydroxyiminofuran-2(3*H*)-one on photolysis of *p*-nitroanisole[97] and 2-nitrofuran[98] respectively can be readily explained in terms of the nitro–nitrite rearrangement, the homolysis of the resulting nitrite into radicals, and their subsequent recombination:



The formation of 4-hydroxypyridine *N*-oxide in the photolysis of 4-nitropyridine *N*-oxide in isopropyl alcohol in the presence of HCl is explained by the intermediate rearrangement to the nitrite[90].

On photolysis of 8-nitroquinoline in benzene and alcoholic solutions, 8-hydroxyquinoline is probably formed also via the nitro-nitrite rearrangement. The intramolecular mechanism of the process is confirmed by the absence of a dependence of the quantum yield in the formation of 8-hydroxyquinoline on the concentration of hydroxide ions in the aqueous alcoholic solution and on the nature of the solvent (aqueous alcohol, benzene)[99].

It is suggested[90,97,99], that nitro-compounds are involved in this reaction in the triplet state. Thus triphenylene (E_T = 67 kcal mole^{-1}) sensitises the photochemical rearrangement of *p*-nitroanisole (E_T = 60.8 kcal mole^{-1}).[97] The conversion of 8-nitroquinoline (E_T = 58 kcal mole^{-1}) into 8-hydroxyquinoline is sensitised by benzophenone (E_T = 69 kcal mole^{-1}) and naphthalene (E_T = 61 kcal mole^{-1}).[99] Under conditions where the light flux (at a wavelength of 254 nm) is absorbed by the sensitiser ($\geq$ 90%), the quantum yield, determined from the decrease in the amount of 8-nitroquinoline, was 4.38×10^{-3} and 1.25×10^{-3} in the presence of benzophenone and naphthalene respectively. On direct excitation of 8-nitroquinoline, the yield is 1.87×10^{-3}.

VII. THE INFLUENCE OF SUBSTITUENTS AND OF THE TYPE OF THE LOWEST TRIPLET STATE ON THE PHOTOCHEMICAL REACTIVITY OF NITRO-COMPOUNDS

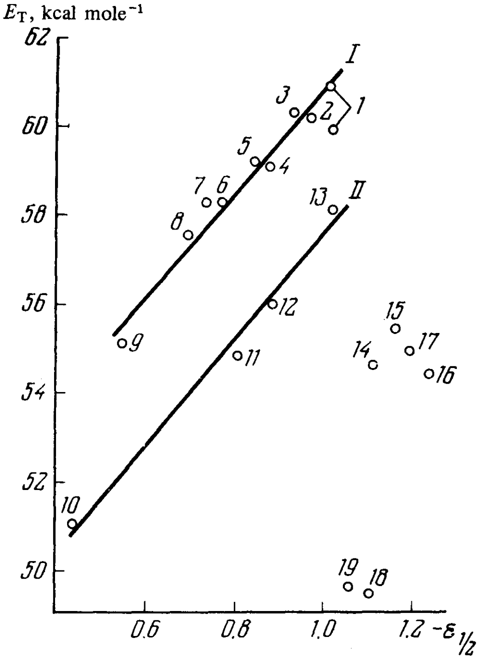
By analogy with the behaviour of ketones in photochemical reduction and on the hypothesis of the dominant role of the triplet state of nitro-compounds in these reactions, it has been suggested[82,100,101] that the reactivities of nitro-compounds in the excited state be classified in terms of their behaviour in photochemical reactions and of the type of the lowest triplet state. Nitrobenzene and its derivatives without strong electron-donating substituents are usually reduced photochemically by protic solvents. It is postulated that the reactive excited state of these compounds is of the n, π^* type[82]. The second group comprises α-nitronaphthalene and nitrobenzenes with electron-donating substituents. In the lowest excited π, π^* state, these compounds undergo photochemical substitution and reduction reactions; their ability to abstract hydrogen is diminished. Finally, the third group consists of nitro-compounds whose excited state includes a large contribution by the charge-transfer state (CTS); they are photochemically stable.

The existence of three types of nitro-compounds with different reactivities in the excited state has been confirmed by a study[101] in which a linear relation between the energy of the 0–0 transition to the triplet state and the potential of the one-electron polarographic reduction for aromatic nitrogen-compounds is reported. Similar relations have been described for aromatic hydrocarbons[102] and ketones[102–105]. In order to account for these correlations, the authors[103–105] represented the energy of excitation to the n, π^* and π, π^* triplet states by the differences between the energies of the n and π^* of the π and π^* orbitals:

$$E_T^{n\pi^*} = \varepsilon_n - \varepsilon_{\pi^*} \quad ;$$
$$E_T^{\pi\pi^*} = \varepsilon_\pi - \varepsilon_{\pi^*} \quad .$$

The introduction of substituents leads to an increase or decrease of the energy of the molecular orbital (MO). The energy of the highest occupied molecular orbital is the same for compounds of the given series (ϵ_n) or if it is linearly related to the energy of the lowest vacant molecular orbital (ϵ_{π^*}), one may expect a linear relation between the energy of the triplet state E_T and ϵ_{π^*}. Since ϵ_{π^*} varies linearly with one-electron reduction potentials[106] ($\epsilon_{1/2}$) (for nitro-compounds, this relation has been published[107]), one may expect also a linear relation between E_T and $\epsilon_{1/2}$, which is in fact the case for the various classes of compounds[101–105].

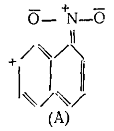
The data of Frolov et al.[101] indicate the existence of three types of relations between E_T and $\epsilon_{1/2}$ (see Figure), which corresponds to the different reactivities of nitro-compounds in the excited state: some are reduced on irradiation (the group of compounds corresponding to line I), others are difficult to reduce but undergo photochemical substitution reactions (group corresponding to line II), while unreactive compounds (nitroanilines and nitronaphthylamines) constitute an isolated group of data in the Figure.



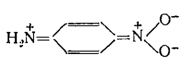
Dependence of the one-electron polarographic reduction half-wave potentials ($-\epsilon_{1/2}$, V) in dimethylformamide on the energy of the 0–0 transition to the triplet state (E_T): *1)* *p*-nitroanisole; *2)* 2-nitrobiphenyl; *3)* nitrobenzene; *4)* 2-nitrofluorene; *5)* 4-nitrobiphenyl; *6)* *m*-nitroacetophenone; *7)* 4,4′-dinitrobiphenyl; *8)* 1,8-dinitronaphthalene; *9)* 1,5-dinitronaphthalene; *10)* 1,4-dinitronaphthalene; *11)* α-nitronaphthalene; *12)* β-nitronaphthalene; *13)* 8-nitroquinoline; *14)* 4-nitrodiphenylamine; [4-nitrobiphenylylamine?]; *15)* 4-nitroaniline; *16)* *NN*-dimethyl-4-nitroaniline; *17)* 2-methyl-4-nitroaniline; *18)* 1-amino-4-nitroaniline; *19)* 2-amino-1-nitronaphthalene; E_T^I (kcal mole^{-1}) = (13.6 ± 0.9) ($-\epsilon_{1/2}$) + (47.5 ± 0.1); E_T^{II} (kcal mole^{-1}) = (12.6 ± 0.9) ($-\epsilon_{1/2}$) + (45.4 ± 0.2).

In connection with the difficulties arising in the study of the phosphorescence spectra (low-intensity structureless spectra, frequently with superposition of the luminescence of an impurity) there are relatively few data concerning the nature of the lowest triplet state of nitro-compounds[108] and those available are contradictory. Judging from the lifetime of the triplet and the fine structure of the phosphorescence spectra, nitrobenzene, 2-nitrofluorene, *p*-nitrobiphenyl, and 1,5-dinitronaphthalene[10,109] are in the *n*, π* state, while 4-nitropyridine *N*-oxide[26,110], 3- and 4-nitroquinoline *N*-oxides[110], and α- and β-nitronaphthalenes[12,23,111] are in the π, π* triplet state. These data account for lines I and II in the Figure. However, it is believed[23] that the π, π* configuration predominates in the triplet state of 1,5- and 1,8-dinitronaphthalenes.

It has also been suggested[101] that the tendency of nitro-compounds in the first group (line I in the Figure) towards reduction is due to the fact that the lowest triplet state is of the *n*, π* type (or of the π, π* type with a large *n*, π* contribution). An increase in the energy of the *n*, π* states and a decrease of the CTS level are probably characteristic of the nitro-compounds corresponding to line II in the Figure, so that there is an increase of the probability of the mixing of the lowest π, π* and CTS levels [there is an increased contribution of the type (A) structure to the triplet state]:



(A)



(B)

.

An appreciable contribution of the charge-transfer state to the *T* state of α-nitronaphthalene is indicated by the marked dependence of the triplet–triplet absorption spectrum of α-nitronaphthalene on the nature of the solvent: the absorption maximum shifts from 525 nm in hexane to 580 nm in ethanol and 615 nm in *N*-methylformamide[25].

The triplet state of nitroanilines and nitronaphthylamines, constituting an isolated group, probably has the nature of an intramolecular charge transfer state [type (B)], characterised by a diminution of the electrophilic properties of the oxygen of the nitro-group as compared with the *n*, π* and π, π* states.

The different reactivities of the *n*, π, π, π*, and charge-transfer triplet states of nitro-compounds in photochemical reduction reactions can be accounted for within the framework of the usual hypotheses adopted to explain the different photochemical reactivities of the triplet states of ketones[112]: owing to the repulsion between unpaired electrons, the excited molecule resembles a "biradical" and, like all free radicals, it abstracts a hydrogen atom[113] or an electron. The electrophilic nature of such a "biradical" and hence the probability of the abstraction of a hydrogen atom (or electron) decrease on passing from the *n*, π* to the π, π* and charge-transfer states, since *n*, π* excitation entails the localisation of the positive charge on the *n* orbital of the oxygen in the nitro-group, while in the π, π* state the positive charge is delocalised over the aromatic system. Intramolecular charge transfer (CTS) leads to the localisation of a negative charge on the oxygen of the nitro-group, which reduces its electrophilic properties to an even greater extent.

---o0o---

The data discussed suggest that the reduction of nitro-compounds stimulated by ultraviolet radiation is complicated by photochemical substitution processes and photochemical rearrangement of the nitro-group. The photochemical reduction of nitro-compounds in acid and alkaline media cannot be described within the framework of the photochemical dehydrogenation mechanism, since the quantum yield of the reaction in acid and alkaline media depends on the concentration of the acid or the alkaline reagent.

A number of problems arising in the study of the photochemical reactions of nitro-compounds have not been elucidated. Thus the available data permit only hypotheses concerning the changes in mechanism in the primary photochemical reduction step on passing from neutral to acid and alkaline media. The nature of the intermediate species in these processes is not clear. The data described are consistent with the orthodox view[1] concerning the dominant role of the triplet state of nitro-compounds in photochemical reduction reactions. With the exception of the study of Capellos and Porter[25], there is no direct evidence for the involvement of the triplet state of nitro-compounds in the reaction. The participation of the excited singlet state of nitro-compounds in the reactions considered has not been disproved experimentally.

The first attempts have been made to explain the influence of substrate structure on the photochemical reactivity of the nitro-group by a change in the nature of the reactive *T* state of nitro-compounds. Systematic studies of the influence of the structure of nitro-compounds on the competition of photochemical reduction and substitution processes and the nitro–nitrite rearrangement have not been made.

Dithiocarboxylic Acids, Their Esters, and Metal Dithiocarboxylates

E.Jansons

The present state of the chemistry of dithiocarboxylic acids is described and methods for the synthesis of both the acids themselves and their esters and metal dithiocarboxylates are discussed. Data are presented on the properties and applications of these substances.

The bibliography includes 350 references.

CONTENTS

I. INTRODUCTION

By analogy with the carboxy-group COOH, the sulphur-containing functional group CSSH is called the dithiocarboxy-group. For this reason, the compounds R-CSSH, in which the organic moiety is linked to the dithiocarboxy-group by a carbon–carbon bond, should be called dithiocarboxylic acids. This term is in fact used in the English and American chemical literature†.

The names of the individual examples of compounds of this class are devised in accordance with the principles of the IUPAC nomenclature on the basis of the name of the corresponding hydrocarbon.

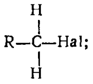
The first example of dithiocarboxylic acids (C_6H_5CSSH) was synthesised more than 100 years ago in 1866[1]. However, due attention was not devoted to compounds of this class for a long time. This can be apparently partly accounted for by the low stability in air of many dithiocarboxylic acids and partly by the unpleasant smell of these substances (particularly the alkyl derivatives) which has been very strikingly described by the first investigators[2].

The chemistry of dithiocarboxylic acids began to develop vigorously in the 1960's. During the last 6–7 years, approximately as many studies have been published as during the previous 100 years. Certain reviews have also been published[3-6], but these do not cover all the aspects of the chemistry of dithiocarboxylic acids. The present paper surveys the literature on dithiocarboxylic acids, their esters, and metal dithiocarboxylates up to 1973 (and partly also 1974).

II. METHODS FOR THE SYNTHESIS OF DITHIOCARBOXYLIC ACIDS

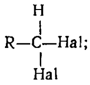
1. Synthesis from Compounds Containing a Halogenomethyl Group

Compounds containing mono-, di-, and tri-halogenomethyl groups may be used as the starting materials of the synthesis of dithiocarboxylic acids:



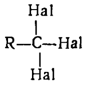
$R{-}CH_2{-}Hal$;

(I)



$R{-}CH(Hal){-}Hal$;

(II)



$R{-}C(Hal)_2{-}Hal$,

(III)

where R is an organic group and Hal a halogen. Compounds (III) can also be used in syntheses with R = H. In all cases, the syntheses are carried out in alcoholic solutions.

The monohalogeno-derivatives (I) react with finely dispersed sulphur in the presence of alkali metal alkoxides. The alkoxide ion, being a strong base, cleaves the eight-membered ring of the sulphur molecule under these conditions[7,8] and gives rise to the chemically highly reactive ion $CH_3O{-}S{-}S_6{-}S^-$, which reacts with the monohalogeno-derivative (I). The dithiocarboxylic acids are synthesised in accordance with the following overall equation:

$$R{-}CH_2Hal + 2S + 2NaOCH_3 \rightarrow R{-}CSSNa + NaHal + 2CH_3OH.$$

After the solution has been acidified, the corresponding dithiocarboxylic acid is isolated. Benzenedithiocarboxylic, 4-chlorobenzenedithiocarboxylic, and 2,6-dichlorobenzenedithiocarboxylic acids have been obtained by this method in methanol solutions[7,9,10].

On interaction with ethanol solutions of KHS, the dihalogeno-derivatives (II) give rise to the corresponding potassium dithiocarboxylates as side products in addition to the disulphide[1,11]:

$$3R{-}CHHal_2 + 7KHS \rightarrow (R{-}CH_2S)_2 + R{-}CSSK + 3H_2S + 6KHal.$$

This method is also of historical importance—it was in fact used to synthesise the first dithiocarboxylic acid[1].

---

†The following section of the original Russian text has been omitted here. However, in the Russian literature compounds containing the carboxy-group are traditionally called carbonic acids and in the present paper the term "dithiocarbonic acids" is used instead of the systematic term "dithiocarboxylic acids".

The trihalogeno-derivatives (III) can be converted into dithiocarboxylate ions by treatment with alkali metal sulphides, hydrogen sulphides, or trithiocarbonates in ethanol or methanol solutions:

$$\mathrm{R{-}CHal_3 + 2K_2S \rightarrow R{-}CSSK + 3KHal;}$$
$$\mathrm{R{-}CHal_3 + 4KHS \rightarrow R{-}CSSK + 3KHal + 2H_2S;}$$
$$\mathrm{R{-}CHal_3 + 2Na_2CS_3 \rightarrow R{-}CSSNa + 3NaHal + 2CS_2.}$$

On subsequent acidification, the corresponding dithiocarboxylic acids are isolated in a free form. The rapidly polymerising dithiocarboxylic acid HCSSH was obtained by this procedure from chloroform and potassium sulphide in ethanol solution[12-14]. It can be obtained in a purer form by carrying out the synthesis in the absence of air and in methanol solutions[15,16].

$C_6H_5CCl_3$ can be converted into benzenedithiocarboxylic acid by treatment with potassium sulphide[17,18] or hydrogen sulphide[19] in ethanol solutions and by potassium sulphide in methanol solution[20]. When sodium trithiocarbonate is used[21,22], the synthesis is carried out in aqueous methanol solution.

Chlorobenzenedithiocarboxylic[17], pyridine-4-dithiocarboxylic[23], quinoline-2-dithiocarboxylic, and quinoline-4-dithiocarboxylic[24] acids have been obtained similarly.

2. Interaction of Organometallic Compounds with Carbon Disulphide.

The first attempts to obtain dithiocarboxylic acids by the interaction of carbon disulphide with organosodium and organozinc compounds were unsuccessful[25]. When triethylaluminium was used, only traces of ethanedithiocarboxylic acid were obtained[26]. Later it was shown that organolithium and organosodium compounds can be used successfully to synthesise dithiocarboxylic acids[27,28]. The reactions with carbon disulphide were then carried out in ethyl ether solutions in an atmosphere of nitrogen:

$$\mathrm{R{-}Me + CS_2 \rightarrow R{-}CSSMe.}$$

Lithium naphthalene-1-dithiocarboxylate $C_{10}H_7CSSLi$ and sodium diphenylmethanedithiocarboxylate $(C_6H_5)_2CHCSSNa$ were obtained in this way.

Organomagnesium compounds have found the widest applications in the synthesis of dithiocarboxylic acids and were proposed for this purpose at the beginning of the century[2,29-32]. Here the starting materials are the corresponding halogeno-derivatives, which react with metallic magnesium in an ethereal medium:

$$\mathrm{R{-}Hal + Mg \rightarrow R{-}MgHal.}$$

Some workers recommend that this reaction be carried out in the absence of air, for example, in an atmosphere of nitrogen[33]. The addition of carbon disulphide to a solution of organomagnesium compound results in the formation of dithiocarboxylates:

$$\mathrm{R{-}MgHal + CS_2 \rightarrow R{-}CSSMgHal.}$$

The dithiocarboxylic acids can be isolated in a free state by treating the reaction mixture with hydrochloric acid.

The diethers of poly(ethylene glycols) have also been proposed as solvents instead of ethyl ether. For example, pyridine-2-dithiocarboxylic acid has been obtained[34] in solution of the dimethyl ether of diethylene glycol. The synthesis can also be achieved in tetrahydrofuran[24].

Organomagnesium compounds have been used to synthesise the following dithiocarboxylic acids: methanedithiocarboxylic[32,35], ethanedithiocarboxylic[2], propanedithiocarboxylic[2], 2-methylpropanedithiocarboxylic[2], 3-methylbutanedithiocarboxylic[2], cyclohexanedithiocarboxylic[36], phenylmethanedithiocarboxylic[29,30,37], hydropinenedithiocarboxylic[31], benzenedithiocarboxylic[18,30,33,38-43], 2-methylbenzenedithiocarboxylic[33,41], 4-methylbenzenedithiocarboxylic[33,41,44,45], 4-chlorobenzenedithiocarboxylic[41,44], 4-bromobenzenedithiocarboxylic[30,47], 5-isopropyl-2-methylbenzenedithiocarboxylic[48], naphthalene-1-dithiocarboxylic[30,33,39,41,49], naphthalene-2-dithiocarboxylic[41,47,50], pyrroledithiocarboxylic[41,51-53], indole-3-dithiocarboxylic[41,52,53], 2-methylindole-3-dithiocarboxylic[52], pyridine-2-dithiocarboxylic[34], quinoline-2-dithiocarboxylic[24], and thiophen-2-dithiocarboxylic[41]. Alkanedithiocarboxylic acids are obtained by this procedure in very low yields (5–25%). The yields of compounds with aromatic groups are very much higher (usually between 40% and 80%) (see also Ref. 54).

3. Interaction of Aldehydes with Hydrogen and Ammonium Polysulphides

Aromatic aldehydes and hydrogen polysulphide form brownish-yellow or reddish resinous products in the presence of condensing agents such as zinc chloride, hydrogen chloride, sulphuric acid, etc. The products are ground and treated with an aqueous or alcoholic solution of KOH and the insoluble residues are filtered off. The filtrate consists of a solution of the corresponding potassium dithiocarboxylate[55-57]. The following dithiocarboxylic acids have been synthesised by this method: benzenedithiocarboxylic[57], 2-hydroxybenzenedithiocarboxylic[55,57], 2- and 4-methoxybenzenedithiocarboxylic[55,57], and furan-2-dithiocarboxylic[58].

The method has not found more extensive applications probably for the simple reason that dithiocarboxylic acids can be obtained from aldehydes more conveniently by the reaction of the latter with ammonium polysulphide. This reaction was used for the first time to synthesise benzenedithiocarboxylic acid[59]. A concentrated solution of ammonia and copper powder was added to an ethanol solution of benzaldehyde, after which the latter was saturated with hydrogen sulphide. Later it was suggested that ammonium polysulphide be prepared beforehand. Dithiocarboxylic acids are synthesised by adding the solution to an aldehyde or to an ethanol solution of an aldehyde[58,60]:

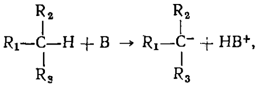
$$\mathrm{R{-}CHO + (NH_4)_2S_2 \rightarrow R{-}CSSNH_4 + NH_4OH.}$$

After acidification with hydrochloric acid, the free dithiocarboxylic acids are obtained.

The following dithiocarboxylic acids have been synthesised by this method: benzenedithiocarboxylic[45,58], 2-chlorobenzenedithiocarboxylic[41,45], 4-chlorobenzenedithiocarboxylic[45], 2-hydroxybenzenedithiocarboxylic[41,45,58,61,62], 4-hydroxybenzenedithiocarboxylic[41,45], 4-methoxybenzenedithiocarboxylic[41,45,58,61,62]; 3,4-dihydroxybenzenedithiocarboxylic[61,62], 4-hydroxy-3-methoxybenzenedithiocarboxylic[45,58,61,62], 3,4-methylenedioxybenzenedithiocarboxylic[45,58,61,62], 4-aminobenzenedithiocarboxylic[45], 4-dimethylaminobenzenedithiocarboxylic[45], 4-acetamidobenzenedithiocarboxylic[41], 3-sulphobenzenedithiocarboxylic[63], 4-hydroxy-3-sulphobenzenedithiocarboxylic[63], 1-phenylethylene-2-dithiocarboxylic[62], naphthalene-2-dithiocarboxylic[64], furan-2-dithiocarboxylic[42,58,61,62,65], and thiophen-2-dithiocarboxylic[41]. The yields are usually between 20 and 45%.

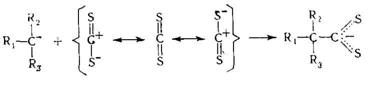
4. Reactions of CH acids with Carbon Disulphide (with Xanthates and Trithiocarbonates)

In the presence of a sufficiently strong base, CH acids react with carbon disulphide to form dithiocarboxylate ions. It is suggested that the reaction proceeds via a mechanism[66-69] which begins with a protolytic reaction:



$$R_1-\overset{R_2}{\underset{R_3}{C}}-H + B \rightarrow R_1-\overset{R_2}{\underset{R_3}{C^-}} + HB^+,$$

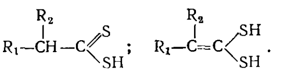
where B is the base and HB^+ the conjugate acid. This is followed by the electrophilic addition of carbon disulphide via its carbon atom to the base (carbanion) $R_1R_2R_3C^-$:



If the initial compound with $R_3 = H$ contains an activated methylene group $R_1R_2CH_2$, then substances of this kind initially react only via the mechanism described above, which results in the formation of $R_1R_2CH-CSS^-$. However, when the dithiocarboxylate ion is still a fairly strong CH acid, the following protolytic reaction takes place:

The subsequent redistribution of charges in such cases yields the dianions of ene-1,1-dithiols:

Here one must note that the treatment of ene-1,1-dithiolate ions with acids can lead to their reconversion into dithiocarboxylate ions[70]. The dithiocarboxylic acids themselves and the ene-1,1-dithiols are isomers:

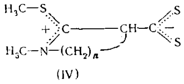


It follows from the foregoing that, in those cases where $R_3 = H$ (or $R_3 = R_2 = H$) in the initial compound dithiocarboxylic acids can occur in the synthesis only as intermediates.

NaOH, KOH, alkoxides [CH_3ONa, C_2H_5ONa, $(CH_3)_3CONa$, and $(CH_3)_2(C_2H_5)CONa$], sodamide ($NaNH_2$), sodium hydride (NaH), and in some cases even metallic sodium are used as bases. Ammonia in the form of a concentrated aqueous solution or in the liquid state sometimes plays the role of this component. Depending on the properties of the reactants, the solvents may be hydrocarbons (pentane, benzene), alcohols (methanol, ethanol), ethers (ethyl ether, dioxan, tetrahydrofuran), acetone, acetonitrile, dimethyl sulphoxide, dimethylformamide, and dimethylacetamide.

Many dithiocarboxylic acids or the corresponding ene-1,1-dithiols have been synthesised by the above method. The starting materials in these processes were aldehydes ($R_1 = CHO$, $R_3 = H$)[71], ketones ($R_1 = RCO$, $R_3 = H$)[38,72-85], nitromethane ($R_1 = NO_2$, $R_2 = R_3 = H$)[86-88], phenols, naphthols, hydroxyquinoline[67,89-91], malonic acid derivatives ($R_3 = H$)[69,76,82,92-101], pyrrole, pyridine, indole, quinoline, and their derivatives[76,102-108], ketimines of cyclohexanone and cyclopentanone [$R_2 = -(CH_2)_n-\underset{|}{C}=N-R$, $R_3 = H$][109,110], compounds with the sulphonyl group ($R_1 = RSO_2$, $R_3 = H$)[111], sodium cyclopentadienide (R_1R_2 = cyclopentadienide ion, $R_3 = H$)[112,113], and pyrazolone derivatives (R_1R_2 = the residue of pyrazolone derivative, $R_3 = H$).[114-116]

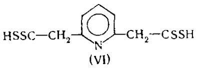
Dithiocarboxylic acids have been obtained by this method also in the reaction of carbon disulphide with the Reissert compound[117], with dinitrotoluene[76], and with the quaternary salts derived from heterocyclic nitrogen compounds[118,119]. Dithiocarboxylic acids which are stable dipoles of type (IV)[120,121], and even the bisdithiocarboxylic acids (V)[122] and (VI)[76] have also been obtained:



(IV)

HSSC—CH₂—CO—CH₂—CSSH

(V)

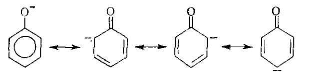


(VI)

A variety of the above method for the synthesis of dithiocarboxylic acids is that consisting of heating phenols with alkali metal xanthates or trithiocarbonates. On increase of temperature, these reactants decompose into carbon disulphide and the alkoxide (sulphide):

$$C_2H_5-O-CSSK \rightarrow CS_2 + C_2H_5OK;$$
$$Na_2CS_3 \rightarrow CS_2 + Na_2S.$$

Alkoxide or sulphide ions play the role of a strong base, the presence of which is necessary for reaction with carbon disulphide. The site of addition of carbon disulphide is determined under these conditions by the existing resonance or tautomeric forms of the corresponding phenoxide ion, for example:

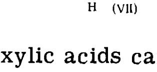


Evidently the addition should take place in the *ortho*- or *para*-positions.

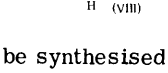
The following dithiocarboxylic acids have been obtained by this method: 4-hydroxybenzenedithiocarboxylic[123], 2,4-dihydroxybenzenedithiocarboxylic[124-127], 2-4-dihydroxy-6-methylbenzenedithiocarboxylic[123], 2,3,4- and 2,4,6-trihydroxybenzenedithiocarboxylic[125,127], 1-hydroxynaphthalene-2-dithiocarboxylic[128], and 8-hydroxyquinoline-7-dithiocarboxylic[124]. The method of synthesis using a xanthate suffers from the disadvantage that the syntheses must be performed at high temperatures and pressures.

5. Other Methods for the Synthesis of Dithiocarboxylic Acids

Under the conditions of the Friedel-Crafts synthesis (with anhydrous aluminium chloride as the catalyst), pyrrole derivatives react with carbon disulphide. The acids (VII) and (VIII) have been obtained in this way[129]:



(VII)

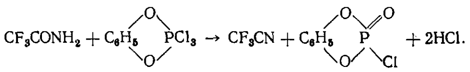


(VIII)

Dithiocarboxylic acids can be synthesised by hydrolysing their esters. Ethane-, methane-, benzene-, 4-methylbenzene-, and phenylmethane-dithiocarboxylic acids as well as HSSC-CSSH have been obtained by treating the corresponding esters with alcoholic KOH solution[130]. 3-Antipyrine-4-dithiocarboxylic acid was obtained after heating its ethyl ester for 1 h on a water bath with a 10% alcoholic KOH solution[131]. The 4-dithiocarboxylic acids of antipyrine[132] and isoantipyrine[133] have been prepared by heating their ethyl esters with an ethanol solution of KHS

(1–2 h, on a water bath). In order to obtain benzenedithiocarboxylic acid, its methyl ester was hydrolysed overnight at room temperature with NaHS solution[134].

Trifluoromethanedithiocarboxylic acid has been synthesised from trifluoroacetamide, which was initially converted into the nitrile by treatment with 1,2-phenylenedioxyphosphorus trichloride[135]:



The nitrile was then thiolysed[136,137] with a mixture of liquid H_2S and HCl (40°C, 28 atm, 2–3 days):

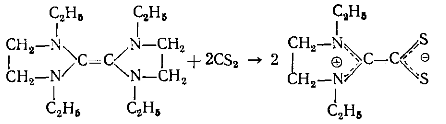
$$CF_3CN + H_2S \rightarrow CF_3CSNH_2;$$
$$CF_3CSNH_2 + H_2S + HCl \rightarrow CF_3CSSH + NH_4Cl.$$

Cyanodithioformate ions are formed[138,139] when cyanide ions interact with carbon disulphide in a dimethylformamide solution:

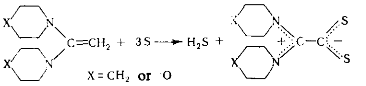
$$CN^- + CS_2 \rightarrow NC\text{—}CSS^-.$$

Cyanodithioformic acid $(NCCSSH)_X$ is obtained by the subsequent addition of concentrated hydrochloric acid.

The synthesis of dithiocarboxylic acids derived from peraminoethylenes is very unusual[140]. The reaction takes place exothermically with 98% yield in accordance with the following equation:



Analogous zwitter-ions were obtained[141] as a result of the interaction of certain compounds containing an active methylene group with elemental sulphur:



X = CH$_2$ or O ;

III. THE PROPERTIES AND APPLICATIONS OF DITHIOCARBOXYLIC ACIDS

1. Physical properties

Dithioformic and cyanodithioformic acids are weakly coloured polymeric substances[13,14,16,138,139,142]. The radius of the dithioformate ion has been calculated from the measured conductivities of the solutions[143].

Aliphatic dithiocarboxylic acids as well as phenylmethanedithiocarboxylic acids are orange oily liquids[2,30,32,130]. This is also true of trifluoromethanedithiocarboxylic acid[136,137]. Cyclohexanedithiocarboxylic acid is a reddish-brown liquid[36]. The dithiocarboxylic acids obtained from iminopentane (IX)[84] and its derivatives[85] and also from cyclopentene and cyclohexene (X) derivatives[109] are crystalline substances melting between 66° and 117°C:

(IX)

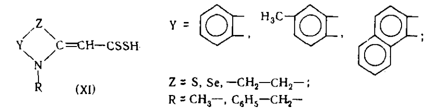
(X)

$n = 3; 4$.

Benzenedithiocarboxylic acid and its halogeno-, methyl, and isopropyl derivatives are red or red-violet oily liquids[1,30,38,44,48,55,57,130]. 4-Hydroxy- and 3,4-dihydroxybenzenedithiocarboxylic acids are likewise oily liquids[62,123,144]. 2-Hydroxy- and 2,4-dihydroxybenzenedithiocarboxylic acids have been obtained in the form of a thick, red, rapidly solidifying mass[144,145]. The latter acid forms a yellow crystalline monohydrate[125,126,146]. 2,3,4-Trihydroxy-[125,128], 4-methoxy-[55,57,62], 4-hydroxy-3-methoxy-[62,147], 3,4-methylenedioxy-[62,148], and 4-hydroxy-3-sulpho-benzenedithiocarboxylic[63] acids are likewise crystalline. Naphthalene-1- and naphthalene-2-dithiocarboxylic acids are dark-red oily liquids[30,33,149,150], while 1-hydroxynaphthalene-2-dithiocarboxylic acid is a dark-yellow crystalline substance[89,128].

Furan-2-[62,65,148], pyrrole-2-[51,52], and indole-3-dithiocarboxylic[52] acids are red oily liquids but the dithiocarboxylic acids obtained from certain pyrrole[108], indole[104], pyridine[103], and quinoline[102] derivatives are crystalline substances. Dithiocarboxylic acids of type (XI) are yellow crystalline substances (m.p. between 200° and 288°C)[119] like the dithiocarboxylic acids obtained from pyrazolone derivatives (m.p. between 115° and 230°C)[114–116,132].

Zwitter-ionic dithiocarboxylic acid has been obtained in the form of dark-red substances melting at 178–179°C[140] and 233–236°C[141]:



Y = ;

Z = S, Se, —CH$_2$—CH$_2$—;

R = CH$_3$—, C$_6$H$_5$—CH$_2$— .

Dithiocarboxylic acids are sparingly soluble in water, dissolving more or less readily in organic solvents.

2. Absorption Spectra

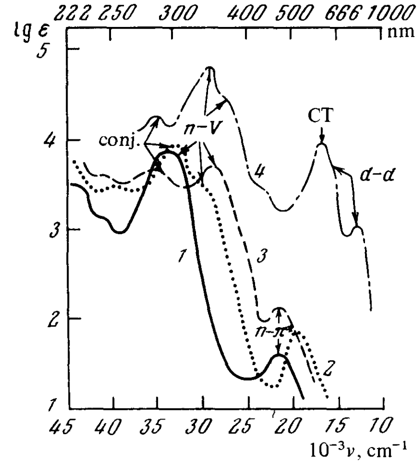
The electronic absorption spectra of dithiocarboxylic acids differ little from those of their esters[151,152]. The electronic absorption spectra of methane-[152], ethane-[153], cyclohexane-[154], phenylmethane-[155,156], benzene-[152,156,157], 4-chlorobenzene-[157], 4-methylbenzene-[158], 2-hydroxybenzene-[145], 4-hydroxybenzene-[144,159], 2,4-dihydroxybenzene-[144,146], 2,3,4-trihydroxybenzene[144], 4-hydroxy-3-methoxybenzene-[147], naphthalene-1- and naphthalene-2-[150], pyrrole- and indole-[160,161], and quinoline-2- and quinoline-4-dithiocarboxylic[162] acids are available in the literature. Other publications quote only numerical data characterising the absorption maxima (wavelengths and molar extinction coefficients). Such data are available for methane-, trimethylmethane-, phenylmethane-, benzene- and 4-methylbenzene-dithiocarboxylic acids[163], for acids (IX)[85] and (X)[109], and for zwitter-ionic dithiocarboxylic acids.

The absorption bands in the electronic spectra of phenylmethane- and benzene-dithiocarboxylic acids have been assigned[156] (see Figure).

The low-intensity band ($\epsilon < 100$) observed in the visible spectra has been assigned to $n-\pi^*$ transitions. Resolution of this band in the absorption spectrum of benzenedithiocarboxylic acid into two components led to the conclusion that there is a hydrogen bond in the dithiocarboxy-group, as in formula (XII)[164]; the energy of this bond is 4.5 ± 0.5 kcal mole^{-1}:

(XII) .

The ultraviolet spectra of phenylmethane- and benzenedithiocarboxylic acids as well as the spectra of the corresponding anions (see Figure) contain a high-intensity band, which has been assigned to $n-V$ transitions[156]. In the spectra of benzenedithiocarboxylic acid and its anion, there is a second high-intensity absorption band, which has been assigned to $\pi-\pi^*$ transitions in the conjugated system of the benzene ring with the dithiocarboxy-group (in the Figure, it is designated by "conj."). These absorption band assignments were extended also 4-chloro- and 4-methyl-benzenedithiocarboxylic acids[165].



Electronic absorption spectra: 1) phenylmethanedithiocarboxylic acid in carbon tetrachloride; 2) benzenedithiocarboxylic acid in ethyl ether; 3) benzenedithiocarboxylic acid in water; 4) nickel benzenedithiocarboxylate in chloroform[157].

Vibrational spectra. A spectrum in the range 526–4000 cm^{-1} was obtained[142] for the dithioformic acid trimer $(HCSSH)_3$. There are numerical data for the same part of the spectrum of the polymeric acid $(HCSSH)_x$.[16,142] The absorption at 2500 cm^{-1} has been assigned to ν(S–H) and that at 1166 and 1048 cm^{-1} to the stretching and deformation vibrations of the CSC group.

The spectrum of cyanodithioformic acid $(NC{-}CSSH)_x$ was recorded in the range 526–4000 cm^{-1}.[166] The (C≡N) band was found at 2250 cm^{-1}, which led to the conclusion that the polymerisation of this acid as well as that of dithioformic acid involves the C=S group.

The spectra of liquid (400–10 000 cm^{-1}) and gaseous (750–10 000 cm^{-1}) methanedithiocarboxylic acid have been obtained[167] and the following assignments of the absorption wavenumbers have been made: 2481 cm^{-1} to ν(SH), 1216 cm^{-1} to ν(C=S), 581 cm^{-1} to ν(C–S) and 860 cm^{-1} tentatively to δ(SH). Calculation of the normal vibration wavenumbers for this acid on a computer[168] led to the following assignments:

2976 cm^{-1} to CH stretch.;
2918 cm^{-1} to CH stretch.;
2481 cm^{-1} to SH stretch.;
1431 cm^{-1} to CH def.;
1357 cm^{-1} to CC stretch. + CH def.;
$\left\{\begin{matrix}1192\\1216\end{matrix}\right.$ cm^{-1} to CC stretch. + SCC def. + SCS def. + CH def.;
$\left\{\begin{matrix}1072\\1107\end{matrix}\right.$ cm^{-1} to SCC def. + SCS def. + SH def.;
903 cm^{-1} to CC stretch.+ CS stretch.+ SH def.;
$\left\{\begin{matrix}860\\873\end{matrix}\right.$ cm^{-1} to CS stretch. + CH def.;
581 cm^{-1} to CS stretch.;
406 cm^{-1} to CCS def.

The spectra of solutions of trifluoromethanedithiocarboxylic acid in carbon tetrachloride and in carbon disulphide have been obtained (670–4000 cm^{-1})[169] as well as numerical data for the absorption wavenumbers[136,137,169]. The following assignments have been made:

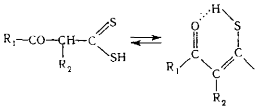
2577-2580 cm^{-1} to ν(SH);
1253 cm^{-1} to $\nu_{asym}(CS_2)$;
933-945 cm^{-1} to δ(SH)?
690-691 cm^{-1} to $\nu_{sym}(CS_2)$.

The vibrational spectrum of benzenedithiocarboxylic acid[20] contains intense absorption bands at 1690 and 1270 cm^{-1}. The shift of ν(SH) on passing from the spectrum of its 20% solution in carbon tetrachloride indicates[170] the existence of the hydrogen bond S–H...S [see also formula (XII)].

The vibrational absorption spectra of 2-hydroxy-[145], 4-hydroxy-[123], and 2,4-dihydroxy-benzenedithiocarboxylic[123,146] acids have likewise been published. The following assignments have been made for the last acid[146]: 2530 cm^{-1} to ν(SH); 1250–1240 cm^{-1} to δ(OH), ν(C=S)?; 685 cm^{-1} to ν(C–S)? The study of the spectrum of 2-hydroxybenzenedithiocarboxylic acid led to the conclusion that there is an intramolecular hydrogen bond in this compound[145].

3. Chemical Properties

There may be a tautomeric equilibrium between dithiocarboxylic acids and the corresponding ene-1,1-dithiols. The equilibrium has been detected[171] in the dithiocarboxylic acids obtained by the reaction between carbon disulphide and ketones:



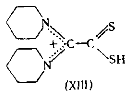
.

Dithiocarboxylic acids enter into a protolytic interaction with water molecules:

$$R{-}C(=S)SH + H_2O \rightleftharpoons R{-}CS_2^- + H_3O^+$$

.

In an alkaline medium, where hydronium ions combine with hydroxide ions, the dithiocarboxylic acids, which are sparingly soluble in water, therefore dissolve in the form of dithiocarboxylate ions:



(XIII)

.

The strongest dithiocarboxylic acid is compound (XIII) ($pK_a \simeq -2$).[141] The pK_a values for other dithiocarboxylic acids vary in the range from 1 to 3 (see Table). $pK_1 < 2$ and $pK_2 \simeq 5.2$ have been found for nitromethanedithiocarboxylic acid[88] (pK_2 corresponds to the second dissociation involving the conversion of the dithiocarboxylate ion into the ene-1,1-dithiolate ion).

Dithiocarboxylic acids are extremely reactive. They undergo intense colour reactions with textiles and form dark stains on leather[30,32,172]. On storage, many dithiocarboxylic acids decompose rapidly or are oxidised. For example, an ethereal solution of benzenedithiocarboxylic acid may be stored without significant changes for more than 1 h only in an atmosphere of an inert gas[172]. This by no means applies to all dithiocarboxylic acids. There are also extremely stable representatives of compounds of this class, for example the dithiocarboxylic acids obtained from derivatives of pyrazolone[114-116, 132], 4-hydroxy-3-methoxybenzenedithiocarboxylic acid[147], and the acids (X), (XI), and (XII).

The pK_a values for dithiocarboxylic acids in aqueous solutions.

When nitromethane-[86], 2,4-dihydroxybenzene-[124, 126], 2,3,4-trihydroxybenzene[125], and 1-hydroxynaphthalene-2-dithiocarboxylic[128] acids are heated with concentrated aqueous solutions of alkalis, sulphur is split off and the corresponding carboxylic acids are formed.

The reducing action of amalgamated zinc on benzene-, 4-methoxybenzene-, and phenylmethane-dithiocarboxylic acids has been investigated in hydrochloric acid solutions. Under these conditions, benzenedithiocarboxylic acid is largely converted after interaction for 10 min into phenylmethanethiol ($C_6H_5CH_2SH$) (yield 25%); stilbene and benzoic acids are also formed and a considerable proportion of the substance char. When the above three dithiocarboxylic acids are reduced polarographically, three waves are observed in each individual instance. The first corresponds to the reduction of the disulphide formed in the solution of the supporting electrolyte, the second to the reduction of the thiocarbonyl group, and the third to the reduction of the dithiocarboxylate ion[54].

When cyclohexane-[36], 4-methylbenzene-[44], and 8-hydroxyquinoline-7-dithiocarboxylic[124] acids are treated with strong oxidising agents ($KMnO_4$, HNO_3), the corresponding carboxylic acids are formed. On oxidation of alkali metal dithiocarboxylates under milder conditions (with iodine, hydrogen peroxide, and atmospheric oxygen), the products are usually disulphides, which precipitate:

The disulphides containing aliphatic groups are as a rule yellow, while those containing aromatic and heterocyclic groups are red. Dithioformic acid gives rise to a polymeric disulphide[12, 173].

Disulphides can be converted into monosulphides by treatment with triphenylphosphine[174]:

$$R-\overset{\overset{\displaystyle S}{\|}}{C}-S-S-\overset{\overset{\displaystyle S}{\|}}{C}-R+(C_6H_5)_3P \rightarrow R-\overset{\overset{\displaystyle S}{\|}}{C}-S-\overset{\overset{\displaystyle S}{\|}}{C}-R+(C_6H_5)_3PS.$$

A solution of bis-(1-thionaphthoyl) disulphide in fused naphthalene exhibits thermochromic properties, i.e. the colour of the solution changes as the temperature is altered[175,176]. This is explained by the formation of free radicals:

$$C_{10}H_7-CS-S-S-CS-C_{10}H_7 \rightleftarrows 2C_{10}H_7-CS-S^{\cdot}.$$

A 0.005% benzene solution or a 0.05% chloroform solution of bis-(2-hydroxythiobenzoyl) disulphide have been suggested as reagents for the extraction-colorimetric determination of microgram amounts of nickel[177].

Dithiocarboxylic acids react with ammonia derivatives such as amines, hydroxylamine, hydrazine, and semicarbazide. The reaction with primary amines $R'NH_2$ yields the corresponding thioamides RCSNHR'. This has been used for the thioacylation of uracil and pyrimidine derivatives[178]. The corresponding derivatives of dithiocarboxylic acid obtained from pyrazolones[114,115,131] and the acids $RCOCH_2CSSH$ have also been synthesised[179,180]. As a result of interaction with dithiocarboxylic acids, 1,2-phenylenediamine yields substituted benzimidazoles[181]. In the presence of an oxidising agent (elemental iodine), dithiocarboxylic acids react with cyclohexylamine and the products are again thioamides[39,182]. The reaction of aromatic dithiocarboxylic acids with hydroxylamine gives rise to the oximes RCH=NOH,[46, 183] while the reaction between hydroxylamine and non-aromatic dithiocarboxylic acids gives rise to the nitriles RCN.[183] Aromatic dithiocarboxylic acids react with hydrazine to form the hydrazones $RCH{=}NNH_2$ and the reactions with methyl-, phenyl-, and methylphenyl-hydrazines result in the formation of the corresponding substituted hydrazones[23,48,114,183-186]. Aliphatic dithiocarboxylic acids react with these reagents to form the thiohydrazides $RCSNHNH_2$. The reaction between semicarbazide and aromatic dithiocarboxylic acids leads to the formation of the semicarbazones $RCH{=}NNHCONH_2$.[47,183]

Benzenedithiocarboxylic acid reacts with thionyl chloride ($SOCl_2$) to form[38, 43, 134] thiobenzoyl chloride  . 4-Methyl-, 3-chloro-, 4-chloro-, and 4-methoxy-benzenedithiocarboxylic acids as well as thiophen-2-dithiocarboxylic acid react similarly[187].

4. Applications of Dithiocarboxylic Acids

Dithiocarboxylic acids can be used in organic synthesis as thioacylating agents. Their reactions with azolides constitute the basis of one of the methods for the synthesis of thioamides[188]. Substituted methane dithiocarboxylic acids can serve as the starting materials for the synthesis of compounds with sulphur-containing rings[189].

Dithioformic acid has been used as a reagent for the introduction of sulphur into proteins[190]. Various dithiocarboxylic acids have been suggested as effective agents accelerating the vulcanisation of raw rubber[58,60,61,191]. Copolymerisation with benzenedithiocarboxylic acid makes it possible to increase the elasticity and to improve other properties of many polymers[192,193]. Hydroxy-derivatives of benzenedithiocarboxylic acid exhibit bactericidal and fungicidal properties and can find appropriate applications[91].

IV. DITHIOCARBOXYLIC ACID ESTERS

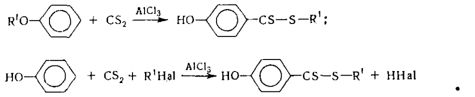
1. Methods of Synthesis

The esters can be obtained from the corresponding dithiocarboxylic acids. Historically, this is the first method for the synthesis of the esters, but it is still used on a fairly large scale. The esters are sometimes obtained by alkylating the dithiocarboxylic acids themselves [109, 119], but normally their salts are used for this purpose: the sodium [41,44,48,54,79,194-197], potassium [13, 18,19,24,57,82,115,116, 132,144,198-200], silver [57], ammonium [146,201], and magnesium halide salts RCSSMgHal, obtained in the synthesis of dithiocarboxylic acids using organomagnesium compounds [37,40,202,205]. The zwitter-ionic dithiocarboxylic acids react directly with methyl iodide [121,141]. Dimethyl sulphate [44,48,54,57,66,82,108,109,115,116,119,132,144,195,197,199,202,203,205], diethyl sulphate [24,108,203,204], methyl iodide [13,121,141,146,196, 200,206], ethyl iodide [13,57,200], propyl iodide [13], butyl iodide [44], 4-nitrobenzyl bromide [44], monochloroacetic acid [18,19,37,40, 41,198], and diazomethane [108,109,129] are used as alkylating agents.

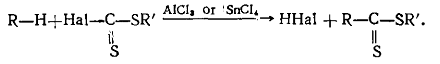
The Friedel–Crafts synthesis of dithiocarboxylic acid esters is used in several versions. The reaction of pyrazolone derivatives with carbon disulphide and ethyl bromide gives rise to the ethyl esters [132,133,207,208]:

$$\mathrm{R{-}H + C_2H_5Br + CS_2 \xrightarrow{AlCl_3} HBr + R{-}CS{-}S{-}C_2H_5}.$$

The esters of aromatic dithiocarboxylic acids containing the OH group in the aromatic moiety can be obtained in two ways [208,209,210]:

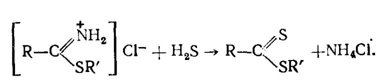


Esters of halogenodithiocarbonic acid may be used in the Friedel–Crafts synthesis instead of carbon disulphide [211,212]:



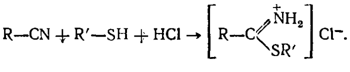
$$\mathrm{R{-}H + Hal{-}\underset{\overset{\|}{S}}{C}{-}SR' \xrightarrow{AlCl_3\ or\ SnCl_4} HHal + R{-}\underset{\overset{\|}{S}}{C}{-}SR'}.$$

Another group of methods for the synthesis of dithiocarboxylic acid esters is based on the interaction of the salts of thioiminoesters with carbon disulphide in an anhydrous medium:



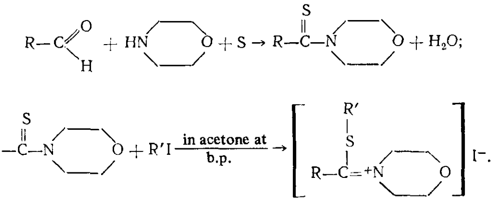
$$\left[\mathrm{R{-}C}\begin{smallmatrix}\mathrm{\overset{+}{N}H_2}\\ \mathrm{SR'}\end{smallmatrix}\right]\mathrm{Cl^-} + \mathrm{H_2S} \rightarrow \mathrm{R{-}C}\begin{smallmatrix}\mathrm{S}\\ \mathrm{SR'}\end{smallmatrix} + \mathrm{NH_4Cl}.$$

Ethyl ester was initially proposed as a solvent for this reaction [130], but higher yields are obtained in dry pyridine [213]. The thioiminoester salts required for the synthesis can be obtained by adding hydrogen chloride to a mixture of equivalent amounts of a nitrile and a thiol [214,215]:



$$\mathrm{R{-}CN + R'{-}SH + HCl} \rightarrow \left[\mathrm{R{-}C}\begin{smallmatrix}\mathrm{\overset{+}{N}H_2}\\ \mathrm{SR'}\end{smallmatrix}\right]\mathrm{Cl^-}.$$

When R = H, i.e. when HCN reacts with thiols, the products are the corresponding dithioformic acid derivatives [216]. The product of the addition of HCN to ketones, i.e. $R_1R_2C(OH)CN$ react with thiols to form thioiminoester salts of the type $\left[\mathrm{R_1R_2C(OH){-}C}\begin{smallmatrix}\mathrm{\overset{+}{N}H_2}\\ \mathrm{SR'}\end{smallmatrix}\right]\mathrm{Cl^-}$ which can also be used [217] to synthesise the corresponding dithiocarboxylic acid esters $R_1R_2C(OH)CSSR'$. Treatment of the latter with thionyl chloride ($SOCl_2$) leads to the substitution of the hydroxy-group by chlorine [217]. It has been suggested recently [218] that thioiminoester salts be obtained from the thioamides $\mathrm{R\overset{\overset{S}{\|}}{C}NH_2}$ and ethyl thiochloroformate ($\mathrm{Cl\overset{\overset{O}{\|}}{C}SC_2H_5}$). Thioiminoester salts in which the hydrogen atoms at the nitrogen atom have been substituted by hydrocarbon groups, i.e. $\left[\mathrm{R{-}C}\begin{smallmatrix}\mathrm{\overset{+}{N}R_3R_4}\\ \mathrm{SR'}\end{smallmatrix}\right]\mathrm{Cl^-}$ can also be used to synthesise dithiocarboxylic acid esters [219,220]. In the specific instance of morpholine, the latter can be represented by the fragment $=\overset{+}{\mathrm{N}}\begin{smallmatrix}\mathrm{R_3}\\ \mathrm{R_4}\end{smallmatrix}$. [54,134,197,221]. Thioiminoester salts can be obtained [221] as follows:



Methods have also been proposed for the synthesis of dithiocarboxylic acid esters by the interaction of unsaturated compounds with thiols [222,223] or with dithiocarboxylic acids [224]. On heating, 2-mercapto-1,1-diphenyl-2-phenylthioethylene is transformed into the phenyl ester of diphenylmethanedithiocarboxylic acid [225]. Methods have also been developed for the synthesis of fluoro-substituted dithiocarboxylic acids [226].

2. Properties of the Esters

The esters RCSSR′, in which both organic groups are aliphatic, are yellow or orange oily liquids. This also applies to cyclohexane- and phenylmethane-dithiocarboxylic acids. However, the esters of dithioformic acid (R = H) are trimeric and therefore crystalline [13,200]. If R is an aromatic group and R′ an aliphatic group, the esters can be both liquid and crystalline red substances. The esters with both groups are aromatic crystalline substances.

If the group R contains substituents capable of splitting off a proton, the ester can exist in two forms, involved in tautomeric equilibrium [171,227,228]:

$$\mathrm{R{-}S}\begin{smallmatrix}\mathrm{S}\\ \mathrm{S{-}R'}\end{smallmatrix} \rightleftarrows \mathrm{R_1{=}C}\begin{smallmatrix}\mathrm{SH}\\ \mathrm{S{-}R'}\end{smallmatrix};\ \mathrm{R{=}R_1H}.$$

Dithiocarboxylic acid esters are insoluble in water, but are usually readily soluble in many organic solvents. When such solutions are heated, thermochromic phenomena may be observed. For example, a solution of methyl naphthalene-1-dithiocarboxylate in ethyl benzoate or ethyl oxalate as well as a solution of phenyl diphenylmethanedithiocarboxylate in xylene change colour on heating. When the solutions are cooled, the initial colour is restored [27,229].

The electronic absorption spectra of the esters differ little from those of the acids themselves [152]. The absorption spectra of the methyl esters of ethane- [205], cyclohexane- [230], benzene- [230], 2,4-dihydroxybenzene- [146], naphthalene-1- [229,230], and naphthalene-2-dithiocarboxylic [230] acids, the ethyl esters of methane- and benzene-dithiocarboxylic acids [152], and the phenyl esters of benzene-, 4-hydroxybenzene-, 2, 4, 6-trimethylbenzene-, and 2-thiophen-dithiocarboxylic [212] acids have been published.

Characteristic absorption maxima at 1050 and 1240 cm^{-1} have been observed in the vibration spectra of the methyl, ethyl, and phenyl esters of aromatic dithiocarboxylic acids[212]. The absorption wavenumbers of the ethyl and isobutyl esters of methanedithiocarboxylic acid as well as the ethyl and butyl esters of ethanedithiocarboxylic acid have been published[213]. The spectra themselves have been published only for the methyl esters of 3-methyl-1-phenyl-5-pyrazolone-4-dithiocarboxylic acid (500–4000 cm^{-1})[199] and 2,4-dihydroxybenzenedithiocarboxylic acid (685 to 3800 cm^{-1})[146].

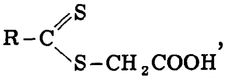
The magnetic permeability of ethyl methanedithiocarboxylate has been determined[231] as well as the NMR chemical shifts of the protons in the ethyl esters of methane-, phenylmethane-, and benzene-dithiocarboxylic acids and methanebis(dithiocarboxylic) acid[232]. The chemical shifts of carbon-13 have also been determined in the last instance[233].

Among the chemical properties of the esters, their ability to hydrolyse to the corresponding dithiocarboxylic acids has already been noted. However, the effect of hydrolysing agents can also lead to monothiocarboxylic or even carboxylic acids[132,203,208,234].

When the methyl esters of aliphatic and aromatic dithiocarboxylic acids are reduced with amalgamated zinc in hydrochloric acid, the main reaction product is the sulphide RCH_2SCH_3, in which the thiono-sulphur atom of the ester has been replaced by two hydrogen atoms[54]. In the polarographic reduction[54] of these esters, the half-wave potentials were in the range between –1 and –1.5 V. The half-wave potentials have also been determined for a number of phenyl esters[212], ranging from –0.95 to –1.30 V.

3. Applications of the Esters

The esters are usually much more stable than the dithiocarboxylic acids themselves. For this reason, they frequently constitute the form in which dithiocarboxylic acids are stored and actually used (for example, for thioacylation[235,236]). The carboxymethyl esters



$R-C(=S)-S-CH_2COOH$

, which form water-soluble alkali metal salts, are particularly convenient for this purpose[37,40,41,237]. When necessary, the dithiocarboxylic acids can be obtained by hydrolysing the esters[130].

The ability of the esters to condense with nitriles, which are CH acids, and to undergo self-condensation can be used also in organic synthesis[238]. The esters can also serve as the starting materials in the synthesis of keten thioacetals[239] or as intermediates in the synthesis of dyes[119,196]. The dyes obtained from the esters of dithiocarboxylic acids of type (XI) proved to be extremely valuable sensitisers in the manufacture of photographic materials[119]. It has been stated in the literature that the esters can be used as antioxidants in lubricating oils[224] and also as bactericidal and fungicidal agents[91].

V. METAL DITHIOCARBOXYLATES

1. Synthesis and Properties

There is an ionic bond between the anion and cation in alkali and alkaline earth metal dithiocarboxylates. For this reason, they are readily soluble in water. Aqueous solutions of the dithiocarboxylates are usually obtained by the reaction of dithiocarboxylic acids with solutions of alkalies. Many sodium and potassium dithiocarboxylates are stable in aqueous solutions for several months[45]. However, alkali metal cyanodithioformates decompose rapidly in aqueous solutions[138] and alkali metal trifluoromethanedithiocarboxylates cannot be obtained at all because of the strong electron-attracting influence of the trifluoromethyl group[137]. Sodium benzenedithiocarboxylate[42,156] and phenylmethanedithiocarboxylate[156] have been obtained in a solid form by the vacuum evaporation of their aqueous solutions, while evaporation of methanol solutions yielded potassium dithioformate[15,240]. Potassium pyridine-4-dithiocarboxylate has been obtained in the solid state by adding ethyl ether to an evaporated methanol solution of the salt[23].

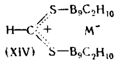
Ammonium dithiocarboxylates are also readily water-soluble ionic compounds. Only ammonium 2-aminocyclopent-1-ene-1-dithiocarboxylate is precipitated from ammonia solutions[84,241]. Quaternary ammonium dithiocarboxylates can be obtained in a crystalline form. In many instances, they are precipitated when aqueous solutions of sodium dithiocarboxylate and the quaternary ammonium halide are mixed. The corresponding salts of naphthalene-1-[49,149,242], naphthalene-2-[50,64], 2-hydroxybenzene-[145], 1-hydroxynaphthalene-2-[243], and indole-3-dithiocarboxylic[53] acids have been obtained in this way. In other instances, cooling or extraction with chloroform followed by the addition of another solvent which causes precipitation are used to isolate the reaction product. Quaternary ammonium salts of thioformic[240] and benzene-, 4-chlorobenzene-, 4-methylbenzene-[244], phenylmethane-[245], quinoline-2-, and quinoline-4-dithiocarboxylic[24] acids have been obtained by this procedure. In the synthesis of tetraethylammonium cyanodithioformate, tetraethylammonium hydroxide is used instead of the corresponding halide[138].

A series of tetraphenylphosphonium[53,148,153,240], tetraphenylarsonium[15,24,139,149,154,240,242], and triphenyltin[240] dithiocarboxylates have also been synthesised. The solubilities of certain 'onium naphthalene-[149], pyrrole- and indole-dithiocarboxylates[246] have been determined.

The introduction of transition or non-transition metal ions into aqueous solutions of ionic dithiocarboxylates often gives the corresponding dithiocarboxylate chelate complexes. The latter are insoluble in water and are precipitated. Among non-transition elements, gallium, indium, thallium, germanium, tin, lead, arsenic, antimony, bismuth, and selenium ions react with dithiocarboxylate ions. Among transition metals, dithiocarboxylate chelates are formed by vanadium, chromium, molybdenum, tungsten, manganese, iron, cobalt, nickel, ruthenium, osmium, rhodium, iridium, palladium, platinum, copper, silver, gold, zinc, cadmium, and mercury ions. The dithiocarboxylates of the majority of platinum metals are formed slowly at the usual temperature, but the reactions can be accelerated by heating. It has been stated in the literature that dithiocarboxylate ions interact with zirconium ions[108]. Among the actinides, uranium interacts with dithiocarboxylate ions.

Metal dithiocarboxylates can also be obtained from organometallic compounds as a result of the dissociation of the C–M bonds and the insertion of carbon disulphide at the site of the break; part of the review of Butler and Fenster[247] is devoted to this problem. Such reactions also include the interaction between organometallic compounds and carbon disulphide, used to synthesise dithiocarboxylic acids (see Section II). It has been stated in the literature that dialkyl-aluminium-, -gallium, and -indium dithiocarboxylates can be obtained in this way[248], although later the same author synthesised these substances by a different method [249]. The method has been used successfully to prepare manganese and rhenium dithiocarboxylatocarbonyls having the general formula $RCSSM(CO)_4$, where R = CH_3, C_6H_5, $CH_3C_6H_4$, ClC_6H_4, $C_6H_5CH_2$, or $(C_6H_5)_3C$.[250-253] However, the attempts to obtain triethyl-lead ethanedithiocarboxylate from tetraethyl-lead and carbon disulphide were unsuccessful[254]. Manganese and rhenium dithiocarboxylatocarbonyls can also be synthesised from the corresponding dithiocarboxylic acids (benzene- [20,255,256] and trifluoromethanedithiocarboxylic acids [135]) or their chlorides (C_6H_5CSCl).[257]

In addition, the following complexes containing dithioformate ions as ligands have been obtained from mixed dithiocarboxylates: $Re(CO)_2(HCSS)[P(C_6H_5)_3]_2$, [258] $[Ru(HCSS)_2][P(C_6H_5)_3]_2$, [259] and compound (XIV).[260-262] Their structures have been elucidated by X-ray diffraction:



(XIV) ; M = Co, Fe .

2. Absorption Spectra

The first electronic absorption spectra of metal dithiocarboxylates were already obtained in the 1920's [152]. However, the bulk of the data on these spectra have been published the last 7–8 years. The spectra or numerical data characterising the absorption maxima of a number of metal dithioformates[15,240], methane- [152,153,163,263], ethane- [153], trimethylmethane- [163], phenylmethane- [155,156,163,263-268], cyclohexane- [154], benzene- [152,156,163,264,269-274], 2-hydroxybenzene- [275], 4-hydroxybenzene- [159,276], 2,4-dihydroxybenzene- [277,278], 2,3,4-trihydroxybenzene- [277], 4-hydroxy-3-methoxybenzene- [147], 4-chlorobenzene- [270,271,274,279], 4-methylbenzene- [163,270-274], napthalene-1- [280], 1-hydroxynaphthalene-2- [243], pyrrole- and indole- [281], and 2-aminocyclopent-1-ene-1-dithiocarboxylates [84] have been described in the literature.

Comparison of the absorption spectrum of the dithioformate ion with that of the thioloformate ion $HCOS^-$ led[240] to the following assignments: 225 nm to the $n - \sigma^*$ transitions, 331 nm to the $\pi-\pi^*$ transitions, and 386 nm to the $n-\pi^*$ transitions.

The electronic absorption spectra of lead, indium, chromium(III), cobalt(III), rhodium(III), iridium(III), nickel(II), palladium(II), and platinum(II) benzene- and phenylmethane-dithiocarboxylates led to the conclusion [156] that the chromophoric groups MS_4 in the ML_2 complexes have the square planar structure, while in the ML_3 complexes the MS_6 chromophores are pseudo-octahedral. A preliminary assignment was also made of the absorption bands (the Figure presents as an example the spectrum of nickel benzenedithiocarboxylate).

The bands in the ranges 208–222 and 250–268 nm were assigned to the vibrations of the benzene ring. One or several intense bands in the range 295–345 nm were assigned to the $n-V$ transitions. The bands which originate from the electronic transitions in the conjugated system of the benzene ring and the dithiocarboxylate group are located between those of the benzene ring and the $n-V$ transitions. In the range 333–455 nm, there are bands which are missing from the spectra of the free ligands. They were assigned to the charge-transfer (CT) bands. In the spectra of the transition metal compounds, there are weak absorption bands above 455 nm due to the $d-d$ transitions in the MS_4 and MS_6 chromophores.

Later, approximately the same assignments were made in the electronic absorption spectra of vanadium [263], nickel, and zinc [163] methanedithiocarboxylates, nickel trimethylmethanedithiocarboxylate [163], iron[264], vanadium[263], nickel, and zinc[163] benzenedithiocarboxylates, vanadium[263], nickel, and zinc [163] 4-methylbenzenedithiocarboxylates, and iron[264], vanadium [263], nickel, and zinc [163] phenylmethanedithiocarboxylates.

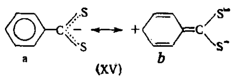
The electronic absorption spectra of arsenic, bismuth, indium, gallium, antimony, mercury(II), lead, tin(II), zinc, and platinum(II) 2,4-dihydroxybenzenedithiocarboxylates led to the conclusion[278] that the absorption band in the range 390–420 nm arises as a result of $n-\pi^*$ transitions. This is nevertheless difficult to accept, since this band is intense (the molar extinction coefficients are between 4×10^4 and 8×10^4).

The vibrational spectra or the wavenumbers in these spectra have been published for a number of metal dithioformates [15,240], cyanodithioformates [166], and methane- [168,252,253,263,282], 2-aminocyclopent-1-ene-1- [84,283], benzene- [252,253,263,284-288], 4-methylbenzene- [253,263,289], 4-chlorobenzene- [253], 4-isopropylbenzene- [289], 2,4-dihydroxybenzene- [290], and naphthalene-1-dithiocarboxylates[285]. The following assignments were made in the spectrum of potassium dithioformate [240] (the wavenumbers are in cm^{-1}): 1250 to $\delta_{asym}(SCS)$, 988 to ν_{asym} (SCS), and 848 to ν_{sym} (SCS).

Comparison of the spectra of sodium and lead methanedithiocarboxylates with those of their deuterated analogues led to the following assignments[282]: 1141 to $\rho(CH_3)$, and $\nu_{asym}(CSS)$, 602 to $\nu_{sym}(CSS)$, 464 to $\omega(CSS)$, 372 to $\delta(CSS)$, and 348 to $\rho(CSS)$. The following assignments were made in the spectra of mixed methanedithiocarboxylatocarbonyl complexes [252,253]: 1146 to $\nu_{asym}(CS_2)$ and 616 to $\nu_{sym}(CS_2)$. Calculation [168] of the normal vibrations of the methanedithiocarboxylate ion and its deuterated analogue permitted the following assignments:

2976 cm^{-1} to CH stretch.;
2915 cm^{-1} to CH stretch.;
1449 cm^{-1} to CH def.;
1349 cm^{-1} to CC stretch. + CH def.;
1141 cm^{-1} to CC stretch. + CS stretch. + SCS def. + CCS def.;
1115
1065 cm^{-1} to CS stretch. + SCC def. + CH def.;
983 cm^{-1} to CH def.;
865 cm^{-1} to CS stretch. + SCC def. + CH def.;
602 cm^{-1} to CS stretch. + CS stretch.;
372 cm^{-1} to SCS def. + SCC def.;
348 cm^{-1} to SCC def.

A number of studies have been made on the spectra of benzenedithiocarboxylates, but the assignments are not unambiguous. In the spectra of lead, cadmium, and thallium benzenedithiocarboxylates, the wavenumbers in the range 940–1000 cm^{-1} are attributed to the vibrations in the CS_2 group[284]. In the study [286,287] of the spectra of nickel(II), palladium(II), cobalt(III), chromium(III), indium, rhodium(III), lead, and iron(III) benzenedithiocarboxylates, comparison with the spectra of the complexes of the deuterated analogues led to the following assignments: 980–1000 to $\nu_{asym}(CSS)$; 940–950 to $\nu_{sym}(CSS)$; 660–670 to $\delta(CSS)$; 360–370 to $\nu_{asym}(MSS)$; and 310–320 to $\nu_{sym}(MSS)$. Furthermore, the differences between the vibrational wavenumbers of the benzene ring in various complex-forming agents led to the conclusion that the contribution of the resonance form of the ligands (XVb) increases with increase of the electron affinity of the central ion:



(XV)

A subsequent study[288] of the spectra of potassium, thallium(I), lead, cadmium, mercury(II), and indium benzenedithiocarboxylate nevertheless provided a justification for a new assignment of certain wavenumbers. The 585–589 cm^{-1} was assigned to the γ(CSS) vibrations and the 320–330 cm^{-1} band to the δ (CSS) vibrations. Objections were raised against the assignment of the 950 cm^{-1} band to the $\nu(CS_2)$ vibrations and of the 670 cm^{-1} band to the δ (CSS) vibrations. The band at 300–350 cm^{-1} was assigned to the latter.

The following assignments were made in the spectra of mixed benzenedithiocarboxylatocarbonyl complexes[252,253]: 1267 to $\nu_{asym}(CS_2)$; 613–631 to $\nu_{sym}(CS_2)$. Assignments were also made in the spectra of 4-methylbenzene-[253,289], 4-chlorobenzene-[253], and 4-isopropylbenzene-dithiocarboxylates[289]. The 1220–1260 cm^{-1} and 590 cm^{-1} bands in the spectra of 2,4-dihydroxybenzenedithiocarboxylates were assigned to the stretching vibrations in the CS_2 group. The bands in the range 970–990 cm^{-1} were assigned to the vibrations of the same group.

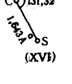
The bands in the range 990–1020 cm^{-1} in the spectra of naphthalene-1-dithiocarboxylates[285] were assigned to the stretching vibrations of the CSS group.

The Structure of Metal Dithiocarboxylates

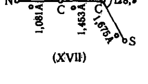
The magnetic properties of iron(III), benzene- and phenylmethane-dithiocarboxylates indicate the presence of low-spin complexes[264,291]. Cobalt(III), indium, rhodium(III), palladium(II), iridium(III), and platinum(II) phenylmethanedithiocarboxylates are diamagnetic, while the corresponding chromium(III) complexes are paramagnetic[156]. Nickel(II), platinum(II), copper(II), zinc, and cadmium 2-aminocyclopent-1-ene-1-dithiocarboxylates are also diamagnetic, which indicates a square planar coordination of the sulphur atoms[283,292]. Magnetic moment measurements have shown[263,293] that vanadium functioning as the complex-forming agent in methane-, phenylmethane-, benzene-, and 4-methylbenzene-dithiocarboxylates is in the +4 state of oxidation. Judging from their magnetic properties[163], nickel methane-, trimethylmethane-, phenylmethane-, benzene-, and 4-methylbenzene-dithiocarboxylates are low-spin complexes. The magnetic permeability of copper(I) naphthalene-1-dithiocarboxylate has also been determined[294].

The number of ESR data is so far small[263,295,296].

A number of metal dithiocarboxylates have been investigated by X-ray diffraction and their structures have been elucidated. The principal data obtained in the study of potassium dithioformate[297] are presented in formula (XVI). In the mixed dithioformatocarbonyl complexes[258,259], the C–S bond length is in the range 1.64–1.70 Å. The data obtained for the cyanodithioformate ion[298,299] are presented in formula (XVII):



(XVI)



(XVII)

The sulphur atoms around the central atom in zinc benzenedithiocarboxylate $Zn(C_6H_5CSS)_2$ form a strongly distorted tetrahedron[300], while in vanadium benzenedithiocarboxylate $V(C_6H_5CSS)_4$ and phenylmethanedithiocarboxylate $V(C_6H_5CH_2CSS)_4$ they form an almost ideal dodecahedron[263,301,302] and in chromium benzenedithiocarboxylate $Cr(C_6H_5CSS)_3$ a distorted octahedron[303]. Crystalline nickel trimethylmethanedithiocarboxylate $Ni[(CH_3)_3CCSS]_2$ is dimeric, since bonds are formed between the nickel atoms and the sulphur atoms in another molecule[304]. The coordination of the sulphur atoms is square planar. Nickel phenylmethanedithiocarboxylate $Ni(C_6H_5CH_2CSS)_2$ is also dimeric, but in this case there is a bond between the nickel atoms[305]. The sulphur atoms surrounding each nickel atom are located in the same plane. Nickel benzenedithiocarboxylate $Ni(C_6H_5CSS)_2$ is a trimer formed by bonds between the nickel atoms and the sulphur atoms in another molecule[306]. The coordination of sulphur atoms about the nickel is square planar.

In dimeric palladium benzenedithiocarboxylate $Pd(C_6H_5CSS)_2$, there are bonds between the palladium and the sulphur atoms in another complex molecule[307]. However, the platinum 4-isopropylbenzenedithiocarboxylate dimer $Pt(C_3H_7C_6H_4CSS)_2$ is formed as a result of bonds between the platinum atoms[289,308]. The sulphur atoms in this compound form a square antiprism, two faces of which contain platinum atoms. Two ligands are then in the bridging positions and are linked to both platinum atoms.

In all the dithiocarboxylates investigated by X-ray diffraction, the two bonds between carbon and sulphur are virtually identical, which indicates the equalisation of electron density:

The length of the bond between the carbon of the dithiocarboxy-group and the carbon of the group R depends on the nature of the latter. If it is aliphatic (this also applies to $C_6H_5CH_2$), the length of this bond corresponds to that of a single bond. However, if the group is aromatic (C_6H_5), the bond length is in the range 1.5–1.5 Å, which indicates a partial double bond character of the linkage, i.e. conjugation over the entire ligand, which is consistent with the conclusions reached in the study of vibrational spectra [see formula (XV)]. Thus three resonance forms contribute to the structure of the ligand:

4. Complex Metal Dithiocarboxylates in Solution

Complex dithiocarboxylates can be extracted from an aqueous medium by organic solvents. The extractability of metal benzene-[309], naphthalene-1-[310], pyrrole- and indole-[53], and quinoline-2- and quinoline-4-dithiocarboxylates[162] by various extractants has been tested qualitatively. The dependence of the optical density of the extract on the pH of the aqueous phase has been elucidated for the extraction of cyclohexane-[154], phenylmethane-[155,265–268], benzene-[269,274], 2-hydroxybenzene-[148,275], 4-hydroxybenzene-[159,276], 2,4-dihydroxybenzene-[277,278], 2,3,4-trihydroxybenzene-[277], 3,4-methylenedihydroxybenzene-[148], 4-chlorobenzene-[270,271,274,279], 4-methylbenzene-[270-274], naphthalene-1-[280], naphthalene-2-[50], furan-2-[148], indole-, and pyrrole-dithiocarboxylates[281,311]. Many of these are extracted from an extremely acid medium.

The molecular weights of chromium(III), cobalt(III), indium, rhodium(III), palladium(II), iridium(III), and platinum(II) phenylmethane- and benzene-dithiocarboxylates dissolved in benzene have been determined by the osmometric method[156], which has also been used to determine the molecular weights of iron(III) phenylmethane- and benzene-dithiocarboxylates in chloroform solutions[264]. The molecular weights of vanadium methane-, phenylmethane, benzene-, and 4-methylbenzene-dithiocarboxylates[263], nickel methane-, trimethylmethane-, phenylmethane-, and benzene-dithiocarboxylates[163], and of the mixed complex[20] $C_6H_5CSSMn(CO)_4$ in solutions have also been determined. Polymeric species were not detected, with the exception of nickel trimethylmethanedithiocarboxylate.

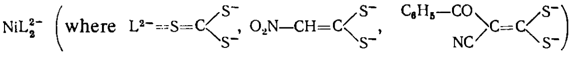
The usual methods have been employed to determine the compositions of the dithiocarboxylates extracted: the isomolar series [continuous variations], molar ratios, equilibrium shift, and other methods as well as the dependence of the formation function[312] and the Leden function[313] on the excess of ligands. In most cases, the composition of the complexes is consistent with the valence of the complex-forming agent[147,159,267-271,273-275,277,278,280,287,311]. However, there are exceptions. For example, nickel forms several compounds[159,276], bivalent cobalt reacts in proportions of 1 : 3, [159,267,270,275,277,287], and molybdenum(V, VI) reacts in proportions of 1 : 2 or 1 : 3. [147,275,277,280]

The stability constant of osmium 2-aminocyclopent-1-ene-1-dithiocarboxylate (2.5×10^9) has been determined in aqueous ethanol[314]. The two-phase stability constants of a number of dithiocarboxylates (the ratios of the concentrations of the complexes in the organic phase to the products of the concentrations of metal ions and free ligands in the aqueous phase) have been determined for a number of dithiocarboxylates. The constants for naphthalene-1-dithiocarboxylates in the water–chloroform system[315] are between 10^9 and 10^{40}. The two-phase stability constants of hydroxybenzenedithiocarboxylates found in the water–3-methylbutanol system[316] are in the range from 10^9 to 10^{22} and those of 2,4-dihydroxybenzenedithiocarboxylates[278] are in the range between 10^5 and 10^{16}.

Attempts have been made at a chromatographic separation of naphthalene-1-dithiocarboxylates using toluene–heptane mixtures as the solvent[317,318].

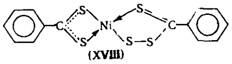
5. Metal Perthiocarboxylates

At the end of the 1940's, it was observed[319] that nickel benzenedithiocarboxylate $(C_6H_5CSS)_2Ni$ combines with sulphur to form a compound in which there are 5 sulphur atoms for each nickel atom. Immediately after the establishment of this fact, it was suggested that the compound formed is a dinuclear complex of nickel(IV). [319-321]. However, the study of the reactions involving the addition of elemental sulphur to ene-1,1-dithiol complexes of nickel



$$NiL_2^{2-}\ \left(\text{where } L^{2-}{=}S{=}C(S^-)_2,\ O_2N{-}CH{=}C(S^-)_2,\ (C_6H_5{-}CO)(NC)C{=}C(S^-)_2\right)$$

showed that the nickel remains bivalent under these conditions and the sulphur atom is inserted in the four-membered chelate ring, expanding it into a five-membered ring[322]. This suggested that sulphur adds similarly to nickel benzenedithiocarboxylate. Somewhat later, it was shown[323] that this does indeed entail the formation of nickel benzeneperthiocarboxylate benzenedithiocarboxylate(XVIII):



(XVIII)

A number of other perthiocarboxylate dithiocarboxylates as well as perthiocarboxylates of metals such as zinc, nickel, iron(III), cobalt(III), palladium(II), and platinum(II) have also been obtained[292,324-327]. For this purpose, zinc perthiocarboxylates are synthesised first. The corresponding aldehyde RCHO in tetrahydrofuran solution is treated with $(NH_4)_2S_2$ and the resulting perthiocarboxylate ions are precipitated in the form of the nickel complex $(RCSSS)_2Zn$. The latter complex is used to synthesise the perthio-complexes of other elements with the aid of the corresponding double decomposition reactions.

Nevertheless, one should note that the formation of perthio-complexes has also been observed in the direct interaction of bivalent nickel and cobalt ions with 2-aminocyclopent-1-ene-1-dithiocarboxylate ions; one molecule of the reactant then decomposes and liberates a sulphur atom, which is necessary for the formation of the five-membered chelate ring[292].

The electronic absorption spectra of a number of perthio- and perthio-dithio-complexes have been published[163,324,326]. On passing from nickel benzenedithiocarboxylate to the benzeneperthiocarboxylate benzenedithiocarboxylate, the charge-transfer band undergoes a hypsochromic shift (approximately 60 nm) and, on passing to the nickel bis(perthio)-complex, the shift is even greater (approximately 180 nm). [324]

X-Ray diffraction analysis of zinc[328], nickel[326-328], and iron(III)[325,329], perthiocarboxylate complexes has shown that all the atoms of the five-membered chelate ring are in the same plane.

6. Applications of Metal Dithiocarboxylates

In view of their high stability in air and in aqueous alkaline solutions, quaternary ammonium, phosphonium, and arsonium dithiocarboxylates can be used as a convenient form for the storage of dithiocarboxylic acids. These compounds have also been proposed as analytical reagents[242].

Dithiocarboxylates are used in analytical chemistry to detect and determine the corresponding elements. Sodium antipyrine-, 3-antipyrine-, and isoantipyrine-dithiocarboxylates have been proposed for the detection of nickel ions[330]. Tervalent arsenic can be detected with the aid of tetraethylammonium naphthalene-1-dithiocarboxylate[331].

Palladium cyclohexanedithiocarboxylate can be used for the extraction-photometric determination of this element[154]. Palladium benzenedithiocarboxylate[332], iron 4-methyl- and 4-chloro-benzenedithiocarboxylates[165], molybdenum 4-hydroxy-3-methoxy-benzenedithiocarboxylate[147], nickel 4-hydroxy-benzenedithiocarboxylate[276], arsenic naphthalene-1-dithiocarboxylate[333], nickel 2-hydroxynaphthalenedithiocarboxylate[334], and nickel 2-aminocyclopent-1-ene-1-dithiocarboxylate[241] have been suggested for the extraction-photometric determination of the corresponding elements. In the case of nickel 1-hydroxynaphthalenedithiocarboxylate[335] and osmium 2-aminocyclopent-1-ene-1-dithiocarboxylate[314], photometric measurements are made on ethanol solutions in which the solubility of these complexes is fairly high. Nickel 2-hydroxynaphthalenedithiocarboxylate can also be used for the gravimetric determination of nickel[334].

Several methods for the quantitative determination of the elements with the aid of antipyrine-, 3-antipyrine-, and isoantipyrine-dithiocarboxylic acids have been proposed. Nickel[330] and cobalt[336] can be determined gravimetrically with the aid of these reagents. A solution of cobalt antipyrine-4-dithiocarboxylate in pyridine is suitable for the photometric determination of cobalt[337]. A chloroform solution of nickel antipyrine-4-dithiocarboxylate can be used for the determination of mercury: the decrease of colour intensity on shaking with solutions of mercury salts is proportional to the amount of mercury[338]. The double decomposition reaction occurring when an aqueous solution of nickel nitrate is shaken with chloroform solutions of bismuth, lead, and thallium antipyrine-4-dithiocarboxylates can be used for the photometric determination of the last three elements[339].

Many metal dithiocarboxylates are highly effective fungicides and can be used to protect fruit trees from fungal disease. Nitromethane-[87,340], benzene-[341], chlorobenzene- (from mono- to penta-chlorobenzene-)[342,343], and 2-hydroxynaphthalene-dithiocarboxylates[341] have been proposed for this purpose. Metal dithiocarboxylates can be used as accelerators of the vulcanisation of raw rubber. It is postulated that they promote the cleavage of the eight-membered sulphur molecule in this process[344].

Various impurity elements can be removed from the surface of silicon $p-n$ structures in the form of 2,4-dihydroxybenzenedithiocarboxylates, which greatly increases the breakdown potential and reduces the leakage current[345]. Water-soluble salts can be freed from heavy metal impurities by adding an ethanol solution of 2,4-dihydroxybenzenedithiocarboxylic acid: the dithiocarboxylates of the impurity elements pass to the solid phase together with the precipitated acid[346].

Tetraethylammonium napthalene-1-dithiocarboxylate, which is an effective flotation agent for many sulphide minerals, has been proposed as the collector in the flotation of ores[347].

VI. QUANTUM-MECHANICAL CALCULATIONS

The energy of the $\pi-\pi^*$ transition in the dithiocarboxylate group has been calculated by the Hückel method[348]. The result obtained agrees well with the experimental absorption of sodium methanedithiocarboxylate.

The energies of the lowest vacant and the highest occupied molecular orbitals have been calculated for nine dithiocarboxylic acids[349]. The energies of the lowest vacant levels are correlated with the polarographic half-wave potentials of dithiocarboxylic acids and their esters[350]. The results of the calculation of the energies of the $n-\pi^*$ and $\pi-\pi^*$ transitions in the molecules of 19 dithiocarboxylic acids agree satisfactorily with the experimental data obtained from the electronic absorption spectra of the corresponding methyl esters[230].

The Chemistry of Tetranitromethane

K.V.Altukhov and V.V.Perekalin

Information on the methods of preparation, physical and chemical properties, and toxicity of tetranitromethane that appeared in print up to 1974 is reviewed systematically. Considerable attention is paid to the diverse reactivity of tetranitromethane with unsaturated compounds that has been discovered during recent years. A list of 317 references is included.

CONTENTS

I. INTRODUCTION

Several research workers have paid close attention to tetranitromethane during the past fifteen years. Thus, whereas around 100 publications appeared during the century after its discovery (Shishkov, 1857), this number had been doubled by 1973. Such vigorous progress in the chemistry of nitromethane is due to the discovery of fundamentally new types of chemical reactions leading to the synthesis of various nitro- and polynitro-compounds. The need therefore arose to summarise the accumulated experimental results, especially as reviews on the chemistry of tetranitromethane are lacking both in the Soviet and in the foreign literature.

Tetranitromethane is a unique nitro-compound, in which a regular tetrahedral structure, absence of polarity, and hence equivalence of all the nitro-groups are combined with great mobility of one of the nitro-groups in chemical reactions, resulting in formation of a nitryl cation NO_2^+ and the dually reactive conjugate trinitromethanide anion $(NO_2)_3C^-$ or the corresponding radical-anions or radical pairs depending on the conditions. Perhaps the most characteristic feature of tetranitromethane—a strong π-acid—is its ability to form with π- or p-electron systems (substituted aryls, alkenes, arylalkenes, dienes, vinyl ethers and esters, etc.) donor-acceptor or charge-transfer complexes which, depending on the structure of the donor and the reaction conditions, are converted into nitroaryls, arylnitroalkenes, α-nitro-ketones, tetranitroalkanes, or dinitroisoxazolidines. The diversity of these transformations constitutes the synthetic value of tetranitromethane.

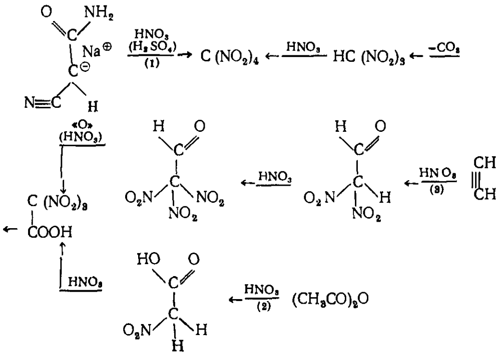
By varying the structure of the donor and the conditions of the reaction we can change the mechanism from heterolytic to radical or radical-ion in photochemical processes, thus changing the direction of the reaction and the structure of the final products, and accomplishing controlled syntheses by means of tetranitromethane.

II. METHODS OF PREPARATION OF TETRANITROMETHANE

Tetranitromethane was first obtained by Shishkov[1,2] in 1857 by the action of a mixture of nitric and sulphuric acids on sodium 2-cyanoacetamide (1), converted further into trinitroacetonitrile, which was then hydrolysed to ammonium trinitromethanide, this being subsequently nitrated with fuming nitric acid to give tetranitromethane. This was the sole method until 1903, when a 10% yield of tetranitromethane was obtained from acetic anhydride and diacetylorthonitric acid[3]. During subsequent years acetic anhydride, acetylene, ethylene, and products of the pyrolysis of natural gas were used as starting materials. Acetic anhydride was nitrated with acetyl nitrate[4], nitrogen pentoxide alone[5] and mixed with nitrogen peroxide[6], and with nitric acid alone[7] and in the presence of glacial acetic acid[8-10] and catalysts (orthophosphoric, sulphuric, and hydrochloric acids, phosphorus pentoxide, phosphoryl chloride, phosphorus pentachloride, sulphuryl chloride, acetyl chloride, and boron triacetate[11]).

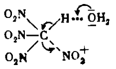
A semi-industrial, convenient, and safe laboratory process giving yields up to 65% was accomplished by nitrating acetic anhydride with nitric acid[12,13]. Nitration takes place in several stages: the nitroacetic acid formed is further nitrated to trinitroacetic acid, which is decarboxylated to trinitromethane, and this is nitrated to tetranitromethane (2).

The use of acetylene and ethylene (Orton, 1918)[14,15] broadened considerably the raw-materials base for the production of tetranitromethane. The nitration of acetylene with 90–97% nitric acid in the presence of oleum or phosphorus pentoxide and mercury nitrate as catalyst also involves trinitroacetic acid and trinitromethane as intermediate species[16] (13).



In 1949 a semi-industrial plant was described for the production of tetranitromethane by the nitration of acetylene[17]. Small industrial plants have been described also for continuous production from pure acetylene[18] and from natural gas by preliminary pyrolysis in an electric arc followed by nitration with a mixture of nitric and sulphuric acids[19].

A study of the kinetics[20] and the mechanism[21] of the final stage in most methods of preparation—the nitration of trinitromethane by nitric acid—showed that, in the presence of 87.5–100% sulphuric acid, the reaction is represented by a third-order equation (containing the concentrations of the nitryl ion, trinitromethane, and water or sulphuric acid) and results from a concerted attack by the nitryl ion at the carbon atom and by the base at the hydrogen atom



.

The formation of a small quantity of tetranitromethane (up to 1%) in the manufacture of trinitrotoluene stimulated a search for methods of obtaining the former from aromatic hydrocarbons and their derivatives[22–26]. However, such methods have not found application because of poor yields.

Treatment of keten with 100% nitric acid gives a 90% yield of tetranitromethane[27]. A low yield can be obtained by nitrating acetone with nitric acid[5,28]. The production of tetra- and tri-nitromethanes from malonamide has been patented[29]; a 58% yield of the latter is formed when this diamide is nitrated with 90% nitric acid in the presence of concentrated sulphuric acid, and a 45% yield of the former in the presence of oleum. The interaction of picrylpyridinium nitrate and nitromethane gives a nearly theoretical yield of tetranitromethane[30]. Rather theoretical interest attaches to the Hantzsch method[31], consisting in the reaction of iodotrinitromethane with silver nitrite in aqueous–alcoholic solution, and the analogous action of nitryl chloride on trinitromethane or its silver and potassium salts (yields 65%, 20%, and 94% respectively)[32].

Among the many processes only the nitration of acetic anhydride and that of acetylene have found industrial application. However, the first of these methods has the disadvantage of using large quantities of strong acids, which corrode the equipment, and the second involves the formation of large quantities of gases. The economics of these methods depends on the degree of utilisation and recovery of byproducts.

III. PHYSICOCHEMICAL PROPERTIES AND STRUCTURE

Physicochemical constants determined for tetranitromethane by different workers differ significantly[33], so that it is difficult to use them to describe the structure of the compound or to assess its purity. The values given below have been adopted by the International Bureau of Physicochemical Standards.

Tetranitromethane is a highly volatile, mobile liquid boiling at 127.5°C under normal pressure[34] and melting at 13.9°C.[35] Experimental values of the vapour density have been given[34,36–39] over the range 0–127.5°C, and it can be calculated by means of the equation $\lg p = 7.23 - 2130/T$.[37] The vapour pressure of tetranitromethane has been determined close to its melting point[40]. The density d is respectively 1.64837, 1.63944, and 1.62178 g cm^{-3} at 15, 20, and 30°C. The change in density per degree is 0.00174 g cm^{-3}, and the coefficient of expansion is 0.00109.

The refractive index[41] at 15°C is given by

$$He_r = 1{,}43655,\ dn/dt = 0.00045;\quad H_\alpha = 1{.}43709,\quad dn/dt = 0{,}00045;\quad D_{Na} = 1{.}44066;\quad He_J = 1{.}44076,\ dn/dt = 0.00046;\ He_V = 1{.}44768;\ dn/dt = 0.00046;\quad H_\beta = 1{.}44937,\quad Veviol = 1{.}45593.$$

The dispersion $H\beta - H\alpha = 0.01228$. Molecular refractions[41] are listed in Table 1. The refraction for the nitro-group in tetranitromethane is 7.20 [42] ($MR_D = 31.40$) and 7.248.[43]

Table 1.

	H_α	D	H_β	H_γ
Found	31.16	31.39	31.65	—
Calculated	29.01	29.30	29.72	30.07
Difference	+2.15	+2.09	+1.93	—

Viscosity has been determined experimentally at 15, 20, 30, and 40°C,[35,41,44] and surface tension at 15, 20, 25, 30, and 50°C.[41,54] The parachor of tetranitromethane has also been calculated[45]. The speed of sound in the liquid is 1039 m s^{-1} at 20°C, with a temperature coefficient in the range 4–6 m s^{-1}.[46]

Both the pure compound[47] and its solution in liquid sulphur dioxide[48] showed negligible electrical conductivity. On the other hand, a solution of tetranitromethane in liquid ammonia was very highly conducting[49], probably because of interaction with the solvent. The dielectric constant of tetranitromethane at 5, 20, and 25°C is respectively 2.15, 2.317, and 2.521 s^2 cm^{-2}.[42,47–54] Birefringence has been reported in an electric field, with a molar Kerr constant of 2.98×10^{-12} cm V^{-2}.[55] Experimental dipole moments[52,55–58] lie in the range $(0.19–0.71) \times 10^{-18}$ D at 25°C. Actually, however, the dipole moment of tetranitromethane is zero[6]: the observed values lie within the limits of experimental error, and have been determined on impure samples. One cause of the high value was determination of the dipole moment in solvents (e.g. benzene) capable of forming donor–acceptor complexes with tetranitromethane.

The magnetic susceptibility and the magnetic permeability have been investigated[59–61]. The magnetic refraction and the Cotton–Moulton effect have been examined[62]. Several nuclear magnetic resonance studies have been made[63–69].

The ultraviolet spectrum of tetranitromethane was first obtained by Zelinskii[70], and was later analysed[38,71–75]. The main absorption band in dichloromethane has $\lambda = 280$ nm and $\epsilon = 135$. Discussion of the infrared spectrum[73,76–84] led to the assignments—asymmetric and symmetric stretching vibrations of nitro-groups at 1618 and 1266 cm^{-1} respectively (both very strong); and other bands at 1645 (medium), 1439 (weak), 1370 (m), 990 (w), and 973 (m) cm^{-1} [73]—and interesting studies were made[78,85] of the infrared spectra of the vapour at 25°C, the liquid at 18°C, and the crystalline state at −40, −88, −104, and −126°C. Tetranitromethane can exist in two crystalline forms, with an isomorphous transition at −99.8°C. The Raman spectra obtained in three different states—solid, liquid, and dissolved in tetrachloromethane—indicate that the molecule possesses the symmetry $D_2 = S_{4u} = V_d = 42m$.[86] The main lattice parameters have been determined by means of X-rays[87-93] (see Fig. 1). The diffraction of X-rays has been studied in the liquid and in its solutions[94-96].

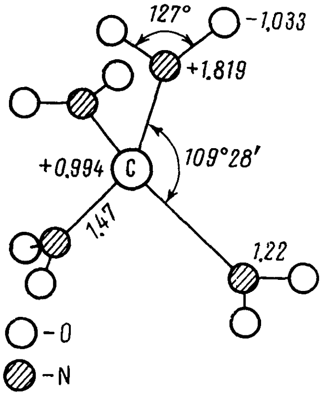


Figure 1. Model of the tetranitromethane molecule.

Heats of formation and combustion were determined[8]:

$$C(\text{diamond}) + 2N_2(\text{gas}) + 4O_2(\text{gas}) = C(NO_2)_4 + 4.7 \text{ kcal mole}^{-1}$$
$$C(NO_2)_4 = CO_2 + 3O_2 + 2N_2 + 89.6 \text{ kcal mole}^{-1}.$$

More recent papers have given more accurate values for the heat of formation (8.9 [97] and 8.8 ± 0.7 [98] kcal mole^{-1}) and the heat of combustion (102.9 kcal mole^{-1} [97,99,100]). Determinations have been made of the latent heat of evaporation[37], the entropy of evaporation[38], and the entropy of vaporisation[101,102]. The energy of dissociation of the carbon–nitrogen bond in tetranitromethane has been estimated as 38.2 [103,104] and 39.3 [105] kcal mole^{-1}. The enthalpy of formation of the compound is 18.5 kcal mole^{-1}.[105,106]

Tetranitromethane is highly toxic[107-112], attacking the respiratory tracts and the central nervous system[112-116]. The threshold concentration is 0.003 mg litre^{-1}, and the permissible limit in air 0.001 mg litre^{-1}.[113-117] Various methods have been worked out for its determination—spectrophotometrically in air and in solutions[113,118,119], calorimetrically in water[120], volumetrically in concentrated nitric acid[121], oscillopolarographically in nitromethane[122], and polarographically in the presence of *m*-dinitrobenzene and 1,3,5-trinitrobenzene[123]—and its use for analytical purposes has been reported[124,125]. Tetranitromethane possesses fungicidal[126,127] and insecticidal[128] properties; data have been published on its biochemical activity[128-131].

Because of the great mobility of one nitro-group in chemical reactions, many investigators suggested that the four nitro-groups were not equivalent. As a consequence, a structure was in various cases attributed to the compound that explained only the particular reaction, without taking into account the great diversity of its chemical and physicochemical properties.

$C(NO_2)_4$

(I)

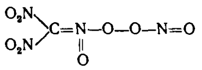
$(O_2N)_3C—O—NO$

(II)

(III)

$(O_2N)_2C : \underset{\ddot{O}}{N} :ONO_2$

(IV)



(V)

In a study of the aci-form of the nitro-group Hantsch[132] suggested the equivalence of all four true nitro-groups (I). Investigation of the behaviour of the compound as a nitrating agent led Schmidt[133] to the nitrite structure (II), adopted by Macbeth[134] on the basis of the similarity in appearance of the ultraviolet spectra of mixtures of tetranitromethane and unsaturated hydrocarbons to those of complexes of alkyl nitrites and unsaturated compounds. Willstätter[135] had deduced the existence of the "cyclic form" (III). Claisen[136] and subsequently Auwers[137] suggested a "nitrone" type of structure (IV) from a study of the physical properties. Finally, examination of the oxidising properties of the compound enabled the "peroxide" structure (V) to be attributed to it[138]. Several investigators assumed[71,139,140] that an equilibrium was established between undissociated and ionic forms.

Later determinations of the dipole moment[56,57,141] and the parachor[45], as well as study of X-ray diffraction patterns[87,94], and the Raman and infrared spectra in the gaseous state[85,142-144] have shown that the molecule has the form of a regular tetrahedron with S_{4u} symmetry.

Quantum-chemical calculation based on the Slater treatment shows[145] that the electron density is considerably raised on the oxygen atoms of the nitro-groups, but significantly lowered on the nitrogen and carbon atoms (Fig. 1).

IV. DONOR–ACCEPTOR (CHARGE-TRANSFER) COMPLEXES

Tetranitromethane is a strong acceptor of electrons and, like Lewis acids, a powerful complexing agent. Its electron affinity has been estimated as 1.7 eV (similar to the value of 1.8 eV for iodine), which is responsible for its great tendency to form complexes with donors[146]. Indeed, one of the most interesting reactions of the compound with alkenes, dienes, arylalkenes, and aryls, yielding a wide range of organic compounds, begins with the formation of charge-transfer complexes, as will be shown below.

The ability of tetranitromethane to form coloured complexes was discovered almost simultaneously by Ostromyslensky[147,148] and by Werner[149] as early as 1909. It is evident as an instantaneous yellow to dark red coloration on addition to a solution of an unsaturated compound. This qualitative test, termed the Ostromyslenskii reaction, is widely used to distinguish tautomeric forms of organic compounds[147,148,150,151] and to detect ethylenic hydrocarbons[152,153], dienes[154], terpenes[155,156], steroids[157], unsaturated ketones[158], dimethylcyclohexanedione derivatives of aldehydes[159], fats and higher unsaturated aliphatic acids[160,161], and aromatic hydrocarbons[150,162-164]. At the same time, this colour reaction is not universally applicable: thus no coloration is observed with benzoic, maleic, and fumaric acids[151], αβ-unsaturated aliphatic acids and their derivatives, αβ-unsaturated aldehydes[154], and halogenated unsaturated compounds[165], owing to the inability of tetranitromethane to form complexes with compounds containing electrophilic groups at the multiple bond. On the other hand, coloured complexes are formed with compounds containing no multiple bond, e.g. cyclopropane[166,167], diethyl sulphide, iodoethane, triethylphosphine, 1,4-dioxan, 1,4-dithian[168-170], dimethyl sulphoxide[171], and various amines[133,172,173]. Not long ago it was proposed that tetranitromethane should be used in the development of chromatograms as a qualitative reagent for organic compounds of bivalent sulphur[174].

Study of the relation between the structure of the unsaturated compound and the colour produced by mixing with tetranitromethane indicated that the intensity of the coloration increased with the basicity of the unsaturated compound[140,175-177]. The ultraviolet spectra of mixtures of aromatic hydrocarbons showed that the colour intensity varied linearly with the concentration of the hydrocarbon and with the number of methyl groups in the benzene ring[178,179].

The mechanism of formation and the structure of the complexes with unsaturated compounds have been discussed since the time of their discovery. Hypotheses involved isomerisation of one or more true nitro-groups into nitrite groups, which form the coloured complex with the alkene[134]. It was assumed also that the coloured complexes were polarised particles retained by electrostatic forces[179,180], or ion-pairs comprising a carbonium ion and a trinitromethanide anion[140,181-183].

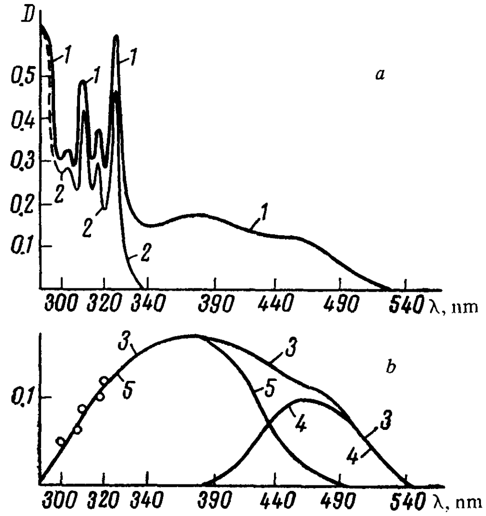


Figure 2. (*a*) Electronic absorption spectrum of 0.80 M tetranitromethane + 0.05 M 2,6-dimethylnaphthalene in heptane: 1) spectrum of tetranitromethane in heptane; 2) long-wavelength region of spectrum of dimethylnaphthalene in heptane. (*b*): 3) spectrum of charge-transfer complex; 4) long-wavelength absorption band of charge-transfer complex; 5) short-wavelength band of charge-transfer complex.

Perekalin et al.[184-189] used electron spectroscopy to study the spectra of the ternary systems formed with a donor and a solvent, in which they detected new bands absent from the initial components, which they ascribed to absorption by the complex. Detailed examination of the charge-transfer spectra with donors, e.g. 2,6-dimethylnaphthalene (Fig. 2), revealed two bands, which were assigned to the same complex[189]. The substantial solvatochroism of the bands due to the complexes, together with their bathochromic displacement with decrease in the ionisation potential of the donor (Table 2), indicated that those at longer wavelengths were intermolecular charge-transfer bands. A modified method of isomolar series throughout the band envelope indicated that the composition of all the charge-transfer complexes was equimolecular[189].

Table 2. Positions of absorption band maxima for charge-transfer complexes in heptane and in nitromethane ν_h and ν_n, extinction coefficients ϵ_{max}, and ionisation potentials *I*.

Donor	ν_h, cm^{-1}	ν_n, cm^{-1}	ϵ_{max}, M^{-1} cm^{-1}	*I*, eV
Anethole	20 400	21 900	720	—
Hexamethylbenzene	20 600	21 850	1 200	7.8
Tetraphenylethylene	20 750	22 950	4 000	—
Mesitylene	25 800	27 350	3 000	8.4
α-Methylstyrene	25 800	28 050	1 100	—
Benzene	31 300	33 000	10 000	9.2

Table 3. Association constants, products $K_c\epsilon_{max}$, and thermodynamic functions of tetranitromethane complexes in heptane.

Donor	K_c	$K_c\epsilon_{max}$	$-\Delta H_c$, kcal mole^{-1}	$+\Delta G_c$, kcal mole^{-1}	$-\Delta S_c$, cal mole^{-1} deg^{-1}
1,1-Di-*p*-methoxyphenylethylene	0.170	93	1.2	1.0	7.5
Anethole	0.114	81	0.9	1.3	7.5
α-Methylstyrene	0.080	88	0.8	1.5	7.8
β-Methylstyrene	0.045	68	0.7	1.9	8.9
Tetraphenylethylene	0.015	60	0.6	2.5	10.6
Hexamethylbenzene	0.153	180	1.5	1.1	8.8
Mesitylene	0.060	180	1.2	1.6	9.7
Benzene	0.020	190	0.9	2.3	11.0

Thermodynamic parameters calculated for several charge-transfer complexes (Table 3) from a spectrophotometric study of the effect of temperature on the association constants[189,190] reveal the weakness of the complexes ($\nu_c \ll 1$, $\Delta H_c \simeq 1.0$ kcal mole^{-1}, $\Delta G_c > 0$). A definite parallelism is evident between the equilibrium constant and the heats of complex formation, with increase in K_c corresponding to increase in the enthalpy[184,190]. The comparatively slight differences in entropy are evidently due to significant polarisation of the charges accompanying formation of the charge-transfer complexes. The closeness of the product $K_c\epsilon_{max}$ (Table 3) to values characteristic of the homologous series of alkenes ($K\epsilon_{max} \simeq 80$),[184] not to those for alkylbenzenes (~180),[187] shows that π-electrons of the multiple bond, not those of the benzene ring, form the centre of coordination in the charge-transfer complexes of arylalkenes.

The complexes become significantly less stable with increase in the dielectric constant of the medium (Table 4). A clear parallelism is evident between *K* and $(\epsilon - 1)/(\epsilon + 2)$.[189] Determination of the dipole moments of the charge-transfer complexes with various hydrocarbons, by the method of spectral shifts (Table 5), was extremely important in establishing the structure of the complexes. From the dipole moments at 20°C and the spectroscopic characteristics a quasi-ionic structure with separated charges (Fig. 3) was attributed to the charge-transfer complexes in the ground state.

Table 4. Association constants of tetranitromethane complexes of anethole and of isodurene in various solvents at 20 ± 0.1°C.

Solvent	(ε−1)/(ε+2)	Anethole	Isodurene
Heptane	0.234	0.114	0.122
Tetrachloromethane	0.292	0.092	0.065
Diethyl ether	0.530	0.018	0.030
Chloroform	0.560	0.012	0.020
Dichloromethane	0.720	0.006	0.008

Table 5. Calculated individual constants C_I^a and dipole moments of complexes.

Donor	α-Methylstyrene	β-Methylstyrene	Anethole	Benzene	Naphthalene
C_I^a av	2700	2500	1700	2000	3000
μ_g, D	6.0	6.0	5.0	5.0	6.5

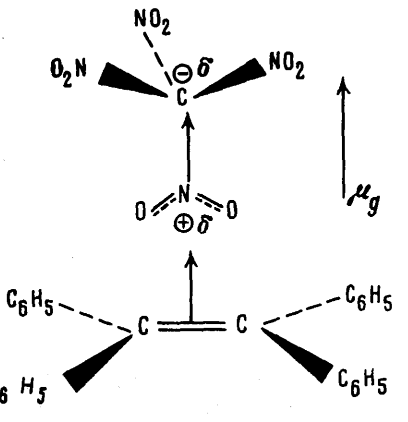

Figure 3. Model of complex of tetranitromethane with tetraphenylethylene.

Existing information on the properties and the structure of the complexes enables us to represent the interaction of unsaturated compounds with tetranitromethane by the scheme

$$\underset{\text{(VI)}}{D + C(NO_2) \rightleftarrows D^{+\delta} \ldots\ldots {}^{-\delta}C(NO_2)_4} \xrightleftharpoons{300\,°K} \underset{\text{(VII)}}{[D \ldots NO_2]^{+\delta}} \ldots {}^{-\delta}C(NO_2)_3$$

$$\rightarrow \text{Transition state} \rightarrow \text{Reaction products}$$

Mixing an alkene with the nitro-compound produces initially charge-transfer complexes of type (VI), which are converted by further interaction of donor and acceptor into charge-transfer complexes with separation of charges (type VII). Redistribution of electron density and change in the steric configuration then convert the latter complexes into a reactive transition state, subsequently settling into the final products depending on its structure and the reaction conditions.

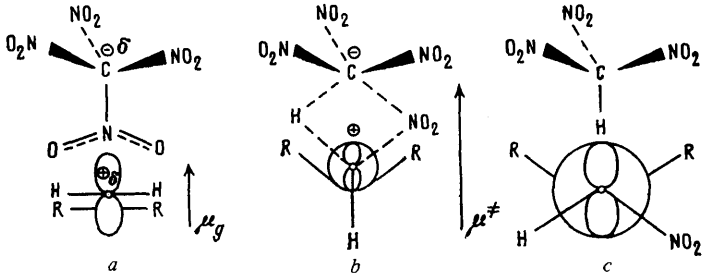
This process was studied experimentally on the reaction with 1,1-di-*p*-methoxyphenylethylene leading to the formation of 1,1-di-*p*-methoxyphenyl-2-nitroethylene (95%). The presence of a sharp isobiestic point in the electronic spectra in different solvents (Fig. 4) confirmed the hypothetical intermediate formation of a charge-transfer complex. Treatment of experimental kinetic results yielded[189] thermodynamic parameters of the limiting stage and dipole moments of the transition state in various solvents (Table 6). The variation from 0.55 to 0.8 in the degree of charge transfer *Q*, defined as the ratio of the dipole moment μ of the transition state to the maximum value $\mu^{\neq}$ for the ion-pair (~20 D), shows that the transition state occupies an intermediate position between the charge-transfer complex and the ion-pair, approaching the latter.

Conversion of the charge-transfer complex via the transition state into the reaction product (the nitroalkene) is shown diagrammatically in Fig. 5. In the complex the π-electron cloud of the double bond of the donor fits into the electron gap of one of the nitro-groups (Fig. 5*a*), which entails weakening of one of the carbon–nitrogen bonds and strengthening of interaction between the cationoid nitro-group and a carbon atom of the multiple bond. The tendency to $sp^2 \rightarrow sp^3$ rehybridisation of the carbon atoms forming the double bond creates favourable steric conditions (rotation about the carbon–carbon bond) for the quasi-carbonium cation (Fig. 5*b*) to settle into the nitroalkene (Fig. 5*c*). Because of the eclipsed configuration and further weakening of the π-bond, state (*b*) has the highest energy content and hence is the decisive transition state. The stage of detachment of a proton is not rate-determining, as is indicated by the absence of a kinetic isotope effect.



R = *p*-$CH_3OC_6H_4$

Figure 5. Models of: *a*) charge-transfer complex; *b*) transition state; *c*) reaction products.

Exposure to monochromatic light of wavelength 405 or 436 nm changes the mechanism of conversion of the charge-transfer complexes and initiates complete transfer of an electron from donor to acceptor with formation of radical-ion species recorded by electron-spin resonance[191–198]. Under the influence of a light quantum the tetranitromethane molecule, by capturing the electron from the donor, passes into an unstable radical-anion, which then breaks down into a trinitromethanide anion and a nitro-radical $\cdot NO_2$. The radical-cation $D^{\dot{+}}$ is stabilised as the nitrocarbonium cation D^+NO_2 by addition of the paramagnetic nitro-radical:

$$D + C(NO_2)_4 \rightleftarrows D^{\oplus\delta}\cdots\cdots{}^{\ominus\delta}C(NO_2)_4 \xrightarrow{h\nu} D^{\dot{\oplus}} + {}^{\dot{\ominus}}C(NO_2)_4 \rightarrow$$
$$\rightarrow D^{\dot{\oplus}} + {}^{\cdot}NO_2 + \overset{\ominus}{C}(NO_2)_3 \rightarrow D^{\oplus}NO_2 + \overset{\ominus}{C}(NO_2)_3 \ .$$

The subsequent course of the reaction is determined by the changes undergone by the trinitromethanide–nitrocarbonium ion-pair.

A radical-ion mechanism is improbable for the reaction with 1,1-di-*p*-methoxyphenylethylene at 300 K), for photoexcitation by a light quantum in the intermolecular charge-transfer band does not influence the rate of transfer, and no induction period is detected even in the presence of oxygen. One-electron transfer may be possible for the reaction with alkenes, terminating in the synthesis of other products, but this mechanism has not been confirmed experimentally.

The alternative of a free-radical decomposition of the charge-transfer complex, leading to a paramagnetic trinitromethyl radical with a subsequent chain reaction, has also been discussed[193–197]. In the absence of illumination at 300 K and of high concentrations of the initial components, however, paramagnetic species are not directly generated by tetranitromethane for alkenes[198]. The nitro-radical and other paramagnetic species sometimes recorded result from thermal decomposition of the nitronic ester of trinitromethane.

Steric rearrangement of the charge-transfer complex by a free-radical mechanism to reaction products is permissible for the reaction with 1,1-di-*p*-methoxyphenylethylene, but the dipole moment of the transition state will then be determined by that of the $(p\text{-}CH_3OC_6H_4)_2C(CH_2NO_2)\cdot$ radical. Comparison of its dipole moment with that of the transition state (~5 and ~15 D) excludes a chain reaction mechanism under the given conditions.

V. CHEMICAL PROPERTIES

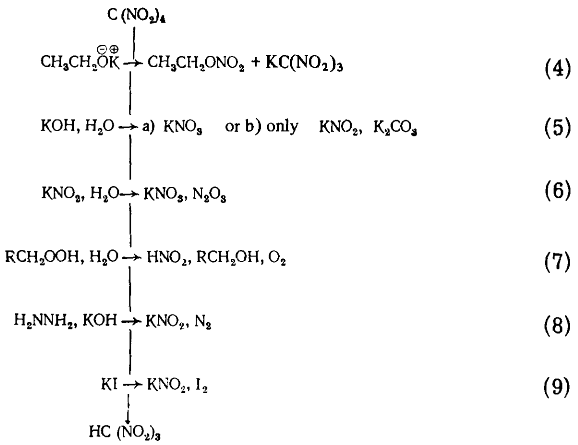
1. Nucleophilic Substitution

The sterically strained arrangement of the four electrophilic nitro-groups in the molecule lowers the activation energy of the carbon–nitrogen bond, enhances the electrophilic character of the carbon atom, usually through the charge-transfer complex stage, and makes it the centre of attack by nucleophilic reagents.

Hantzsch and Rinckenberger[199] found that tetranitromethane is smoothly converted in almost theoretical yield into its salt by the reaction (4) which has remained to the present time the most convenient laboratory method for obtaining trinitromethane (by the action of an alcoholic solution of potassium hydroxide or ethoxide). However, aqueous potassium hydroxide, depending on its concentration, either gives the same results with the formation of potassium nitrate or causes complete degradation to potassium nitrite and carbonate[133,200] (reaction 5). The potassium salt of trinitromethane can be obtained also by the reaction of tetranitromethane with potassium hydroxide dissolved in aqueous glycerol[201].

A patented process of obtaining trinitromethane and its salts is based on the hydrolysis of tetranitromethane in the presence of nitrites of light metals, the consumption of which is diminished by conducting the reaction in the presence of a base—potash, potassium hydroxide, potassium or sodium acetate, etc. (reaction 6).[202] At the same time a detailed kinetic study was made of the reaction of tetranitromethane with hydroxide and nitrite ions[203,204]. The rate-determining stage is formation of a charge-transfer complex in the first case, and in the second case the reaction is of the first order with respect to both tetranitromethane and the nucleophile. Alkyl hydroperoxides are a thousandfold as effective as hydroxide ions in accelerating the reaction[204] (7).

Attempts to obtain the sodium salt of trinitromethane by the action of sodium methoxide on tetranitromethane were unsuccessful[205]. Compounds used as denitrating agents were potassium sulphite and phosphite, hydrazine[206], hydrogen peroxide[24], potassium hexacyanoferrate(II),[207] potassium iodide[208], etc. The reaction with hydrazine can be used for the quantitative determination of tetranitromethane from the nitrogen evolved (8).[206] Phenylhydrazine in the presence of caustic potash converts tetranitromethane into the potassium salt of nitromethane[201]. The reaction of tetranitromethane with sodium sulphite underlay a method for purifying crude trinitrotoluene by washing it with 3–5% sodium sulphite solution[209]. Iodometric[210] and spectrophotometric[211] methods of determining tetranitromethane are based on its reaction with potassium iodide (9) in aqueous alcohol; overall the reaction has the second order, and the first order with respect to each of the components[211,212].



$$C(NO_2)_4 + CH_3CH_2\overset{\ominus\oplus}{O}K \rightarrow CH_3CH_2ONO_2 + KC(NO_2)_3 \quad (4)$$

$$KOH, H_2O \rightarrow \text{a) } KNO_3 \text{ or b) only } KNO_2, K_2CO_3 \quad (5)$$

$$KNO_2, H_2O \rightarrow KNO_3, N_2O_3 \quad (6)$$

$$RCH_2OOH, H_2O \rightarrow HNO_2, RCH_2OH, O_2 \quad (7)$$

$$H_2NNH_2, KOH \rightarrow KNO_2, N_2 \quad (8)$$

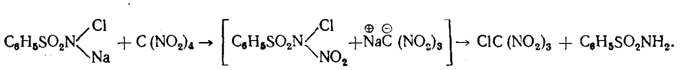
$$KI \rightarrow KNO_2, I_2 \quad (9)$$

$$HC(NO_2)_3$$

The action of lithium, potassium, rubidium, and caesium halides on tetranitromethane in dimethylformamide can be used for the separation of halogenotrinitromethanes[213,214]:

$$C(NO_2)_4 \xrightarrow[-KNO_2]{KX} XC(NO_2)_3$$
$$X = Cl, Br, F.$$

The next two reactions are essentially non-nucleophilic, but yield substitution products. In dimethylformamide and dimethyl sulphoxide tetranitromethane reacts readily with chloramine B to form chlorotrinitromethane via a stage involving *N*-chloro-*N*-nitrobenzenesulphonamide and sodium trinitromethanide[215,216]:



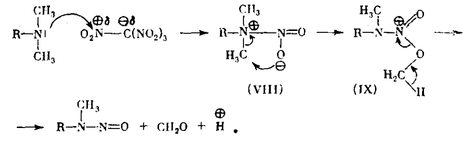
$$C_6H_5SO_2N\genfrac{}{}{0pt}{}{Cl}{Na} + C(NO_2)_4 \rightarrow \left[C_6H_5SO_2N\genfrac{}{}{0pt}{}{Cl}{NO_2} + \overset{\oplus\ \ominus}{NaC}(NO_2)_3\right] \rightarrow ClC(NO_2)_3 + C_6H_5SO_2NH_2.$$

Recent reports[217,218] that a nitro-group in tetranitromethane can be replaced by an alkyl in a medium comprising acetone and Hexametapol or dimethylformamide have aroused interest in connection with a discussion of the reaction mechanism[214,219].

2. Nitrosation of Tertiary Amines

Schmidt[133,220-222] accomplished by means of tetranitromethane the nitrosation of aliphatic and aromatic tertiary amines in pyridine and of ring-halogenated aromatic tertiary amines in acetic acid.

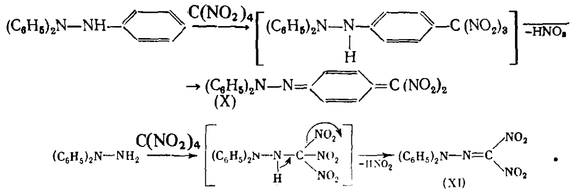
The nitrosation of ethylbenzylamine yields 14% of *N*-nitrobenzylamine and 70% of nitrosoethylbenzylamine[223]. The conversion of tertiary amines into nitrosamines probably involves intermediate formation of a nitroammonium ion (VIII); four-centre transfer leads to rupture of the nitrogen–carbon bond with formation of a nitronic ester (IX), which dissociates into a nitrosamine and an aldehyde[140]:



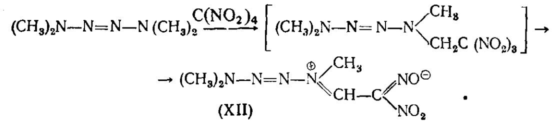
Michler's ketone and *p*-iodo-*NN*-dimethylaniline are probably nitrosated similarly[224]. However, the mechanism of the nitrosation of tertiary amines by tetranitromethane requires further elaboration.

3. *gem*-Dinitromethylation

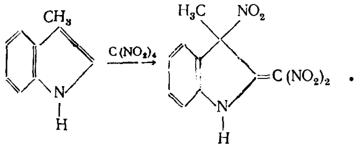
In several cases tetranitromethane acts as a *gem*-dinitromethylating agent as well as an oxidant. Thus with triphenylhydrazine it forms (X),[225] and with *αα*-diphenylhydrazine it gives (XI).[226] In all cases initial trinitromethylation of the nucleophilic compound (as a result of a four-centre transfer) is followed by elimination of one nitro-group, leaving a *gem*-dinitromethylene derivative:



Tetramethyltetrazen is converted into the zwitterion (XII):[227]



With skatole the *gem*-dinitromethylated product contains another nitro-group[228]:



In a brief communication on the reaction of tetranitromethane with cycloalkenes[229] a dinitromethane structure was incorrectly attributed to the main reaction product[230,231].

4. Electrophilic Substitution

Nitroalkanes, *gem*-dinitroalkanes, aromatic hydrocarbons, and arylalkenes having an activated multiple bond undergo mild nitration by tetranitromethane (in an alkaline medium). Mononitroalkanes and *gem*-dinitroalkanes in an alkaline medium yield trinitroalkanes[232,233]:

$$RCH_2NO_2 \xrightarrow{KOH} RCH{=}NOOK \xrightarrow[-KC(NO_2)_3]{C(NO_2)_4} RCH(NO_2)_2 \xrightarrow{KOH}$$
$$\rightarrow RC(NO_2)_2{=}NOOK \xrightarrow[-KC(NO_2)_3]{C(NO_2)_4} RC(NO_2)_3 .$$

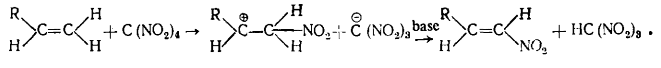
Several aromatic hydrocarbons undergo nitration in the presence of strong nucleophilic reagents (caustic alkalis, pyridine); e.g. *p*-cresol is nitrated to *m*-nitro-*p*-cresol[234], and naphthalene to 1-nitronaphthalene[183]. *NN*-Dimethyl-*p*-toluidine (in a neutral medium) forms with tetranitromethane a salt of trinitromethane and *m*-nitro-*NN*-dimethyl-*p*-toluidine, which on treatment with alkali is converted into *m*-nitromethyl-*p*-toluidine[234]. In the absence of alkali *N*-alkylcarbazoles are nitrated in the ring, slowly but with high yields[235]; nitration is considerably accelerated by ultraviolet irradiation. Kinetic investigation of the nitration of *para*-substituted phenols[236] in water and in 95% ethanol showed in both cases the second order with respect to the phenol, the limiting stage being dissociation of the charge transfer-complex.

The nitration of tyrosine at pH 8.0 by tetranitromethane to 3-nitrotyrosine stimulated intensive research on proteins containing tyrosine residues[237-248]. Alkaline nitration has been used to obtain nitro-derivatives of azulenes. Thus an 85% yield of 1-nitro-2,4,8-trimethylazulene was isolated from the nitration of 2,4,8-trimethylazulene in the presence of pyridine[249,250]. Cyclopenta[*c*]thiapyran gave with tetranitromethane the corresponding mononitro-derivative[251].

Arylalkenes in which the double bond was conjugated with the ring were nitrated by Schmidt[222,234] in the presence of pyridine and acetone to the corresponding β-nitroalkenylarenes: e.g.

$$CH_3OC_6H_4CH{=}CH_2 \xrightarrow[\text{pyridine}]{C(NO_2)4} CH_3OC_6H_4CH{=}CHNO_2 \ .$$

Nitration of the same arylalkenes in methyl and ethyl alcohols yielded α-alkoxy-β-nitro-compounds[222]. Unconjugated arylalkenes[222], containing the double bond in the allyl position with respect to the ring, are not nitrated under these conditions. Bülich[181], Patterson[140], and Titov[252,253] assumed that the reaction with arylalkenes takes place by an ionic mechanism; the formation of conjugated nitroalkenes on alkaline nitration was regarded as the result of consecutive reactions involving the base—electrophilic addition to the alkene of the nitronium cation produced by heterolytic breakdown of tetranitromethane, formation of an ion-pair, nucleophilic attack by the base on the nitrocarbonium cation, and its stabilisation, with elimination of a proton, as a conjugated nitroalkene:

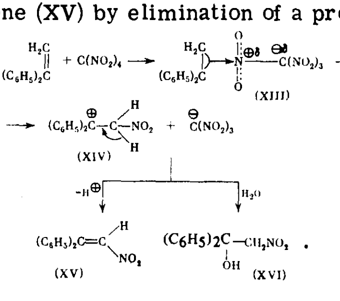


In the absence of bases addition products are formed by tetranitromethane with such alkenes, e.g. p-anethole[254].

5. Electrophilic Addition

A comprehensive investigation by Perekalin and Altukhov[263,264] of the reaction with substituted alkenes, arylalkenes, vinyl ethers, and dienes revealed fundamentally new reaction paths. For example, several conjugated nitroalkenes were obtained by the action of tetranitromethane on alkenes in a neutral medium.

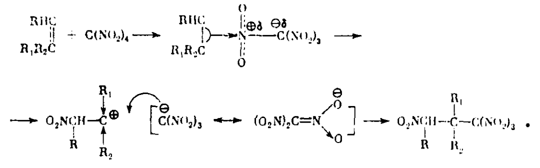
Tetraphenylethylene does not react owing to steric hindrance of the double bond and the absence of ethylenic hydrogen atoms; the behaviour of 1,1-diphenylisobutene is similar. In these cases interaction between the hydrocarbon and tetranitromethane ceases at the charge-transfer complex stage, with equilibrium displaced towards the initial components. When one or two phenyl groups attached to the same ethylenic carbon atom in tetraphenylethylene are replaced by hydrogen atoms, steric hindrance is diminished, and reaction with tetranitromethane becomes possible. Thus triphenylethylene[255], 1,1-diphenylethylene[255,256], and 1,1-di-p-methoxyphenylethylene[257] in the absence of basic catalysts form conjugated nitroalkenes via the stage of a charge-transfer complex (XIII), which is converted by electrophilic incorporation of a nitronium cation into a nitrocarbonium cation (XIV) (with the trinitromethanide anion as gegenion), and this is stabilised as the nitroalkene (XV) by elimination of a proton:



Intermediate formation of an ion-pair is confirmed, in particular in the case of diphenylethylene, by isolation from the reaction medium of the corresponding nitro-alcohol (XVI) resulting from attack by the hydroxide ion (in the presence of water) on the nitrocarbonium cation. The presence of an ion-pair has been established also by electron spectroscopy in the action of tetranitromethane on 1,1-di-p-dimethylaminophenylpropene[258]. Shielding of the cationoid carbon atom by the two phenyl groups excludes nucleophilic addition of the trinitromethanide anion. The reactivity of 1,1-diarylethylenes with tetranitromethane increases with the electron-donating power of the double bond.

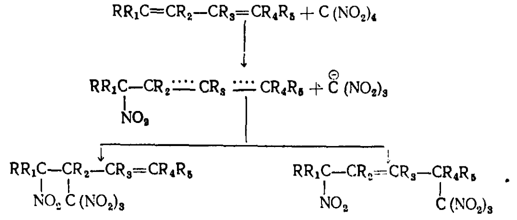
The action on alkenes in which the number of bulky phenyl rings has diminished at least to one at each carbon atom forming the double bond is more complicated and results in different final products depending on steric and electronic factors (alkyl groups adjoining the double bond and substituents in the aromatic ring). This is due to diminished steric hindrance at the cationoid carbon atom of the intermediate nitrocarbonium cation, which enables it to interact with the ambident trinitromethanide anion at its two reaction centres—an oxygen atom of the nitro-group (C-alkylation) and the carbon atom (C-alkylation)—depending mainly on the nature of the nitrocarbonium cation and to some extent on the character of the solvent.

Accumulation of nucleophilic groups in the initial alkene enhances the basic character of the double bond, increases the degree of delocalisation of the positive charge on the electrophilic centre of the nitrocarbonium cation, and causes it to react at the carbon atom of the trinitromethanide anion—the reaction centre having a smaller electron density—to form C-alkylated products (nitrotrinitromethylation)—1,1,1,3-tetranitroalkanes:



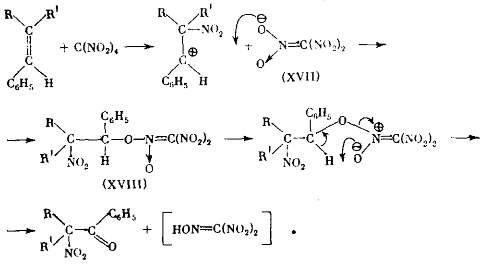
R- Ar ; R_1, R_2- Alk

Such behaviour is exhibited by styrene derivatives alkylated at the α and β positions[259,260], arylcyclenes[231,260], and styrene derivatives *para*-substituted by electron-donating groups[254,257,261–266]. Dienes containing two or more methyl groups also undergo C-alkylation by tetranitromethane[267–269]:



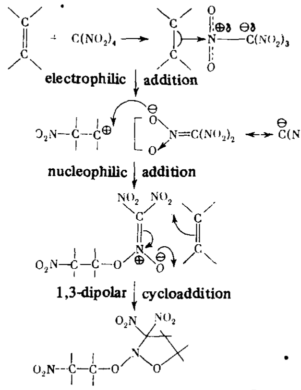
The conjugated nitrocarbonium cation formed reacts with the trinitromethanide anion either at the 1,2-positions (2,3-dimethylbutadiene) or at the 1,4-positions (2-methylpenta-2,4-diene, 2,4-dimethylpenta-1,3-diene, and 2,5-dimethylhexa-2,4-diene) to form the corresponding tetranitroalkenes.

In the action of tetranitromethane on less basic unsaturated compounds the nitrocarbonium cation (XVII) appears with a considerable positive charge on the electrophilic carbon atom, and the trinitromethanide anion adds to it at the nitro-oxygen atom having the greatest electron density (*O*-alkylation) with formation of an unstable nitroalkyl ester of aci-trinitromethane (XVIII), which is a 1,3-dipole capable of 1,3-addition of a second molecule of the alkene. However, the presence even of one substituent (phenyl or alkyl) in the β-position of the initial alkene, i.e. in the styrene derivative, makes addition of a second molecule of the alkene sterically impossible, and the resulting nitronic ester (XVIII) undergoes thermal decomposition by an intramolecular redox reaction with formation of α-nitro-ketones and dinitroformaldehyde oxime[255,257,264,270]:



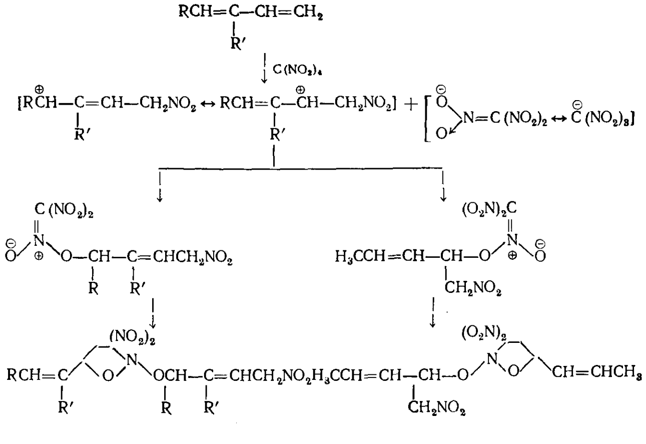
An indispensable condition for this process to occur is the presence of an α-hydrogen atom in the nitroalkyl ester (XVIII). The unstable oxime decomposes with the liberation of nitrogen sesquioxide, which nitro-nitrosates the initial alkene (yield 3–22%) and oxidises part of the oxime to trinitromethane. Formation of nitro-ketones is often accompanied by more fundamental degradative oxidation processes. Thus tetranitromethane reacts with *p*-methoxy-ββ-dimethylstyrene[256] and with cyclohexene[270] in the absence of a solvent to give anisic and adipic acids respectively. Carboxylic acids were obtained also[160] by heating tetranitromethane with elaidic acid, stilbene, and but-2-ene. Tetranitromethane smoothly oxidises quinol to quinone, and dimethylaniline to Crystal Violet[147,151].

The action of tetranitromethane on unsaturated compounds containing adjacent to the double bond less bulky groups than phenyl (ethylene, its alkyl derivatives independently of the number and arrangement of the groups about the double bond, and also allyl and vinyl ethers), as well as styrene derivatives unsubstituted at the β-position, leads to the synthesis of 3,3-dinitroisoxazolidine derivatives[231,255,257,261,270–274]:



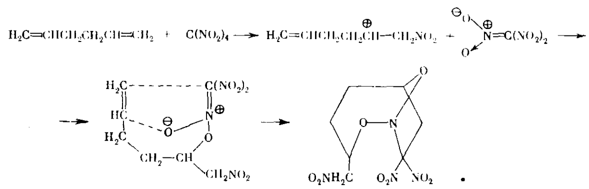
Formation of the charge-transfer complex and the ion-pair is followed by nucleophilic attack on the nitrocarbonium cation by an oxygen atom of the trinitromethanide anion to give a reactive ester of aci-trinitromethane. This reacts synchronously with a second molecule of the initial alkene, by a mechanism of 1,3-dipolar cycloaddition, to give the 3,3-dinitroisoxazolidine derivative.

With $\pi\pi$-conjugated systems tetranitromethane forms 3,3-dinitroisoxazolidine derivatives containing multiple bonds in the side-chains, as a result of 1,4-addition to butadiene and isoprene, and 1,2-addition to pentadiene; cycloaddition takes place only at the less substituted multiple bond in a diene[267,269]:

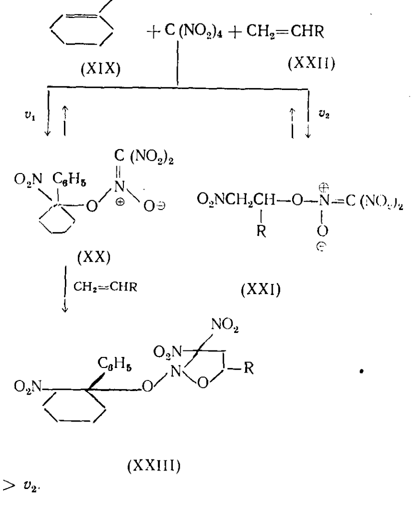


R, R'=H; R=H, R'=CH₃ .

As a result of intramolecular cyclisation of the intermediate nitronic ester the reaction with hexa-1,5-diene yields a bicyclic isoxazolidine[267]:



Intermediate formation of nitronic esters of trinitromethane is supported by the controlled synthesis of substituted 3,3-dinitroisoxazolidines (of mixed composition) from tetranitromethane and two different alkenes[259,275,276]. Initially the reaction of tetranitromethane with the sterically hindered but more nucleophilic alkene (XIX) produces the nitronic ester (XX) more rapidly than the nitronic ester (XXI) is formed from the less nucleophilic and also sterically less hindered alkene (XXII); the ester (XX) then reacts with the sterically unhindered alkene (XXII), and is stabilised as the substituted dinitroisoxazolidine (XXIII) (the steric hindrance in (XIX) makes reaction of the alkene (XIX) with the nitronic esters (XX) and (XXI) impossible):



$v_1 > v_2$.

6. Acceptance of Radicals

A considerable number of studies have been made on the homolytic decomposition of tetranitromethane by the action of bases, ultraviolet radiation, or γ-rays.

Electron-spin resonance has shown that reaction with strong nucleophiles (benzidine, *NNN'N'*-tetramethylbenzidine[277], and sodium 2,4,6-tri-t-butylphenoxide[278]) begins with the appearance of charge-transfer complexes and concludes with formation of the corresponding radical-anions, which break down into anions and radicals, e.g. the 2,4,6-tri-t-butylphenoxyl radical and the trinitromethanide anion. Similar results were obtained for the action of tetranitromethane on 1,3-dicarbonyl compounds in alkaline media or under ultraviolet irradiation[279,280].

A radical-dianion of trinitromethane has been detected in the electrochemical reduction of tetranitromethane in dimethylformamide, acrylonitrile, and water[281]. Photolysis of tetranitromethane by ultraviolet radiation in water and methanol[282], in the presence of ketones, $\alpha\beta$-unsaturated ethers and esters, cyclohexene, styrene[283], and benzene derivatives[198], generates $NO_2\cdot$ radicals. The trinitromethyl radical was not detected owing to its great activity and rapid interaction with the solvent. The fragmentation of tetranitromethane has been studied mass-spectroscopically[284,285].

The radiolysis of tetranitromethane by γ-rays at 77°K is accompanied[286] by its breakdown into $\cdot NO_2$ and $\cdot C(NO_2)_3$ radicals. The latter is represented in the e.s.r. spectrum by a sextet having relative intensities 1 : 3 : 6 : 6 : 3 : 1. However, it is not recorded in solution or in the presence of organic compounds[286-288]. The main products of radiolysis in aqueous solution by cobalt-60 γ-rays are the $\cdot NO_2$ radical and trinitromethane in yield $I = 3.75/100$ eV, which is increased by the presence of small quantities of organic compounds (ethanol, benzene, ethyl acetate, etc.)[289-295].

Being an acceptor of radicals, tetranitromethane effectively slows down the polymerisation and the cross-linking of polymers initiated by radiation[296,297] or by free radicals[298-303]. The "spin echo method" has shown for methyl methacrylate as example that retardation of polymerisation is favoured by increasing the number of nitro-groups in the polynitroalkane[301]:

$$CH_3NO_2 < CH_3COO\,(CH_2)_2C\,(NO_2)_2(CH_2)_2COOCH_3 <$$
$$< CH_3CH\,(NO_2)_2 < (O_2N)_3C\,(CH_2)_2COOCH_3 < C\,(NO_2)_4 \ .$$

Tetranitromethane inhibits the radical polymerisation of methyl methacrylate in the presence of benzoyl peroxide owing to the formation of relatively inactive free radicals causing chain termination; at the same time it accelerates decomposition of the benzoyl peroxide[304]:

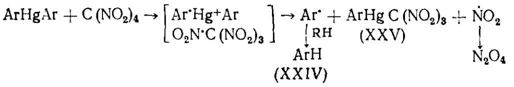
$$(O_2N)_3C\underset{\textstyle OM}{-N}\!\!\longrightarrow O^{\cdot} + M \longrightarrow (O_2N)_3C{-}N{=}O + \sim\!\sim M{-}O{-}M\sim\!\sim \ .$$

M - Monomer

As a strong acceptor of electrons, tetranitromethane initiates ionic polymerisation. Thus oxetan is polymerised by a cationic mechanism on the addition of 1,1-diphenylethylene and tetranitromethane[256], which is explained by formation of a nitrocarbonium cation as initiator. Vinylcarbazole is polymerised similarly[305-307] in the presence of methyl methacrylate (1–10%) and tetranitromethane. Donor–acceptor interaction between tetranitromethane and cyclic sulphides[308] promotes ring opening and subsequent polymerisation.

The rules found in the reactions of tetranitromethane with unsaturated compounds are general in character and can be extended to the reactions of these alkenes with trinitromethane derivatives containing other substituents (chloro-, bromo-, and iodo-trinitromethane, trinitroacetonitrile, trinitroacetic ester). Replacing a nitro-group by a different residue changes the direction of addition of the trinitromethanide anion to the carbonium cation and hence the proportions of the reaction products. For example, the tendency of the intermediate trinitromethanide anion to *C*-alkylation is greater with bromo- and iodo-trinitromethane[309-311].

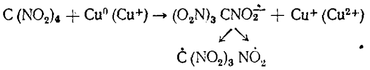
Since the Review was presented for publication several interesting communications have appeared on the chemistry of tetranitromethane. It reacts similarly with mercury and tin aryls[312] and with phenylmagnesium chloride[313]; with aryl derivatives of mercury the products are the corresponding aromatic hydrocarbons (XXIV) and the aryltrinitromethylmercury (XXV). The oxidation involves a stage of one-electron transfer followed by formation of an aryl radical and its interaction with the solvent (RH):



$$ArHgAr + C\,(NO_2)_4 \rightarrow \begin{bmatrix} Ar^{\cdot}Hg^{+}Ar \\ O_2N^{\cdot}C\,(NO_2)_3 \end{bmatrix} \rightarrow \underset{\underset{(XXIV)}{ArH}}{\overset{}{Ar^{\cdot}}\big\downarrow{\scriptstyle RH}} + \underset{(XXV)}{ArHg\,C\,(NO_2)_3} + \underset{N_2O_4}{\dot{N}O_2\big\downarrow} \ .$$

The detection of $\cdot NO_2$, $\cdot C(NO_2)_3$, and radicals from nucleophiles in the photolysis of tetranitromethane and in its dark reaction with various nucleophilic reagents supports the hypothetical one-electron mechanism in several of its reactions with nucleophiles and provides information on possible modes of breakdown of the tetranitromethane radical-anion in the matrix[314].

The reaction with metallic copper probably also involves a stage of one-electron transfer, with formation of the radical-anion (XXVI), which breaks down into the $\cdot C(NO_2)_3$ and $\cdot NO_2$ radicals[315]:



$$C\,(NO_2)_4 + Cu^0\,(Cu^+) \rightarrow (O_2N)_3\,CNO_2^{\dot{-}} + Cu^+\,(Cu^{2+})$$
$$\swarrow\ \searrow$$
$$\dot{C}\,(NO_2)_3\ \ N\dot{O}_2 \ .$$

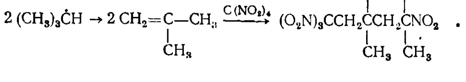
(XXVI)

Discussion has continued on the mechanism of the formation of trinitroethane from iodomethane and tetranitromethane[316]. The mechanism

$$S + C\,(NO_2)_4 \rightarrow \underset{(XXVII)}{S \cdots\cdot NO_2 \cdots\cdot C\,(NO_2)_3} \xrightarrow{CH_3I} CH_3C\,(NO_2)_3 + S + INO_2$$

has been suggested for the process in a polar solvent. In the complex (XXVII) formed by tetranitromethane with the solvent, which was isolated and examined by physicochemical methods, polarisation of a carbon–nitrogen bond facilitates attack by iodomethane and the formation of 1,1,1-trinitroethane.

The formation of 3,3,5-trimethyl-1,1,1,5-tetranitrohexane by the thermolysis of trimethylacetic acid in tetranitromethane is attributed[317] to conversion (which requires further evidence) of the t-butyl radical into isobutene and telomerisation of the latter involving tetranitromethane:



$$2\,(CH_3)_3\dot{C}H \rightarrow 2\,CH_2{=}\underset{\textstyle CH_3}{\underset{|}{C}}{-}CH_3 \xrightarrow{C\,(NO_2)_4} (O_2N)_3CCH_2\overset{\textstyle CH_3}{\overset{|}{\underset{\textstyle CH_3}{\underset{|}{C}}}}CH_2\overset{\textstyle CH_3}{\overset{|}{\underset{\textstyle CH_3}{\underset{|}{C}}}}NO_2 \ .$$

Industrial Applications of Free and Immobilised Enzymes

W.Marconi

The methods for the preparation and purification of immobilised enzymes are briefly reviewed and examples are given of the utilisation in industry (mainly not in the food industry) of enzymes such as amylases, proteinases, cellulases, glucose oxidase, glucose isomerase, lipase, and invertase. Various procedures for the immobilisation of enzymes are described. The principal aspects of catalysis by immobilised enzymes are examined, particularly from the standpoint of the stability of the enzymes, reaction kinetics, and the influence of diffusion. Certain examples of the employment of enzymes incorporated in fibres are presented (hydrolysis of penicillin, cleavage of milk lactose, and isomerisation of glucose). The bibliography includes 65 references.

CONTENTS

In recent years, enzymatic reactions have found extensive applications in chemical and pharmaceutical industries. The present review is concerned with examples of the industrial (in the main not in the manufacture of food products) employment of enzymatic reactions, achieved both with the aid of enzymes in solution and with the aid of immobilised enzymes, which is particularly important in connection with their increasing value as industrial catalysts[†].

I. ENZYMES IN SOLUTION

For technical and economic reasons, microbiological systems are the most important source of enzymes used in industry. The relevant micro-organisms are grown in surface or bulk-phase cultures. Aqueous extracts containing enzymes are then subjected to further treatment by various methods for the purpose of concentration, partial purification, stabilisation, and conversion of the enzyme material into the finished commercial product.

Extracellular enzymes are normally used, which makes it possible to isolate them relatively simply, and does not require the disruption of cells, although nowadays this can be easily done with the aid of modern homogenisers[1]. The scheme for the isolation of enzymes illustrated in Fig. 1 is usually employed[2].

When necessary, preservatives are added, for example, toluene, organic acids, phenolic compounds, quaternary ammonium salts, or sodium fluoride. Enzymes are precipitated by adding to the purified solutions or liquid concentrates, under strictly controlled conditions, precipitants such as organic solvents (acetone, ethanol), inorganic salts (sodium or ammonium sulphate, disodium hydrogen phosphate), or macromolecular compounds [poly(ethyleneglycol)]. The precipitated enzyme, isolated by filtration or centrifugation, is dried at atmospheric pressure or *in vacuo* at a low temperature, and the solid concentrate is ground to the required particle size. The concentrate obtained contains, apart from the required enzyme, other proteins and also moisture, carbohydrates, and inorganic salts[3]. Since the cost of the preparation is usually more important for commercial purposes than high purity, it is

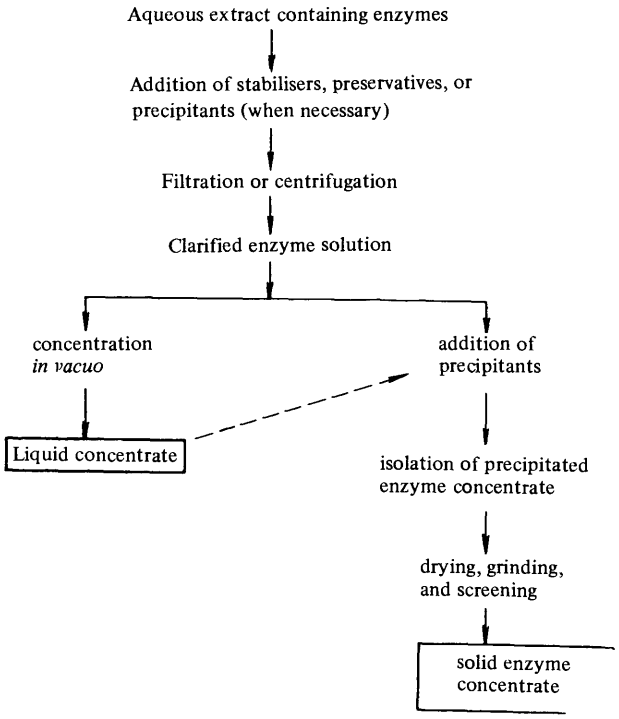

Figure 1. Scheme for the isolation of enzymes.

[†] At the present time, this problem is dealt with most completely in the collected volume edited by I. V. Berezin, "Immobilizovannye Fermenty" (Immobilised Enzymes), Izd. Moskov. Gos. Univ., Moscow, 1975 (a). The kinetic and thermodynamic aspects of catalysis by immobilised enzymes are described by I. V. Berezin, A. M. Klibanov, and K. Marinek, Uspekhi Khim., 44, 17 (1975) [Russian Chemical Reviews, No. 1 (1975)].

not subjected to further purification. However, in certain cases the presence of contaminating enzymes or other substances in the preparation is undesirable if they can have an unfavourable influence on products or processes. Thus the enzymes used for special analytical purposes, certain pharmaceutical processes, and research must be carefully purified[2]. In the manufacture of high-purity enzymes, it is necessary to employ special methods, for example fractional precipitation, differential adsorption and elution[4], chromatography[5], electrophoresis[6], dialysis[7], crystallisation, and lyophilisation.

Table 1. Some industrial enzymes and their microbiological sources[8].

Source	Enzyme	Microorganism
Mould fungi	amylases	*Aspergillus oryzae*
	glucosidases	*Aspergillus flavus*
	proteinases	*Aspergillus niger*
	pectinases	*Aspergillus niger*
	glucoseoxidase	*Penicillium notatum*
	catalase	*Aspergillus niger*
Bacteria	amylases	
	proteinases	*Bacillus subtilis*
	penicillinase	
Yeast	invertase	*Saccharomyces cerevisiae*
	lactase	*Saccharomyces fragilis*

Table 1 lists the commercial enzymes manufactured mainly from various strains of mould fungi, bacteria, and yeast[8]. The most important examples of such enzymes are amylase, certain other carbohydrases, proteinases, glucose oxidase, and pectinase. Methods involving bulk-phase (immersed) cultures are used for their manufacture.

In writing the review of the applications of enzymatic processes in solution in "non-food" industry, the author found that, apart from the manufacture of starch and detergent powders (which will be considered in greater detail in view of their commercial importance), enzymes are used in textile, paper, leather, pharmaceutical, and other branches of industry.

In the textile industry, bacterial amylases are used both for the preparation of modified starch adhesives and for the removal of adhesives from fabrics. Preparations of bacterial amylases, which retain their activity at much higher temperatures than amylases from moulds, have to a larger extent replaced malt and pancreatin. In the paper industry, certain bacterial amylases are used to modify starch for coating paper. Proteinases from *Bacillus subtilis*[9] are employed in the manufacture of tanned leather to remove hair and largely for the softening of leather after tanning by the proteolytic decomposition of gelatin formed from collagen. Such treatment enhances the protective properties and improves the structure of leather[10]. Proteinase preparations should also find future applications as depilatory agents (preparations for the removal of hair) in cosmetics[11].

Mould or pancreatic amylases, proteinases, and lipases and mould cellulases are used as digestion-promoting agents. Steptokinase, trypsin, and other proteinases have found applications in the treatment of wounds and as anti-inflammatory or fibrinolytic agents. Among hydrolytic enzymes, invertase (catalysing the hydrolysis of sucrose to glucose and fructose), used in the preparation of highly concentrated invert sugar syrups and for special purposes, for example for the preparation of soft kinds of chocolate, is of considerable industrial interest. In contrast to the sucrose obtained by acid hydrolysis, enzymatically inverted sucrose does not have an undesirable taste and colour caused by decomposition products (for example, furfural). Of the two possible enzymes hydrolysing sucrose, only β-fructofuranosidase is used. In this case, the centre of attack is the fructose end of the sucrose molecule. This intracellular enzyme, obtained from yeast (usually from *Saccharomyces cerevisiae*), retains its catalytic properties at temperatures of 65–70°C and has the maximum activity at pH 4.5. The purification of invertase by the removal of the majority of impurities increases the sensitivity of the enzyme to physical damage[12]. Unpurified preparations containing small amounts of other enzymes (catalase, hexokinase) are therefore usually employed.

Amylases are extracellular enzymes hydrolysing starch molecules to dextrins and a set of compounds with lower molecular weights consisting of glucose units. They are divided into two classes: endoamylases and exoamylases. Endoamylases act at random on the $1 \rightarrow 4$ linkages in starch, liberating certain reducing groups and forming dextrins with various chain lengths. The $1 \rightarrow 6$ linkages, , which are the branching points in amylopectin and glycogen, are not attacked under these conditions. Exoamylases attack polysaccharides only from the non-reducible terminal groups. They can either cleave each linkage with formation of glucose only (amyloglucosidases) or they can rupture alternate bonds with formation of maltose (β-amylases, which are given this name because the maltose obtained has the β-configuration).

Amyloglucosidases from *Aspergillus niger* are capable of hydrolysing both $1 \rightarrow 4$ and $1 \rightarrow 6$ glucoside linkages in oligosaccharides, but in the latter case the rate of reaction is much lower[13].

Table 2. Microbial amylases*.

Properties	Bacteria		Mould fungi		Other sources	
	solubilisation	saccharification	*Rhizopus*	*A. oryzae* or *A. niger*	*Endomycopsis*	*Oospora*
Thermal stability, °C	65–90	55–70	50–65	55–70	35	50–70

Effect on maltose	—	—	—	—	+	—
Effect on phenylmaltose	—	+	+	+	+	—

*According to data of Dr. J. Fukumoto.

Microbiological α-amylases are obtained either from moulds (mainly *Aspergillus orizae*) or from bacteria (mainly from *Bacillus subtilis*). All the known sources of amylases are listed in Table 2.[13] Commercial α-amylases, obtained from various bacteria and moulds, are characterised by different temperature and pH optima, different stabilities, and different extents to which they decompose starch. In view of its high thermal stability, bacterial α-amylase from thermophilic strains of

Bacillus subtilis can be used to solubilise starch. For this purpose, it is added to the doughy mass of the non-gelatinised starch grains (preferably from potatoes or sweet potatoes), which proceed to the gelatinisation stage and are mixed in the reactor[14]. Industrial processes using glucoamylase from surface *Rhizopus* cultures have been devloped in Japan[15]. Japanese investigators have also suggested that bulk-phase cultures of *Endomyces* strains be used for the preparation of glucoamylase[16]. Processes for the preparation of glucoamylase from *Aspergillus* in immersed cultures have been developed in the USA. This method gives higher yields. The enzyme from *Aspergillus* has excellent properties—a high temperature optimum, a higher stability, and a wider pH range in which it retains its activity.

All commercial glucoamylase preparations must be completely freed from transglucosidase, which is responsible for the formation of small amounts of oligosaccharide impurities, particular isomaltose, which hinder the manufacture of glucose. Several methods have been proposed whereby it is also possible to reduce the content of transglucosidase in glucoamylase preparations: (a) special cultures have been developed, which do not produce transglucosidase; (b) the unpurified enzyme is treated with agents which remove transglucosidase [these include clay minerals[17], sulphonated alcohols[18], $Mg(OH)_2$,[19] and acids[20]]; ion-exchange resins[21] etc. are also employed.

Amylolytic enzymes are used mainly in the manufacture of starch syrups (concentrated aqueous solutions of starch hydrolysates) and crystalline glucose (dextrose). The employment of suitable combinations of α- and β-amylases, amyloglucosidases, isoamylases, or maltases makes it possible to obtain an infinite variety of starch hydrolysis products and hence syrups with any desired properties, for example with a maltose content exceeding 80%.[22]

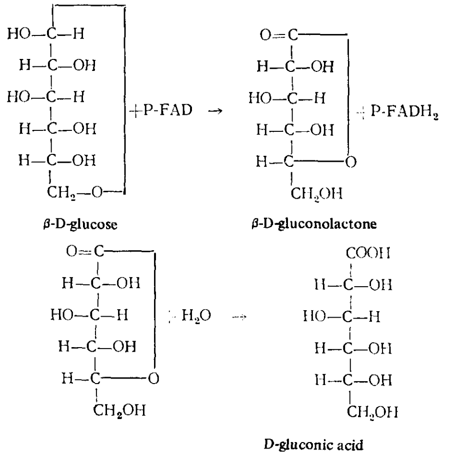
Another interesting enzyme catalysing the conversion of glucose into fructose, is glucose isomerase obtained from certain *Streptomyces* strains and bacteria. Depending on the temperature, the degree of conversion can reach approximately 50%. Since fructose is sweeter than glucose, sweeter syrups can be obtained in this way[14].

Another class of hydrolytic enzymes which are of industrial importance consists of proteinases. They can be of animal origin, for example trypsin, which is obtained from bovine pancreas as a side product after the extraction of insulin and has extensive pharmaceutical applications. Other proteinases are of plant origin, for example ficin, papain, or bromelain, and are mainly used as agents for tenderising meat. Proteinases can be obtained by microbiological methods, with the aid of both mould fungi and bacteria; several species of bacteria are normally employed—such as *Bacillus subtilis*, *Aspergillus niger*, and *Aspergillus oryzae*.

Microbiological proteinases are divided into three groups: acid, neutral, and alkaline[9]. Acid proteinases, which originate mainly from moulds (*Aspergillus*, *Rhizopus*) and are most active in pH range 2–5, are insensitive to the action of compounds with thiol groups, substances forming chelates with metals, and heavy metals, and catalyse the hydrolysis of many peptide linkages. Neutral proteinases are zinc-containing metalloenzymes which are therefore deactivated by chelating agents. The optimum conditions for these enzymes are pH 7–8 and a temperature in the range 45–50°. They do not exhibit esterase activity and mainly cleave peptide linkages of the following type: His-Leu, Ala-Leu, Tyr-Leu, Gly-Phe, and Phe-Phe.

Alkaline proteinases constitute the most important group, since they are widely used in combination with detergents for the removal of stains of protein origin, for example, blood, casein, etc. The most familiar enzymes of this group are subtilisins[9], for example subtilisin *Novo* or subtilisin *Carlsberg* from various *Bacilli* or strains of *Bacillus subtilis*. Alkaline proteinases are active over a wide pH range, from 6 to 11, the maximum activity being shown at pH 9.5–10.5. They exhibit a high esterase activity and cleave peptide linkages of several types.

Proteinases are also used in small amounts in dry cleaning, for the isolation of silver from used photographic film, and for the preparation of protein hydrolysates. Yet another enzyme, namely glucose oxidase, an FAD-dependent aerobic dehydrogenase, has found extensive industrial applications. It converts glucose into gluconic acid with simultaneous formation of equimolar amounts of hydrogen peroxide via the following reactions:



$$\text{P-FADH}_2 + O_2 \rightarrow \text{P-FAD} + H_2O$$

(Here P-FAD = glucose oxidase).

The microbiological source of this enzyme is *Penicillium notatum* and particularly *Aspergillus niger*. The intracellular enzyme from *A.niger* has an optimum in the pH range 4.0–6.5. The commercial enzyme contains catalase, which facilitates its industrial application. Glucose oxidase is used to remove oxygen from preserved non-alcoholic beverages, mayonnaise, and fruit juices, and also for the removal of glucose from eggs before drying.

Catalase, which decomposes hydrogen peroxide to water and oxygen, is used in the manufacture of cheese in order to decompose hydrogen peroxide residues after cold sterilisation, in the manufacture of foam rubber (foam plastics) and porous cement, and to accelerate the bleaching of fur and bird feathers.

Lipase, one of the hydrolytic enzymes, is contained in pancreatin and is produced by many micro-organisms. It is used commercially as an agent promoting digestion, in enzymatic dry cleaning apparatus, for the elimination of waste, and for the decomposition of fats to the fatty acids constituting the basis of ordinary soap[11].

Cellulases are new industrial carbohydrases. The cellulase complex is a mixture of extracellular enzymes (mainly from *Aspergillus niger* or *Trichoderma viridae*)[23] containing, firstly, an enzyme which acts non-specifically, hydrolysing highly oriented solid celluloses (C_1) and, secondly, a multicomponent fraction of $\beta(1 \rightarrow 4)$glucanases (called C_X) both of the exo-type (these remove single glucosidic units from the non-reducible ends of the cellulose chain) and of the endo-type, which yield cellulodextrins, and, thirdly, β-glucodimerases, which act on glucose β-dimers, for example cellobiose. The employment of the cellulase complex from *Trichoderma viridae* made it possible to hydrolyse pretreated cellulose free from lignin to give unpurified extracts containing 8% of glucose[23,24]. Later investigations employing cedar sawdust yielded solutions containing more than 20% of glucose[25]. These extracts can be used to manufacture fermentation products or individual cell proteins. Other promising applications of cellulase may be its use for the removal of plant fibres from wool, or as agents promoting digestion, or for enzymatic dry cleaning.

II. IMMOBILISED ENZYMES

The advantages of immobilised enzymes as catalysts have been described in numerous reviews. Their use in chemical catalysis and automatic analysis is based on the possibility of their repeated use in combination with a high selectivity of the catalysis and a low cost of their preparation and purification; in many cases, the reaction volume can also be reduced. For research purposes, immobilised enzymes can be regarded as specific reagents readily removed from the system, which do not contaminate the products obtained. Furthermore, immobilisation makes it possible to increase the stability of enzymes. Artificially immobilised enzymes can be used, like model systems, to investigate the mechanism of the action of enzymes in biological membranes.

For biomedical purposes, enzymes can be used only in the immobilised form, in order to prevent the allergic response by the organism or undesirable interactions between the enzyme and individual components of the organic solutions being treated. Covalently bound enzymes have assumed increasing importance in the isolation of coenzymes and natural enzyme inhibitors by affinity chromatography from unpurified extracts or partly purified solutions.

These varied and attractive possibilities drew the attention of many investigators during the last few years to the investigation of immobilised enzymes. Various methods for the preparation of immobilised systems have been discovered and the activities of the enzymes obtained have been investigated. The theoretical aspects of the kinetics of the action of these enzyme systems are being vigorously studied together with the engineering problems of the construction of reactors using immobilised enzymes.

Immobilisation Methods

In the discussion of the problem of the utilisation of immobilised enzymes as industrial catalysts, we shall consider only relatively cheap carriers and simple methods for the attachment of enzymes.

Four main methods are used to prepare water-insoluble enzymes: (a) physical incorporation (i.e. incorporation into porous materials, whose cavities are bounded by walls impermeable to proteins but allowing the passage into the cavities of substances with low molecular weights). As an example of such carriers, one may quote polyacrylamide or starch gel, microcapsules, and fibrous matrices. (b) Covalent binding of enzymes to organic or inorganic carriers via the reactions of the functional groups of the proteins which are not responsible for catalytic activity. (c) The formation of covalent intermolecular bonds in the interaction of enzymes with the corresponding bifunctional reactants. (d) Adsorption on insoluble matrices (on ion-exchange resins or an inert support, for example as a result of hydrophobic interactions).

A combination of (c) and (d), i.e. adsorption of the protein on an appropriate carrier followed by the formation of intermolecular bonds, is being successfully used. Table 3 presents some of the most important examples of covalent binding.

We shall now consider the advantages and disadvantages of some of the immobilisation methods quoted above.

Table 3. Methods for the covalent binding of enzymes.

Activator	Carrier
Isothiocyanate	Sephadex Enzacryl AA
Azide	CM-cellulose Enzacryl AH
Carbodi-imide	CM-cellulose acrylamide – acrylic acid
Maleic anhydride	ethylene – maleic anhydride copolymer
Diazo-compounds	Enzacryl AA Polystyrene *p*-aminophenylalanine – leucine copolymer
Cyanogen halide	cellulose Sephadex polysaccharide
N-Ethyl-5-phenyl-isoxazolium-3-sulphonate	polyacrylic acid polyglutamic acid CM-cellulose
Trichloro-*s*-triazine	cellulose DEAE-cellulose DE-cellulose
Glutaraldehyde	AE-cellulose nylon
Silane	glass
Bisdiazobenzidine-2,2′-disulphonic acid	collodion

Physical incorporation in the gel. The inclusion of enzymes in gels such as three-dimensionally "cross-linked" polyacrylamide or starch has the advantage that it can be carried out under fairly mild conditions. Here the carrier has a minimal influence on the immobilised enzyme. The absence of covalent bonds between the enzyme and the matrix makes this method applicable, in principle, to any enzyme.

The relative inaccessibility of enzymes to substrates with large molecular weights, the appreciable influence of the diffusion of substrates and products, and the possible losses of the enzyme as a result of its elution from loose network gels must be regarded as disadvantages of the method[26]. An interesting variety of this immobilisation procedure involves enclosure in microcapsules[26] made of thin spherical semipermeable nylon or collodion membranes, which are used mainly for biomedical purposes.

Incorporation in fibrous structures. The method of incorporating enzymes in a fibrous structure developed in our laboratory belongs to the category of physical incorporation method. It involves the preparation of an emulsion by mixing an aqueous solution of the enzyme with a solution of the polymer in a solvent immiscible with water. The emulsion is then forced through thin draw plates into an immiscible liquid, which results in the coagulation of the polymer[28]; the protein is then included in the pores of the moist, coiled synthetic fibre. The pore size can be varied within certain limits by altering the experimental conditions. Fig. 2 presents an electron microscope photograph of a transverse section through the fibre. This "trapping" technique is very simple, can be applied to any proteins, and makes it possible to achieve both the simultaneous incorporation of several different proteins in the matrix and the incorporation of large amounts of a single protein. The purity of the protein does not affect the "trapping" and the method can be used to incorporate individual organelles, cells, or spores. The enzymes incorporated into the matrix by this procedure are protected from the action of microbes and macromolecular substances produced by microbes, for example proteinases.

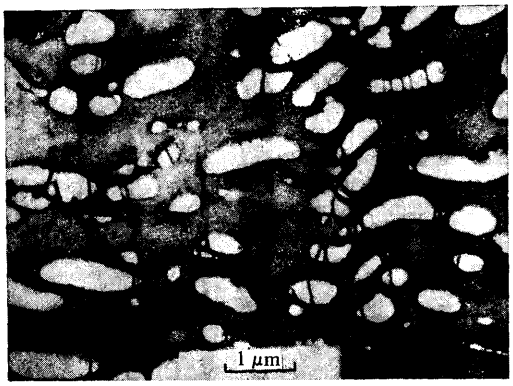


Figure 2. An electron microscope photograph of the transverse section through polymeric fibres.

Evidently in the future it will be possible to increase the stability of the incorporated enzyme by selecting as carriers polymers capable of interacting with the protein globule of the enzyme, stabilising the latter.

Covalent binding. The covalent binding of enzymes to a solid matrix is one of the most widely used methods which have been investigated in detail. Covalent binding has the advantage that the systems obtained are not broken down by altering the pH or the ionic strength and following the addition of the substrate. However, by altering the chemical structure of the enzyme, this method of binding can also alter its reactivity (either as a result of the blocking of the active enzyme centre by the binding reaction or as a result of the involvement in the reaction of the aminoacid residues which participate in the mechanism of enzyme action[26]). Mild conditions, moderate ionic strengths, pH 4–10, and a temperature in the range 0–35°C should obtain during the fixation process. In the course of immobilisation, the active site of the enzyme must be protected by employing covalent blocking agents or by carrying out the reaction in the presence of a substrate or inhibitors. The carrier must be hydrophilic, its porosity must be high, and it is usually necessary to convert it into an active form for reaction with the enzyme. The particle size determines to a large extent the amount of bound enzyme per gram of carrier[29]. An increase of the surface area of the carrier increases the amount of bound enzyme per unit weight and an increase of the number of hydrophilic regions in the polymer also usually increases its binding capacity.

The most suitable centres for the binding of enzyme molecules to the matrix are the terminal amino-groups as well as the lateral amino groups in the lysine residues. The imidazole rings of histidine and the guanidine groups of arginine can participate in the binding process. The acid carboxy-groups of the glutamic and aspartic residues and the C-terminal groups of the proteins can also be effective. Another binding site may be the hydroxyphenyl group of the tyrosine residue, which readily interacts with diazonium reagents.

The immobilisation of enzymes by the formation of intermolecular bonds has been achieved successfully using bifunctional reagents containing two identical functional groups[30] as well as different groups or groups having different reactivities.

It is noteworthy that, although the method of covalent binding of enzymes to suitable carriers does prevent the elution of the enzyme and makes it possible to control the physical properties and particle size of the final product, nevertheless it suffers from certain limitations owing to the sensitivity of many enzymes to chemical modification[30].

Adsorption and methods involving the formation of cross links. Various adsorbents are used to adsorb enzymes—both charged resins and neutral surfaces. The adsorption method does not guarantee complete immobilisation. High concentrations of the salt or substrate increase the rate of desorption of the enzyme. This can be avoided by the formation of intermolecular bonds in proteins after their adsorption. Thus highly active synthetic membranes have been obtained by the formation of a "network" of enzyme molecules adsorbed on collodion[30] or on cellophane membranes[31], or by the formation of a network of enzyme and inactive protein molecules[31].

III. PRINCIPAL ASPECTS OF CATALYSIS BY IMMOBILISED ENZYMES‡

Stability of Immobilised Enzymes

The activity of immobilised enzymes, referred to unit weight, depends on the amount of bound enzyme, which can vary from several milligrams to several grams per gram of carrier, and on the activity of the enzyme itself, which varies from <10% to >100% of the initial value and can actually exceed the activity which the enzyme would have had in the same amount in solution. This depends largely on the various microenvironments of the enzyme on the surface and in the pores of the polymer matrix.

Immobilisation as a rule increases the effective lifetime and thermal stability of the enzyme, but in some cases the opposite effect is also possible: a carrier containing hydrophobic groups to a large extent denatures the protein, while a hydrophilic carrier with a positive or negative charge can influence the stability of the immobilised enzyme as a result of electrostatic interactions between the bound enzyme and the carrier[30]. Proteolytic enzymes are stabilised on immobilisation also because their autolysis is prevented.

The form of the pH dependence on the activity of the immobilised enzyme can differ appreciably from the

---

‡ These processes are described in greater detail in Berezin's collective volume (a) and particularly in the review of Berezin et al. (b) (see the footnote to p. 1067).

analogous relation for the same enzyme in solution owing to the changes induced by the polyelectrolyte carrier molecule on the effective acid dissociation constants of the ionisable groups in the active centre of the enzyme. However, more important interactions of the charge–charge type take place between the ionic charges of the substrate or other components in solution and the residual charges on the matrix. If the solution components have a charge opposite to that of the matrix, their concentration near the surface and in the pores of the matrix becomes higher than in the bulk of the solvent; the opposite behaviour is observed for charges of the same sign[33]. For example, the alkaline branch of the pH dependence of the activity of ficin bound to CM-cellulose is displaced by 0.5 of a unit towards higher pH values, since the concentration of protons within the matrix increases owing to their interaction with the field of the negatively charged carboxy-groups[33]. These anomalies disappear at high ionic strengths.

Reaction Kinetics

Enzyme molecules are bound to the carrier as a rule at several points, which leads to the formation of a certain number of cross links and this may hinder the access of the substrate to the bound or shielded enzyme molecule[34]. Another factor influencing the concentration of the substrate in the microenvironment of the active centre of the bound enzyme is diffusion. The particles of the immobilised enzyme in an aqueous suspension are surrounded by an unstirred layer of solution in which a substrate concentration gradient is established[35]. As a result, the saturation of the immobilised enzyme by the substrate takes place at substrate concentrations higher than are required for the saturation of the active centre in solution. This leads to an increase of the effective Michaelis constant. Owing to diffusion, insoluble enzymes exhibit an activity maximum only at fairly high rates of stirring of the solution[36–38]. An example of the favourable influence of diffusion is provided by insoluble polyenzyme systems which are more effective than the individual enzymes in solution, since the product formed in the initial stages does not diffuse instantaneously into the bulk phase but remains on the support at high concentrations, which favours the subsequent stages of the reaction[39].

The effective Michaelis constant for the immobilised enzyme depends on the charge of the matrix if the substrate is also charged[26]: it increases when the signs of the charges of the matrix and the substrate are the same, since the substrate is repelled by the matrix, and decreases for the opposite signs of the charges, since the substrate is then attracted to the matrix and its concentration in the microenvironment of the enzyme is higher than in the bulk of the solution. The Michaelis constant can vary by an order of magnitude and more as a result of these factors.

IV. EXAMPLES OF THE POSSIBLE INDUSTRIAL APPLICATIONS OF IMMOBILISED ENZYMES

Separation of Racemic Mixtures

Numerous studies have been made on the resolution of DL-aminoacids using acylases obtained from microorganisms and pig kidneys.

Chibata and coworkers[40-46] were successful in separating DL-methionine on acylases. There have been reports about the construction of an industrial apparatus with an output of 20 tonnes per month. The author used various methods for the immobilisation of enzymes: (a) ionic adsorption on DEAE-cellulose and DEAE-Sephadex; (b) covalent binding to iodoacetylcellulose; (c) incorporation in a polyacrylamide gel.

Pig kidney acylase, incorporated in fibrous cellulose triacetate, was investigated in the author's laboratory. A highly reactive catalyst was obtained (17 700 μmole h^{-1} per gram of dry fibre at 37°C). Under the conditions of their utilisation at 25°C, the activity of these fibres fell by 25% in 650 h, during which 550 g of L-methionine had been obtained per gram of the dry fibre.

Saccharification of Starch

Lilly and coworkers[47] carried out the covalent binding of amyloglucosidase to DEAE-cellulose with the aid of 2-amino-4,6-dichloro-*s*-triazine. The activity of the resulting enzyme is not specific. However, one should note that it remains constant during 28 days of employment of the enzyme. In a subsequent study[48], it was reported that the protein can be bound in amounts up to 120 mg per gram of carrier and that the activity is approximately 20–30% of that of the initial enzyme. Under the experimental conditions at 50°C, the activity decreases by approximately 30% in 21 days, but at 25°C the enzyme is completely stable.

Smiley and coworkers[49] investigated the ionic binding of amyloglucosidase to DEAE-cellulose. It was found that the activity is 55% of the initial value and remains constant for three weeks at 40°C. Amyloglucosidase from *Aspergillus niger*, incorporated in a polyacrylamide gel[50], has an activity equal to 20% of that of the enzyme in solution, a high thermal stability, and a pH dependence analogous to that for the initial enzyme. The activity persists for approximately 15 h at 60°C and then decreases at a rate of 1.5% per hour. At 50°C the activity is constant for 150 h, after which inactivation begins.

Glucoamylases incorporated in cellulose triacetate fibres were investigated in the author's laboratory[51]. The activity of the insoluble residues in relation to solubilised starch is one tenth of its activity in relation to maltose (possibly because the diffusion of starch molecules, having a high molecular weight, is hindered). The activity of fibres with attached enzyme remains constant during employment for six months in the reaction with maltose at 25°C; in 30% solutions of solubilised starch at 45°C, the activity of the fibres persists for 300 h.

A method has been proposed for the separation of the reaction products from the enzyme and the substrate by means of ultrafiltration membranes[52]. In this case, the enzyme is retained by the membrane and can be used again.

The covalent binding of amyloglucosidase to porous glass was achieved recently[53]. The yield of the binding reaction amounts to 40–60% and may even reach 80%. In the usual method of preparation at 45°C, the average lifetime is 650 days. It has been calculated that 500 columns (with a volume of one cubic foot, i.e. 0.028 m^3) with immobilised glucoamylase would produce sufficient glucose to supply the requirements of the USA.

Numerous studies have been made on the immobilisation of α- and β-amylases. However, the activity of the resulting insoluble derivatives is very low (6–15%) and their stability is unsatisfactory. The immobilisation of pullulanase[54] by covalent binding to the acrylamide–acrylic acid copolymer with the aid of carbodi-imide was reported recently. The degree of binding is 34% and the activity 43%, but the system obtained is unstable.

Isomerisation of Glucose

Glucose isomerase has been immobilised by incorporation in polyacrylamide gel and also as a result of its covalent binding to porous glass. The enzyme proved to be unstable in both cases.

Experiments have been carried out on the incorporation of glucose isomerase in cellulose triacetate fibres[55]. Highly active fibres were obtained and the activity remained virtually constant for two months at 45°C.

The Reduction of Lactose in Milk Products

Immobilised β-galactosidase has been obtained by various investigators. For example, Sharp et al.[56] achieved the covalent binding of the enzyme from *E.coli* to triazinylcellulose derivatives. The stability of the specimens obtained depended markedly on temperature and the presence of possible poisons.

The treatment of milk with immobilised fungal lactase, obtained in the polymerisation of acrylic monomers in the form of spherical pellets, has been reported[57]. The amount of enzyme incorporated is 5.6 mg per gram of carrier. The activity of the specimens is 36%.

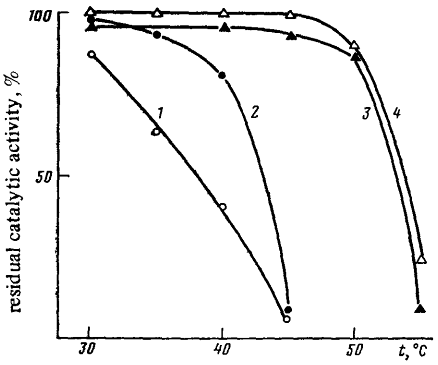

Figure 3. Thermal stability of free yeast β-galactosidase: 1) after incubation for 22 h; 2) after incubation for 6 h; thermal stability of free β-galactosidase from *E.coli*: 3) after incubation for 22 h; 4) after incubation for 6 h.

The properties of yeast β-galactosidase incorporated in cellulose triacetate fibres have been investigated in the author's laboratory[58,65]. The activity of the immobilised β-galactosidase is about 40% of the activity of the free enzyme. Both the free and the immobilised enzymes have an activity maximum at pH 6.0–7.0 (Fig. 3) and 37°C. Milk and pure lactose are hydrolysed at approximately the same rates. The immobilised galactosidase retains the initial activity during employment for 80 days. When very active fibres containing 1500 units of the enzyme per gram of fibre are used, it is possible to hydrolyse milk lactose at low temperatures (5°C) without the risk of altering the organoleptic properties of the treated milk/or of contamination by bacteria (Table 4). The experimental apparatus operating under these conditions demonstrates the possibility of the industrial hydrolysis of milk lactose, which would solve the problem of the elimination of lactose from food products.

Table 4. The influence of the density of filling of columns with cellulose triacetate fibre incorporating yeast β-galactosidase on the hydrolysis of milk lactose.

Amount of fibre, g per ml of column volume	Degree of hydrolysis of milk lactose, %*			
	30 min	60 min	120 min	180 min
0.115	7.75	12.4	23.7	33.7
0.250	7.75	15.0	27.0	38.5
0.400	11.0	14.4	29.8	40.7

*500 ml of milk at 25°C circulated through the column at a rate of 10 litre h^{-1}.

Hydrolysis of Penicillin

Penicillin acylase has been immobilised by covalent binding to derivatives of chloro-*s*-triazinylcellulose[59,60]. It has been shown[59] that the immobilised enzyme has an activity of 25% of the value in solution and retains it during employment for eleven weeks at 37°C. In another investigation[60], the best specimens had an activity between 70 and 120 μmole min^{-1} per gram of carrier, which is 45–80% of the activity of the enzyme in solution.

Penicillin acylase from *E.coli* has been immobilised in the author's laboratory[61] on cellulose triacetate fibres. The activity reaches 40 μmole min^{-1} per gram of carrier and remains constant for 150 days at 37°C. The degree of hydrolysis of penicillin on the enzyme amounts to 98%.

Insoluble specimens with an activity of 110 μmole min^{-1} per gram of carrier have now been obtained in the author's laboratory; with their aid, it is possible to hydrolyse a 12% solution of penicillin in a short time. The synthesis of ampicillin from 6-aminopenicillanic acid and phenylglycine esters has been achieved on the same fibres in a yield of about 70%. Furthermore, the hydrolysis of cephalosporins, which are penicillin derivatives, also takes place in a high yield.

Rearrangements in Steroids

The cells of *Curvularia lunata* trapped in a polyacrylamide gel are used for the 11-β-hydroxylation of Reichstein compounds[62]. The same paper reports the preparation of immobilised *Corynebacterium simplex* cells, which retain the Δ-1-dehydrogenase activity and can be used in columns. However, in both cases the activity of the systems is too low for industrial application.

Consecutive Reactions

The possibility of catalysing a number of consecutive reactions without the isolation of intermediates is of great theoretical and practical interest. Brown et al.[63] investigated the cleavage of glucose by four glycolytic enzymes: hexokinase, phosphoglucoisomerase, phosphofructokinase, and aldolase. The enzymes are incorporated in a polyacrylamide gel and placed in a column in the required sequence.

Mosbach and Mattiasson[39,64] investigated enzyme complexes bound to the same matrix. They obtained[39] β-galactosidase, hexokinase, and glucose-6-phosphate dehydrogenase bound to Sephadex. It was found that a bound complex of this kind has a higher activity than in solution; the authors explained this by the influence of diffusion.

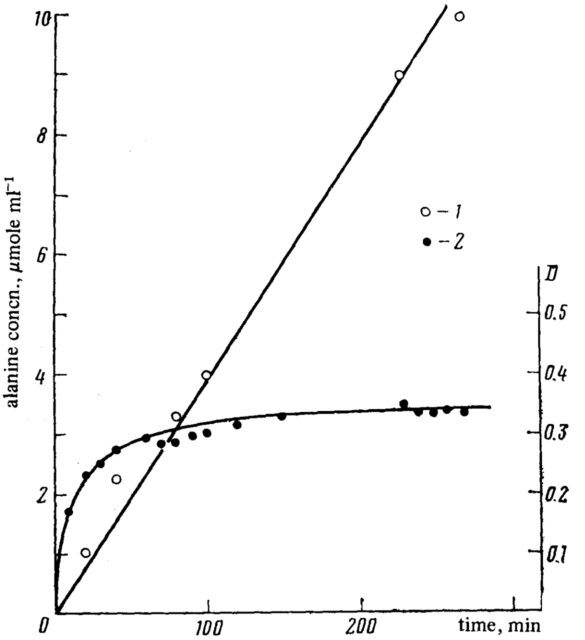

Figure 4. Kinetics of the formation of alanine catalysed by lactate dehydrogenase and alanine dehydrogenase immobilised on fibres: 1) increase of alanine concentration; 2) variation of NADH concentration (D = optical density at 340 nm).

Lactate dehydrogenase and alanine dehydrogenase have been incorporated in fibres in the author's laboratory in order to obtain alanine from lactate and ammonia:

$$(1)\ CH_3CHOHCOO^{(-)} + NAD^+ \rightleftarrows CH_3COCOO^{(-)} + NADH + H^+ \ ;$$

(2) 
$$CH_3COCOO^{(-)} + NH_3 + NADH + H^+ \rightleftarrows CH_3{-}\underset{NH_2}{\underset{|}{CH}}{-}COO^{(-)} + NAD + H_2O \ .$$

Fig. 4 presents typical kinetic curves showing that the concentration of alanine increases linearly, while the concentration of NADH reaches a steady-state value in approximately 100 min. The time required for the attainment of a steady-state concentration is determined by the diffusion of NADH from the microcavities in the fibres to the bulk of the solution.

Charge Transfer in Complexes of the Donor-Acceptor Type

O.Kh.Poleshchuk and Yu.K.Maksyutin

Data on the application of physical methods for the estimation of the degree of charge transfer and the nature of charge distribution in complexes of the donor-acceptor type are examined and described systematically. The dipole moment method, infrared spectroscopy, nuclear quadrupole resonance, Mössbauer spectroscopy, X-ray electronic spectroscopy, and quantum-chemical calculations are considered.
The bibliography includes 105 references.

CONTENTS

I. INTRODUCTION

Numerous studies have been devoted to donor–acceptor interaction and the results have been surveyed in a number of reviews and monographs[1-9]. Interpretation of the experimental data in terms of thermodynamic parameters (equilibrium constants, enthalpy, and entropy) does not as a rule present special difficulties. Complexes of different compositions, with different initial components and with different numbers and structures of the latter, can be compared in terms of these parameters, i.e. thermodynamic parameters are to some extent universal. Interpretation of data is somewhat different as regards the structural aspect. In this case, only a comparison is made in terms of spectroscopic data and other characteristics. A general interpretation of the experimental data therefore requires the selection of universal parameters of the same type as in the study of the thermodynamics of the complexes. We believe that such parameters should be charge transfer and the nature of charge distribution in the complex. They are in fact responsible for the changes in structure and physicochemical and chemical properties on complex formation. Unfortunately the available data on charge transfer have not been arranged in an adequately systematic form.

In the present article, an attempt is made to review such estimates of the degree of charge transfer and of the nature of charge distribution in complexes of the π_σ, n_σ, π_v, and nv types. Data on charge transfer in $\pi\pi$ complexes have been adequately described in a number of communications[2,3,5,6] and are not therefore dealt with in the present review.

II. THE EFFECTIVE CHARGE

The concept of the charges of atoms in molecules is fundamental for the description of the electronic structures of chemical compounds. Naturally, complexes constitute merely a specific instance. It is therefore necessary to elucidate the definition of the charge of an atom in an individual molecule and to specify its physical significance.

The simplest and clearest description of the electronic structure of molecules involves the attribution of effective charges to atoms in the molecules†. It is understood that the very concept of the charge depends on the experimental method used to determine it. It is known that an atom in a molecule does not retain its "individuality" and the greater its loss, the less adequate is the description of the observed properties of the molecule in terms of purely atomic characteristics[12]. However, at the present state of development of theoretical chemistry one can employ with some caution the concept of the effective charge of an atom to describe the experimentally observed characteristics[13].

The model of the effective charge presupposes that the entire electronic charge of the atom can be represented by a point charge, coinciding with the nucleus. We shall assume after Mulliken that the electron density resulting from the overlapping of the wave functions of the atoms is shared between them in accordance with their non-equivalence. On the other hand, Levdin began with a basis set of atomic orbitals subjected to preliminary orthogonalisation[12]. There is then no need for assigning the overlap densities to the atoms. In principle, Levdin's definition of the effective charge reflects more satisfactorily the true charge distribution in the molecule, but so far virtually all investigations have been based on the analysis of Mulliken populations. In the present review, we shall therefore also estimate the effective atomic charges by Mulliken's method[2,14,15].

The formation of a complex of the donor–acceptor type is known to be caused by charge transfer from the donor to the acceptor[9]. We shall therefore consider charge transfer in the ground state of the complex and shall confine ourselves to an examination of the simplest wave function of the ground state (ψ_N):

$$\psi_N = a\psi_0(DA) + b\psi_1(D^+A^-). \tag{1}$$

The coefficients a and b in Eqn. (1) characterise the fractions of the structure "without bonds" and of the structure with complete charge transfer. When the ratio b/a is small, the fraction of the state with charge transfer is likewise small and the complex is stabilised mainly by electrostatic forces (dipole–dipole, dipole–induced dipole, ion–dipole, etc.). When b/a is large, the contribution of the charge-transfer state is likewise large and the forces caused by charge transfer can appreciably exceed the usual intermolecular forces.

The coefficients a and b are related by the normalisation condition:

$$\int \psi_N^2 d\tau = 1 \quad \text{or} \quad a^2 + b^2 + 2abS_{01} = 1 \ ,$$

where S_{01} is the overlap integral of the wave functions ψ_0 and ψ_1. Here S_{01} is linked to the overlap integral S_{DA} of the wave functions of the donor (ψ_D) and acceptor (ψ_A) in the following way[9]:

$$S_{01} = \frac{\sqrt{2}\,S_{DA}}{(1 + S_{DA}^2)^{1/2}} .$$

The degree of charge transfer has been defined in different ways by different workers: b^2, $b^2/(a^2 + b^2)$, and $b^2 + abS_{01}$. It follows from estimates of Mulliken populations that the degree of charge transfer is more correctly characterised by the quantity $b^2 + abS_{01}$. For weak complexes, where $b \ll a$, different definitions of charge transfer lead to virtually identical numerical results, but for strong complexes the differences are significant. In all cases, we chose the same definition of the degree of charge transfer in terms of the quantity $\Delta = b^2 + abS_{01}$. The results presented in the Tables have been recalculated in those cases where the authors used other definitions of the degree of charge transfer.

There are many physical methods which make it possible to estimate the transferred charge in complexes and such estimates are based on Mulliken's definition of the charge. The methods include electronic absorption spectroscopy, the dipole moment method, infrared spectroscopy, nuclear quadrupole resonance (NQR), nuclear gamma-resonance (NGR) or the Mössbauer effect, X-ray electronic spectroscopy, and quantum-chemical calculations. Electronic spectroscopy permits the estimation of the coefficients a and b only for very weak complexes and we shall not therefore consider results obtained by this method.

Since the application of such different research techniques leads in essence to an adequate estimation of the degree of charge transfer, it is of interest to compare the transferred charges and the nature of their distribution in complexes, obtained by different methods for the same compounds.

III. THE DIPOLE MOMENT METHOD

One of the first methods used to investigate charge transfer in complexes was the dipole moment method. This method is very sensitive to changes in the charge distribution in the molecule, partial transfer of electron density from the donor to the acceptor resulting therefore in the generation of a very significant additional dipole moment.

Briegleb[3] obtained an expression for the dipole moments of the complex (μ_N):

$$\mu_N = a^2\mu_0 + b^2\mu_1 + abS_{01}(\mu_1 + \mu_0),$$

where $\mu_0 = \mu_D + \mu_A$ is the vector sum of the dipole moments of the non-interacting donor and acceptor for a specified configuration of the complex and μ_1 is the dipole moment of the complex with complete charge transfer. For convenience, the expression can be transformed as follows:

$$\mu_N - \mu_0 = (b^2 + abS_{01})(\mu_{DA} + \mu_D' + \mu_A' - \mu_D - \mu_A), \tag{2}$$

---

† An attempt was made recently to formulate a general quantum-mechanical definition of the charge of an atom in a molecule and of bond orders[10,11]. This approach employs the technique of projection operators and electron density operators. However, despite its advantages (the generality of the procedure, the invariance of the results with respect to any orthogonal transformations, etc.), the results are difficult to interpret. For example, all the atomic charges are found to be negative, etc.[10]

where μ_{DA}, μ'_D, and μ'_A are the respective dipole moments of the donor–acceptor bond and of the components corresponding to complete charge transfer. It is seen from Eqn. (2) that the additional dipole moment $\mu_N - \mu_0$ is due to the dipole moment of the donor–acceptor bond $(b^2 + abS_{01})\mu_{DA}$ and the changes in the dipole moments of the initial components as a result of complex formation $(b^2 + abS_{01})(\Delta\mu_D + \Delta\mu_A)$. It follows from Eqn. (2) that $b^2 + abS_{01}$, i.e. a quantity close to the Mulliken population, is a characteristic of the degree of charge transfer determined from dipole moments.

In practice, the degree of charge transfer is usually calculated in the following way: the dipole moments of the initial components are substracted from the observed dipole moment and the resulting difference is attributed to the dipole moment of the donor–acceptor bond. The latter is divided by er, where r is the distance between the directly coordinated atoms, and the transferred charge is thus obtained. It is seen from Eqn. (2) that this estimate is approximate and the calculated degree of charge transfer is closer to the true value the smaller the changes in the dipole moments of the components as a result of complex formation. This has been described in adequate detail in a monograph[9]. Here one need only mention that the dipole moment is a quantity characterising the charge distribution in the molecule of the complex as a whole, and not in its individual fragments. Because of this, the method of dipole moments cannot in principle yield the true degree of charge transfer and the difference between the true value and the value determined from the vector scheme will be greater the more effective the transfer of the influence of complex formation from the coordinating centres to other fragments of the molecules.

Table 1. The experimental dipole moments (μ) and the degrees of charge transfer ($b^2 + abs_{01}$) in the complexes $I_2.L$.[3,16,18]

Complex	μ_D, D	μ_N, D	S_{01}	$\Delta = (b^2 + abS_{01})$, e
$I_2 \cdot C_5H_5N$	2.21	4.50	0.1	0.25
$I_2 \cdot (CH_2)_4S_2$	0	2.15	0.1	0.11
$I_2 \cdot (CH_3)_2S$	1.40	3.62	0.1	0.12
$I_2 \cdot (CH_3)_4CSN_2$	4.70	7.52	0.1	0.18
$I_2 \cdot (CH_3)_4CON_2$	3.66	5.20	0.1	0.09
$I_2 \cdot (CH_2)_4O_2$	0	1.30	0.1	0.06
$I_2 \cdot (CH_3)_2SO$	3.85	5.59	0.02	0.18
$I_2 \cdot (C_8H_{17})_3PO$	4.10	6.21	0.02	0.21
$I_2 \cdot C_5H_5NO$	4.22	6.66	0.02	0.24
$I_2 \cdot 4\text{-}CH_3C_5H_4NO$	4.73	7.43	0.02	0.26
$I_2 \cdot (C_6H_5)_3AsO$	5.25	8.87	0.02	0.37

The most accurate results in studies on charge transfer should be obtained for complexes with non-polar components. In this case, the dipole moments of the donor, μ_D and μ'_D, are zero. Furthermore, for halogens μ_A is equal to zero; assuming that the charge is transferred to σ antibonding orbitals, one can assume that μ'_A is likewise zero. The additional dipole moment of the complex is then caused only by charge transfer. Thus the degree of charge transfer in the complex $I_2.C_6H_6$ found from the values of μ_N derived from two different sources[3,5] is 0.03 e or 0.08 e. The results of studies on charge transfer between the non-polar acceptor I_2 and polar donors are presented in Tables 1 and 2.

The Tables show that the degree of charge transfer varies within wide limits depending on the strength of the donor. In the complexes $TiCl_4.L$ (Table 2), the contribution of μ_A to the dipole moment of the complex is zero because of the square structure of $TiCl_4$ in the complexes. The main uncertainty into the calculation of the degree of charge transfer is therefore introduced by the change of the dipole moment of the donor. In the complexes $SnCl_4.L$ (Table 2), an additional error is introduced into the calculation of the transferred charge by the change in the dipole moment of the Sn–Cl bond. It is at present difficult to estimate the accuracy of the determination of the degree of charge transfer—the uncertainty in the contributions of the above factors makes it virtually impossible to make such an estimate.

Table 2. The dipole moments (μ), the degrees of charge transfer ($b^2 + abS_{01}$), and the heats of formation of donor–acceptor bonds (ΔH) for complexes of the $n\sigma$ and nv types[9].

$BF_3 \cdot C_4H_8O$	5.68	1.70	2.6	1.54	0.35	18.8

The method involving the estimation of charge transfer from the enthalpies of complex formation ($-\Delta H$) may be regarded as a "derivative" of the dipole moment method. The linear relation $-\Delta H = 35.3\ \mu_{DA}/er_{DA}$ makes it possible to determine the transferred charge from the known value of ΔH (Table 2). For small and moderate charge transfers, this equation yields fully acceptable results. However, for large values of $-\Delta H$ and μ_{DA}, the coefficient of the relation between $-\Delta H$ and μ_{DA} will be different and cannot be used to determine the degree of charge transfer. For example, in the study of complexes of SO_3 with ethers[18], the coefficient μ_{DA}/er_{DA} proved to be 79.96.

IV. INFRARED SPECTROSCOPY

Infrared spectroscopy is one of the main methods used to estimate the degree of charge transfer. The degree of charge transfer can be estimated from the changes in the force constants of the halogen–halogen bonds for σ acceptors, and metal–halogen bonds for v acceptors with the aid of the force constants of the donor–acceptor bonds and from the relative changes in the stretching vibration frequencies on complex formation. One should note that the most correct values should be obtained using force constants, since in this case there is no reduced mass effect. However, owing to the difficulties in the calculation of the force constants of bonds, estimates of the degree of charge transfer from changes in the frequencies of the stretching vibrations have become most common, and in almost all studies of this kind complexes of σ acceptors are considered. The formation of complexes by v acceptors as a rule leads to a decrease of the stretching vibration frequencies of the metal–halogen bonds, but the degree of charge transfer cannot be estimated unambiguously from the relative shift of these frequencies, since the formation of complexes by v acceptors entails a change in the hybridisation of the central atom and hence a change in the parameters of the metal–halogen bonds (the amount of ionic character, the amount of double bond character, etc.), which must naturally be reflected in their frequencies.

Table 3. The degree of charge transfer in complexes of σ acceptors according to infrared spectroscopic data*.

*The degrees of charge transfer Δ_1, Δ_2, and Δ_3 have been calculated by Eqns. (4), (3), and (5) respectively.

In complexes formed by halogens, the stretching vibration frequencies of the halogen–halogen (X–X′) bonds are also reduced[19–28]. Mulliken[2] links such changes to the degree of charge transfer by the relation

$$\Delta = b^2 + abS_{01} \simeq \frac{8}{3} \cdot \frac{\Delta\nu}{\nu_1}, \tag{3}$$

where $\Delta\nu = \nu_1 - \nu_0$ is the difference between the vibration frequencies of the X–X′ bond in the free halogen molecule and in the molecule bound in the complex. The third column of Table 3 lists the degrees of charge transfer Δ_2 obtained from the literature data using Eqn. (3). In order to estimate $b^2 + abS_{01}$, one can also use the change in the stretching vibration frequencies of the bonds of the donor molecules. However, in this case the coefficient of $\Delta\nu/\nu_1$ is unknown. Furthermore, complex formation results in changes in the stretching vibration frequencies of many bonds in donor molecules and it is impossible to select a single vibration as a criterion for the estimation of the degree of charge transfer.

As mentioned above, the most accurate degrees of charge transfer are obtained when the force constants $f_{X\text{-}X'}$ of the halogen–halogen bonds are used. Thus, following Mulliken[2], many workers employ $f_{X\text{-}X'}$ to estimate the contribution of the dative structure to the electronic ground state of the complexes[19,22,29,30]. The relation for the estimation of the degree of charge transfer can then be represented in the form

$$\Delta = b^2 + abS_{01} = \frac{f^0_{X\text{-}X'} - f_{X\text{-}X'}}{f^0_{X\text{-}X'}}, \tag{4}$$

where $f^0_{X\text{-}X'}$ and $f_{X\text{-}X'}$ are the force constants of the halogen–halogen bond in the free halogen molecule and in the complex. The second column of Table 3 lists the degrees of charge transfer Δ_1 calculated by Eqn. (4) from the literature data both by Person and coworkers[22,23] and in some cases by the present authors. Comparison of the transferred charges obtained from Eqns. (3) and (4) shows that the agreement between them is poor. Bearing in mind that Eqn. (4) gives a better estimate of the degree of charge transfer than Eqn. (3), we attempted to find another coefficient of $\Delta\nu/\nu_1$ in Eqn. (3) from the correlation between $\Delta\nu/\nu_1$ and $(f^0_{X\text{-}X'} - f_{X\text{-}X'})/f^0_{X\text{-}X'}$. The degrees of charge transfer in halogen complexes were determined from the resulting relation:

$$\Delta = b^2 + abS_{01} \simeq 1.42\,\Delta\nu/\nu_1 + 0.02 \quad . \tag{5}$$

The fourth column of Table 3 shows that the degree of charge transfer Δ_3 calculated by Eqn. (5) is closer to the values obtained from the ratio of the bond force constants and, furthermore, that Eqn. (5) holds satisfactorily for different types of complexes—both $\pi\sigma$ and $n\sigma$.

Analogous results are also obtained in the study of complexes of chlorine and olefins. The degrees of charge transfer have been calculated[31] by Eqn. (3). However, the results (based on the donor properties of olefins) appear to be too high, since the transferred charges are the same as in the stronger $n\sigma$ complexes of iodine and amines. On the other hand, the estimates by Eqn. (5) lead to more acceptable values (Table 4).

The degree of charge transfer can also be estimated from the force constants f_{DA} of the donor–acceptor bonds. Here one usually begins with the hypothesis that f_{DA} is determined solely by the contribution of the dative structure[9]:

$$\Delta = b^2 + abS_{01} \approxeq f_{DA}/f^0_{DA}, \tag{6}$$

where f^0_{DA} is the force constant of the donor–acceptor bond in the purely dative structure. The simultaneous application of Eqns. (4) and (6) leads to the expression[9]

$$f^0_{DA} = \frac{f_{DA} f^0_{X\text{-}X'}}{f^0_{X\text{-}X'} - f_{X\text{-}X'}}. \tag{7}$$

f^0_{DA} calculated by Eqn. (7) from the experimental values of f_{DA} and $f^0_{X-X'}$ for halogen complexes[22] proved to be 2.5×10^5 dyn cm^{-1}, i.e. close to the values of f_{DA} for the most stable donor–acceptor complexes of Group III metal halides, where the contribution of the structure with charge transfer plays the dominant role. An estimate of the transferred charge[9] showed that it amounts to (0.4–0.8) e for complexes of aluminium halides[29] and (0.2–0.4) e for complexes of iodine with various donors[22].

Table 4. The degrees of charge transfer in the $\pi\sigma$ complexes of Cl_2 with olefins[31]*.

* Δ_1 and Δ_2 are the degrees of charge transfer calculated by Eqns. (5) and (3) and ν^{c}_{Cl-Cl} is the stretching vibration wavenumber of the Cl–Cl bond in the complex.

Interesting results were obtained for complexes of v acceptors[32]. The authors calculated the force constants of the metal–halogen bonds in the complexes $BX_3.NCCH_3$ (X = F, Cl, or Br). Table 5 presents the force constants of the metal–halogen bonds calculated using symmetrical (A) and asymmetric (E) vibrations and it also includes the degrees of charge transfers obtained by the authors. One should note that the large differences between the degrees of charge transfer in the complex $BF_3.NCCH_3$ calculated from the force constants of the symmetrical and asymmetric vibrations cast doubt on the validity of the calculation of the force constants in this case.

Table 5. The degrees of charge transfer in the complexes of BX_3 with CH_3CN. [32]

V. NUCLEAR QUADRUPOLE RESONANCE AND MÖSSBAUER SPECTROSCOPY

Nuclear quadrupole resonance (NQR) began to be used in the study of charge transfer comparatively recently. The method makes it possible to estimate the degree of charge transfer in complexes and the nature of charge distribution in the components. The changes in the quadrupole interaction constants (QIC) or the electric field gradient (EFG) on complex formation are directly related to the changes in electron density at all the atoms of the interacting molecules. As a result of this, the extent of the change in the charges of the quadrupole nuclei can be estimated from the changes in the QIC (or EFG). For atoms whose nuclei do not have a quadrupole moment in the ground state, one can employ the Mössbauer method. Mössbauer spectra also make it possible to obtain the values of the QIC and in addition the isomeric shifts δ, which is related to the population of the s orbitals of the atom investigated. However, the population of the s orbitals is difficult to estimate quantitatively from the isomeric shift, since the shielding of the s electrons by p and d electrons exerts a major influence on δ.

Relations between the EFG (Δq_A), on the one hand, and the degree of charge transfer b^2 and the nature of charge distribution c^2_{At} in the acceptor molecule on the other have been obtained[33] using the Mulliken theory:

$$\Delta q_A=\frac{b^2}{1+S^2_{DA}}\sum_t c^2_{At}q_t, \qquad (8)$$

where S_{DA} is the overlap integral of the wave functions ψ_D and ψ_A, c^2_{At} the electron density of the t atomic orbital of the electron-accepting molecular orbital, and q_t the contribution to the EFG at the given nucleus of the acceptor molecule due to a single electron in this atomic orbital.

For diatomic halogens and interhalogen compounds, Eqn. (8) simplifies:

$$\frac{\Delta\nu}{\nu}\simeq\frac{\Delta q_{zz}}{q_{zz}}=-\frac{b^2}{2(1-S^2_{DA})}, \qquad (9)$$

where Δq_{ZZ} is the change in the EFG on complex formation and $\Delta\nu$ the change in the NQR frequency of the halogen atom. It is seen from Eqn. (9) that Δq_{ZZ} is directly proportional to the degree of charge transfer. An increase in σ-electron density in the molecule leads to an increase of the population of the p_Z orbital of the halogen atom, which decreases the EFG and the NQR frequency. One should note that in this approximation account is taken of the change in the charge only of the molecule, disregarding the overlap integral of the wave functions of the donor and the acceptor.

For the more involved complexes of v acceptors, it is impossible to obtain an analytical expression giving an estimate of the degree of charge transfer. Quantitative estimates of this kind can be made only with the aid of specific calculations.

We shall examine certain quantitative results for complexes of halogens and interhalogen compounds. Complexes of bromine with π and n donors have been most fully investigated[34–37]. The observed low-frequency shifts are small and lie in the range 0.01–0.04%. Table 6 presents the NQR frequencies of ^{81}Br and the degrees of charge transfer calculated by Eqn. (9). Complexes of chlorine with π and n donors have been less thoroughly studied[38]. In these complexes, low-frequency shifts are also observed and the degrees of charge transfer can be estimated by Eqn. (9) (Table 6). The degree of charge transfer for complexes of both Br_2 and Cl_2 is evidently insignificant and agrees well with the results obtained by other methods[9].

The complexes of halogens and interhalogen compounds (I_2, Br_2, ICl, and IBr) with certain nitrogen-containing donors are extremely involved and interesting objects for the study of the transferred charge and particularly of its distribution in the acceptor molecule. The NQR spectra of these complexes show that the QIC of the central halogen atoms are greater than the QIC of the same atoms in the individual molecules. To explain this, it has been suggested[39,40] that the acceptor molecules behave as *v* acceptors in the stable complexes of halogens and interhalogen compounds with nitrogen-containing donors. Here the central iodine atom is sp^3d-hybridised, three orbitals are occupied by the lone electron pairs, one is involved in the formation of a covalent bond with another halogen atom, and one is involved in intermolecular interaction.

Table 6. The parameters of the NQR spectra and the degrees of charge transfer in bromine and chlorine complexes.

Complex	ν^*, MHz	b^2, *e*	Complex	ν^*, MHz	b^2, *e*

* The ^{81}Br and ^{38}Cl wavenumbers respectively are quoted.

The application of the Dailey–Townes theory shows that the degree of charge transfer is in this case 40–50%, which agrees well with infrared spectroscopic and dipole moment data. The authors[41,42] observed only one NQR frequency for the central iodine atom in complexes with nitrogen-containing ligands. Owing to the inadequacy of the experimental data, it was assumed[39] that the amount of ionic character of the iodine–halogen bond does not change on complex formation. On the other hand, the frequencies of the terminal halogen atoms were also observed in the NQR spectra of the complexes $ICl.C_5H_5N$ and $ICl.4\text{-}CH_3C_5H_4N$, [43] as well as the complexes of ICl, IBr, and Br_2 with $3,5\text{-}Br_2C_5H_3N$.[41] The appreciable decrease of these frequencies on complex formation indicates a significant change in the amount of ionic character of the halogen–halogen bonds. Taking this into account, the authors[43,44] estimated the charge distribution in the complexes (Table 7). It was found that there is always a positive charge on the central halogen atom. The study of the NQR spectra[45,46] and calculation by the CNDO method without taking into account the *d* orbitals[47] of the trihalide ions also lead to a positive charge on the central halogen atom. The charge distributions in such ions, calculated by Harada et al.[45] and Gabes et al.[46], are presented in Table 7.

Such charge distribution can be explained within the framework of a three-centre delocalised σ orbital. The simplest wave function of the ground state of stable *nσ* amine–halogen complexes (NX_2) can be formulated as follows:

$$\psi_N = a\psi(N, X_2) + b\psi(N^+—X_2^-).$$

When account is taken of the polarisation of the acceptor molecule, we obtain

$$\psi_N = a\psi(N, X_2) + b_1\psi(N^+XX^-) + c\psi(N^+X^-X) + d\psi(NX^+X^-). \tag{10}$$

The positive charge on the central halogen atom indicates the considerable importance of the polarisation term $d\psi(NX^+X^-)$ in Eqn. (10). In stable *nσ* complexes and trihalide ions, the polarisation of the acceptor molecule apparently plays a significant rôle.

Table 7. The charge distribution in complexes of the *nσ* type and trihalide ions.

Comparison of the transferred charges calculated using the sp^3d hybridisation of the central atom and three-centre orbitals shows that the degrees of charge transfer in the complexes are similar in the two cases. However, treatment of the problem from different standpoints leads to differences in charge distribution in the acceptors.

The application of the Mössbauer method for the estimation of charge transfer in iodine complexes has been demonstrated[48]. The authors studied the complex $I_2.C_6H_6$. The employment of the dependence of the isomeric shift of ^{127}I on the number of vacancies in the 5*p* shell led to a degree of charge transfer of 26%. This value is not confirmed by data obtained by other methods, including the NQR method[41]. Presumably a relation of this kind does not permit a correct estimate of the degree of charge transfer.

As mentioned previously, a single relation, similar to Eqn. (8), linking the change in the EFG to the degree of charge transfer, cannot be obtained for complexes of *v* acceptors. The formation of complexes by *v* acceptors leads in most cases to a complete rearrangement of the entire electronic system of the molecule and to the formation of one or several additional vacant orbitals. Such rearrangement leads also to a change in the parameters of the metal–halogen bonds (amount of ionic character, amount of double bond character, etc.). In most cases a detailed analysis of the changes in the EFG is therefore possible only on the basis of a detailed calculation for each specific complex. If it is possible to obtain the QIC for all the acceptor atoms, the calculation of charge transfer for a complex with a known geometry can be performed on the basis of the Dailey–Townes theory. Otherwise, one can only consider qualitative changes in the degree of charge transfer within the limits of a series of complexes.

Interesting results have now been obtained for complexes of Group III, IV, and V metal halides. Much attention has been devoted[49–52] to the study of the octahedral complexes $SbCl_5.L$. The known geometry of the complexes[51] made it possible to carry out calculations by the molecular orbital method. It was shown that the electron density at the equatorial chlorine atoms should be smaller than at the axial atom. Indeed, such electron density distribution has been observed in the complexes of $SbCl_5$ with methyl and ethyl alcohols, acetonitrile, and dimethylformamide. On the other hand, in the remaining complexes the steric influence of the donor molecules on the quadrupole frequencies of the equatorial chlorine atoms is pronounced and the NQR frequencies of chlorine cannot be assigned to the axial and equatorial atoms. However, the employment of average frequency shifts on complex formation makes it possible to estimate the degree of charge transfer Δ and the charge distribution in all $SbCl_5.L$ complexes. Table 8 presents data for all the $SbCl_5.L$ complexes investigated[51,52] with $e^2Qq^{Sb}_{am}$ = 1300 MHz [53] and a positive sign of the EFG at the antimony atom[54,55]; Δ_{Sb} is the change of the charge of the antimony atom on complex formation and Δ_{Cl} the corresponding change for all the chlorine atoms. Table 8 shows that complex formation results in a significant increase of electron density at the chlorine atoms of the acceptor molecule and in a slight decrease of the electron density at the antimony atom.

Table 8. The degrees of charge transfer in the complexes $SbCl_5.L$.

Complex	Δ, e	Δ_{Sb}, e	Δ_{Cl}, e	Complex	Δ, e	Δ_{Sb}, e	Δ_{Cl}, e
$SbCl_5 \cdot POCl_3$	0.26	—0.04	0.30	$SbCl_5 \cdot CH_3OH$	0.29	—0.11	0.40
$SbCl_5 \cdot CH_3CN$	0.23	—0.09	0.32	$SbCl_5 \cdot C_2H_5OH$	0.28	—0.11	0.39
$SbCl_5 \cdot C_6H_5CN$	0.24	—0.09	0.33	$SbCl_5 \cdot (CH_2Cl)_2O$	0.25	+0.02	0.23

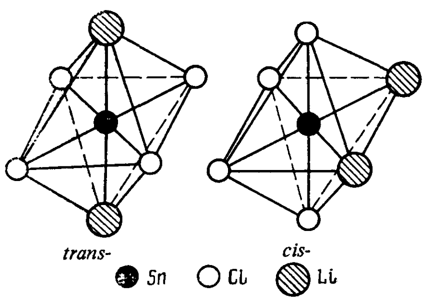

Figure 1. The *cis–trans* isomerism in the octahedral complexes $SnCl_4.L_2$.

Among the complexes of Group IV elements, very vigorous studies are being made on the octahedral complexes $SnCl_4.L_2$ (Fig. 1) both by the NQR method[42,56–59] and by Mössbauer spectroscopy[60–63]. One should note that, whereas the degree of charge transfer in the complexes $SbCl_5.L$ was estimated from the known QIC of the antimony atom obtained from the NQR spectra, in the complexes $SnCl_4.L_2$ the degree of charge transfer was calculated using the quadrupole splitting by the tin atom observed in the Mössbauer spectra[64,65]. Table 9 presents the calculation of the degree of charge transfer in all the $SnCl_4.L_2$ complexes investigated hitherto, taking into account the sign of the EFG at the tin atom[60]. As in the complexes $SbCl_5.L$, there is a significant increase of electron density at the chlorine atom in the acceptor. However, in contrast to the complexes $SbCl_5.L$, there is a fairly considerable increase of the positive charge of the tin atoms in almost all the complexes $SnCl_4.L_2$. It is also important to note[64] (Table 10) that, as expected from calculations by the molecular orbital method[56], in complexes having a *cis*-structure, the electron density at the axial chlorine atoms is smaller than at the equatorial atoms. Such redistribution of electron density is consistent with the concept of the mutual influence of ligands in complexes of non-transition elements[66].

$SnCl_4 \cdot 2(CH_3)_2CO$	0.17	0.23	0.40
$SnCl_4 \cdot 2CH_3CN$	0.15	0.19	0.34
$SnCl_4 \cdot 2POCl_3$	0.14	0.20	0.34
$SnCl_4 \cdot 2CH_3OCH_2Cl$	0.10	0.18	0.28
$SnCl_4 \cdot 2(CH_3)_2SO$	0.24	0.27	0.51

Calculation for the complex of $SnBr_4$ with hexamethylphosphoramide from the data of Petrosyan et al.[67] and Philip et al.[68] yielded a transferred charge of 0.37 e. The nature of the change in the charge on the acceptor atoms proved to be the same as in the complexes $SnCl_4.L_2$. The negative charge on the bromine atoms increases by 0.60 e while the positive charge on the tin atom increases by 0.23 e.

The study of the complexes $SbCl_5.L$ and $SnCl_4.L_2$ using the Mössbauer effect[54,55,60–63] should yield information about the populations of the 5s and 5p orbitals of the antimony and tin atoms. Fig. 2 presents the relation between the isomeric shift δ and the QIC of ^{121}Sb in certain complexes $SbCl_5$. RCN.[54] An increase of the isomeric shift leads to an increase of the QIC. The parallel variation of δ and QIC for ^{119m}Sn is also observed for the complexes $SnCl_4.L_2$. The relation may be caused both by a decrease of the population of the 5*s* orbitals by an increase of the shielding of the 5*p* orbitals[69]. It is therefore impossible to discover unambiguously for both types of complexes, on the basis of the Mössbauer spectra, how the populations of the orbitals of the antimony and tin atoms change on complex formation.

Among complexes of Group III elements, Tong made a detailed study of the complexes of $GaCl_3$ with a number of *n* donors[70]. The lack of specific data for NQR frequencies precludes the calculation of the degrees of charge transfer in these complexes. However, the relation between the ^{35}Cl and ^{69}Ga NQR frequencies permitted the estimation of the charge distribution in these complexes. It has been shown[39] that 2/7 of the transferred charge is located at the gallium atom and 5/7 is distributed between the three chlorine atoms.

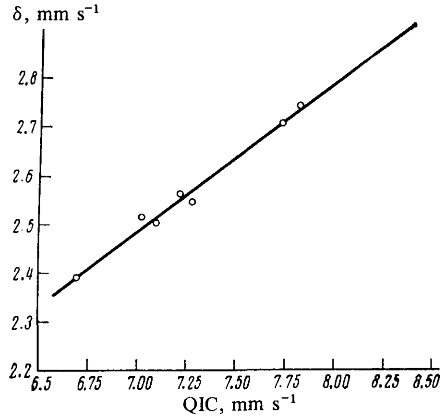

Figure 2. Relation between δ and the ^{121}Sb QIC in the complexes $SbCl_5.RCN$.

The complexes of antimony and arsenic trihalides with aromatic bases have been very widely investigated[71-75]. The attempt to estimate the degrees of charge transfer in these complexes undertaken by the present authors[75] was unsuccessful owing to the incorrect selection of the sign of the EFG at the nucleus of the antimony atom[76, 77]. This failure is probably associated with the lack of the exact knowledge of the hybridisation of the antimony and arsenic atoms in these complexes.

A Mössbauer study of the complexes $n SbHal_3.Ar$ [76, 77] yielded additional information about charge transfer in them. The authors believe that the population of the 5*s* orbitals of the antimony atom varies insignificantly owing to the slight change of the isomeric shift. The use of the relation between the isomeric shift and the population of the 5*p* orbitals of the antimony atom[78] made it possible to estimate the latter[76] (Table 11). However, as shown previously, the decrease of the isomeric shift is caused both by the decrease of the population of the 5*s* orbitals of antimony and by the increase of the shielding of the 5*p* orbitals[69]. The results presented in Table 11 are therefore to some extent controversial.

A study was made of the change in the charge on the acceptor atoms in all the complexes. There is no doubt that the changes in the charge on the donor atoms are of considerable interest. Unfortunately, there have been virtually no NQR studies on these lines. Only two investigations may be noted. Negita et al.[79] studied the complexes of acetonitrile with chlorine and bromine. The observation of NQR signals due to the nitrogen and halogen nuclei made it possible to estimate the degree of charge transfer in these complexes both from the NQR spectrum of the donor and from the spectrum of the acceptor (Table 12). The authors' explanation of the difference between the transferred charges calculated from the ^{14}N and ^{81}Br QIC is that part of the charge is transferred from the CH_3CN molecule via the d_z^2 orbitals of the bromine atom, which make a much smaller contribution to the EFG than the p_z orbitals.

Table 11. The degrees of charge transfer in the complexes $n SbCl_3.Ar$ from Mössbauer spectroscopic data[76]*.

Complex	n_p	Δ, *e*	$\vert\psi(0)\vert^2/a_0^3$
$SbCl_3$	1.35	—	33.0
$2SbCl_3 \cdot C_6H_6$	1.57	0.22	32.5
$2SbCl_3 \cdot C_6H_5CH_3$	1.47	0.12	32.9
$2SbCl_3 \cdot 1,4\text{-}(CH_3)_2C_6H_4$	1.53	0.18	32.6
$SbCl_3 \cdot 1,3,5\text{-}(CH_3)_3C_6H_3$	1.60	0.25	32.3
$2SbCl_3 \cdot C_6H_5OCH_3$	1.53	0.18	32.6
$SbCl_3 \cdot C_6H_5C_2H_5$	1.30	—	33.1
$2SbCl_3 \cdot C_6H_5C_6H_5$	1.35	—	33.0
$2SbCl_3 \cdot C_{10}H_8$	1.50	0.15	32.8

---

*n_p is the number of vacancies in the 5*p* shell of the antimony atom, Δ the degree of charge transfer, and $|\psi(0)|^2/a_0^3$ the overall electron density of the antimony nucleus.

Table 12. The degrees of charge transfer in the complexes $2CH_3CN.Hal_2$.

Complex	Change in charge, *e*	
	on nitrogen	on halogen
$2CH_3CN \cdot Cl_2$	+0.028	−0.021
$2CH_3CN \cdot Br_2$	+0.029	−0.00

The charge distribution in the complexes $AlBr_3.SbBr_3$ and $AlBr_3.BiBr_3$ has been investigated[80]. The transferred charge Δ was calculated from the QIC of the antimony, bismuth, and bromine atoms forming part of the donor molecules. The change in the charge on the aluminium atom in consequence of complex formation was estimated relative to the Al_2Br_6 dimer from the change in the QIC of the bromine atoms. The results (Table 13) showed that the charge in the donor molecules is transferred directly from the lone pair of the central atom and hardly involves the halogen atoms of the donor.

Thus the application of the NQR and Mössbauer methods to the calculation of the degree of charge transfer and of charge distribution in the complexes leads to very interesting results. The degree of charge transfer is satisfactorily correlated with data obtained by other methods. The most important factor is that NQR and the Mössbauer effect made it possible to obtain the distribution of the transferred charge, in contrast to the other methods described previously. One can now assume that both in complexes of the $n\sigma$ type and in complexes of v acceptors, the polarisation of the valence shells of the central complex-forming atom apparently plays a significant role. Furthermore, in v-acceptor molecules, the changes in atomic charges on complex formation are associated with the changes in the hybridisation of the central atom.

Table 13. The degrees of charge transfer in the complexes $AlBr_3.L$.

Complex	Δ, e	$\Delta_{Sb\,(Bi)}$, e	Δ'_{Br}, e	Δ_{Al}, e	Δ_{Br}, e
$AlBr_3 \cdot SbBr'_3$	0.20	—0.15	—0.05	—0.08	0.28
$AlBr_3 \cdot BiBr'_3$	0.27	—0.29	0.02	—0.05	0.32

VI. X-RAY ELECTRONIC SPECTROSCOPY

X-Ray electronic spectroscopy of complexes has been developing very vigorously recently. The application of X-ray electronic spectra in the study of donor–acceptor interaction is based on the parallel variation of the effective charges of the atoms investigated and of the shift of the X-ray electronic lines. One can therefore infer the changes in the electron densities at the atoms from the changes in the energy of the binding of electrons (E_b).

Using the electrostatic potential model[81], the shift of the internal energy level can be formulated thus:

$$\Delta E_b = Kq_i + V_i + l, \tag{11}$$

where

$$V_i = \sum_{j \neq i} q_j / R_{ij}$$

is the molecular potential in the vicinity of the nucleus i, q_i the charge on the atom i, R_{ij} the distance between the nuclei i and j, and l a constant determined by selecting the starting point of the readings. The constant K is approximately equal to the integral of the electrostatic interaction between the internal orbital under consideration and the valence orbital in the same atom. Eqn. (11) can be simplified to

$$\Delta E_b = K'q_i.$$

According to the free ion model[82], $K' \simeq 1/r$, where r is the radius of the valence shell. The radius of the radial distribution density of valence electrons in carbon, oxygen, and nitrogen atoms is approximately 1 Å (1 Å $\simeq$ 2 atomic units) and, when a single electron is removed, the shift in the binding energy of the internal electrons per unit charge is 14 eV.

The free ion model can be improved by taking into account the fact that the valence electrons are not transferred to an infinite distance on formation of a chemical bond. If the distance between the nuclei is R_{ij}, the shift of the internal electron energy can be formulated as follows:

$$\Delta E_b = \left(\frac{1}{r} - \frac{\alpha}{R_{ij}}\right) q_i, \tag{12}$$

where α is the Madelung constant[83]. For ionic crystals, the shift of the internal electron energy calculated by Eqn. (12) is approximately 5 eV per unit charge. However, it is clear that the use of even an improved free ion model for the calculation of the shift of the internal electron energy when one electron is removed in complexes with appreciably covalent bonds cannot in principle lead to a satisfactory quantitative estimate of the degree of charge transfer. This is why the degree of charge transfer which we estimated with the aid of the improved free ion model does not agree very well with data obtained by other methods.

Charge transfer in the complex $ICl.C_5H_5N$ has been investigated[84] using K' = 14 eV per unit charge. A change in the energy of the ^1S state of the nitrogen atom by 0.9 eV leads to the appearance of a +0.06 e charge on the nitrogen atom of the pyridine molecule. When we used K' = 5 eV per unit charge, the charge on the nitrogen atom was found to be +0.18 e, i.e. closer to the transferred charge obtained from dipole moment and NQR data.

The photoelectronic spectra of certain complexes of tin halides have been studied[85] and the shift of the internal electrons of the donor atom directly involved in complex formation has been determined[85]. We estimated the degree of charge transfer Δ in these complexes also using K' = 5 eV per unit charge (Table 14).

Table 14. The degrees of charge transfer in the complexes $SnCl_4.L_2$ obtained from photoelectronic spectra[92].

Complex	ΔE_b, eV	Δ, e
$SnBr_4 \cdot 2(C_6H_5)_3PO$	0.2	0.04
$SnCl_4 \cdot 2(C_6H_5)_3PO$	0.2	0.04
$SnCl_4 \cdot 2(CH_3)_2NCS$	0.9	0.18
$SnBr_4 \cdot \alpha, \alpha'\text{-}C_{10}H_8N_2$	1.7	0.34
$SnCl_4 \cdot 2C_5H_5N$	2.0	0.40

A recently published report[86] describes a study of photoelectronic spectra of $SbCl_5$ solutions for certain n-donor solvents. The energies of the binding of $3d_{5/2}$ internal electrons of the antimony atom were compared with the enthalpies of formation of the complexes or with Gutman's donor numbers (DN).[87] The observed correlation between ΔE and DN (Fig. 3) is described by a straight line. However, it is known that the change in electron density at halogen atoms in the complexes obtained from NQR spectra (Δ_{Cl}) depends directly on DN.[67] Comparison of these two correlations, the dependence of ΔE on DN and of Δ_{Cl} on DN, makes it possible to obtain the relation between ΔE and Δ_{Cl}, which can be represented in the following form:

$$\Delta E = 321.5 + 3.16 \Delta_{Cl} \pm 0.2 \text{ (eV)}. \tag{13}$$

The fairly large error precludes quantitative estimates of the shift of the binding energy of the internal electrons of the antimony atom, but Eqn. (13) permits a qualitative estimate of the change in this energy.

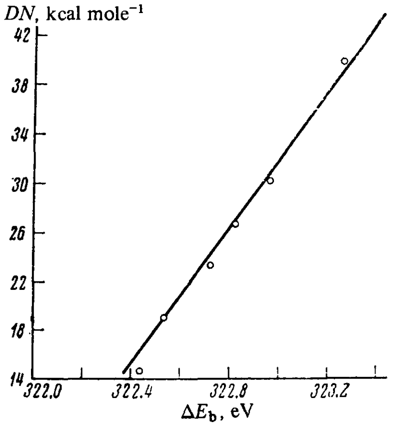

Figure 3. Relation between ΔE_b and DN.

It is now clear that X-ray electronic spectroscopy together with NQR and quantum-chemical calculations can yield unique information about the charge distribution in complexes among all the atoms of the interacting molecules. However, there have been so far no studies dealing with the X-ray electronic spectra of all the atoms in the complex. It is therefore of interest to carry out such investigations with the aid of the X-ray electronic spectra of the complexes which have been studied by other methods.

VII. QUANTUM-CHEMICAL CALCULATIONS

Quantum-chemical calculations constitute nowadays one of the principal methods whereby one can estimate the changes in the charge on each atom of the complex. However, the charge depends markedly on the chosen method of calculation. The most rigorous calculations of the *ab initio* type can be carried out only for small molecules with a small number of orbitals. On the other hand, semi-empirical calculations yield an electron density distribution which depends significantly on the choice of the parameters of the calculation. Furthermore, the use of semi-empirical methods for calculations on complexes is limited by the lack of sufficiently reliable parameters for elements with a large number of orbitals. As a result, comparatively few calculations have so far been made on complexes of the $\pi\sigma$, $n\sigma$, and nv types.

We shall begin the discussion of the available data with non-empirical methods, which lead to more accurate results.

A calculation has been made[88] on BF_3 complexes with various ligands by the *ab initio* method. Table 15 presents the distributions of the transferred charge in the acceptor molecule which were calculated from the orbital populations. It can be readily seen that there is a significant shift of electron density in these complexes to the fluorine atoms ($\Sigma\Delta_F$) of the acceptor molecule. Furthermore, part of the charge is transferred to the boron atom (Δ_B). The distribution of the transferred charge in the acceptor molecule is different for different complexes. Table 15 presents the ratios of the charge transferred to the boron atom and of the degree of charge transfer (Δ_B/Δ).

Table 15. The degrees of charge transfer in the complexes $BF_3.L$.[88]

L	Δ, e	Δ_B, e	Δ_F, e	$\Sigma\Delta_F$, e	Δ_B/Δ, e
NH_3 (eclipsed)	0.269 0.269	0.092 0.080	0.059 0.063	0.177 0.189	0.34 0.30

Much attention has been devoted to calculations on borazane BH_3NH_3.[89-95] The results of these studies agree well with one another. As an example, Table 16 lists the populations of the atomic orbitals in the BH_3, NH_3, and $BH_3.NH_3$ molecules[89] and our calculated degrees of charge transfer Δ. The greatest changes were observed in the populations of the $2p_z$ orbitals of the boron and nitrogen atoms. When the complexes are formed, 0.1 e is transferred to the orbitals of the boron atom and 0.16 e to the 1s orbitals of the three hydrogen atoms. Evidently, in this complex there is also a significant displacement of electron density to the hydrogen atoms of the acceptor molecule. The complexes $BH_3.CO$,[89] $BF_3.C_6H_5CHO$,[96] BF_3 complexes with ethers[97], and $BH_3.PH_3$[98] have also been investigated by the *ab initio* method. All the calculations lead to the same charge distributions as for the complex $BH_3.NH_3$. One need only note that, in the boron halide complexes, the shift of electron density to the halogen atoms is greater than the shift to the hydrogen atoms in the BH_3 complexes. This is probably associated with the greater electronegativity of the halogen atoms.

We can now proceed to the discussion of the semi-empirical methods for calculations on complexes. Calculations have been made[99,100] on complexes of iodine with benzene, pyrrole, furan, and thiophen on the basis of the perturbation theory. The change in charge distribution in the $I_2.C_6H_6$ complex[99] is illustrated in Fig. 4, which shows that the charge is distributed uniformly between the two iodine atoms. In the remaining complexes, the charge distribution is similar. However, the use of more accurate methods of calculation leads to a different charge distribution in the acceptor molecule. Thus the electronic structures of the complexes $I_2.C_6H_6$ and $I_2.NH_3$ have been investigated[101] by a modified PNDO method. An excess positive charge of 0.06 *e* appears in the $I_2.C_6H_6$ complex on the iodine atom directly coordinated to the ring, while on the other iodine atom there is a negative charge of −0.09 *e*. Such charge distribution is consistent with the marked influence of polarisation in the complexes. The charge distribution in the complex $I_2.NH_3$ (Fig. 5*a*) is the same as in the benzene complex, but the low degree of charge transfer is inconsistent with experimental data for iodine complexes with *n* donors. The charge distribution in the complexes $F_2.NH_3$ and $Cl_2.NH_3$, obtained by the PNDO method[102], is illustrated in Figs. 5*b* and 5*c*. The electron density at the halogen atoms linked directly to the nitrogen atom is also reduced in these complexes.

Table 16. The orbital populations in $BF_3.NH_3$.[89]

Atom	Orbital	BH_3	NH_3	$BH_3 \cdot NH_3$	Δ, *e*
B	s	3.137		2.994	−0.143
	$2p_x$, $2p_y$	0.902		0.876	−0.026
	$2p_z$	0		0.275	0.275

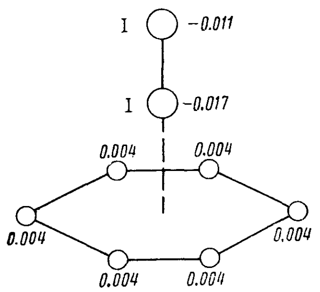

Figure 4. The changes in the atomic charges in the complex $I_2.C_6H_6$.[97] The charges are positive on the I atoms and negative on the C atoms.

Among complexes of *v* acceptors, the calculation on the octahedral complex $TiCl_4.2HCN$ by the CNDO method[103] is of interest. The calculation is one of the first designed to investigate the electronic structure of complexes of the donor–acceptor type in which the central atom contains *d* electrons. The calculated degree of charge transfer proved to be 0.2 *e*. It is interesting to trace the changes in the populations of the valence atomic orbitals on complex formation. Table 17 shows that the population of the *s* orbitals of the titanium atom diminishes, the overall population of the *p* orbitals increases, and the population of the *d* orbitals remains unchanged. There is a significant increase in the pupulations of the p_z and d_{z^2} orbitals of the titanium atom on complex formation, but, owing to the decrease of the populations of the other orbitals, the overall charge on the titanium atom remains unchanged. There is a significant increase in electron density at the chlorine atoms, the increase being greater at the equatorial atoms than at the axial atoms. Although the titanium atom has a partially filled *d* shell, in contrast to tin or antimony atoms, the similarity of the complex formation processes permits a comparison of the charge distribution in the acceptor molecule in the $TiCl_4.L_2$ complexes with that in the complexes $SbCl_5.L$ and $SnCl_4.L_2$. Table 17 shows that the nature of the changes in the charge on the acceptor atoms in the $TiCl_4.L_2$ complexes is the same as in the complexes $SbCl_5.L$ and $SnCl_4.L_2$, which has been demonstrated by the NQR method.

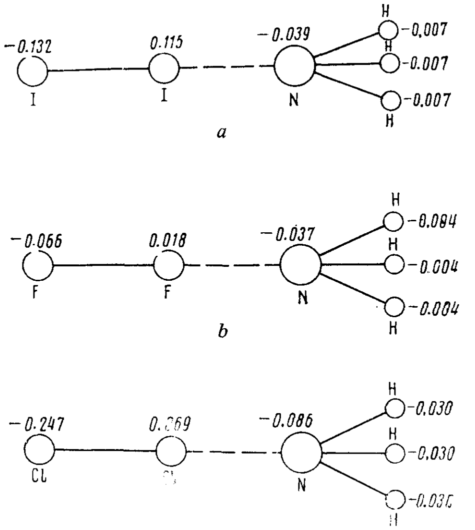

Figure 5. The changes in the atomic charges in the complexes $NH_3.Hal_2$.[99,100] The charges are positive on the halogen atoms remote from the nitrogen atoms and negative on the halogen atoms linked to the nitrogen atoms.

Calculations have been made[104] on complexes of organometallic compounds and boron and aluminium halides by the CNDO method. Table 18 presents the changes in the charges of the component atoms which we calculated from the authors' data. As in the preceding calculations, the formation of boron and aluminium halide complexes entails a significant increase of electron density at the halogen atoms.

Calculations have been made by the Hückel method for a number of BF_3 complexes[105-107], where the charge distribution in the acceptor molecule proved to be similar to the charge distribution obtained in calculations by more accurate methods.

One must note that, although different methods of calculation yield different orbital populations, the transferred charge and the nature of its distribution in the same complexes depend little on the specific method of calculation. The charge distribution obtained by quantum-chemical calculations on complexes of both σ and v acceptors agree well with the charge distribution obtained with the aid of experimental methods for the investigation of complex compounds.

Table 18. The degrees of charge transfer in boron and aluminium complexes.

VIII. CONCLUSION

All the methods which have been used to determine the degree of charge transfer can be divided into two groups. One group includes the dipole moment and infrared spectroscopic methods. The degree of charge transfer is determined either from the dipole moment of the donor–acceptor bond or with the aid of force constants (or the stretching vibration frequencies) of the bonds. The nature of the changes in the charge on the atoms in the donor and acceptor molecules cannot then be determined. This is because the experimental quantities refer solely to the bonds and do not therefore permit inferences about the changes in the atomic charges. The second group of methods includes NQR, Mössbauer spectroscopy, X-ray electronic spectroscopy, and quantum-chemical calculations, which characterise directly the atoms in the molecule, and therefore permit estimates of the effective atomic charges.

Comparison of the degrees of charge transfer calculated for the same complexes by different methods permit certain conclusions. Although the methods in the second group, with the exception of quantum-chemical calculations, do not take into account the electron density in the region of the overlap of the wave functions of the donor and the acceptor, the numerical values of the degree of charge transfer are similar (Table 19). This shows that the electron density in the region of the donor–acceptor bond does not contribute significantly to the degree of charge transfer.

It is so far difficult to assess the accuracy of the charge transfer data obtained and it is therefore impossible to decide which method leads to more correct results. This is because each method is associated with certain assumptions, the role of which is not always susceptible to exact experimental estimation. Furthermore, one must bear in mind that neither the possibility of the formation of a π bond between the donor and acceptor molecules nor the possibility of their mutual polarisation is as a rule taken into account in calculations on the degree of charge transfer. In general, one should note that a procedure whereby account can be taken of polarisation in the estimation of the degree of charge transfer in stable complexes has been hardly developed so far, although it has been shown above that polarisation may play a significant role in complex formation processes.

Mass-spectrometric Analysis of Solids Using Laser Ion Sources

G.A.Maksimov and N.V.Larin

The development of lasers has permitted their application in the evaporation and ionisation of comparatively small sections of the solids to be investigated with subsequent mass-spectrometric analysis of the vapours and ions formed. Mass-spectrometric analysis using lasers has many advantages compared with the traditional procedures (spark, thermal emission) for the ionisation of solids. In the review, attention is concentrated on the analytical characteristics of the method of the laser evaporation and ionisation of solids in the ion sources of mass-spectrometers.
The bibliography includes 61 references.

CONTENTS

I. INTRODUCTION

The development of radioelectronics, the physics of superconductors, nuclear energetics, and other fields of science and engineering has led to a need for methods of analysis of high-purity solids. The optical, emission, radioactivation, and X-ray fluorescence analytical methods were developed first, and followed in recent years by mass-spectrometric analysis using a spark ion source[1].

The development of laser techniques [2,3] permitted the application of lasers in the evaporation and ionisation of comparatively small sections of test solids with subsequent mass-spectrometric analysis of the ions formed. Mass-spectrometric analysis employing lasers has many advantages, which include the comparatively simple design of the mass-spectrometer having a laser ion source, rapidity of analysis, the possibility of layer-by-layer studies and local analysis of the surface of solids, the simplicity of the mass spectra obtained, and the possibility of analysing not only metals and semiconductors, but also dielectrics. All these factors make mass spectrometry with a laser ion source very promising for the investigation of the content and distribution of impurities in solids. In the first studies on the interaction of laser radiation with solids, use was made of mass spectrometers of the Mattauch–Herzog type[4] as well as time-of-flight instruments [5,6].

Two fundamental operating modes of pulsed lasers are distinguished: the free running mode and the use of a Q-switched resonator[2] ("giant" pulses). In the first case, the radiation pulse has a lifetime $\tau \simeq 10^{-3}$–10^{-4} s and a power $P \simeq 10^3$–10^6 W. For giant radiation pulses, $\tau \simeq 10^{-7}$–10^{-9} s and $P \simeq 10^6$–10^8 W. The interaction of the laser radiation pulse with the substance depends significantly [2,3] on the time τ and P. In this review, we shall therefore consider separately the application in mass-spectrometric analysis of lasers operating in different modes. Attention will be concentrated on the analytical characteristics of the method of laser evaporation and ionisation of solids in the ion sources of mass-spectrometers.

II. ANALYSIS USING A LASER OPERATING UNDER FREE RUNNING CONDITIONS

Under the influence of the laser pulse with a lifetime $\tau \simeq 10^{-3}$ s and a power density of the focussed radiation $q \simeq 10^5$–10^7 W cm^{-2}, a given section of the test specimen undergoes intense evaporation. The diameter of the resulting crater is determined by the conditions of focussing of the radiation and its depth[3] can vary from 10 μm to 10^3 μm, depending on the type of substance, the duration of the pulse, and the energy density in the beam.

The vapour of the substance formed in the laser flash is partly ionised. The ratio of the neutral and ionised vapour components is described satisfactorily by the Sacha–Langmuir equation[4]. The neutral vapour component has a kinetic energy spread $\Delta T \simeq 1$ eV and, after its ionisation (for example by an electron beam), can be analysed with respect to mass in a time-of-flight mass-spectrometer with single space-time focussing. The ionic component of the vapour [2,3] is characterised by the quantity $\Delta T \leqslant 10$ eV. In order to achieve adequate mass resolution, one therefore employs a double focussing instrument or a time-of-flight instrument in which the ionic component is accelerated to energies T such that $\Delta T/T \ll 1$ (the condition for a monoenergetic ion beam).

The problems of the mass-spectrometric applications of lasers operating in the free running mode for the determination of the composition of solids and the investigation of the distribution of impurities in the specimens have been discussed in a number of cases[7-29]. A large group of investigations[7-13,18] have been devoted to the analysis of gases in solids. A typical experimental arrangement[7-9] is illustrated in Fig. 1. The gas evolved from the specimen under the influence of the radiation enters the ion source of a MSKh-3 Chronotron (or MSKh-3A) time-of-flight instrument, where it is partly ionised by the electron beam and, after passing through the drift tube, is recorded by the electron multiplier. In order to eliminate the single-pulse nature of the recording of the spectra and accumulate the evolved gases, the effusion method[17] has been used[13].

A number of investigators[10-12,18] placed the test specimen between the electrodes of the ion source of the MSKh-3A instrument to improve the sensitivity of the analysis. The working pressure in the measuring chamber of the mass-spectrometer was maintained at a level of 5×10^{-9}–5×10^{-8} mmHg and the mass resolution did not exceed 20.

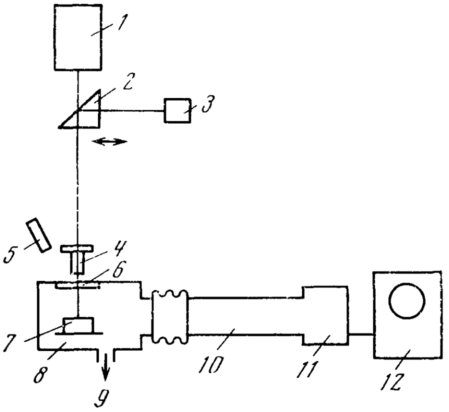

Figure 1. Schematic representation of the instrument with a time-of-flight analyser: 1) laser; 2) prism; 3) eye-piece; 4) object lens; 5) illuminator; 6) inlet window; 7) specimen; 8) vacuum chamber; 9) outlet to vacuum point; 10) "Chronotron" sensor; 11) electronic component; 12) secondary electron multiplier.

By applying the method of calibration graphs, procedures were developed for the quantitative analysis of hydrogen, oxygen, and nitrogen, in titanium, silicon, and zirconium specimens[8,9] as well as in aluminium, titanium, and niobium alloys[11,12]. Reference specimens would apparently extend the range of substances susceptible to analysis by the above method. The experiments carried out with silicon of different origins[8] yielded identical dimensions of the craters formed by the laser pulse regardless of the impurity concentration. Consequently the volume of the sample taken for analysis is independent of the content of the alloying impurities, which leads to a linear relation between the height of the mass-spectrometric peak for the impurity and its concentration in the specimen. Over a wide range of impurity concentrations, the calibration graph consists of a straight line with a slope determined by the type of impurity and the matrix in which it is contained.

In estimating the sensitivity of the method, investigators[9,11,12] used specimens saturated by the given gas to a specified concentration. The lower limit of the observation was[12] 1×10^{-4} wt.% for oxygen and nitrogen, and 5×10^{-5} wt.% for hydrogen with 95% confidence limits. A decrease of the pressure of the residual gases by evacuating the system led to a further improvement of sensitivity[9].

It was shown that the degree of localisation of the analysis is determined by the type of test substance and the conditions governing the focussing of the radiation. For example, the diameter of the focussed spot was 30 μm in one investigation[11], while other workers[7] investigated the distribution of hydrogen in the grains and in the intergranular boundaries of aluminium by interposing a diaphragm in the laser beam. The errors in the determination of the concentration of gases ranged from 5 to 25%, depending on their content and the nature of specimen. The scatter of the analytical results is apparently determined by the variations in the size of the sample evaporated per laser flash and can also be a consequence of the inhomogeneous distribution of the impurities in the specimens analysed.

Gaseous impurities in the bulk phase, in a surface layer approximately 50 μm thick, and on the surface of nickel have been studied[10] with a time-of-flight MSKh-3A mass-spectrometer using a laser to evaporate the sample material (radiation energy $E \simeq 2$ J, $\tau \simeq 0.5$ ms). The authors noted that, bearing in mind that the binding energy of the sorbed gases is approximately 10 kcal mole^{-1}, in a study of the surface desorption of gases one must employ a defocussed laser beam with $q \simeq 10^3$ W cm^{-2}. In this case, the surface gases are fully desorbed for only slight heating of the surface, which does not therefore entail the desorption of gases from the bulk phase. In an experimental test of the distribution of oxygen in the surface layer and in the bulk phase, nickel specimens were employed. The results of laser probing were compared with data obtained on etched plates by a dynamic method at 900°C. The comparison demonstrated a satisfactory agreement of the results obtained by the local and integral methods. The amount of gases (H_2, H_2O, $CO + N_2$, O_2, and CO_2) present in the surface layer exceeded by a factor of 2–3 their concentration in the bulk of the material. However, one should note that the application of a laser operating in the non-Q-switched mode has led[10] to unduly thick layers (~ 20 μm) removed per laser flash and the distribution of gases with respect to depth in the material could be investigated only very approximately. According to the authors' estimates, the sensitivity of the layer-by-layer analysis of gases was in the range 5×10^{-5}–1×10^{-4} wt.% and the reproducibility of the results was within approximately 50%.

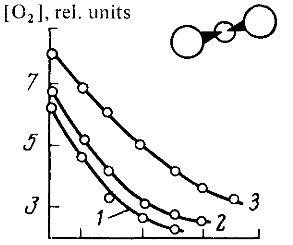

Figure 2. Curves for the distribution of oxygen with respect to the depth of the crystals after oxidation for 20 h at different temperatures (0°C): 1) 400; 2) 500; 3) 650.

The distribution of gases at different depths in the specimens has also been investigated in a study[13] where the distribution of oxygen in a cadmium telluride crystal was determined. These data (Fig. 2) are apparently of the same kind as obtained in another study[10], but similar curves are not quoted. Fig. 2 shows that the probing of the depth of specimens using a free running laser is restricted to a 20 μm region.

A novel problem, involving the study of the composition and partial pressures of the gases within the cavities of the 22KhS ceramic and also the study of its gas content due to its natural porosity, has been solved[18]. The authors note that the laser ($E \simeq 2$ J, $\tau \simeq 0.5$ ms) makes it possible to "open" cavities (0.5–1.2 mm in size) and pores in the ceramic material and cause the complete evolution of the gas contained therein, followed by its analysis on a time-of-flight mass-spectrometer. The experimental data obtained for the gas content in the cavities and pores led to the conclusion that the composition of the gases in the cavities differs somewhat from that in the pores in containing a higher proportion of carbon-containing gases. It was also established that the gas pressure varies linearly with the reciprocal of the radius of the defect.

Thus methods for local, rapid, and quantitative mass-spectrometric analysis of gases in elements[8,9], alloys[10,12], and chemical compounds[13,16] have been developed using a free running laser. The laser has been used in these studies to evaporate small (20–100 μm) sections of the specimen with subsequent ionisation of the evolved gas by an electron beam and the analysis of the ions on a time-of-flight mass-spectrometer of type MSKh-3A. Analysis based on the plotting of calibration curves makes it possible to investigate the distribution of gaseous impurities in the specimen.

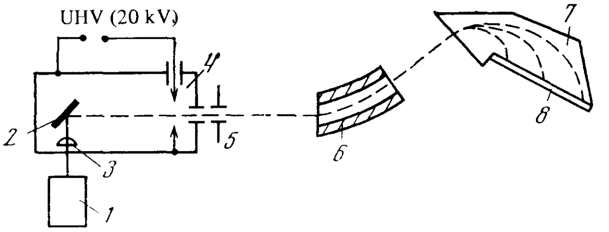

Figure 3. Schematic representation of the instrument with an analyser of the Mattach–Herzog type: 1) laser; 2) specimen; 3) focussing lens; 4) electrodes of the spark generator; 5) mass-spectrometer slit; 6) electrostatic analyser; 7) magnetic analyser; 8) recording plate.

The laser has been used[19–28] both for the evaporation and ionisation of chemical compounds. In this case, the resolving power of the mass-spectrometer (R) should be higher than in the analysis of light gases. Furthermore, in selecting the mass-spectrometric apparatus, it is necessary to take into account the considerable (~10 eV) scatter of the kinetic energies of the ionic component of the laser plasma and the complexity of the mass-spectra obtained[20,22–28]. Mass-spectrometers with an analyser of the Mattauch–Herzog type[19,25–28] (Fig. 3) having $R \geqslant 1000$ or with a time-of-flight analyser[20,22–24] having a resolution of approximately 100 have been used for the analysis. In order to obtain such resolution, the authors[20,22–24] achieved a monoenergetic ($\Delta T/T \ll 1$) ionic component of the laser plasma by accelerating it specifically using the electrodes of the ion source (Fig. 4). The detector could record both the ionic and neutral components of the plasma generated by the laser radiation. The spectra of neutral vapours have been obtained[20,22–24] following their ionisation by an electron beam with an energy of 15 eV, while other investigators[25–28] ionised the neutral component in a high-frequency spark discharge.

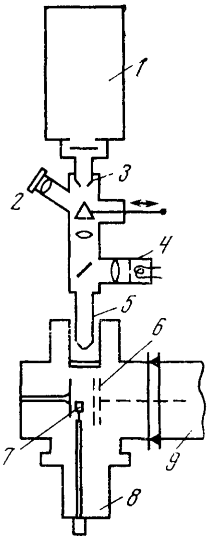

Figure 4. Schematic representation of the ion source: 1) ruby laser; 2) eye-piece; 3) diaphragm; 4) illuminator; 5) object lens; 6) accelerating grid; 7) specimen; 8) vacuum manipulator; 9) flight tube.

Studies have been made[20,22–24] on the products of the evaporation by the laser beam ($q \simeq 10^7$ W cm^{-2}) of Group VA and VIA elements, their intermetallic compounds[22–24], and also certain solid organic polymers[20]. It has been noted that the spectrum contains a large number of polyatomic ions of the elements and their compounds and that the number of polyatomic compounds in the mass-spectrum of the neutral component is greater than in the spectrum of the ionic component of the vapour. The results presented in these studies indicate a considerable difference between the laser and the usual (for example Knudsen) thermal evaporation. This difference is reflected in the type of polyatomic fragments constituting the vapour, the relative intensities, and the maximum number of atoms entering into the compound. The correlation between the type of polyatomic formations in the vapour and the structure of the condensed phase has been discussed[23,24]. It has been shown[24] that the structural difference between the polymorphic modifications of As_2O_3 is reflected in the type of polyatomic compounds present in the vapour. However, this relation has not been observed in all cases[22]. The relative intensities of the peaks of the polyatomic formations are in some instances unexpected. For example, Te_5, Sb_3, and Bi are the strongest ionic components in the vapours of tellurium, antimony, and bismuth respectively. In the experiments[30] on the usual thermal evaporation, these components are present in small amounts or are altogether absent. Fragmentation may occur in the vapour as a result of the high (close to critical) temperatures and pressures obtained in the zone where the laser radiation operates. The analytical characteristics of the apparatus are not indicated[20,22–24], but the Tables of the mass-spectra presented[20] show that the resolving power was approximately 100.

Mass-spectrometric studies of the plasma produced on evaporation of ferrites and semiconductor compounds of the type A(III)B(V) by a laser have been carried out[25,27]. When nickel ferrite ($NiO.Fe_2O_3$) is atomised, the ionic part of the vapour consists of products of the complete dissociation of its constituent oxides. Additional ionisation by a high-frequency spark does not affect the quantitative and qualitative compositions of the mass spectrum. The ratio of the intensities of the isotopic iron and nickel ions corresponds approximately to the stoichiometric formula of this ferrite. A study of yttrium ferrite ($(Y_2O_3).(Fe_2O_3)$) showed[25] that, together with the dissociation products (Fe,Y,O), oxygen-containing groups of atoms, in the first place YO and FeYO, are present in the mass spectrum. The ratio of the Y^+ and Fe^+ ionic currents deviates appreciably from that required by the stoichiometric formula. Additional ionisation by high-frequency sparks leads in this case to an appreciable redistribution of the ionic currents of the elements and compounds. It is believed[25] that the difference between the degrees of ionisation of iron and yttrium in the laser plasma can be accounted for by the difference between their ionisation potentials.

Analysis of intermetallic compounds of the type A(III)B(V) showed[27] that the Ga^+, As^+, and As_2^+ ions derived from gallium arsenide specimens and the Ga^+, P^+, and P_2^+ ions derived from gallium phosphide specimens predominate in the mass spectrum of the ionic component of the vapour. Ionisation of the neutral vapour causes an increase of the relative content of ions of the type As_n^+ and P_n^+, which the authors believe indicates the predominance of these species in the neutral part of the vapour. Comparison of the results of the laser and the usual thermal evaporation of compounds of the type A(III)B(V) leads to the conclusion that the degree of ionisation of gallium vapour following evaporation by laser radiation is much higher than in thermal evaporation. Lasers operating under specific conditions are preferable for the analysis of impurity concentrations averaged with respect to the volume of the specimen on a static mass-spectrometer of the Mattauch–Herzog type. For example, a laser with a radiation pulse frequency of 6.25 Hz has been used to analyse geological specimens[19]. Each pulse had $\tau \simeq 2.5 \times 10^{-4}$ s and $E \simeq 0.15$ J. The specimen analysed was moved automatically at a rate of 1 mm min^{-1}. The ion current generated by the laser radiation was 10^{-11} A, which, according to the authors, permitted analysis with a fairly short exposure time. The shape of the mass-spectrometric lines on the photographic plate was much more distinct than in the mass spectra obtained using a spark ion source. It was shown[19] that the presence of 5 wt.% of graphite increases the sensitivity of the method for certain elements (Si, Ti, and Fe), probably because the presence of carbon in the laser plasma promotes the dissociation of the metal–oxygen bonds. The concentrations of the majority of the impurities detected in the above study[19] (with the exception of alkali metals) were in the range 10^{-2}–10^{-3} at.%.

It is seen from the results quoted above that the published reports of investigations do not contain data on the coefficients of relative sensitivity for various (non-gaseous) impurities. There are no estimates of the lower limit at which impurities can be detected and of the accuracy of the results. Thus methods for quantitative mass-spectrometric analysis of non-gaseous impurities in solids using lasers operating under free running conditions have not so far been developed.

III. ANALYSIS USING A LASER OPERATING WITH A Q-SWITCHED RESONATOR (GIANT PULSE CONDITIONS)

When a giant laser pulse ($\tau \simeq 10^{-7}$–10^{-9} s, $q \geqslant 5 \times 10^8$ W cm^{-2}) acts on a solid, a highly ionised plasma is produced[2,3]. The diameter of the resulting crater is determined by the focussing conditions and its depth $H < 1$ μm depends on the type of substance and the power density in the laser beam.

The appreciable spread (0.5–2 k eV) of the initial energies of the ions formed when giant laser pulses act on a solid[3] makes many instruments with ordinary focussing unsuitable for mass-spectrometric analysis in this case. For example, the design of a time-of-flight mass-spectrometer with a laser ion source has been described[31], but its low resolving power (< 10), caused by the appreciable spread of the initial ion energies, apparently precludes its use for analytical mass-spectrometry. Calculations[32] for a time-of-flight mass-spectrometer with a laser source, designed for the analysis of gaseous mixtures in metals, showed that the high initial spread of the kinetic ion energies ($\Delta T \simeq 1000$ eV) requires an additional acceleration of the ion beam in order to achieve adequate mass resolution. The authors quote data for the time and amplitude characteristics of the accelerating potential pulses necessary to achieve a mass resolution of approximately 15. Theoretical estimates of the sensitivity of this instrument yield approximately 10^{-7}–10^{-8} at.% in the determination of gaseous impurities. However, allowance for the influence of the space charge of the ion beam apparently leads to an impairment of the analytical characteristics of the instrument compared with the calculated characteristics.

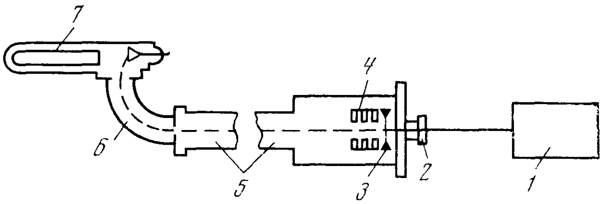

Figure 5. Schematic representation of the instrument with an energy analyser: 1) Q-switched laser; 2) object lens; 3) foil specimen; 4) single-potential lens; 5) flight space; 6) energy analyser; 7) scintillation detector.

In order to improve the resolution of the mass-spectrometer, an electrostatic analyser with a 90° deflection of the ion beam was placed[33] at the end of the flight tube (Fig. 5). Nevertheless, the resolving power of the instrument did not exceed 30. This is probably due to the high space charge in the ion beam. In order to improve the resolving power of the instrument (up to 90), some investigators[35-39] placed at the end of the flight tube (approximately 3 m long) an analyser with crossed electrostatic and magnetic fields (Fig. 6). The design of the instrument also made it possible to employ the electrostatic and magnetic analysers separately. A characteristic feature of the time-of-flight instrument used in some investigations[41-47] (Fig. 7) involves the use of the analytical component of a commercial MKh 1303 mass-spectrometer as the analyser. A resolution of 100 was obtained at the 5% level of the peak height. The fundamental analytical characteristics of the instrument employed[41-47] are as follows: lower limit of detection approximately 1×10^{-4} at.%, error of analysis 15% for an impurity concentration of approximately 10^{-2}%, information capacity[48] of the mass-spectrometer approximately 5×10^3 bits. The parameters of the laser radiation were $E \simeq 1$ J, $\tau \simeq 40$ ns, and $q \simeq 2 \times 10^9$ W cm^{-2}. The high density of the laser plasma[2,3] and the large scatter of the ion energies forced the investigators[35-39,41-47] to reject any ion-optical systems in the laser source. The ions spread throughout the flight tube with the energies which they acquired at the initial stage of the fragmentation of the condensed portion of the plasma. The lack of ion focussing and the considerable length of the flight space lead to an appreciable impairment of the transmission coefficient and hence to a decrease of sensitivity to approximately 10^{-5}–10^{-4} at.%.

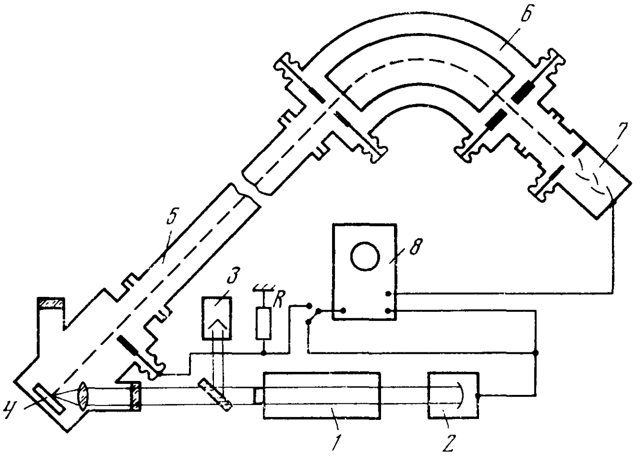

Figure 6. Schematic representation of the instrument with an analyser comprising cross electrostatic and magnetic fields: 1) laser; 2) photoelectric cell; 3) energy measuring device; 4) specimen; 5) time-of-flight analyser; 6) analyser with crossed electrostatic and magnetic fields; 7) secondary electron multiplier; 8) recording oscillograph.

When Q-switched lasers were used, several interesting analytical problems were solved. A Q-switched ruby laser ($\tau \simeq 30$ ns, $q \simeq 10^{10}$ W cm^{-2}) was used to evaporate and ionise thin specimens of a solid[33]. According to the authors' estimates, the efficiency of the ionisation of copper was 10^{-2} ions per atom. The ionisability of certain other thin metallic foils (Al, Fe, Ag, Au, and Li) was approximately the same with the exception of sodium and potassium films, the ionisability of which was higher. Apart from these substances, specimens of solutions of various substances, particularly metal nitrates, hydroxides, and chlorides, were also investigated. Copper and aluminium foils served as supports for these solutions. Peaks corresponding to singly charged and multicharged atomic ions only were observed in the resulting mass spectra. The ionisation efficiencies of various metals in such specimens were approximately the same, but for other components of the specimen, for example H, N, O and Cl, the differences between ionisabilities reached two orders of magnitude.

Figure 7. The abundances of the isotopes of elements atomised by laser pulses ($\tau \simeq 40$ ns, $E \simeq 0.5$ J) have been measured[36]. The authors note that the accuracy of the determination of the isotope ratios (approximately 3% of the measured quantity) is lower than in measurements on instruments of the static type, because of the relatively low accuracy of the measurements which is in general characteristic of dynamic instruments. It was concluded that fast measurements of the isotopic abundances, restricted to a region limited mainly by the aberrations of the optical system and the divergence of the laser beam, may be made by the proposed method.

Analysis of lead, indium, and niobium specimens led to the detection of impurities[39] whose content in the lead specimen was approximately 10^{-4} at.%. The authors believe that the sensitivity of the instrument is sufficient to detect impurities at concentrations of approximately 10^{-5} at.%.

The possibility of investigating the elemental composition of multicomponent geological rocks has been reported[37]. The ion source used to evaporate and ionise the sample was a neodymium laser ($\tau \simeq 40$ ns, $q \simeq 4 \times 10^{10}$ W cm^{-2}). Comparison of the results with data from emission spectroscopic analysis showed that elements with low atomic weights can be more effectively determined on a laser mass-spectrometer. In order to determine the concentrations of the elements in geological rocks, the energy distributions of the detected ions were found from the experimental results. Integration of the distributions makes it possible, according to the authors, to obtain the average atomic concentrations of the elements present in the sample. However, this method of determining the concentrations of the elements is extremely laborious and unsuitable for local or layer-by-layer analysis of the impurities present in the specimen. It should also be noted that, in order to employ this method, it is necessary to make sure initially that the ionisations of the atoms of various substances under the influence of laser radiation with flux density $q \simeq 4 \times 10^{10}$ W cm^{-2} are equally probable.

The experimental determinations of the stoichiometric compositions of ionic crystals of the type $A_nB_mC_p$ have been published[38]. The power density of the laser emission was $q \simeq 2 \times 10^9$ W cm^{-2} in the analysis. The stoichiometry of the selected crystals was determined from the ratio of the peak heights for singly charged ions of the elements A, B, and C having an energy of 100 eV. This method for the determination of stoichiometry conflicts with other data[33], which, however, may be accounted for by the differences between the objects analysed in the two investigations[33,38] and also by the differences between the energies of the ions used for analysis†.

Using a time-of-flight mass spectrometer (with an electrostatic analyser to improve mass resolution) in combination with an "Arzni" laser, Kholodar' et al.[40] studied the distribution of carbon in silicon specimens. By scanning the surface of the specimen with a laser beam, they established that carbon may be present in the form of inclusions consisting (according to electron diffraction data) of the β-phase of silicon carbide. The size of the inclusions, determined by electron microscopy, is between 0.1 and 20 μm. The analytical characteristics of the mass-spectrometer are not quoted.

It is seen from the above results that the problem of the consistency between the composition of the substance in the solid phase and the composition of the ions formed from the solid under the influence of giant pulses of laser radiation was not studied in the above investigations[31-40]. The relevant reports do not therefore describe methods for the quantitative analysis of impurities in the elements and in the compounds, stating merely the possibility of the qualitative analysis of solids using laser ion sources. For a quantitative determination of impurities, it is necessary to know the coefficients of the relative sensitivity to impurities in different matrices, or the instrument must be calibrated against standards with known impurity contents, or analytical methods without standards must be developed‡.

In view of the foregoing considerations, the authors[41-46] concentrated attention on the justification of methods for the quantitative mass-spectrometric analysis of the elements using calibration graphs[42,43] and an internal standard[46] as well as the method of the layer-by-layer analysis[44,45,47] of solids with ionisation of the sample by giant laser pulses.

For the purpose of mass-spectrometric analysis using a laser ion source, it was necessary to elucidate the dependence of the ejected mass of the irradiated specimen (the sample size) on the concentration of its impurities. The upper limit of the impurity concentrations for which the mass ejected from specimens with a matrix of the given type changes under the influence of irradiation by giant laser pulses was studied using silicon, iron, and aluminium specimens with significantly different types of chemical bonds between the atoms in the lattice. The form and concentration of the impurities in these specimens were known. It was found[46] that the ejected mass is independent (within the limits of a 12% experimental error) of the content of impurities if the concentration of the latter does not exceed 9, 6, and 0.9 at.% for aluminium, iron, and silicon specimens respectively.

In the development of the method for the quantitative analysis of steel for carbon, manganese, and chromium, spectroscopic standards were used[43]. It was established that the dependence of the height of the mass-spectrometric peak of the impurity element on its concentration is linear. The sensitivity of the instrument to the impurity depends on its nature and can vary severalfold. The data used to plot calibration graphs for each impurity were reproduced several times and the slope (sensitivity) for each impurity did not vary with time. It was concluded that the sensitivity of the instrument to carbon in silicon is twice as high as the sensitivity to carbon in steel and approximately equal to the sensitivity to vanadium in steel. Consequently the sensitivity depends not only on the nature of the impurity element but also on the nature of the main substance. Thus, quantitative mass-spectrometric analysis of solids requires at least one standard of the same type as the specimen analysed.

---

†The energy spectrum of the ions formed under the influence of giant laser pulses is complex (see, for example, Bykovskii et al.[60]) and the form of the spectrum has still not been fully explained. Unfortunately, the authors of the analytical studies do not by any means always state the energies of the ions used for analysis. The problems of the determination of the stoichiometric compositions of solid binary compounds have been investigated in greatest detail by I.D.Kovalev, N.V.Larin, and G.A.Maksimov [Letters to Zhur.Tekh.Fiz., 1, 798 (1975)] and by G.G.Devyatykh, I.D.Kovalev, N.V.Larin, and G.A.Maksimov [Dokl.Akad.Nauk SSSR, 226, 109 (1976)], whose papers were published after this review had been written.

‡The problems of the development of methods without standards are dealt with in the reports by I.D.Kovalev, G.A.Maksimov, and N.V.Larin ["XI Mendeleevskii S'ezd po Obshchei i Prikladnoi Khimii; Analiticheskaya Khimiya, Referaty Dokladov" (The XIth Mendeleev Congress of General and Applied Chemistry. Analytical Chemistry. Abstracts of Reports), Izd.Nauka, Moscow, 1975, p.110] and Yu.A.Bykovskii, G.I. Zhuravlev, L.M.Babenkov, T.A.Basova, X.I.Belousov, V.M.Gladskoi, V.V.Gorshkov, V.G.Degtyarev, and V.N.Nevolin [V Vsesoyuznaya Konferentsiya po Polucheniyu i Analizu Veshchestv Osoboi Chistoty, Gor'kii, Tezisy Dokladov" (The Vth All-Union Conference on the Preparation and Analysis of Specially Pure Substances, Gorky. Abstracts of Reports), Izd.Nauka, Moscow, 1976, p.125], which were published after this review had been written. The second communication reports the attainment of a detection limit of 10^{-7} at.%.

Despite its satisfactory accuracy (to within approximately 8%), the method of quantitative analysis using calibration graphs plotted from the determinations of impurities in standard specimens suffers from a number of disadvantages associated with the lack of standard specimens for different impurities in matrices of various types. For this reason, a method has been developed for quantitative mass-spectrometric analysis without standards[46]. In a study of the effect of giant laser pulses on the elements, the authors established that, for these substances, the number of ejected atoms (N), the yield of ions (n^+), and the ionisability ($\epsilon = n^+/N$) have a periodic relation to the atomic number of the element. The absolute ionisability of iron, for example, is 1.4%§, which is close to the value of Fenner and Daly[33]. It has been shown that the ratio of the ionisability of the impurity to the ionisability of the matrix is equal to the coefficient of relative sensitivity[49] in mass-spectrometric analysis¶. Depending on the nature of the material of the matrix and the impurity, the above coefficient can vary by a factor of ten[46]. A method for the quantitative analysis of the elements using an internal standard, which is the substance of the matrix of the given specimen, has been developed on the basis of these data.

Since the coefficient of relative sensitivity K for many pairs of elements is unknown, a formula has been proposed[46] for the estimation of this quantity:

$$K = \frac{\Delta Q_0 \varphi_i \sigma_0^2}{\Delta Q_i \varphi_0 \sigma_i^2}\ , \qquad (1)$$

where ΔQ is the heat of sublimation, φ the ionisation potential, σ the cross-section for the ionisation of the atoms by electrons, and the subscripts i and 0 refer to the corresponding impurity element and the matrix. For the majority of the elements, the calculated and experimental data are in satisfactory agreement.

The results of the analysis of the impurities in various standard steels, specimens of silicon, chromium, germanium, copper, and aluminium indicate the possibility of employing the method with an internal standard. The accuracy of the analysis is to within approximately 15% for an impurity concentration of approximately 10^{-2} at.% and the lower limit of the detection of impurities is 10^{-4}–10^{-3} at.%, depending on the nature of the impurity and the main substance.

The effect of the giant laser radiation pulse on the solid leads to the appearance of a crater at the point of the interaction of the laser beam with the surface of the specimen[3]. The average thickness (H) of the layer of substance removed by one laser pulse has been determined[45] from the results of Devyatykh et al.[41] The results of the calculation of H are presented in the Table with a relative error not exceeding 20%. The thicknesses of the layers removed from the majority of elements are not quoted in the literature, but the values of H for silicon agree satisfactorily with the data of Grevtsev et al.[50] The determination of H for different energy densities of the laser beam showed that an increase of the energy density from 0.35×10^2 to 1.6×10^2 J cm^{-2} leads to an increase of the thickness of the layer removed by a factor of 2–4.

The average thicknesses (H) of the layer removed for a radiation energy of 1 J, area exposed to radiation $S = 1 \times 10^{-2}$ cm^2, and a pulse duration of 40 ns.

Element	H, µm	Element	H, µm
C(graphite)	3.22	Zn	0.53
Al	0.7	Ge	1.92
Si	1.49	Zr	0.37
Mg	1.08	Nb	0.16
V	0.29	Mo	0.17
Cr	0.25	Ag	0.51
Fe	0.42	Cd	0.64
Ni	0.45	Sn	2.19
Cu	0.21		

The concentrations of the impurities detected in the layer of substance can be determined from the mass spectrum. The lower limit of the detection of impurities in the layer-by-layer analysis is at the level of 10^{-4} at.% and can vary over a factor of ten depending on the ionisability of the matrix and the impurity; the error of the measurements is approximately 25%. The spatial resolution with respect to depth in the method involving the laser probing of solids is at least 0.5 µm for the majority of the substances investigated (see Table). For iron, niobium, molybdenum, and many other transition metals, the resolution with respect to the depth of the layers removed reaches 0.05 µm for an energy density of the giant laser pulse of approximately 0.35×10^2 J cm^{-2}. The layer-by-layer analytical method has been used[47] to investigate the distribution of carbon in chromium films. It is seen from the results that the employment of giant laser pulses to evaporate and ionise a sample in the ion source of the mass spectrometer makes it possible to take into account the distribution of impurities in thin layers of solids.

Taking into account the above features, the use in mass spectrometry of lasers working under giant pulse conditions may be regarded as promising for the determination of the average content of impurities and for the elucidation of their distribution with respect to depth and on the surface of solids†.

---

§The dense plasma formed under the influence of giant laser pulses is almost fully ionised ($\epsilon \simeq 100\%$). However, at the end of the laser pulse, there is sufficient time for the dispersal of only a small part (n^+) of the peripheral ions. The so called "quenching" of the degree of ionisation is observed for ions of this kind[60]. These ions can in fact be recorded in mass-spectrometric analysis. The remaining ions on the inner part of the concentrated region of the plasma recombine almost completely to neutral atoms within distances of the order of the initial size of the plasma[61]. Attempts to remove all the ions from the concentrated part of the plasma have not so far been described in the literature.

¶Ions corresponding to the high-energy maximum[60] in the energy distribution for the given element have been used for analysis[41–47].

†The report by S.V.Gaponov, I.D.Kovalev, V.I.Luchin, G.A.Maksimov, L.I.Pontus, and A.I.Suchkov in "V Vsesoyuznaya Konferentsiya po Polucheniyu i Analizu Veshchestv Osoboi Chistoty, Gor'kii, Tezisy Dokladov" (The Vth All-Union Conference on the Preparation and Analysis of Specially Pure Substances, Gorky. Abstracts of Reports), Izd.Nauka, Moscow, 1976, p.132, was published after this review had been written. The authors obtained a focussed spot 15 µm in diameter, which enabled them to investigate the distribution of microinclusions in solids.

IV. COMPARATIVE CHARACTERISTICS OF LASER, SPARK, AND THERMIONIC ION SOURCES USED IN THE MASS-SPECTROMETRIC ANALYSIS OF SOLIDS

An ion source with surface ionisation (a thermionic source) was proposed for mass-spectrometers by Dempster in 1918. In 1936, he developed methods for obtaining ions based on the electrical breakdown of the interelectrode gap *in vacuo* (spark ion source). The first publications[4-6] on the use of lasers in the ion sources of mass-spectrometers appeared in 1963. A monograph dealing with the mass-spectrometric methods using ion sources with electric discharges[53] states that the authors included in the book a chapter on a laser source which successfully supplements the technique employing a spark source. It is also noted in this monograph that the available information about laser sources is at present inadequate. The comparative characteristics of the thermionic, spark, and laser mass-spectrometric methods are described below. The source with secondary ion–ion emission has been excluded from consideration, because quantitative analytical methods have not so far been developed for this method of obtaining ions from a solid.

When the surface of a metal with the electron work function φ and the first ionisation potential I is heated to a certain temperature, there is a definite probability of evaporation of positive and negative ions together with neutral species. The relative intensities of the fluxes of positive ions n^+ and neutral atoms n^0 are defined by the Sacha–Langmuir equation (see, for example, Kaminsky[54]). The ionisation efficiency varies exponentially with the difference between the electron work function and the ionisation potential. For alkali metals on the surface of tungsten, $\varphi - I > 0$ and the ionisation efficiency in evaporation is approximately unity. If the difference $\varphi - I < 0$, which occurs with the majority of elements, the ratio n^+/n^0 decreases[1] to 10^{-6}. In order to employ the thermionic emission effect in mass-spectrometry, ion sources with one or three tungsten filaments[1,54] and a crucible ion source[55] are used. The mass-spectrometers of types MI 1305, MI 1308, MI 1309, MI 1310, and MI 1311 produced in the USSR are nowadays equipped with three-filament ion sources with surface ionisation.

Three types of sources can be distinguished in accordance with the method used to achieve the electrical breakdown of the vacuum gap[1,49]: the high-frequency spark source, the source of the "vacuum vibrator" type, and the low-voltage source. The high-frequency spark source has been used most frequently in analytical mass-spectrometry. It has been shown in a report by Gorman[56] and in many subsequent publications that the efficiencies of the ionisation of the atoms of various elements are different in the high-frequency spark source. The quantity characterising this difference is the coefficient of relative sensitivity K which is determined empirically using standard specimens. Extensive data on the determination of relative sensitivity coefficients have been compiled in a monograph[49]; it has been noted that K remains constant for a wide range of impurity concentrations in the matrix investigated. The same applies to a laser ion source[43,46]. In the spark source, the differences between the relative sensitivity coefficients for a given impurity in different matrices can reach an order of magnitude. For example K for indium[49] is 1.1 in iron and 9.2 in zinc. The differences between the values of K for a laser source[46] are of the same order of magnitude‡. Consequently, when no account is taken of the corrections introduced by the coefficient of relative sensitivity, the error in the determination of the concentration (for both spark and laser sources) may reach 1000%. Since the values of K for all impurities in different substances cannot be obtained experimentally, attempts have been made in spark mass-spectrometry to determine them from certain physical parameters characterising the substance. The best agreement with experiment is given by the calculation of K from the formula[49] $K = \sigma/\Delta Q\varphi^4$, where σ is the effective ionisation cross-section of the atom, ΔQ the heat of sublimation, and φ the ionisation potential. Comparison of the above relation with Eqn. (1) demonstrates some similarity between the evaporation and ionisation processes when the substance is acted upon by the laser radiation and the "spark".

Thus the differences between the ionisabilities of the atoms of various elements in spark and laser sources are an order of magnitude. A much higher selectivity in the ionisation of the substance is characteristic of the thermionic source, the difference between the ionisation efficiencies reaching in this case six orders of magnitude. However, in view of the limitations of the thermionic emission method associated with the difficulty of preparing the samples for analysis, the possibility of their contamination, and the effect of the "memory" of the thermionic source[57], the authors of a monograph[52] note that the method is not universally applicable in mass-spectrometry.

The sensitivity of the analysis by spark mass-spectrometry is 10^{-5}–10^{-7} at.%.[1,49,53] The sensitivity of the determination of impurities when a laser ion source is used amounts to 10^{-4}–10^{-5} at.%, but the comparatively low sensitivity of the laser method can be explained by the inadequacy of the ion-optical systems of the mass spectrometers§ which have been used in combination with this ion source; there was no ion-optical arrangement directly in the source[33-46]. In the thermionic emission method, the sensitivity of detection is 10^{-5}–10^{-7} at.% only for alkali metals, while for the majority of other elements it is less satisfactory by several orders of magnitude[1,57].

The formation of ions in the laser source is probably more efficient than in the spark source. Thus it has been stated[49] that, in order to detect an impurity at the level 10^{-3} at.% in substances with a high atomic weight, the volume of the specimen which must be atomised in the ion source is approximately 3×10^{-5} cm^3. This corresponds (for average densities of the substance $\rho \simeq 5$–6 g cm^{-3}) to the atomisation of a mass of approximately 2×10^{-4} g. The ejection of such a mass may be achieved only for comparatively long exposures to the spark. In a laser ion source, impurities at a concentration of 10^{-3} at.% can be detected after a single exposure to a giant laser pulse. The ejected mass does not then exceed 10^{-6} g for the majority of substances. The integral ion current generated under the influence of a single laser radiation pulse is then > 1 A. The coefficient of the ionisation efficiency is $n^+/n^0 \simeq 10^{-2}$. The corresponding currents for spark ion sources are not quoted in the literature.

The comparatively long exposures to the spark required to detect an impurity at a level $\geqslant 10^{-3}$ at.% hinder to a large extent local layer-by-layer analysis of solids. The scope of the laser ion source for local layer-by-layer analysis is characterised by average thicknesses of the layer removed by a single layer pulse (see Table). The size of the spot in analysis using a laser reaches 10^{-5} cm^2

and the ease with which a given section of the surface to be irradiated is selected makes it possible to investigate, for example, the distribution of gases in the grains and along the intergranular boundaries of metals. For the above reasons, the method of layer-by-layer analysis using a laser[45] is simpler than the corresponding method using a spark ion source[58]. There are no methods of layer-by-layer analysis using a thermionic source.

The spark ion source does not apparently allow experiments designed to investigate the surface sorption of gases. The application of a laser makes it possible to investigate the composition of the gases sorbed on the surface, since giant laser pulses with $q \simeq 10^7$ W cm^{-2} do not disrupt the specimen but do eliminate the gases present on the surface of the sample[45,59].

The employment of a laser in the ion source permits a rapid determination of the composition of the substance. The time consumed in obtaining the complete mass-spectrum of the impurities in the substances analysed does not exceed 2–5 min. When the spark source is used, the time is several hours. The simple structure of laser mass spectra (giant pulses), consisting of the lines corresponding to singly and multiply charged atomic ions[35,46], permits a rapid interpretation of the spectrogram, while the structure of the spark mass-spectra is very complex[1,49,53]. The lines recorded in the spectrum correspond to a wide variety of multiply charged and polyatomic ions. The number of lines depends on the number of isotopes of the element, its physical properties, and the parameters of the spark discharge. The mass-spectrum always contains lines due to the ionisation of the residual gases. In order to take into account the organic impurities and to make sure that the lines of the multiply charged and polyatomic ions detected in the mass-spectrum do not overlap, the analytical lines of the impurities, the resolving power of the mass-spectrometer must be fairly high ($\geqslant$ 1000).

In analysis using a laser ion source, it is in fact immaterial whether the test specimen is a conductor, a dielectric, or a semiconductor. Analysis of dielectric materials and geological rocks on a mass-spectrometer with a spark ion source requires fairly complex preliminary operations owing to the impossibility of the direct analysis of non-conducting solids in a spark source. Analysis of dielectrics is based on the application of special "igniting" electrodes (probes) made of conducting high-purity materials. The electrodes for the analysis of non-conducting powders are made by packing the samples into metallic tubes, by pressing them with added graphite powder, or by sputtering films of the dielectric investigated onto metallic electrodes[49]. The complexity of the spark mass-spectra is in this case aggravated by lines due to the conducting additives introduced into the substance analysed.

The error in the determination of the concentration of impurities using a laser ion source is 12–15%, which corresponds approximately to the errors in spark mass-spectrometry[49]. Such non-reproducibility of the results is caused mainly by the scatter in the parameters of the laser radiation pulses. The rapid development of laser techniques gives rise to the hope that in the immediate future the characteristics of the lasers will be improved and that this will increase the accuracy of the results obtained on mass-spectrometers with laser ion sources.

The characteristics of laser ion sources described above indicate the possibility of extending the range of problems soluble by the mass-spectrometric analysis of solids as well as good prospects for the development of the mass-spectrometric analytical method using laser ion sources.

The Chemical Aspect of Exoemission

I.V.Krylova

The results of studies on exoemission employing various excitation procedures are examined from the single standpoint of physicochemical reactions on the surfaces of solids. The prospects for the application of exoemission in scientific research and in engineering are discussed.
The bibliography includes 164 references.

CONTENTS

I. THE PROBLEM OF EXOEMISSION

Exoemission is a new type of emission of negative charges—slow electrons and ions—together with thermal emission, autoemission, photoemission, and secondary emission. In contrast to the types of emission known previously, it appears after a solid has been subjected to various influences inducing the formation of excited states and exhibits an appreciable inertia. On subsequent heating in the pre-Richardson region, the emission exhibits a number of peaks characterising the energy spectrum of the charge localisation levels on the surface.

The emission may be excited either by physicochemical reactions in the surface layers accompanying adsorption (desorption), oxidation, corrosion, and catalytic processes, phase transformations, etc. or as a result of external influences—mechanical, radiation, etc. Since emission occurs at low temperatures, the emitting surface may be assumed to be in a thermodynamic non-equilibrium state and to retain the properties resulting from its previous history. This gives rise to the prospect of employing exoemission in the study of physicochemical processes on the surface.

Detailed investigation of this effect began with Kramer's studies in 1950.[1] Despite the publication of numerous reports, particularly in recent years[2], exoemission continues to remain a relatively little investigated phenomenon, which is considered only by a limited circle of physicists.

There is at present no theory whereby one could explain from a single standpoint the emission from metals and non-metallic crystals, semiconductors, and dielectrics. Kramer[1] suggested that mechanical influences on the surface of metals result in the formation of an amorphous phase (the Beilby layer) and that the emission is a consequence of the exothermic transformation during its recrystallisation. This hypothesis still stands, but the effect described by Kramer has been called "exoelectron emission" (The First International Symposium, Innsbruck, 1957).[3] Unfortunately there is a confusion in terminology and the individual types of manifestation of exoemission are referred to as "chemoemission",[4] stimulated emission[5], sorption emission[6], and low-temperature emission[7]. This situation merely complicates the development of a single mechanism of this phenomenon and hinders mutual understanding between teams of research workers concerned with the problem of exoemission.

In order to explain exoemission from metals, a hypothesis has been put forward[8] according to which electrons are emitted as a result of the heat of adsorption of active gases and the peaks of the thermally stimulated emission correspond to centres with different adsorption potentials.

The problem of the nature of emission from ionic crystals—crystalline phosphors and coloured alkali metal halides for which electron energy level schemes have been developed fairly satisfactorily—has been investigated to the greatest extent. The majority of studies in this field are based on the experimental analogy between the phenomena of exoemission and luminescence and are directed to the investigation of the physical aspect of this phenomenon[1,9-12]. According to the most general Bohun-Nassenstein theory[10,12], the electrons entering the conductivity band on excitation are localised at shallow capture levels. After the removal of excitation, the trapping levels are gradually vacated owing to thermal energy with transfer of electrons via the conductivity band outside the limits of the crystal—afteremission is observed or, when the electrons enter activator levels, there is an afterglow (phosphorescence). Decaying afteremission frequently occurs only on stimulation with light and in this case the emission is said to be photostimulated. In a number of studies it has been assumed[13] that the thermally stimulated emission (TSE) and the photo-stimulated emission (PSE) are two different phenomena involving different mechanisms, which should be considered separately.

The afteremission phenomena are due to the relaxation processes of the excited states and in the general case can be described by a sum of exponential terms or by the empirical law $I \propto I_0 t^{-n}$, where $n \simeq 1$. When the temperature is increased uniformly, deeper levels are vacated—thermally stimulated emission is observed with a set of maxima corresponding to localisation levels of different depths. For the analysis of the energy spectrum of the capture levels, the mathematical procedures of the theory of luminescence developed by Randall and Wilkins[14] are used. In the mathematical treatment of exoemission kinetics, one usually calculates the depth of the localisation levels (more precisely the activation energy for the release of electrons) and the pre-exponential factor. A very thorough critical review of studies concerning the kinetic analysis of exoemission phenomena has been published[15]. The authors note the deficiencies of the mathematical procedure of the luminescence theory (of Randall and Wilkins, Lushchik, etc.) and its modification in relation to calculations of the depth of the localisation levels of exoelectrons[14,16]. A method has been proposed for the analysis of the complex spectra of thermally stimulated emission when several unresolved peaks are superimposed. The possibility of resolving the TSE peaks and of determining their parameters has been demonstrated. Similar problems are being solved in the theory of thermal luminescence and in the analysis of thermal desorption spectra.

On the basis of "physical considerations", exoemission has been considered[15] as one of the possible channels for the relaxation of excited solids. The simplified relaxation mechanism proposed by the above workers is given below:

exoemission or thermal luminescence

other channels for relaxation involving the same capture centre.

The results of non-isothermal experiments undertaken in the study of thermally stimulated emission, thermal luminescence, etc. led to a method for the interpretation of experimental data[17] whereby one can determine the parameters of the two processes involved in the mechanism. Recommendations have been made for computer calculations on the kinetics of relaxation processes (programming). The authors note that the correct determination of the kinetic parameters by any of the methods described in the literature is then possible only when account is taken of the multichannel processes in relaxation. According to Burkhanova et al.,[15] the proposed mathematical models are of interest for the construction of a physical picture of the relaxation; they have been analysed in detail[15] and will therefore not be considered in the present review.

Thermally stimulated emission takes place as a result of the thermal liberation of negative charges in the pre-Richardson region when the energy of the electrons in the state of thermodynamic equilibrium is insufficient to overcome the surface potential. Photo-stimulated emission takes place under the influence of light with a wavelength exceeding the red limit of the photoeffect. Thus the phenomena considered are observed in the region of stimulating influences below the threshold values for thermal emission and photoemission and one of the central problems of the theory is the origin of the energy required for the release of electrons.

It has been suggested[18,19] that the energy required for the release of electrons is supplied by electron–hole recombination processes in transitions between the bands ("Auger recombinations"). This energy is transferred, for example, by the exciton mechanism, to the electrons localised at shallow capture levels near the surface. According to Bohun, only the high-energy component of the Maxwellian distribution of conductivity electrons is emitted (in the author's terminology[19], the "Maxwell tail theory"). It is noted that the "Auger mechanism" is valid only for dielectrics, where the width of the forbidden gap exceeds the electron affinity of the crystal, but does not explain the emission from semiconductors.

Assuming that TSE is a quasistationary process, Bohun[14] combines the equations of thermionic emission and thermoluminescence and obtains expressions describing the experimental data for emission from coloured or activated alkali metal halides.

The mathematical models for calculations on exoemission kinetics, based on the most general physical concepts, make it possible, according to Burkhanova et al.,[15] to determine the energy spectrum of the surface traps; the role of the surface potential in the exoemission phenomena is not discussed in this connection. The mathematical apparatus of Bohun's theory[14] represents the electron liberation processes as processes in which the surface potential is overcome. The role of the electron work function (electron affinity) has been considered theoretically also in a number of other studies[20], but the experimental results concerning the influence of the surface potential on the exoemission parameters are contradictory.

It has been established[21] that the intensity maxima of thermally stimulated emission from certain metals correspond to the minimum electron work functions and exoemission has been suggested[22] as a method for the determination of the surface potential. An unambiguous correspondence between the parameters of exoemission and the electron work function has not been found in recently published investigations[23,24]: the emission capacity can increase after both a decrease and an increase of the electron work function. The results make it necessary to approach with even greater caution the interpretation of the results of studies on exoemission from the standpoint of the band theory of solids. Analysis of the available data shows that the fundamental exoemission parameters (decay constants, the number and positions of the peaks on the temperature curves characterising the spectrum of the energy states on the surface) are not determined by the nature of the emitting substance—the width of the forbidden gap, the type of conductivity, the nature of the chemical bond, and whether or not the substances are semiconductors or dielectrics, metals, oxides, or salts[25].

In view of the presence of non-compensated bonds, the surface of a real solid is known to be always covered by adsorption layers, particularly water. Since emission takes place from shallow surface layers, the adsorption film should play a significant role in emission processes. A phenomenological theory of the origin of exoemission has been proposed[25]. It is based on the interpretation of the physicochemical processes accompanying the formation and relaxation of the excited states in surface layers in the presence of adsorption films.

The chemical aspect of exoemission is considered in the present review. Various types of manifestation of emission accompanying the physicochemical processes on the surface or arising as a result of external influences are discussed. The results are considered from the single standpoint of the physicochemical reactions accompanying the relaxation processes in the damaged surface layer.

II. EXPERIMENTAL METHODS FOR THE INVESTIGATION OF EXOEMISSION

In view of the low currents (10^{-17}–10^{-19} A), exoemission is studied under conditions where individual pulses are counted. Geiger counters or secondary electron multipliers (SEM) are used in combination with standard radiometric apparatus[26]. Since the exoelectron energies are small (from a few tenths of an electron-volt to several electron-volts), the electrons do not pass through the mica window and the emitter must be placed within the counter. The designs of special counters of this type have been described[27]. Some investigators use closed counters applying an accelerating potential before the inlet window[28]. Gas-flow counters are more convenient and reliable. The working plateau (500 V) hardly changes when the temperature is raised to 400°C.[29] The application of an accelerating potential to the grid over the specimen constitutes a significant improvement to the operation of the counters; this not only increases the sensitivity but also reduces the scatter of the results.

In experiments with gas-filled counters, it is impossible to investigate the role in exoemission of physicochemical factors due to adsorption-desorption, catalytic, and other processes. The development of the chemical aspect of exoemission has become possible after secondary electron multipliers of the open type have been devised and high and ultrahigh vacuum techniques have been employed. The method of the physicochemical investigation of exoemission developed in a number of studies[25,30,31] involves special "cleaning" of the emitter in a high or ultrahigh vacuum and simulation of the emitting surface by the adsorption of the corresponding gases and vapours under controlled conditions.

The autoradiographic method, based on the familiar Russell effect[32,33], is used for the analysis of structural changes under mechanical influences. This method is not suitable for studies *in vacuo* and its sensitivity is low. An image of the structure of a high quality surface was obtained after the development of channel multipliers. Microchannel plates, consisting of a system of close-packed channel multipliers, make it possible to obtain directly the image of the emitting surface. An exoemission microscope has been developed on the basis of microchannel plates[34,35].

Studies *in vacuo* using a secondary electron multiplier with application of a deflecting magnetic field established the occurrence of the emission of negative ions together with that of electrons[36-38]; the ionic component was observed only in TSE measurements on substances containing adsorption layers. It therefore appears useful to replace the generally accepted term "exoelectron emission" by the term "exoemission".

Numerous studies dealing with the distribution of exoelectron energies have been published recently. The average energy of the electrons emitted after Emery powder has been ground is 0.65 eV.[39] The most probable energy of the electrons in the afteremission from BeO caused by electron bombardment is 0.1 eV.[40] A Maxwellian distribution of electrons, with average energies amounting to a few tenths of an electron-volt, has been found for photostimulated emission from K_2SO_4.[41] It was noted that the electron energy depends on the accelerating potential, the charge acquired by the specimen as a result of the emission, the optical stimulation energy, temperature, and the presence of adsorption layers. A study has been devoted[42] to special problems of the influence of the charging of the specimen surface, occurring both on excitation and as a result of emission processes, on the distribution of exoelectron energy.

The average energy of the emitted electrons in thermally stimulated emission from $BaSO_4$ ($t_{max} = 160°C$) was 1.1 eV, only 10% of the electrons had an energy of 2.7 eV, 1% had an energy of 5 eV, and the energy of 0.1% was greater than 8 eV.[43] The average exo-electron energies for TSE from ceramic BeO specimens were 0.5 eV.[44] The energy distribution depended on the technology of the manufacture of the ceramic; for $t_{max} = 250°C$, the maximum electron energy varied from 1.5 to 16 eV. Even higher energies (up to 80 eV) were found[45] for thermally stimulated emission from the surface of oxidised silicon. It is noteworthy that such high electron energies cannot be achieved, for example, as a result of exothermic chemical reactions, Auger recombination processes, or the emission of the high-energy component of the Maxwellian distribution, i.e. they cannot be understood on the basis of the available models of the origin of exoemission[18,19]. In order to account for the high electron energies, a theory was proposed[45] postulating the possibility of the acceleration of electrons in the strong field of the electrical double layer comprising the dielectric—the oxide covering the semiconductor. However, it is possible that the high electron energies observed by the authors are due to methodological errors.

A study of TSE from LiF specimens showed that a Maxwellian distribution of exoelectron energies occurs only at temperatures ≤ 100°C; with increase of temperature, deviations from the Maxwell law are observed. The authors note that the interpretation of the energy measurements in terms of the approximate equations of thermionic emission must be treated with caution. Studies on the distribution of the energies of exoelectrons from an aluminium surface (TSE)[47] also showed that the average energies and their temperature dependence are inconsistent with the exoemission models based on the band theory and the thermionic emission approximations.

III. EXOEMISSION ACCOMPANYING PHYSICOCHEMICAL PROCESSES

1. Emission in Adsorption and Oxidation of Metals

Studies under conditions of high and ultrahigh vacuum have now established that atomically clean metal and semiconductor surfaces lack exoemission capacity[48-50]. When active gases are admitted, particularly oxygen and water vapour, an intense emission of negative charges is observed. It has been established that the occurrence of the emission accompanying adsorption and oxidation requires photostimulation[48], but in some studies such emission has been observed in the dark[51].

A freshly formed layer of aluminium *in vacuo* ($p \simeq 10^{-7}$ mmHg) does not emit electrons. When oxygen is admitted ($p \simeq 10^{-5}$ mmHg), emission, decaying over a period of time, takes place[52]; in order to excite the emission, a continuous incidence of oxygen molecules on the surface is necessary. The emission in the adsorption of oxygen on a nickel film sputtered under ultrahigh vacuum conditions ($p \simeq 10^{-10}$ mmHg) has been studied[53]. Each successive admission of oxygen is accompanied by an emission flash, whose "yield" is 10^{-10} electrons per molecule. At room temperature the emission intensity initially decreases and then rises again, the number of emitted electrons depending strongly on the time interval between the successive doses of oxygen. The observed phenomena are explained by the gradual incorporation of the adsorbed molecules in the lattice, which terminates in several minutes; according to approximate estimates, two oxygen monolayers are sorbed. Similar processes occur when oxygen is sorbed by atomically clean tungsten and copper surfaces[53].

In some studies, an atomically clean metallic surface was formed as a result of the removal of oxide by milling[48,49,54]. The admission of oxygen at a specified pressure (5×10^{-5} mmHg) to a zinc surface cleaned with a steel brush gives rise to emission, whose intensity passes through a maximum[54]. A similar result was obtained for zinc and aluminium under ultra-high vacuum conditions[48].

The residual gas pressure has a significant influence on two factors: the time interval elapsed after cleaning the surface before the appearance of the maximum and the intensity of the latter (Fig. 1). After the maximum, the emission intensity diminishes exponentially; at a residual pressure $p \simeq 1 \times 10^{-8}$ mmHg, neither dark nor photostimulated emission was observed in the course of 10 min. Comparison of the time required for the appearance of the emission maximum (τ'_{max}) and the time required for the formation of a monolayer (τ'') showed that τ'_{max} exceeds τ'' by a factor of 10^3–10^4. The results were examined taking into account the Cabrerr–Mott mechanism of the oxidation of metals and it was concluded that the exoemission is not associated with the adsorption step but is due to a slower process—the initial oxidation stage. A shift of the limit of the photoeffect to the long-wavelength region in adsorption and oxidation takes place according to some investigators[48,49], owing to the decrease of the photoelectron work function of the oxide layer formed, although the corresponding measurements of φ were not made.

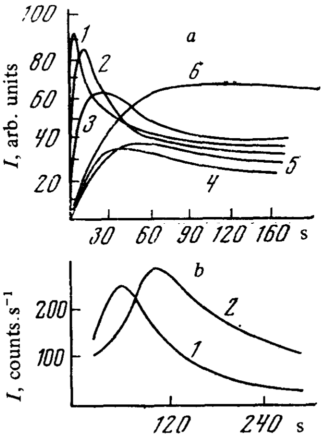

Figure 1. Time variation of the PSE intensity: *a*) from a zinc surface after cleaning at different residual gas pressures[49] [pressure (mmHg): 1) 5; 2) 3; 3) 2; 4) 1; 5) 0.7; 6) 0.2]; *b*) from an aluminium surface after mechanical treatment by impact[60] [time (min): 1) 1; 2) 4].

Simultaneous studies on photostimulated emission and the surface potential in the oxidation of metals have been made by Gel'man and Fainshtein[55]. The surface was cleaned in air and the emission was recorded by means of an open proportional counter. An increase of the surface potential φ corresponded to a fall of the PSE intensity I in the initial stage of oxidation; after a further growth of the oxide layer, the emission intensity increased and passed through a maximum and the correspondence between I and φ broke down. Since the experiments described were performed under non-controlled conditions, it is difficult to interpret the results, in particular it is impossible to take into account the role of the adsorbed water and oxygen.

Measurements of PSE and of the surface potential under controlled conditions with the aluminium surface cleaned in an ultrahigh vacuum were carried out by Linke and Born[56]. At a residual pressure $p < 10^{-5}$ mmHg, the emission intensity passed through a maximum after the surface had been cleaned, as in other studies[49,54]. In an ultrahigh vacuum ($p \simeq 10^{-10}$ mmHg), PSE was not observed even after a very vigorous mechanical treatment. Emission did not appear even after several hours following the admission of oxygen ($p \simeq 10^{-4}$ mmHg). It was found that the presence of adsorbed water is necessary for the appearance of PSE. Fig. 2 illustrates the variation of the "tribophotostimulated" emission from an aluminium surface in an atmosphere of water vapour and oxygen. In the former case, the emission intensity increased to a limit, falling after the next admission of oxygen. The authors[56] believe that, in the case of metals coated by adsorbed layers with a thickness of several angstroms, PSE represents photoemission of electrons from the metal; here the shift of the limit of the photoeffect occurs as a result of changes in electron work function in the presence of adsorbed molecules. This conclusion was confirmed by direct measurements of the photoelectron work function by Fowler's method. The admission of water reduced φ from 4.5 to 3 eV and led to the appearance of emission following illumination with red light.

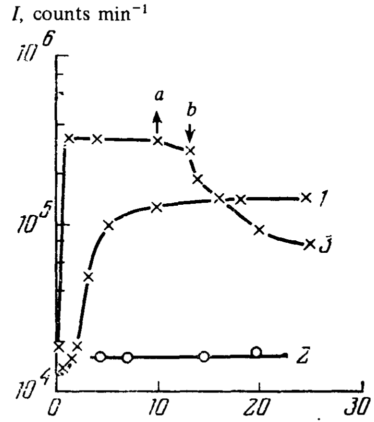

Figure 2. Time variation of the intensity of PSE from an aluminium surface after cleaning in different atmospheres: 1) H_2O (7.5×10^{-8} mmHg); 2) O_2 (8×10^{-8} mmHg); 3) H_2O (1×10^{-6} mmHg); *a*) evacuation; *b*) admission of O_2 (4×10^{-6} mmHg).[56]

The experiments described above led to a second fundamental conclusion[56]: the structural defects generated by mechanical treatment do not form emission centres in the absence of adsorbed layers. This postulate is consistent with Scharmann and Seibert's data[48] and demonstrates the lack of validity of the view of some investigators on the nature of exoemission from deformed metals, who failed to take into account the decisive role of the physical chemistry of the surface in exoelectron emission processes[57-60].

2. Thermally Stimulated Emission in Desorption

For the majority of substances investigated—metals, elementary semiconductors, oxides, and ionic crystals (salts)—the phenomenon of "self-excited" emission has been observed: when the initial specimens are heated without any preliminary external influences (excitation[3]), peaks appear on the temperature curves. These effects are manifested particularly clearly when the test substances are subjected to a preliminary treatment leading to the hydration of the surface. Intense TSE is observed after metals are wetted with water[61], semiconductors are etched[37], alkali metal halides are hydrated[36,62], etc.

The initial metals[61], which did not exhibit emission, were wetted with water, dried, and heated at a linear rate in air, while recording the charges with an open counter. The "self-excited" TSE curves (t_{max} = 295°C for Al, 225°C for Fe, and 225° and 270°C for Cu) were compared with the curves obtained for the same specimen after mechanical cleaning. A satisfactory agreement of the temperatures of the peaks was observed, but the intensity of the maxima was significantly higher for the metals wetted with water. For germanium specimens subjected to mechanical treatment and wetted with water, the temperatures of the peaks varied in the range between 240° and 360°C, depending on the duration of treatment with water, i.e. the degree of hydration. It was concluded[61] that the exoemission parameters are not constants of the substance, but are determined by the method used for the preliminary treatment. The processes occurring in the oxide film are responsible for the emission. On dehydration, structural changes take place in the oxide and lead to the formation of capture levels (emission centres).

Direct experiments *in vacuo* established[30,63–65] that, when highly hydrated oxides such as Al_2O_3, MgO, synthetic zeolites, etc. are heated, the increase in TSE intensity is accompanied by vigorous gas evolution at certain temperatures (140–160°, 280°, and 360°C). Later these results were checked and confirmed[15]. Simultaneous studies of thermally stimulated emission and thermal desorption accompanied by condensation or mass-spectrometric analysis led to the conclusion that the self-excited emission is caused by the desorption of water. Calculation showed that one electron is emitted for approximately 10^6 desorbed molecules. Fig. 3 presents the results of studies on TSE and the rate of thermal desorption from magnesium oxide[64]. The present author's special experiments[50] under ultrahigh vacuum conditions (10^8–5 × 10^{-9} mmHg) showed that the observed effects are not a consequence of "parasitic" signals arising in the detector due to gas evolution, as suggested by Burkhanova et al.[15]

Bohun, who is the author of the most widely accepted theory of exoemission based on the band model[14], notes that some results do not fit within the framework of this concept. Thus distinct TSE peaks have been observed for initial alkali metal halides without colour centres in the range 230–430°C, particularly when the specimens were wetted with water, alcohol, etc.[62] It was suggested that reactions take place on the surface of the crystal coated by the adsorption film and result in the emission and desorption of both neutral and charged species. However, since the experiments were carried out in air and the emission was recorded with an open counter, the above postulates could not be subjected to an experimental test. Studies *in vacuo*, in which the emission was recorded with a secondary electron multiplier accompanied by mass-spectrometric analysis, showed[36] that the "self-excited" TSE from sodium chloride is due to the desorption of water (in the form of negative ions).

Thus it has now been established for substances of different classes—metals, semiconductors, and dielectrics—that emission occurs not only as a result of adsorption with liberation of energy but also accompanies desorption processes involving the absorption of energy. These phenomena could not be understood from the standpoint of the available hypotheses and were explained from the standpoint of the physicochemical mechanism of exoemission developed by the present author[25] (see also Section VI).

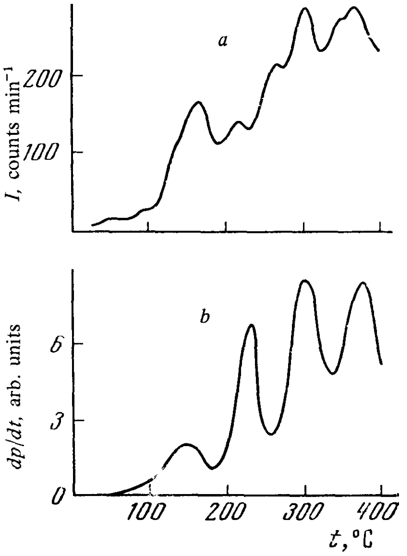

Figure 3. Temperature variation of the intensity of "self-excited" TSE (*a*) and of the rate of thermal desorption (*b*) from an MgO surface[64].

Desorption, which is an important stage in the activation of many adsorbents and catalysts, leads, according to the data examined above, to the formation of excited states with long relaxation times, which is important for the understanding of the processes involving the formation of an active surface.

3. Exoemission and Catalysis

According to modern ideas, heterogeneous-catalytic processes take place at active centres where electron exchange in the catalyst–substrate system is facilitated. Exoemission also occurs from a small fraction of the surface (active centres) where the binding of electrons is weakest; only approximately 10^{-6} of the surface atoms are capable of emission. Since such emission is observed over a wide range of temperatures, including the temperatures where heterogeneous-catalytic reactions occur (20–500°C), exoelectrons may participate in catalytic reactions. On the basis of these considerations, some workers pointed out a possible relation between emission and catalysis already in the early stages of this research[62,66]. Definite correlations were established between catalytic activity and emission capacity for substances of different classes—metals, semiconductors, and adsorption catalysts[67-69] (Fig. 4). As in studies involving the application of the majority of physical methods, catalysis and exoemission were investigated in such research under different conditions and only indirect conclusions about the causes of the observed correlations could be made.

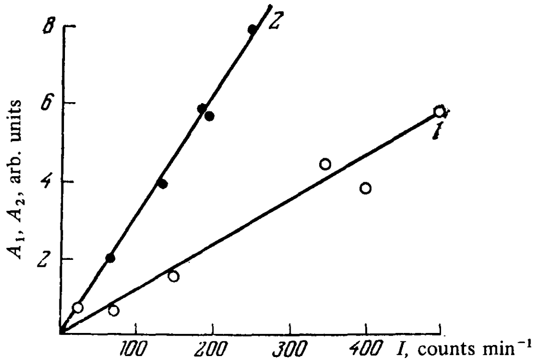

Figure 4. Relation between the emission capacity and catalytic activity: 1) $Pt(SiO_2$ with different platinum contents in the vapour-phase hydrogenation of cyclohexene[69]; 2) ZnS.Cu with different copper contents in the decomposition of methanol[68].

Studies have now been published where the heterogeneous-catalytic reactions were carried out directly in the chamber for the measurement of exoemission with simultaneous recording of the emitting charges. Exoemission from a silver catalyst in the course of the partial oxidation of ethylene has been investigated[70]. It was shown that the emission intensity in the range 150–210°C is proportional to the rate of formation of epoxyethane. At a constant temperature (250°C), non-decaying emission, accompanying the oxidation reaction, was observed. Exoemission under such conditions is regarded as thermal electron emission from a thin semiconductor oxide layer, for which the electron work function is reduced as a result of the adsorption of the epoxyethane formed. The authors support this view by the finding that exoemission is not observed during the reaction on copper, nickel(II) oxide, and iron(III) oxide, where only complete oxidation of ethylene takes place.

However, it is noteworthy that the authors[70] carried out experiments in which emission was recorded by a gas-filled counter and a component of the reaction mixture (ethylene) played simultaneously the role of the quenching gas. Under these conditions, the presence of oxygen and of water vapour (produced by the reaction) in the atmosphere of the quenching gas might have interfered with the operation of the counter and might have distorted the results of the measurements.

Another investigation[71] was undertaken to study the emission accompanying the catalytic oxidation reactions of CO, H_2, and NH_3 on a heated platinum wire. The experiments were performed *in vacuo* at partial pressures of the reacting gases of 10^{-6} mmHg. The authors attempted to discover whether exoemission is a necessary stage in the heterogeneous oxidation or whether it merely accompanies the catalytic reaction but has no influence on the latter. It was found that the increase or suppression of the emission capacity of the platinum catalyst when a negative potential is applied to it is accompanied by the simultaneous increase or decrease of the rate of catalytic oxidation. Hence it was concluded that exoelectrons are directly involved in heterogeneous-catalytic reactions. It is suggested that the observed correspondences are based on the same rate-limiting stage in both processes—the adsorption stage—which is believed[53] to be accompanied by intense emission.

However, the observed effects[71] can hardly be attributed to the involvement of exoelectrons in the reactions. This is indicated by two fundamental factors: the fairly high temperatures at which the emission and catalytic reactions take place (⩾ 800°C) and the fairly large currents (~ 10^{-8} A), which are not characteristic of exoemission. It is more likely that Richardson thermal emission from the platinum wire and the changes in its intensity owing to the increase or decrease of the thermal electron work function following the adsorption of oxygen, hydrogen, etc. are involved here.

The phenomenon of exoemission accompanying catalytic reactions in the adsorption layer at temperatures between 100° and 400°C, typical for catalytic reactions, has been observed and investigated[72,73]. A study was made of the catalytic oxidation and decomposition reactions on metals, oxide semiconductors, and ionic crystals. The experiments were formulated on the basis of the following initial postulates. The binding energy of oxygen in the surface layer of oxides is known to determine to a large extent their catalytic properties in oxidation reactions. Only "mobile" oxygen participates in reactions on specimens with inhomogeneously bound oxygen[74]. On the other hand, it has been shown that thermally stimulated emission processes are accompanied by the desorption of active gases and vapours[30,31]. Analysis of the results of comprehensive studies led to the conclusion that the emission and desorption centres are formed by mobile oxygen atoms on the surface layer of the oxide[25].

The oxidation of hydrogen and carbon monoxide has been studied[73] on oxides with hole (NiO) and electronic (ZnO) types of conductivity and on a metal (platinum black). The reaction was carried out in a cell for the measurement of exoemission with simultaneous recording of negative charges by a secondary electron multiplier. The catalyst was activated in oxygen (400°C) and hydrogen was then adsorbed. Emission, decaying with time, was observed for platinum black even at room temperature. The decay was found to be represented by the sum of two exponential functions with relaxation times τ_1 = 300 s and τ_2 = 3700 s. This was accompanied by the emission of not only electrons but also ions, the presence of which was detected by measurements in a deflecting magnetic field. Subsequent heating at a linear rate of both platinum and NiO led to the appearance of more or less distinct emission peaks at 130–150°, 180–190°, and 240–260°C. Repeated heating results in a change of the relative intensities of the peaks, which indicates the formation of active centres during the reaction (Fig. 5). The conclusion that catalytic reactions occur under the given conditions was confirmed by the results of thermal desorption analysis[73].

In conformity with the mechanism proposed by the present author[25] and later by Euler et al.[134] for exoemission from oxides, the TSE peaks are due to valence transformations in the layer of adsorbed oxygen, for example:

$$O_2\,(\text{ads.}) + e \underset{\text{stimulation}}{\overset{\text{excitation}}{\rightleftarrows}} O_2^-\,(\text{ads.})$$

The same forms of oxygen are reactive in heterogeneous-catalytic oxidation[74]:

$$O_2 \rightarrow O_2^- \text{ (ads.)} \rightarrow O^- \text{ (ads.)} \rightarrow O^{2-} \text{ (ads.)} .$$

When charged forms of oxygen interact with the substance being oxidised, there is a reverse electron transfer to the catalyst according to Boreskov[74]. It follows from the data in Fig. 5 that the electrons liberated in the catalytic step can leave the surface ("exoemission"). A possible reaction mechanism is presented below[73]:

$$O^{2-} \text{ (ads.)} + H \text{ (ads.)} \rightarrow OH^- \text{ (ads.)} + e \text{ (loc.)} + Q_{rec}, \quad (1)$$

$$O^- \text{ (ads.)} + H \text{ (ads.)} \rightarrow OH^- \text{ (ads.)} + Q_{rec}, \quad (2)$$

$$OH^- \text{ (ads.)} + H \text{ (ads.)} \rightarrow H_2O^- \text{ (ads.)} + Q_{rec.} \rightarrow H_2O^- \text{ (gas)}, \quad (3)$$

$$e \text{ (loc.)} + Q_{rec} \rightarrow e\uparrow \quad \text{etc.} \quad (4)$$

Electrons are ejected outside the limits of the crystal as a result of the recombination energy of ions and radicals[25,73]. A similar oxidation mechanism, but without allowance for electronic transitions, has been proposed by Khasin and Boreskov[75].

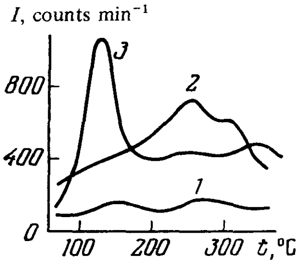

Figure 5. Thermally stimulated emission from an NiO surface: 1) before admission of reaction mixture; 2) after admission of reaction mixture (H_2–O_2); 3) after subsequent heating[73].

Analogous results were obtained in studies on the exoemission accompanying the catalytic decomposition in the adsorption layers of methanol (on Al_2O_3 and NaCl powders) and formic acid (on an NaCl single crystal).[72] It was established that the appearance of the most intense maxima at $t > 200°C$ is accompanied by the formation of decomposition products. The smaller low-temperature peaks are due to fluctuation processes in the adsorption layer (the "pre-catalytic" state). The emission of negative charges—electrons and ions—in catalytic decomposition processes in the adsorption layer is also explained from the standpoint of the radical mechanism of exoemission proposed by the present author[25]. The formation of radicals as intermediates in the catalytic decomposition of alcohols has been demonstrated experimentally[76].

It was found that the decomposition of methanol on a hydrated NaCl surface is accompanied by a shift of the most intense TSE peak to lower temperatures[77]. The products of the dissociative adsorption of water, particularly protons, can serve, by virtue of their high mobility, as energy transferring agents in surface migration and recombination processes; this in fact explains the promoting role of water. The surface diffusion of water plays a decisive role in many cases in chemisorption and catalysis[78].

4. Thermally Stimulated Emission in Phase Transformations

It was shown for the first time in 1950[1] that phase transformations are accompanied by the emission of negative charges. A sharp increase of emission was recorded in the solidification of Wood's alloy and in the allotropic transformations of chromium, selenium, etc. modifications. It was suggested that the emission is caused by exothermic processes. Later these studies were developed further[79-81]. Exoemission has been observed in the transition from the hexagonal to the cubic configuration of thallium[79], in the solidification of bismuth, cadmium, and their alloys[80], in the solidification of aqueous ammonia solutions[81], and in liquid gallium at the temperatures corresponding to structural transformations[82]. The emission was recorded with gas-filled or open counters. Studies on exoemission in phase transformations have already been reviewed in detail[83].

The authors[80-82] emphasise that the observation of exoemission from metals and alloys in their phase transformations requires photostimulation and suggest that the emission of charges is caused by deformations in the oxide film and not by its disruption.

Studies with a gas-filled counter led to the observation of the exoemission accompanying the solidification of lead (t_{max} = 235°C), tin (t_{max} = 235°C), and the lead–tin eutectic alloy (t_{max} = 180°C).[84] However, experiments showed[85] that *in vacuo* emission accompanying phase transformations is not recorded. The available data concerning the coincidence of the TSE peaks with the temperatures of allotropic transformations are also contradictory. Thus, in a study of the transformation of layers of the hexagonal modification of chromium obtained by an electrolytic method, a TSE maximum was observed at 230°C, while the phase transition temperature is 180°C. It is suggested[85] that the thermally stimulated emission is caused by oxidation processes.

In contrast to earlier investigations[84,88], peaks of exoemission from tin and lead were found[87] not only on solidification processes but also on fusion, and for bismuth the emission maximum was observed only on fusion. It was established that, in the absence of an oxide film, there is no emission and that the most intense TSE peaks are observed for an optimum thickness of the oxide layer. The authors[87] suggest that the phase transitions occurring on solidification lead to stresses in the oxide layers, which are removed by the migration of dislocations. The annihilation of dislocations carrying opposite charges leads to the release of phonons, whose energy is sufficient for the liberation of electrons from capture levels.

Despite the ambiguity of the results and of their interpretation, exoemission is recommended for the determination of phase transformation temperatures in those cases where they cannot be found by other methods, for example by thermal analysis. Rostovtsev[88] determined the limits of the solubility of zinc in aluminium (at 100–275°C), the emission being recorded with a gas-filled counter. It was established for a series of alloys of different compositions that TSE peaks correspond to the thermal decomposition temperatures of the solid solution (α) with formation of crystals (β). The results agree with data for the solubility of zinc in aluminium obtained by other methods.

The ageing processes in the aluminium–magnesium–silicon alloy have been investigated[89]. The PSE decay curve at a constant temperature shows a maximum corresponding to the segregation of the excess of the Mg_2Si phase from the supersaturated solid solution. This emission flash is shown 60 min after the start of "ageing" and occurs at the instant of segregation of Mg_2Si found by other methods (for example by electron microscopy). It was concluded that exoemission is a simple and extremely sensitive method for the investigation of the technologically important alloy ageing processes.

Studies have been made on the exoemission in second-order phase transformations[90–93]. The exoemission method has been used to investigate the γ–ϵ transformations of the manganese austenite alloy and of the first- and second-order phase transformations in iron–manganese alloys of different compositions[91,93]. The emission was recorded *in vacuo* with the aid of a secondary electron multiplier. The TSE peaks occurring on heating and cooling were attributed to first-order ($\epsilon \rightleftharpoons \gamma$) and second-order (for example, the transition from antiferromagnetic austenite to paramagnetic austenite) phase transformations. The results were explained[92] by the increased mobility of dislocations at the phase transition temperatures. It is suggested that the intensity of the TSE peaks is associated with the "degree of completion of the phase transformation and the number of structural defects"[93] and the role of physicochemical processes in oxide and adsorption films is not taken into account.

The magnetic transformations in nickel, chromium, and the oxide films coating them have been investigated[92,94,95], the emission being measured with a gas-filled counter. The TSE maxima were observed under illumination at the temperatures corresponding to the Néel points for the oxides (NiO and Cr_2O_3) covering the metal and at the Curie point of the initial nickel. It was established that the fundamental parameters—the temperatures of the peaks and the emission intensity—are determined by the thickness of the oxide layer. It was concluded that the exoemission method can be used to investigate not only phase transformations but also the gas corrosion of metals and in the solution of the problem of the formation of protective coatings in the form of thin films of metals and dielectrics.

Exoemission on heating and cooling has been observed for $Fe_{1-x}S$ pyrite specimens cut out of a lump of the mineral[96]. The peaks and inflections on the curves were attributed to the polymorphic and magnetic transformations in microregions of the crystal with a different phase composition. The powdered specimens did not exhibit emission peaks under these conditions. The exoemission method was suggested for the study of the degree of homogeneity and composition of complex minerals in those cases where the phase transition points depend strongly on the stoichiometry.

The changes in emission intensity at the phase transition points are said[95] to be caused by processes occurring on the specimen surface, for example, the generation of stresses and cracks during plastic deformations in the oxide film owing to abrupt changes in the thermal expansion coefficients. The observed emission is accounted for by the possible local decrease of the electron work function owing to the displacement of dislocations onto the surface followed by adsorption (photosorption) or heterogeneous-catalytic processes when the emitter interacts with the quenching vapour of the counter, etc.[95]

Thus the data available at the present time for exoemission in first- and second-order phase transitions in metals and alloys are contradictory. Depending on the previous history of the specimen and the state of the surface, the TSE peaks may or may not coincide with the phase transition points; the emission observed on heating the specimens, i.e. in phase transformations involving absorption of energy, is difficult to interpret.

There are two views on the nature of the emission in phase transformations. The first is based on the consideration of physical processes only. The emission peaks observed on heating certain ferroelectric substances, for example, are regarded[97] as a result of the "filling of traps with electrons and the liberation of electrical energy in phase transitions". The second view, which takes into account the role of physicochemical factors, is based on the absence of exoemission from metals and alloys lacking an oxide layer, which has been firmly established experimentally[85,87]. A detailed analysis of the available data leads to the conclusion that the emission accompanying phase transitions is caused by a set of complex physicochemical transformations in the oxide and sorption films and can be understood on the basis of the physicochemical concept described below (see Section VI).[25]

In studies of the thermally stimulated emission accompanying the decomposition of certain salts, particularly hydrated salts, it was observed that heating of hydrated quinine sulphate gave rise to an intense emission at 75–100°C; the corresponding emission peak was also observed on cooling[1]. It is suggested that these phenomena are caused by the liberation and absorption of water[1]. Later these studies were repeated[98,99]. The emission and the accompanying luminescence phenomena were absent when quinine sulphate had been dehydrated beforehand.

More detailed studies of emission from hydrated sulphates, chlorides, carbonates, etc. were made by Hanle et al.[100] The charges were recorded *in vacuo* with the aid of a secondary electron multiplier. In all the cases investigated, the liberation of the water of crystallisation was accompanied by the emission of negative ions. The number of TSE peaks corresponded exactly under these conditions to the number of singular points associated with the decomposition of hydrates of different composition; however, the TSE maxima were somewhat displaced towards higher temperatures.

Exoemission was also observed in the decomposition of certain nickel compounds[101]. Thermally stimulated emission was recorded by a gas-filled counter under illumination. The TSE peaks corresponded to the decomposition temperatures of the initial compounds, which was confirmed by X-ray diffraction analysis. Repeated heating led to the observation for all the compounds of the same maximum at 230°C, which was attributed to a phase transition in nickel(II) oxide (the Néel point). The author[101] notes that the method described makes it possible to investigate the kinetics of the thermal decomposition of chemical compounds and to analyse the decomposition products.

IV. EXOEMISSION AND MECHANOCHEMISTRY

1. Metals

For metals, exoemission caused by mechanical influences is in fact of greatest interest. This is because of the possibility of employing exoemission in the study of deformations, the processes involved in the mechanical treatment of machine components, the fatigue resistance of materials, etc. Studies in this field have been concerned with the emission caused by plastic and other deformations, friction, milling, sand-blasting, etc.[1,26,48, 58,59,102]. In these excitation methods, dislocations and point defects (vacancies) and their diffusion and annihilation play a significant role. Secondary surface processes take place simultaneously—the disruption of the oxide film and desorption as well as adsorption and oxidation, these being largely caused by the migration of dislocations onto the surface.

On the other hand, the influence of the physical chemistry of the surface on the mechanical (plastic) properties of metals has been vigorously investigated recently. Deformations are known to be facilitated by adsorption, the effect having been explained by Likhtman et al.[103] The significant influence of oxide and other special coatings on the mechanical properties of metals has been demonstrated. Oxide and other surface formations lead to the generation of energy barriers, preventing the emergence of dislocations; the decrease of the height of these barriers on polishing, etching, and the adsorption of surfactants facilitates deformation.

There is experimental evidence showing also that adsorption processes are the cause of deformations in the surface layer: depending on the nature of the adsorbent-adsorbate system and on the degree of surface coverage, both expansion and contraction can take place[104]. It follows from the foregoing that exoemission, deformation, and adsorption (desorption) phenomena are indissolubly linked and that they should be considered simultaneously.

There exist at present two fundamental and in a certain sense contradictory views on the nature of exoemission from deformed metals. Some investigators[105-108] believe that the processes determining emission occur in oxide layers, while others[57-59] claim that the emission kinetics are determined by the diffusion of defects (dislocations, vacancies) and that emission occurs as a result of the decrease of the electron work function caused by deformations.

A quantitative correspondence between the degree of deformation and the intensity of exoemission has been found[105,106]. The following emission mechanism has been proposed[106]. Plastic deformations lead to the generation of mobile point defects (vacancies) which migrate towards the surface and form capture layers in the forbidden gap of the oxide. The defects produced behave as centres of photoemission and thermally stimulated emission. The significant role of the formation and migration of vacancies and dislocations has been emphasised also in other investigations[57-59,107-109]. It has been shown that the emission intensity $I \propto \epsilon^n$, where n is the degree of deformation. After carrying out experiments on emission from deformed aluminium coated by oxide films of different thickness, Sujak[107] concluded that the emission takes place from charged cracks in the oxide. This model is analogous to that proposed previously[110]. It has been shown[111] that the intensity of emission on deformation increases significantly in the presence of moisture in the atmosphere of the quenching gases of the counter. It is suggested that moisture neutralises the strong electric field arising across the cracks, which hinders the release of electrons. Results obtained with a Geiger counter were confirmed by experiments *in vacuo* using a secondary electron multiplier as the recording instrument[112].

In other studies[57-59], it was suggested that exoemission is determined by the proportion of defects and by the nature of the elementary deformation steps, which depend on the nature of the metal itself. The authors believe that the "deformation excitation" possesses definite specific features and that the emission of electrons accompanying it should be regarded as an independent type of emission. There are numerous experimental facts indicating the lack of validity of these claims. It is also difficult to justify theoretically the existence in a conducting metal of trapping levels giving rise to the prolonged relaxation times of the excited states responsible for exoemission[48,114]. For example, it has been shown[25,48] that exoemission parameters are independent of the method of excitation. On deformation, the emission intensity always increases to a certain limit, after which it falls exponentially (Fig. 1). A similar type of curve with a maximum occurs when an atomically clean metal surface is exposed to active gases[49] and is explained by adsorption and oxidation phenomena. In support of their view that the exoemission on deformation is caused exclusively by the formation of structural defects, the authors[113] present the results of experiments in an ultrahigh vacuum, where PSE was observed following the extension of an aluminium specimen and attribute fundamental importance to them. No account was taken of the fact that, under the conditions of treatment adopted (degassing at 400° C), an atomically clean surface is not obtained and that the observed emission is caused by the degradation of the oxide layer. It has been shown[48,56] that, in the case of an atomically clean surface, mechanical treatment under the conditions of an ultrahigh vacuum does not lead to the occurrence of either photoemission or thermally stimulated emission.

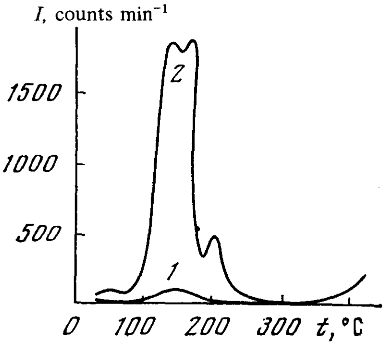

Figure 6. Thermally stimulated emission from a quartz specimen after vibromilling *in vacuo* (curve *1*) and in an atmosphere of oxygen (curve *2*).[125]

Depending on the thickness of the oxide layer, either PSE, which depends on the pressure of the residual gas (layer thickness $d \leqslant 45$ nm), or dark emission ($45 \leqslant d \leqslant 230$ nm) is observed on deformation by extension[114]. In the former case, PSE is analogous to that observed when the surface is cleaned[56] and is caused by the decrease of the electron work function owing to the adsorption of water. In the latter case exoemission is due to the disruption of the oxide film and occurs without photostimulation.

In calculations on the kinetics of exoemission from deformed metals, the authors[115,116] also took into account the cracking of the oxide film, the diffusion of vacancies to the surface, and the interaction of the freshly formed surface with the gases in the surrounding medium followed by oxidation, in contrast to earlier views[57-59].

Exoemission on friction has been examined in detail by Evdokimov and Semov[102], who investigated emission under dynamic conditions during friction and after its cessation, in the absence and presence of lubricating materials. The photostimulated emission was recorded by an open counter in air. For different types of steel and cast iron, the PSE intensity after the cessation of friction passed through a maximum; for the chemically more reactive aluminium, emission whose intensity diminished exponentially was observed. These findings are analogous to those obtained on deformation[57,58] and on adsorption of active gases on freshly formed surfaces[48,56].

Thus the kinetics of exoemission on deformation of metals, friction, and adsorption of gases on freshly formed surfaces are determined by the physicochemical transformations which accompany the relaxation processes in a damaged surface layer.

2. Non-Metallic Crystals

For non-metallic crystals, emission decaying over a period of time has been observed after comminution and grinding[1]. Numerous minerals and inorganic and organic crystals have been investigated. It has been noted[1] that, on comminution *in vacuo*, the crystals acquire an appreciable charge, which plays a significant role in the observed effects. The formation of charges accompanying emission on heating single crystals (LiF) was recently confirmed by direct measurements[117]. The density of the elementary charges was 10^{10} cm^{-2}, but the charging mechanism is not clear. One of the possible explanations is based on the model involving the formation of a "triboplasma", arising when the crystal is cleaved. High energy levels of the emitted electrons were observed; the greatest number of electrons had an energy of 20 keV, while the maximum observed energy was approximately 120 keV. The field strength calculated from the formula $E = \sigma/\epsilon_0$ proved to be approximately 10^5 V cm^{-1}, so that the observed emission is not cold ("field") emission.

Independently of Kramer's study[1], the phenomena of the emission of negative charges in processes involving the dissociation of adhesion and cohesion linkages were investigated and described by Krotova[118], who observed the emission of fast electrons with energies of several keV. It was suggested that the high energies are caused by the acceleration of electrons in the strong fields of the electrical double layer arising following the breakdown of contacts. The phenomenon was called "mechanoemission". The mechanism of these processes is probably different from that of the exoemission of slow electrons. However, it must be emphasised that the after effects, consisting in the relaxation of the excited states arising following the breakdown of adhesion and cohesion contacts, are exoemission. This is indicated by the emission kinetics, which are the same as those observed after excitation by other methods, the low electron energies, and a number of other factors.

The significant role of dislocations in exoemission from ionic crystals has been noted. It has been established[119] that, when LiF is cleaved, mobile dislocations with a free path of several centimetres are formed. The hypothesis has been put forward that these dislocations transport the excitation energy generated by electron bombardment. The intensity of thermally stimulated emission from LiF caused by irradiation with X-rays increases with increase of the density of dislocations[120]. According to Knab and Urusovskaya[120], the observed effect is a consequence of the increase of the number of point defects owing to the interaction of dislocations. The thermal stability of the *F*-centres (the position of the TSE peak) is determined by the interaction of the point defects with dislocations of different types[121]. The authors do not take into account the possible processes involving radiation-induced and postradiation adsorption following the excitation of specimens in air and the recording of the emission by a counter. The conclusion concerning the lack of influence of adsorption layers on exoemission from deformed LiF crystals, reached in some investigations[122,123], are insufficiently justified, since the authors did not undertake special cleaning of the surface, although they recorded the emission under ultrahigh vacuum conditions.

It has been shown[124] that the cleavage of alkali metal halide crystals is accompanied by appreciable gas evolution. It was found that the structural defects generated by the vibromilling of quartz are capable of emission only in the presence of adsorbed oxygen (Fig. 6).[125] Under these conditions, the TSE peak ($t_{\max} \simeq 150°$C) coincides with the maximum in the rate of desorption of oxygen from such oxides[126].

A detailed analysis of data for exoemission caused by mechanical influences on metals and non-metallic crystals leads to the conclusion that the presence of adsorption layers plays a decisive role under these conditions.

V. EXOEMISSION AFTER EXCITATION BY IONISING RADIATION

1. Metals, Semiconductors, and Oxides

Like mechanical treatment, ionising radiation does not excite exoemission from the atomically clean surfaces of metals and semiconductors[45,48]. It is therefore useful to examine emission only from real metals and semiconductors coated by an oxide layer. It has been established[127-129] that, independently of the nature of the metal, the thermally stimulated emission peaks occurring after excitation by X-rays are located in the same temperature ranges (140-160° and 260-280°C). The same peaks have been observed for aluminium[48] acted upon in other ways: milling and exposure to β-radiation. It was concluded that exoemission is excited from the capture levels in the oxide layer.

It has been established for the majority of powdered oxides, excited by electron bombardment, that the TSE peaks are located in the same temperature ranges as for metals[30,127] (Fig. 7). The number and relative intensities of the peaks are independent of the nature of the oxide (semiconductors with electron or hole conductivity as well as insulators), but are not determined by its previous history. The emission capacity of the oxide can be significantly reduced by vacuum heat treatment and increased as a result of the adsorption of active gases and vapours.

It has been established[130] that, following the adsorption of electron-donating gases (hydrogen), the emission capacity of Al_2O_3 excited by X-rays increases, while, on treatment with electron-accepting gases (N_2O, CO_2), it falls. It is suggested[131] that hydrogen adsorbed in the atomic form generates shallow donor levels and that hydrogen and deuterium atoms lead to the formation of donor levels of different depths (the "isotope effect").

The authors of the above investigations begin their interpretation with the concepts of the band model of exoemission and the electronic theory of chemisorption, assuming that the molecules (atoms) of the adsorbed gases generate donor (acceptor) levels, increasing (decreasing) the concentration of the conductivity electrons responsible for exoemission.

More detailed studies for more oxides showed that, in contrast to electrical conductivity, the emission capacity is not determined by the electron-donating or electron-accepting nature of the adsorbed molecules (atoms): the adsorption of oxygen, a typical electron acceptor, on the surfaces of silicon, ZnO, ZnS, SiO_2,[25,37,132,133] and BeO[134] leads to an increase of emission capacity. The band model, which takes into account the role of the concentration of conductivity electrons and of the surface potential in exoemission, cannot explain these results. It is suggested that thermally stimulated emission takes place directly from the capture levels generated by different forms of adsorbed oxygen[30,133,134].

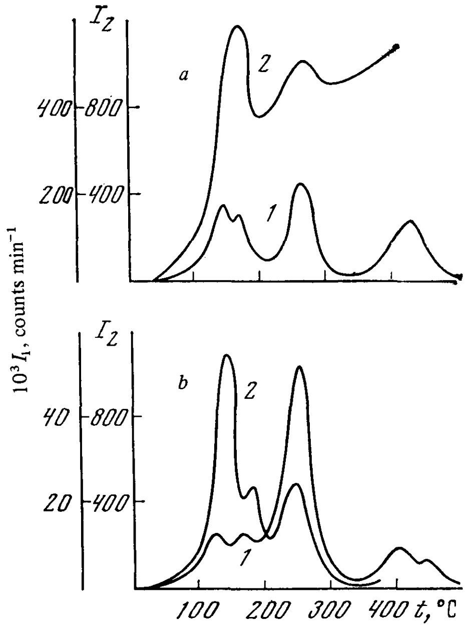

Figure 7. Thermally stimulated emission after excitation by electron bombardment: *a*) from aluminium[129] (curve *1*) and corundum[30] (curve *2*) surfaces; *b*) from nickel[129] (curve *1*) and nickel(II) oxide[73] (curve *2*) surfaces.

It has been established in a recently published study[132] that the surface states responsible for exoemission from oxidised silicon excited by low-energy electrons are generated by adsorbed oxygen (O_2^-). The physical model of the excitation and emission of exoelectrons is based on the potential curves for the excited state of the negatively charged form of adsorbed oxygen. It is concluded that the TSE method can yield valuable information about the state of the adsorbed molecules. This is of interest for both fundamental and applied research, particularly in the field of heterogeneous catalysis.

2. Ionic Crystals

For ionic crystals (crystalline phosphors and alkali metal halides), the commonest method of excitation is treatment with ionising radiation. The electronic energy level schemes for crystalline phosphors and coloured alkali metal halides have been deduced theoretically and investigated experimentally in considerable detail. An analogy has been found between exoemission and luminescence phenomena[1,9–11], which has in fact served as a basis for the development of the most widely accepted band model of exoemission. Like luminescence, exoemission can be excited by short-wavelength light and by high energy radiation (electronic and ionic bombardment, by X-irradiation and β-irradiation, by exposure to a glow discharge, etc.). After the removal of excitation, the decay of the afteremission and the afterglow are described by the same laws. Heat treatment frequently leads to the appearance of TSE peaks and thermoluminescence in the same temperature ranges. It is believed[11] that the analogy is based on common elementary physical processes. At the same time there are also differences between luminescence (bulk-phase effects) and exoemission (a surface phenomenon) phenomena. Luminescence is associated with the presence of activator atoms, while, according to the band scheme, exoemission should be independent of their presence.

Results which do not fit within the framework of the proposed model have been published. For example, it has been found that the intensity of the afteremission excited by electron bombardment depends on the activator concentrations[52]. Agreement between the numbers and temperatures of the exoemission and luminescence peaks is not always observed. The discrepancies between the results of different workers and the marked dependence of the thermally stimulated emission spectra on the technology of the preparation of the phosphors[135] led to the conclusion that surface states are involved in these phenomena; however, the nature of these states has not been considered.

The main objects of the fundamental investigations of exoemission and luminescence are sulphides, sulphates, and alkali metal halides. A correlation between the temperatures of the PSE and thermoluminescence peaks has not been observed for sulphides[136,137]. On the basis of the results of studies *in vacuo*, Behmenburg[136] suggested that in the case of zinc sulphide thermoluminescence is caused by the presence of capture levels in the crystal, while thermally stimulated emission takes place from trapping levels in the adsorption layer (for example, of oxygen). However, the nature of this layer was not investigated.

Exoemission from activated sulphides has been studied[67,138,139] using both a gas-filled counter and a secondary electron multiplier *in vacuo* as recording instruments. In the former case, it was found that the activator (Cu, Ag) has a significant influence on the absolute and relative intensities of the TSE peaks[67,138]. The observed direct relation between exoemission and catalytic activity permitted the conclusion that the emission centres (activator ions) are either the centres of the activated adsorption of methanol or the catalytic centres.

After electron bombardment, TSE peaks were observed for ZnS.Cu, ZnS.Ag, and ZnS.Al single crystals[139] in the same temperature ranges: at 120–140°, 160–180°, and 220°C. Vacuum heat treatment and heat treatment in hydrogen reduced significantly the emission intensity, while the adsorption of oxygen, water vapour, and methanol increased it. The adsorption of an electron-donating gas is known to increase the concentration of conductivity electrons in a semiconductor and to reduce the surface potential, while the adsorption of oxygen acts in the opposite direction. These findings lead to the conclusion that, in contrast to the hypothesis of the band model, the exoemission from the sulphide surface takes place without the participation of the conductivity electrons and that the emission parameters are not influenced by the surface potential either.

Thermally stimulated emission from sulphates has been studied[1,9,11,135]. The emission intensity was measured using as recording instruments a counter after excitation with X-rays or a secondary electron multiplier *in vacuo* after excitation by electron bombardment. Data concerning the positions of the TSE peaks and their correlation with thermoluminescence (TL) are contradictory; the involvement of the activator in the formation of the electron localisation levels on the surface of sulphates is likewise controversial. These contradictions are associated with the differences in the technology of the preparation of the specimens[135], in the methods and duration of their storage[140], and in the methods of excitation and recording which have a significant influence on the state of the adsorption layers. Depending on its previous history, the temperatures of the TSE and thermoluminescence peaks for the same specimen can both coincide and diverge[141].

A correlation between the thermally stimulated emission and thermoluminescence phenomena is observed when gas and vapour molecules adsorbed during technological treatment, during excitation of the emission (radiation-induced adsorption), or during recording (postradiation adsorption of the quenching vapour of the counter) are involved in these processes. Luminescence is a bulk-phase phenomenon and the role of adsorbed gases is not usually considered in this connection, although in dispersed systems it can be considerable. Studies where it has been shown that the luminescence of a crystalline phosphor is stimulated as a result of adsorption, particularly of oxygen and water vapour, have been published only recently. The investigations of the comparatively new phenomena of adsorbo-[142] and radicalo-luminescence[143] are noteworthy.

The exoemission from alkali metal halides coloured by ionising radiation has been the subject of detailed research[19]. It is suggested that the TSE maxima correspond to the thermal decomposition of definite colour centres regardless of the method of their generation (additive electrolytic and photochemical colour generation). For example, the TSE peak for NaCl at 110°C has been explained by the thermal decomposition of the *M*-centres and that at 280–290°C by the decomposition of the *F*-centres. A detailed analysis of the available data has shown, however, that, for alkali metal halides too, the technology of the preparation, the method and duration of the storage of the specimen, and the method of excitation and recording (gas-filled counter, secondary electron multiplier *in vacuo*) play a much more significant role in the TSE phenomena than the presence of particular colour centres and the nature and concentration of activators.

It has been established[36] that the intensity of the fundamental peaks of the TSE from NaCl, which have been attributed to the thermal ionisation of colour centres, decreases appreciably as a result of vacuum heat treatment (at 400°C) and is restored after hydration of the specimens. The adsorption of active gases and vapours (hydrogen, carbon monoxide, oxygen, and water and alcohol vapours) on the NaCl surface excited by electron bombardment causes a marked activation of exoemission[144].

It follows from the foregoing that the defects arising under the influence of ionising radiation on alkali metal halides (colour centres) give rise to emission centres only in the presence of adsorption layers.

3. Principles of Exoemission Dosimetry

The proportionality between the emission intensity and the dose of the exciting radiation was established for the first time in 1957 for calcium sulphate[145]. The introduction of an activator (manganese) makes it possible to determine very low radiation doses (0.1 mrad). The first exoemission dosimeters, based on the recording of both photostimulated[146] and thermally stimulated emission[147], were developed using calcium sulphate. The following fundamental advantages of exoemission dosimetry have been noted: the possibility of wide variation of the emitting materials, their low cost, the lack of their sensitivity to light before exposure to the action of ionising radiation, the simple technology of their treatment, the possibility of their repeated employment, and their high sensitivity to the action of low-energy radiation.

Further studies on the scope of exoemission dosimeters and their commercial production were continued in 1966–1970. Sulphates, alkali metal halides, and particularly beryllium oxide, both in the initial state and activated by the addition of metals, have been used as the materials for the preparation of the dosimeters. The number of such studies has greatly increased in the last 3 years. TSE dosimeters based on BeO have been developed in the USA for specific applications and have undergone prolonged field tests[148]. These dosimeters have definite advantages over those usually adopted (for example, luminescence dosimeters) for the accurate measurement of small doses of low-energy radiation, particularly in mixed radiation fields. A detailed review of the problem of exoemission dosimetry has been published[149]. The main unsolved problems, preventing the commercial production of exoemission dosimeters, is the stability and reproducibility of readings. It has been found that the emission parameters (the number, temperatures, and intensities of the peaks) depend significantly on the technology of the preparation and methods of storage of the dosimeters[148].

The parameters of the thermally stimulated emission from $CaSO_4$ specimens, used as a basis for the development of TSE dosimeters in the USSR, have been investigated[141]. The "ageing" effect has been observed and investigated for the activated sulphates. Thus high-temperature emission peaks are characteristic of the initial $CaSO_4$ prepared by fusion; after prolonged storage in air, the "population" of the capture levels changes—the low-temperature peak (140–160°C), characteristic of all the metals and oxides investigated, predominates. Experiments on the influence of adsorption on the TSE spectrum showed that the "ageing" effect is a consequence of the adsorption of water.

Thus the problems of the stability of the operation of highly sensitive and promising exoemission dosimeters can be solved only by detailed investigation of the physical chemistry of the surface under storage and operating conditions.

VI. THE PHYSICOCHEMICAL NATURE OF EXOEMISSION

A phenomenological theory, permitting a description and an examination of exoemission from metals, semiconductors, and dielectrics from a single standpoint, has been proposed[25]. As shown in Section I of this review, exoemission occurs as a result of the relaxation processes of the excited states and the study of its mechanism involves the analysis of the kinetic parameters—the quenching constants of the afteremission at a constant temperature and the activation energy and pre-exponential factors in the recording of thermally stimulated emission. A formal kinetic treatment of the emission processes and a mathematical model based on general physical considerations taking into account the band theory of solids have been described in a detailed review of these problems[15]. On the basis of the chemical aspects dealt with in the above review, we shall consider in this section the physicochemical picture of the exoemission phenomenon.

The emission of charges is the result of a complex set of physical and physicochemical processes in the damaged surface layer. Here the fundamental parameters are determined by the slowest stage of the reactions taking place. The coincidence of the TSE peaks for substances of different classes shows that the rate-limiting stage occurs in the surface layer whose nature is independent of the "support", for example it can be a layer of adsorbed oxygen[30,133,134].

The present author[25] believes that these layers are mobile ("quasi-insulated" from the support). In this case, the temperature of the peak, which in the general case determines the activation energy[15] of the emission processes, should depend only slightly on the nature of the adsorbent, which has been observed experimentally[25]. The mobile layer can be formed in the surface phase as a result of the adsorption of gases and vapours from the residual atmosphere *in vacuo* on excitation or heat treatment of the specimen, as suggested by Maenhout-Van der Vorst and Demuer[133], or on degradation of the oxide (adsorption) film present on the surface[150,151]. Hence it follows that the pressure and composition of the surrounding atmosphere during excitation and recording are of fundamental importance for the solution of the problem of the emission mechanism.

The fundamental emission parameters for metals, oxides, and ionic crystals (crystalline phosphors) have been compared using a counter (argon–alcohol atmosphere) as the recording instrument *in vacuo* (10^{-5} mmHg) with a residual air atmosphere and in an ultrahigh vacuum (10^{-8}–5×10^{-9} mmHg) with a residual hydrogen atmosphere[25,151]. It was found that for metals the fundamental parameters (the quenching kinetics and the positions of the TSE peaks) are independent of the method of recording, whereas for ionic crystals (phosphors) a significant discrepancy between the results is observed. This is associated with the possibility of the formation of stable radiation-induced defects in ionic crystals, stimulating the radiation-induced adsorption of gases from the surrounding medium, including the quenching gases of the counter. Experimental evidence in support of this phenomenon has been obtained in studies[139,144,152,153] where it has been shown that the radiation-induced adsorption of active gases and vapours has a significant influence on the number, temperatures, and intensities of the TSE peaks.

For excitation and recording *in vacuo*, the spectrum of the trapping levels characterised by the thermally stimulated emission is independent of the pressure and composition of the residual gases in the vacuum (air, $p \simeq 10^{-5}$ mmHg; hydrogen, $p \leq 10^{-8}$ mmHg) and of the presence of the lubricant vapour[151]. This implies that the "mobile" adsorption layer, responsible for the exoemission processes, is formed as a result of the degradation of the surface layer of the emitter on excitation.

It was shown above that exoemission takes place as a result of mechanical treatment, the action of ionising radiation, phase transformations, adsorption, desorption, and catalysis in adsorption layers. Fig. 8 presents the results of the study of TSE after exposure to different influences. The temperatures of the peaks are the same, so that the rate-limiting stage in the emission kinetics is determined by the same elementary processes regardless of the method used to generate the excited states. When mechanical influences are employed, the role of the formation of dislocations and vacancies as well as their diffusion and emergence on the surface is significant. Secondary processes take place at the same time—the disruption of the oxide film, adsorption, and oxidation, which take place primarily at the sites where dislocations and other defects emerge on the surface. Phase transitions are also coupled with the rearrangement of the structure, accompanied by the formation and degradation of the oxide layer; under these conditions, the mobility of the defects and the probability of their emergence on the surface increases and the adsorption and oxidation are activated. The adsorption and desorption processes are in their turn the cause of the deformations in the surface layer[104].

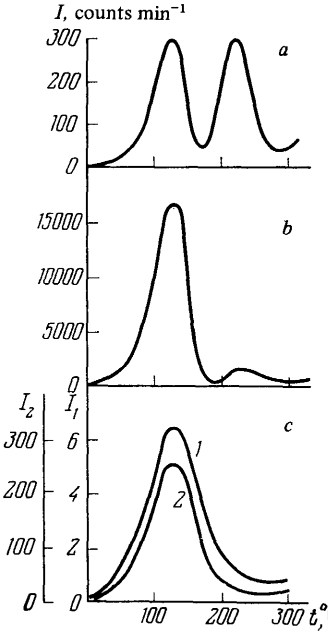

Figure 8. Thermally stimulated emission from a silicon single crystal: *a*) "self-excited" emission after etching[37]; *b*) after electron bombardment; *c*) after treatment with emery (curve *1*) and after polishing combined with exposure to X-rays[57] (curve *2*).

In constructing both the physical and the physicochemical model of exoemission, one of the central problems is the origin of the energy necessary for the release of electrons. The present author[25], who devised the physicochemical concept, believes that the source of this energy is the recombination reactions of the active species (ions and radicals) in the damaged surface layer of the solid. In a recently published study[154], it was demonstrated by direct experiments that the recombination reactions of atomic hydrogen and oxygen on the surface of the solid (for example, activated sulphates) result in the emission of negative charges (electrons and ions). On subsequent heating, thermally stimulated emission is observed. This phenomenon has been called[154] "radicalo-recombination emission".

The formation of active species (radicals, radical-ions) is possible for all the methods of excitation of the solid described above, giving rise to exoemission. Mechanical, radiation, and other influences as well as phase transformations are known to lead to the same effects—the rearrangement of the structure and ultimately the dissociation of chemical bonds and the formation of free radicals (radical-ions) together with structural defects. It has now been established by electron spin resonance that radicals are formed under radiation-induced mechanical influences during adsorption and catalysis in the adsorption layer. Mass-spectrometric studies of gas evolution from the surface of oxides have shown that electron bombardment—one of the common methods of exciting emission—causes the degradation of the hydrate coating with formation of hydrogen and oxygen[150,151].

Data illustrating the physicochemical mechanism of exoemission, based on the above reactions in the surface layer, have been published[25,30,155]. Thermally stimulated emission is a result of the following set of processes: heat treatment, phase transformations in adsorbed surface compounds (for example hydrates), the formation of a mobile adsorption layer, desorption, the generation of stresses, the relaxation of stresses (deformations in the surface layer) and electron emission (the acquisition of a positive charge by the surface). The desorption step is preceded by surface migration (de Boer's migrating or "jumping" molecules)[156]. The recombination of ions, radicals, and other active species results in two-dimensional condensation. The recombination energy is consumed in the liberation of the electrons localised on the surface. The trapping levels can be produced either by surface defects such as colour centres or by adsorbed ions (O_2^-, O^-, OH^-, etc.). The active species are recombined near specific sites (defects), energetically insulated from the lattice, where the liberated energy is not dissipated in the form of phonons, but is consumed in the excitation of electrons. The probability of triple collisions (two active species colliding with a lattice defect) is low, and this accounts for the extremely low emission currents (10^{-17}–10^{-19} A). At the excitation temperature, only part of the radicals (ions) formed recombine—afteremission and gas evolution are observed. Subsequent heat treatment leads to the stepwise recombination of the active species—thermally stimulated emission and the accompanying thermal desorption take place. The experimental evidence for the simultaneous occurrence of the thermally stimulated emission and thermal desorption processes, thermally stimulated emission and catalysis in the adsorption layer, as well as examples of reactions illustrating the physicochemical mechanism of the exoemission phenomena described above (the "chemical mechanism of the processes") are described in Section III of the present review.

Thus, according to the concepts developed by the present author[25], exoemission is a consequence of the stepwise recombination of active species in the mobile adsorption layer arising during the excitation processes. The thermally stimulated emission peaks are caused by the valence transformations in the layer of adsorbed oxygen[132].

VII. THE PROSPECTS FOR THE APPLICATION OF EXOEMISSION IN SCIENTIFIC RESEARCH AND IN ENGINEERING

The above review of the phenomena accompanied by the low-temperature emission of negative charges shows that exoemission can serve as an extremely sensitive indicator of physicochemical processes in the surface layers of solids: adsorption, desorption, oxidation, corrosion, heterogeneous-catalytic reactions, etc. Studies have shown that thermally stimulated emission makes it possible to follow the formation of the active surfaces of catalysts and adsorbents during preliminary treatment (for example, dehydration) and their activation processes, to investigate the action of the individual components of the reaction and the reaction mixture on the "energy relief" of the surface, etc.[73]

Studies on TSE during catalysis permit conclusions concerning the mechanisms of certain reactions in both the adsorption layer[72,73] and in the gas phase[70,71]. A direct relation between catalytic activity and emission capacity has been established for certain deposited and promoted systems[67,69], so that the emission intensity can serve as the basis of a method for estimating the activities of catalysts, particularly when they are poisoned by admixtures in the starting material[157].

Since exoemission is extremely sensitive to radiation, the TSE method can be used to investigate the radiation-induced damage in semiconductors and dielectrics[37,158], the phenomena of radiation-induced adsorption and catalysis[159], and heterogeneous radiolysis[159]. A relation has been established between the exoemission parameters, the proportion of defects, and the "radiation stability"[157] of materials used as the elements of lasers. The author recommends the exoemission method for the quality control of the surfaces of the elements of solid-state lasers.

The adsorption layers formed during the technological treatment of the components and their storage or operation are known to determine in many instances the reliability of the apparatus in the electrovacuum industry and in semiconductor engineering. Exoemission, which is extremely sensitive to the presence of adsorption films, particularly those of water and oxygen, can serve as an effective method for the control of technological processing in many industries[37,160].

The "ageing" effects on active surfaces, for example those of catalysts, exoemission dosimeters, and crystalline phosphors, etc. are also associated with the formation of adsorption layers. The exoemission method makes it possible to follow the changes in the state of the surface during the storage of such systems exhibiting adsorption activity[140].

Exoemission was already suggested in the initial stage of research[26] for monitoring certain technical processes involving the treatment of metals, plastic deformations, etc. This applies particularly to processes employing lubricating materials, i.e. where the structure and mechanical properties of the surface of metals play an important role. For example, exoemission from the surface of a bearing under the conditions of prolonged working of a Mercedes-Benz goods truck has been investigated[1]. A study has been made of exoemission during the deformation of technically important materials and friction[58,59,102]. It was noted above that thermally stimulated emission is also recommended for the study of first- and second-order phase transformations in metals and alloys.

Exoemission has proved to be an effective method for the investigation of comminution and sintering processes (for example in the paint and varnish industry and in powder metallurgy[26]). There is evidence for the possibility of employing exoemission in "photography"[1]. Exoemission microscopes, permitting a detailed study of the defect structures of metallic and non-metallic surfaces after mechanical, radiation, and other treatments, have been developed recently in the USA[35]. Exoemission microscopy has many advantages over electronic, thermionic, etc. microscopy. It makes it possible to reduce appreciably the temperature of the test specimens and to eliminate the activation of the surface (for example by barium, strontium, and caesium) necessary in thermionic emission from metals, and permits the investigation of semiconductors with a wide forbidden gap as well as insulators.

The likely usefulness of exoemission in biological research has been claimed recently[161]. There are publications concerning the thermally stimulated emission from certain aminoacids[162], kidney stone[163], etc. On the basis of the results obtained, the authors recommend exoemission for research in medicine and pharmacology. Mention should also be made of attempts to employ exoemission in radiological studies connected with the development of highly sensitive exoemission dosimeters for specific applications[149]. Exoemission from bone tissue, dental enamel, collagen, etc. after exposure to radioactive emission has been investigated[164].

Studies of heterogeneous-catalytic reactions have shown that oxidation processes are accompanied by spontaneous emission, particularly when they occur with proton or electron transfer. Presumably exoemission will serve as an effective method for the investigation of biochemical reactions, especially in the solution of problems such as those of photosynthesis and cell bioenergetics. These reactions are also known to include stages accompanied by the transfer of both electrons and protons.

---o0o---

The above review of the results and their analysis have shown that exoemission is a complex physicochemical phenomenon and that the elucidation of its detailed mechanism is closely related to the problem of the physics and physical chemistry of the surface. Despite the fact that approximately 25 years have elapsed since the first studies by Kramer in this field, exoemission continues to be a relatively little investigated phenomenon, whose study is the concern of only a few scientists—physicists and metallurgists. However, it is known that the solution of the problems of chemisorption, catalysis, adhesion, mechanochemistry, surface phenomena in semiconductors, and the physics of thin films is closely related to the problem of exoemission and requires the joint efforts of physicists and chemists[164].

Catalytic Oxidation of Ammonia

N.I.Il'chenko

Data on the catalytic properties of various substances (metals, their alloys, simple and complex oxides, and zeolites containing metal cations) in the oxidation of ammonia are described systematically and reviewed. The kinetics and mechanism of the reaction are discussed and the factors determining the activity and selectivity of the catalysts are identified. Fundamental relations between the physicochemical and catalytic properties of substances of different types are formulated and the relations between the oxidation of ammonia and the selective oxidation reactions of organic substances are analysed.

The bibliography includes 61 references.

CONTENTS

I. INTRODUCTION

The catalytic oxidation of ammonia is one of the most interesting and important heterogeneous catalytic processes. It can proceed in the following three principal ways:

$$2NH_3+1\frac{1}{2}O_2=N_2+3H_2O+151\ \text{kcal}, \quad (I)$$

$$2NH_3+2O_2=N_2O+3H_2O+132\ \text{kcal}, \quad (II)$$

$$2NH_3+2\frac{1}{2}O_2=2NO+3H_2O+108\ \text{kcal}. \quad (III)$$

In the presence of many catalysts, all three nitrogen-containing products (N_2, N_2O, and NO) are formed simultaneously at 400-500°C in various proportions. On the other hand, in the presence of selective catalysts and when the process is carried out under specific conditions (mainly at specific temperatures), one of the reactions (I)-(III) takes place preferentially. In the presence of platinum or cobalt oxide catalysts at 750-900°C, the main product is nitric oxide. The oxidation of ammonia in the presence of platinum catalysts (they usually consist of platinum-rhodium or platinum-rhodium-palladium alloy gauze) constitutes the basis of the modern industrial manufacture of nitric acid[1]. In the presence of manganese oxide catalysts at lower temperatures (300-400°C), nitrous oxide is formed in fairly high yields[2]; this product is a valuable anaesthetic used in medicine. In the presence of vanadium pentoxide at 500-600°C, ammonia is oxidised only to molecular nitrogen, the process being of practical interest for aviation[3]. Thus each of reactions (I)-(III) is of practical value.

The catalysts of these reactions described above have been discovered empirically. The improvement of the existing catalysts for the oxidation of ammonia and the search for new, more reactive catalysts require the development of scientific principles of the selection of catalysts for this process. This necessitates a systematic arrangement and classification of the available experimental data, a detailed study of the reaction mechanism, and a study of the relation between the catalystic and physicochemical properties of substances.

Very many studies have been made on the catalytic oxidation of ammonia[1,2]. Most of them concern the reaction in the presence of industrial platinum (and certain oxide) catalysts for the synthesis of NO operating at high temperatures under diffusional conditions. The main feature of this review, which distinguishes it from other surveys dealing with the catalytic oxidation of ammonia, is that attention is concentrated on the experimentally proved detailed mechanism and chemical kinetics of the reaction and also on the problem of the relation between the catalytic and physicochemical properties of the relevant substances. These problems were hardly considered in previous studies because the principal experimental and theoretical investigations on these lines have been carried out only in recent years.

The elucidation of the characteristics of the catalytic oxidation of ammonia is important not only from the standpoint of the practical selection of process catalysts but is also of general theoretical interest for the solution of fundamental problems of oxidative heterogeneous catalysis.

The reaction occupies in some respects an exceptional position among other oxidative processes. On the one hand, it has much in common with the oxidation reactions of other inorganic substances (hydrogen, carbon monoxide, etc.) for which the problem of the prediction of catalytic activity is of primary significance. On the other hand, in the oxidation of ammonia there arises the problem of the selectivity of catalytic action, which makes this process similar to many oxidation reactions of organic substances.

In organic catalysis, it is usual to distinguish the products of mild and extensive oxidation. The latter are characterised by a relatively high atomic fraction of oxygen. In the series of ammonia oxidation products N_2-N_2O-NO, the atomic fraction of oxygen rises from zero to 1/2. The degree of oxidation of nitrogen and the number of O_2 molecules required to oxidise one NH_3 molecule increase in the same sequence [see reactions (I)-(III)]. It is therefore natural to assume that molecular nitrogen is a mild oxidation product, while nitrogen oxides are products of the extensive oxidation (NO is a more oxidised species than N_2O).

At the same time, there is a difference between the ammonia and organic substance oxidation reactions, involving their thermodynamics. In the oxidation of organic compounds, the products of extensive oxidation are thermodynamically more resistant to further oxidation than the mild oxidation products. In the oxidation of ammonia, the opposite situation obtains, as can be seen from a comparison of the standard heats of reactions (I) to (III) (when the entropy change is taken into account, the situation does not change). This feature of the thermodynamics of the reactions is manifested by the fact that completion of the oxidation of a mild oxidation product by molecular oxygen involves a consecutive reaction mechanism in the oxidation of organic substances, while in the oxidation of ammonia the reduction of the product of extensive oxidation by the initial oxidisable substance proceeds via this mechanism:

$$2NH_3 + 3N_2C = 4N_2 + 3H_2O, \tag{IV}$$

$$2NH_3 + 8NO = 5N_2O + 3H_2O, \tag{V}$$

$$2NH_3 + 3NO = 2\frac{1}{2}N_2 + 3H_2O. \tag{VI}$$

This feature has a significant influence on the process kinetics.

The data discussed in this review have been divided on the basis of the principal types of ammonia oxidation catalysts (metals, their alloys, simple oxides, complex and promoted oxide catalysts, zeolites). The usefulness of such subdivisions follows from the fact that the most clear-cut relations between the catalytic and physicochemical properties of the relevant substances are to be expected within a group of similar catalysts for this process. Each section is arranged as follows: data on the catalytic properties (activity and selectivity series) are considered first, next the chemical kinetics and reaction mechanism are discussed, and finally the problem of the relation between the catalytic and physicochemical properties of substances of the given type is analysed on this basis.

II. OXIDATION OF AMMONIA IN THE PRESENCE OF VARIOUS CATALYSTS

1. Oxidation of Ammonia in the Presence of Metals

The catalytic properties of various metals in the oxidation of ammonia under kinetic conditions have been investigated[4,5]; the experiments were carried out at low temperatures (up to 370°C), where the reaction products are N_2 and N_2O. Table 1 shows that at 300°C the specific catalytic activity of metals for the overall process decreases in the sequence†

$$Pt > Pd > Cu > Ag > Ni > Au > Fe > W > Ti.$$

In general, there is a similarity between this series and the series observed in the oxidation of hydrogen[6] (Pt > Pd > Ni > Fe > Cu > Ag > Au > Ti), gas containing SO_2 [7] (Pt > Pd > Au > W), and lower olefins[8] (Pt > Pd > Au > W). At high temperatures (500–700°C), the activity of platinum in the oxidation of ammonia exceeds those of rhodium, palladium, and iridium[9].

An effect of the reaction medium on copper, titanium, and tungsten, leading to partial oxidation of these metals, has been noted[5]. At high temperatures, this effect is intensified and platinum and other metals become susceptible to it[1]. The oxidation of ammonia in the presence of platinum begins at temperatures of the order of 150 to 200°C. Under these conditions, the only nitrogen-containing reaction product is molecular nitrogen. With increase of temperature, nitrous oxide appears in the products, its yield passing through a maximum. At temperatures of the order of 300°C, nitric oxide begins to form; its yield increases with temperature and can reach 90% at 700 to 1000°C. Under conditions favourable for the synthesis of NO, the reaction takes place under diffusion-limited conditions[1,2].

Table 1. The oxidation of ammonia in the presence of metals*.[4,5]

Catalyst	r, mol. cm^1 s^{-1}, (at 300°C)	E, kcal mole^{-1}	Temperature of onset of formation, °C	
			N_2	N_2O
Pt	$1.70 \cdot 10^{17}$	27	195	215
Pd	$2.69 \cdot 10^{16}$	5	100	150
Cu	$3.31 \cdot 10^{15}$	12	175	260
Ag	$2.52 \cdot 10^{15}$	15	200	210
Ni	$1.23 \cdot 10^{15}$	12	210	270
Au	$8.32 \cdot 10^{14}$	4	180	300
Fe	$6.76 \cdot 10^{14}$	9	230	270
W	$5.90 \cdot 10^{14}$	13	225	300
Ti	$2.24 \cdot 10^{14}$	5	180	**

*Composition of reaction mixture: $p_{NH_3} = 0.1$ atm; $p_{O_2} = 0.9$ atm.

**Up to 370°C, nitrous oxide is not formed.

A similar behaviour has been observed also in the presence of other metallic catalysts. Table 1 shows that, for each metal, nitrogen begins to form at a lower temperature than nitrous oxide. NO is formed at still higher temperatures[1].

At low temperatures (Table 1), the process takes place under kinetic conditons and the ammonia oxidation products in the presence of various metals are N_2 and N_2O. Under these conditions, the selectivity with respect to nitrous oxide increases with temperature[4,5]. In the presence of transition metals, the selectivity with respect to this product increases in the sequence

$$Pt, Pd > Ni > Fe > W > Ti,$$

i.e. the selectivity in relation to the extensive oxidation of ammonia varies in parallel with the catalytic activity in the overall process[5]. Experimental studies on the mechanism of the oxidation of ammonia in the presence of metals have been carried out mainly in recent years. In previous studies, a multiplicity of hypothetical mechanisms were put forward, postulating the intermediate formation of species such as NH_2OH, HNO, NH, and others (see the review of Dixon and Longfield[2]). However, these mechanisms were not supported by experimental evidence, which is the reason for their abundance.

In order to elucidate the composition of the intermediate surface complexes formed in the catalytic oxidation of ammonia, the composition of the species generated when the NH_3–O_2 mixture interacts with metals and the species desorbed from their surface following the application of a strong electric field was investigated[10] by autoionisation mass-spectrometry. The experiments were performed using emitters in the form of a platinum needle and a

---

†Below 250°C, palladium is more active than platinum.[5]

tungsten filament; some of the experiments were performed using ammonia labelled with ^{15}N. Apart from the ions corresponding to the starting materials and the final reaction products, those of the intermediate HNO and NH (nitroxyl and imide) formed on the surface were also detected.

The kinetics of the oxidation of ammonia on massive platinum have been studied[4] by the flow method (for conversions not exceeding 15%) and by the flow-circulation method at atmospheric pressure. The experiments were performed under conditions where the products were N_2 and N_2O. The partial pressure of ammonia in the reaction mixture (p_{NH_3}) was varied in the range 0.05–0.20 atm and the partial pressure of oxygen (p_{O_2}) was varied in the range 0.20–0.95 atm; the ratio p_{O_2}/p_{NH_3} was varied from 1 to 18.9. The results refer to the steady state of the catalyst. The study of the temperature variation of the reaction rate revealed a sharp and abrupt increase of the rate on reaching 240°C. This was accompanied by a rapid and marked increase in the catalyst temperature. Such effects were observed for different compositions of the reaction mixtures, different flow rates, and in experiments using both the flow and flow-circulation methods. The results discussed below[4] refer to the temperature range where the above complications are absent.

At temperatures up to 230°C, the rates of reactions (I) and (II) and selectivity are independent of contact time (for virtually constant p_{NH_3} and p_{O_2}). This implies that nitrogen and nitrous oxide are formed simultaneously under these conditions. At the same time it also follows that the reaction products whose concentration varies severalfold do not influence the rate of oxidation of ammonia.

The variation of the rate of the overall process and of the rates of formation of the individual products (r_{N_2} and r_{N_2O}) with p_{NH_3} and p_{O_2} is described by hyperbolic curves. For low values of p_i, the rates are proportional to the p_i (first-order reaction), while, for high values of p_i, the rates are virtually independent of the latter (zero-order reaction). The attempts to describe the observed variation by kinetic equations of the Langmuir–Hinshelwood type were unsuccessful. Taking into account the results of a mass-spectrometric study of the composition of the intermediates formed on the surface of platinum and tungsten during the catalytic oxidation of ammonia[10] and data on the sorption of oxygen on platinum, the authors[4,11] proposed the following reaction mechanism‡:

$$\begin{array}{lcc}
 & N^{(\mathrm{I})} & N^{(\mathrm{II})} \\
1)\ O_2 + (\ ) \rightarrow (O_2) \xrightarrow[\text{fast}]{(\ )} 2\,(O) & 1\frac{1}{2} & 2 \\
2)\ NH_3 + (O) \rightarrow (NH) + H_2O & 2 & 2 \\
3)\ (NH) + (O) \rightleftarrows (HNO) & 1 & 2 \\
4)\ (NH) + (HNO) \rightarrow N_2 + H_2O + 3\,(\ ) & 1 & 0 \\
5)\ (HNO) + (HNO) \rightarrow N_2O + H_2O + 4\,(\ ) & 0 & 1 \\
\hline
N^{(\mathrm{I})}: 2NH_3 + 1\frac{1}{2}O_2 = N_2 + 3H_2O & & \\
N^{(\mathrm{II})}: 2NH_3 + 2O_2 = N_2O + 3H_2O & &
\end{array} \qquad \text{(VII)}$$

The reaction proceeds via two kinetically independent routes $N^{(\mathrm{I})}$ and $N^{(\mathrm{II})}$, the corresponding sets of the stoichiometric numbers of the stages being shown on the right-hand side of scheme (VII) and the overall chemical equations (I) and (II). The first stage of the process involves the chemisorption of oxygen with intermediate formation of the anion $(O^2)^-$; on the basis of the available data[12], it is suggested that the adsorption of O_2 on platinum at 200–250°C leads ultimately to the formation of atomic oxygen ions (O) having a negative charge. This stage is irreversible. In the second stage, ammonia molecules react with the surface coated by oxygen and form adsorbed species (NH), which are converted in the third (quasi-reversible) stage into the surface nitroxyl (HNO). Analysis of the kinetic data[13] suggests that the (NH) species occupies one elementary surface site and the (HNO) species two such sites. Since the catalyst gives up electrons to the adsorbed oxygen in the first stage, it is natural to assume that, in the interaction of ammonia with platinum coated by oxygen, electrons are transferred from ammonia to the catalyst. The final reaction products in the last two stages are N_2 from (NH) and (HNO), on the one hand, and N_2O from two nitroxyls, on the other.

The following kinetic equations for the rate of the overall process r, the steady-stage degree of surface coverage by atomic oxygen θ, and the selectivities with respect to N_2 and N_2O (S_{N_2} and S_{N_2O}) correspond to the above process mechanism[13]:

$$r = \frac{1}{2} k_2 p_{NH_3} \theta = \frac{1}{2} k_1 k_2 p_{O_2} p_{NH_3} / (k_1 p_{O_2} + \bar{\nu} k_2 p_{NH_3}), \tag{1}$$

$$\theta = \frac{k_1}{k_2} \frac{p_{O_2}}{p_{NH_3}} \Big/ \left(\frac{k_1}{k_2} \frac{p_{O_2}}{p_{NH_3}} + \bar{\nu} \right), \tag{2}$$

$$S_{N_2} = \frac{\mu}{\mu + \theta}, \tag{3}$$

$$S_{N_2O} = \frac{\theta}{\mu + \theta}, \tag{4}$$

where

$$\mu = k_4 / k_5 K_3. \tag{5}$$

In these equations, k_i are the rate constants for the various stages, K_3 is the equilibrium constant for the first stage, and $\bar{\nu}$ is a stoichiometric coefficient showing how many O_2 molecules are consumed on average in the oxidation of one NH_3 molecule; the experimental value[4] is $\bar{\nu} = 0.78 \pm 0.02$. Eqns. (1)–(4) have been derived on the assumption that the reaction proceeds in an ideal monolayer and that the degree of surface coverage by atomic oxygen is much greater than the coverage by other species.

Fig. 1 shows that Eqn. (1), according to which the relation between p_{O_2}/r and p_{O_2}/p_{NH_3} should be linear, describes satisfactorily the variation of r with the composition of the reaction mixture. The slope of the straight line is $2/k_2$ and its intercept on the ordinate axis is $2\bar{\nu}/k_1$. Hence k_1 and k_2 were calculated. The temperature variation of these constants obeys the Arrhenius equation and the heats of activation for the first two stages are $E_1 = E_2 = 32$ kcal mole^{-1}.

Eqns. (3) and (4) show that, at a constant temperature, the selectivity of the given catalyst should be determined by the degree of surface coverage by oxygen θ, which depends in its turn on the mixture composition, i.e. on the ratio p_{O_2}/p_{NH_3}. It follows from Eqn. (2) that θ increases with increase of p_{O_2}/p_{NH_3} ($\theta \rightarrow 0$ when $p_{O_2}/p_{NH_3} \rightarrow 0$ and $\theta \rightarrow 1$ when $p_{O_2}/p_{NH_3} \rightarrow \infty$). It is expected that, with increase of p_{O_2}/p_{NH_3}, i.e. with the increase of θ, the selectivity with respect to the mild oxidation product (nitrogen) should fall continuously $[dS_{N_2}/d\theta = -\mu/(\mu + \theta)^2 < 0]$ and that the selectivity with respect to the extensive oxidation product (nitrous oxide) should increase ($dS_{N_2O}/d\theta = -dS_{N_2}/d\theta > 0$). Eqns. (3) and (4) predict that when $\theta \rightarrow 0$, i.e. when $p_{O_2}/p_{NH_3} \rightarrow 0$,

---

‡Here and henceforth the symbols for substances enclosed in brackets denote surface species, while brackets enclosing a blank space denote free surface sites.

S_{N_2} tends to unity and S_{N_2O} tends to zero. When $\theta \to 1$ (for high values of p_{O_2}/p_{NH_3}), S_{N_2} and S_{N_2O} tend to constant values, which are respectively $\mu/(\mu+1)$ and $1/(\mu+1)$. The quantity μ can be calculated from the values of S_i and p_{O_2}/p_{NH_3} for a single experiment by Eqn. (3) or (4) [taking into account Eqn. (2)] and then the variation of the selectivity with θ (or with p_{O_2}/p_{NH_3}) may be calculated for a wide range of compositions of the reaction mixture. The results of such calculations are presented in Fig. 2 (in the form of continuous curves). The satisfactory agreement with experiment (circles in Fig. 2) demonstrates the validity of Eqns. (3) and (4).

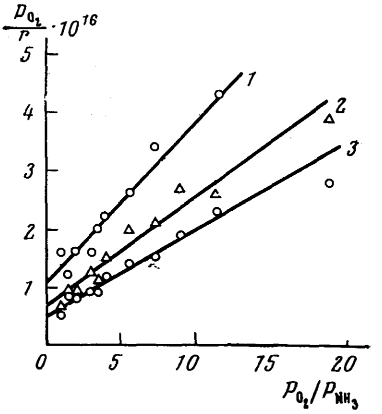

Figure 1. Variation of p_{O_2}/r with p_{O_2}/p_{NH_3} in the presence of a platinum catalyst[4] at different temperatures (°C): 1) 220; 2) 225; 3) 230.

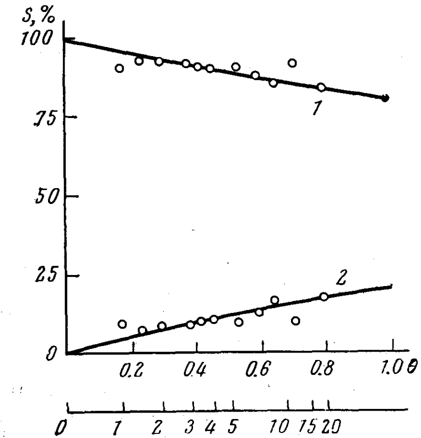

Figure 2. Variation of the selectivity with respect to N_2 (line 1) and N_2O (line 2) with p_{O_2}/p_{NH_3} and θ at 230°C on a platinum catalyst[4] ($\mu = 3.8$; $k_1/k_2 = 0.2$).

Thus the experimental kinetic data agree with scheme (VII). Hence it follows that this scheme reflects the essential features of the reaction mechanism on the platinum catalyst.

With increase of temperature, the parallel-reaction mechanism of the oxidation of ammonia is converted into a parallel-consecutive-reaction mechanism; at 235°C, an increase in contact time entails a decrease of selectivity with respect to N_2O. This has been explained[4] by the fact that, for fairly high values of p_{N_2O}, in addition to reactions (I) and (II), reaction (IV) also occurs, leading to the conversion of a definite proportion of the nitrous oxide formed into nitrogen. The probable process mechanism under these conditions can be described as follows[4]:

$$\begin{array}{lccc} & N^{(I)} & N^{(II)} & N^{(IV)} \\ 1)\ O_2 + (\ ) \xrightarrow[\text{fast}]{} (O_2) \xrightarrow[\text{fast}]{(\ )} 2\,(O) & 1\frac{1}{2} & 2 & 0 \\ 2)\ NH_3 + (O) \to (NH) + H_2O & 2 & 2 & 2 \\ 3)\ (NH) + (O) \rightleftarrows (HNO) & 1 & 2 & 1 \\ 4)\ (NH) + (HNO) \to N_2 + H_2O + 3\,(\ ) & 1 & 0 & 1 \\ 5)\ (HNO) + (HNO) \to N_2O + H_2O + 4\,(\ ) & 0 & 1 & 0 \\ 6)\ N_2O + (\ ) \to (O) + N_2 & 0 & 0 & 3 \end{array} \qquad \text{(VIII)}$$

$$N^{(I)}: 2NH_3 + 1\frac{1}{2}O_2 = N_2 + 3H_2O\ ;$$

$$N^{(II)}: 2NH_3 + 2O_2 = N_2O + 3H_2O\ ;$$

$$N^{(IV)}: 2NH_3 + 3N_2O = 4N_2 + 3H_2O\,.$$

The reaction proceeds via three fundamental routes, $N^{(I)}$, $N^{(II)}$, and $N^{(IV)}$, to which the overall Eqns. (I), (II), and (IV) correspond. Scheme (VIII) is obtained from scheme (VII) when the latter is supplemented by a sixth stage, in which nitrous oxide is irreversibly converted on the surface into adsorbed oxygen and N_2. The (O) atoms formed in this stage subsequently react with NH_3, together with the (O) atoms generated in the first stage as a result of the adsorption of molecular oxygen. It has been shown[4] that, under the experimental conditions used in the oxidation of ammonia, the rate of desorption of oxygen formed in stages (1) and (6) can be regarded as extremely small compared with the rates of the forward reactions in these stages.

The application of the theory of complex steady-state reactions[14] to scheme (VIII) taking into account the postulates noted above leads to the following selectivity equations[4]:

$$S_{N_2} = \frac{r_{N_2}}{r} = \frac{r^{(I)} + 4r^{(IV)}}{r} = \frac{\mu}{\mu+\theta} + \frac{2\bar{\nu}k_6}{k_1}\,\frac{p_{N_2O}}{p_{O_2}}\,, \tag{6}$$

$$S_{N_2O} = \frac{r_{N_2O}}{r} = \frac{r^{(II)} - 3r^{(III)}}{r} = \frac{\theta}{\mu+\theta} - \frac{2\nu k_6}{k_1}\,\frac{p_{N_2O}}{p_{O_2}}\,, \tag{7}$$

where $r^{(I)}$, $r^{(II)}$, and $r^{(IV)}$ are the rates of the reactions via routes $N^{(I)}$, $N^{(II)}$, and $N^{(IV)}$, while the remaining quantities have the previous significance. The expressions for r and θ are again determined by Eqns. (1) and (2).

By oxidising ammonia using the flow-circulation method with virtually constant p_{NH_3}, p_{O_2}, and θ but significantly variable values of p_{N_2O}, the authors[4] established that the selectivity with respect to N_2O decreases linearly with increase of p_{N_2O}, which confirms the validity of Eqns. (6) and (7). The latter equations can be put in the form

$$S_{N_2} = (S_{N_2})_0 + \Delta, \qquad S_{N_2O} = (S_{N_2O})_0 - \Delta, \tag{8}$$

where $(S_{N_2})_0$ and $(S_{N_2O})_0$ are the selectivities with respect to N_2 and N_2O when the reaction proceeds exclusively via the parallel-process mechanism [Eqns. (3) and (4)] and

$$\Delta = \frac{2\bar{\nu}k_6 p_{N_2O}}{k_1 p_{O_2}} = \frac{2\bar{r}_6}{r_1} \tag{9}$$

reflects the change in selectivity caused by the appearance of the consecutive-reaction mechanism (IV); this quantity is determined by the ratio of the rates of the sixth and first stages. Eqn. (9) shows that the higher the rate of decomposition of N_2O compared with the rate of absorption of O_2, the greater the contribution to the observed selectivity by the consecutive-reaction scheme; in this case, the dominant source of adsorbed oxygen is N_2O and not O_2. A decrease of contact time leads to a decrease of p_{N_2O}, so that, when $\tau \to 0$, i.e. when $p_{N_2O} \to 0$, Δ tends to zero—the parallel-reaction mechanism obtains exclusively [Eqns. (6) and (7) are identical with Eqns. (3) and (4)].

As mentioned above, when the temperature is raised appreciably, NO appears in the reaction products in addition to N_2 and N_2O, i.e. all three processes (I)–(III) take place at once. At temperatures in the range 700 to 1000°C in the presence of platinum catalysts, mainly NO is formed. At the same time, the process is inhibited by diffusional factors, since the overall rate of reaction increases sharply. For the stoichiometric [in relation to reaction (III)] $O_2 : NH_3$ ratio, the observed rate of oxidation of ammonia is determined by the rate of diffusion of oxygen to the outer surface of the massive catalyst (gauze); in the presence of an excess of oxygen relative to stoichiometry of more than 30%, the diffusion of ammonia is rate-limiting[1].

As a result of macrokinetic inhibition of this kind, the kinetics and mechanism of the reaction at high temperatures, i.e. under conditions where reaction (II) also occurs, have been scarcely investigated experimentally. One can only mention one study[15] where the oxidation of ammonia was investigated on platinum at low pressures (where the diffusion of gases if facilitated) and it was shown that the rate of the overall process is described by the first-order equation

$$r = kp^1_{NH_3}p^0_{O_2}. \tag{10}$$

Despite the lack of the necessary experimental data (which will evidently become available in the future), it is useful to discuss the problem of the probable behaviour which may be expected when reactions (I)–(III) occur simultaneously under kinetic conditions and provided that a parallel-process and purely heterogeneous mechanism operates. In this case the following mechanism can be postulated[13]:

$$\begin{array}{llccc}
 & & N^{(I)} & N^{(II)} & N^{(III)} \\
1)\ O_2 + (\ ) & \to (O_2) \xrightarrow[\text{fast}]{(\ )} 2(O) & 1\frac{1}{2} & 2 & 2\frac{1}{2} \\
2)\ NH_3 + (O) & \to (NH) + H_2O & 2 & 2 & 2 \\
3)\ (NH) + (O) & \rightleftarrows (HNO) & 1 & 2 & 2 \\
4)\ (NH) + (HNO) & \to N_2 + H_2O + 3(\ ) & 1 & 0 & 0 \\
5)\ (HNO) + (HNO) & \to N_2O + H_2O + 4(\ ) & 0 & 1 & 0 \\
6)\ 2(HNO) + (O) & \to 2NO + H_2O + 5(\ ) & 0 & 0 & 1 \\
\hline
\end{array} \qquad (IX)$$

$$N^{(I)} : 2NH_3 + 1\frac{1}{2}O_2 = N_2 + 3H_2O;$$

$$N^{(II)} : 2NH_3 + 2O_2 = N_2O + 3H_2O;$$

$$N^{(III)} : 2NH_3 + 2\frac{1}{2}O_2 = 2NO + 3H_2O.$$

Scheme (IX) is obtained from scheme (VII) when the latter is supplemented by the postulated stage (6)§, which results in the appearance of a third reaction pathway $N^{(III)}$ and the overall Eqn. (III) applies.

Eqn. (I) for the overall rate of the process remains unchanged under these conditions. The equations for the selectivity then become

$$S_{N_2} = \frac{\mu}{\mu + \theta + \mu'\theta^2}, \tag{11}$$

$$S_{N_2O} = 1 - \frac{\mu}{\mu + \theta + \mu'\theta^2} - \frac{\theta}{1/\mu' + \theta + \mu/\mu'\theta}, \tag{12}$$

$$S_{NO} = \frac{\theta}{1/\mu' + \theta + \mu/\mu'\theta}, \tag{13}$$

where μ is again defined by Eqn. (5) and $\mu' = k_6'/k_5$ [k_6' is the rate constant for the sixth stage in scheme (IX)].

The heat of the sixth stage is significantly smaller than that of the fifth stage. Indeed the difference between the heats of these stages is $q_6 - q_5 = 2q_{NO} - q_{(O)} - q_{N_2O}$, where q_i are the heats of formation of the reactants; the difference $2q_{NO} - q_{N_2O} = -23.7$ kcal[16] is negative and, since the heat of adsorption of oxygen $q_{(O)} > 0$, the difference $q_6 - q_5$ is significantly smaller than zero. On the basis of the Brønsted–Temkin relation, the heat of activation for this stage is the higher the lower is its heat of reaction. For this reason, the heat of activation for the sixth stage is higher than for the fifth stage, so that μ' increases with temperature. If the temperature is low, μ' is close to zero; Eqn. (13) shows that, under these conditions, $S_{NO} \simeq 0$ and Eqns. (11) and (12) become identical with Eqns. (3) and (4). At high temperatures, μ' is high and S_{NO} is considerable. This is consistent with the fact that the oxidation of NH_3 to NO is as a rule carried out at high temperatures.

Eqns. (11)–(13) have the following consequences. For mixtures rich in ammonia (when $p_{O_2}/p_{NH_3} \to 0$ and $\theta \to 0$), $S_{N_2} \to 1$ and S_{N_2O} and S_{NO} tend to zero. With increase in the excess of oxygen in the reaction mixture (with increase of θ), S_{N_2} falls, tending to the constant value $\mu/(\mu + 1 + \mu')$ (when $\theta = 1$), while S_{NO} increases, tending to the corresponding limit $\mu'/(\mu + 1 + \mu')$. The variation of S_{N_2O} with θ is more complex: for fairly large values of μ', it passes through a maximum. To illustrate all these findings, Fig. 3 presents the results of a model calculation of the variation of the selectivity with θ and p_{O_2}/p_{NH_3} when $\mu' = 100$ (continuous curves) and $\mu' = 10$ (dashed curves); it was assumed in both cases that $k_1/k_2 = 1$, $\bar{\nu} = 1$, and $\mu = 1$. Evidently, the higher the value of μ', the higher the selectivity with respect to NO, and the lower the selectivity with respect to N_2 and N_2O.

In order to test the theoretical calculations, it is necessary to investigate the kinetics of the oxidation of ammonia at elevated temperatures under conditions ruling out the influence of transport processes and of consecutive reactions of the products. The theoretical and experimental data can already be compared to some extent. Thus Eqn. (10) for the rate of the overall process, corresponding to high temperatures of the catalytic reaction on platinum[15], is the same as Eqn. (1): with $k_1p_{O_2} \gg \bar{\nu}k_2p_{NH_3}$, Eqn. (1) becomes identical with Eqn. (10). The dependence of the selectivity with respect to NO on p_{O_2}/p_{NH_3} observed at 900°C on platinum[1] is very close to that illustrated in Fig. 3. Since the process is distorted by the influence of external diffusion under these conditions, the above comparison is not rigorous, but can nevertheless serve as an argument in support of Eqn. (13).

For a complete description of the reaction kinetics under conditions corresponding to the formation of N_2, N_2O, and NO, it is necessary to take into account the

---

§Experimental data justifying the above formulation of stage (6) are as yet unavailable; it is possible to postulate other versions, for example (HNO) + (O) → NO + (OH) + 2 ( ) with subsequent conversion of (OH) into H_2O, etc.

interaction of NH_3 with NO, i.e. reactions (V) and (VI), in addition to reactions (I)–(IV). The kinetics of the platinum-catalysed reaction (VI) have been investigated[17] and it has been shown that the reaction is strongly inhibited by oxygen. The mechanism of reactions (V) and (VI) on platinum has been studied by the isotopic tracer method[18]. The authors[18] concluded that, in the course of the above reactions at 200°C, NH_3 molecules dissociate on the surface of platinum with formation of the (NH_2) species, which then react with NO, yielding N_2 and H_2O. At high temperatures, further dissociation of (NH_2) with formation of (NH) is postulated.

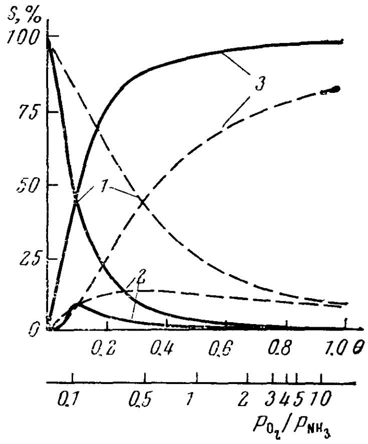

Figure 3. Variation of S_{N_2} (curve *1*), S_{N_2O} (curve *2*), and S_{NO} (curve *3*) with mixture composition[13,46].

The second stage in schemes (VII)–(IX), reflecting the interaction of NH_3 with adsorbed oxygen, is probably in reality more complex than would follow from the equation quoted for this stage. Possibly the formation of the (NH) species from NH_3 and (O) is preceded by the activation of the ammonia molecules on the metal surface free from oxygen[4,5]. This hypothesis is confirmed by the finding that mechanical admixtures of platinum to cobalt, manganese, and vanadium oxides accelerate their reduction by ammonia[19]. The activation of NH_3 molecules on the surface of platinum and other transition metals may involve the dissociation (or marked weakening) of the N–H bond. As pointed out by the present author and Golodets[4,5], this is supported by the fact that transition metals actively catalyse the NH_3–D_2 exchange, although this happens at temperatures lower than those corresponding to the oxidation of NH_3: the exchange between NH_3 and D_2 involves an intermediate stage with partial dissociation of ammonia molecules[20]. As mentioned above, it is natural to suppose that ammonia behaves as an electron donor in its reaction with (O). The conclusion that electrons are transferred from the adsorbed ammonia molecules to the metal follows from a study[21] where the adsorption of NH_3 on gold was investigated by electrophysical methods.

All the schemes described presuppose a purely heterogeneous mechanism of the oxidation of ammonia. Many investigators have considered the possibility of a heterogeneous-homogeneous mechanism of this reaction on platinum, particularly at high temperatures[1,2]. It has been concluded[22,23] that this process is transferred to the bulk phase. It was mentioned above that an abrupt acceleration to the process on platinum has been observed[4] on reaching 240°C. Similar "critical" phenomena have been observed in another investigation[24]. One of their likely causes, according to the present author and Golodets[4], is the transfer of the process to the bulk phase, where the reaction proceeds via a radical-chain mechanism. On the other hand, other investigators (see, for example, Epshtein[25] and Nutt and Kapur[26]) reject a heterogeneous-homogeneous mechanism of the oxidation of ammonia. Thus Nutt and Kapur[26], using mass-spectrometric analysis, failed to detect the presence in the gas phase of unstable intermediate species which might serve as the active centres for the bulk-phase chains in the catalytic oxidation of ammonia; they carried out the catalytic process on platinum at low pressures over a wide range of temperatures (up to 1300°C).

Evidently the discrepancies between the conclusions reached in different investigations can be largely attributed to different experimental conditions. The problem of the role of bulk-phase chains in the mechanism of the catalytic oxidation of ammonia requires further study under conditions as close as possible to the usual conditions in the catalytic process.

We shall now consider the problem of the relation between the catalytic properties of metals in the oxidation of ammonia and their physicochemical (thermodynamic) properties. The discussion may be based[27,28] on mechanism (VII) and the corresponding kinetic equations (1)–(4).

It is natural to suppose that the mechanisms of reactions occurring on different transition metals are similar. This is indicated, in particular, by the finding that the compositions of the intermediate nitrogen compounds desorbed from the platinum and tungsten surfaces after the catalytic process are similar[10]. The differences between the catalytic activities and selectivities of different metals for a constant composition of the reaction mixture and temperature are determined by the differences between the constants in Eqns. (1)–(4).

The relation between the rate constants for different stages and the thermodynamic characteristics of the catalysts is given by the Brønsted–Temkin equation

$$k_i = g_i K_i^{\alpha_i} = g_i \exp\left(\frac{\alpha_i \Delta S_i^0}{R}\right)\cdot\exp\left(\frac{\alpha_i q_i}{RT}\right), \qquad (14)$$

where K_i is the equilibrium constant for the ith stage, q_i the heat of this stage, ΔS_i^0 the standard entropy of the stage, and g_i and α_i are constants for a number of similar catalysts for the given process (ΔS_i^0 in the given series may be regarded as approximately constant[29]).

A common feature of the different stages of mechanism (VII) is that they involve the formation or dissociation of the oxygen–catalyst bond. Consequently, the catalytic activity and selectivity should depend significantly on the energy of this bond, which may be measured by the heat q_S of the binding of oxygen to the surface[30]: $\frac{1}{2}O_2 + (\ ) = (O)$. At the same time, bonds between the catalyst and other atoms (for example, nitrogen) may be formed and dissociated during the reactions. The approximation employed is that the energies of these bonds change much less on passing from one catalyst to another than the q_S.[32] The fact that the energy of the metal–oxygen bond depends much more markedly on the nature of the metal than those of the metal–nitrogen and metal–hydrogen bonds is an argument in support of this hypothesis[31]. Furthermore, since the typical value of the coefficient α in Eqn. (14) is 0.5, [29] we shall assume that the α_i for different stages are the same and equal to α, which somewhat simplifies the analysis.

The variation of the catalytic activity with q_S is described by the function $\rho = \partial \ln r/\partial q_S$ for T, p_i = const., where r is defined by Eqn. 1. On differentiating Eqn. (1)¶ and taking into account Eqn. (14) as well as the fact that $q_1 = 2q_S$ and $q_2 = q'_2 - q_S$ (where q'_2 is a combination of the terms of the approximation employed), we obtain

$$\rho = \frac{\alpha}{RT}(2-3\theta). \tag{15}$$

Here

$$\theta = \left[1 + \frac{\bar{\nu}}{A}\exp\left(-\frac{3\alpha}{RT}q_s\right)\right]^{-1}, \tag{16}$$

where A is a constant. The last equation shows that θ increases with increase of q_S, tending to unity. If the range of variation of q_S is fairly large, then the variation of $\ln r$ with q_S passes through a maximum, since $\rho > 0$ when $\theta \to 0$ and $\rho < 0$ when $\theta \to 1$. The maximum corresponds to $\rho = 0$, whence the optimum value of θ is 2/3 according to Eqn. (15). This implies that, in the group of similar catalytic systems, the catalyst for which q_S corresponds to $\theta = 2/3$ exhibits the highest specific activity at the given temperature and for the given mixture composition.

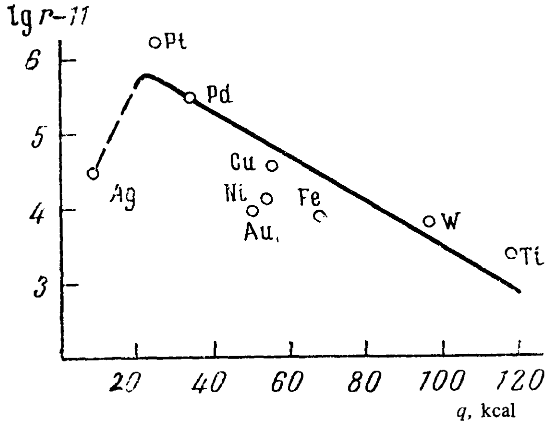

Figure 4. Variation of the specific catalytic activity of metals in the oxidation of NH_3 at 300°C with the energy q_S of the bond between the catalyst and oxygen[30]; mixture composition: $p_{NH_3} = 0.1$ atm; $p_{O_2} = 0.9$ atm.[5]

In the region where θ is close to unity (this is attained by carrying out the catalyst process in the presence of a large excess of O_2), the variation of $\ln r$ with q_S should be represented by a straight line with a negative slope:

$$\rho = -\alpha/RT, \tag{17}$$

i.e. the specific activity should fall steadily as q_S increases. Fig. 4 shows that this is indeed observed. It follows from Eqn. (1) that in this region $r \simeq \frac{1}{2}k_2 p_{NH_3}$, i.e. the decrease of the activity with increasing q_S is caused by the fact that the rate is determined by stage (2), where the bond between oxygen and the catalyst dissociates. The observed relation between $\log r$ and q_S is analogous to corresponding relations found earlier [30] for the oxidation of hydrogen, carbon monoxide, and organic substances.

The type of variation of the selectivity with q_S is determined, as can be seen from Eqns. (3) and (4), by the dependence of θ and μ on q_S. Using Eqn. (14) to determine k_4 and k_5 and taking into account Eqn. (5), we obtain

$$\mu = B\exp\left[\frac{\alpha}{RT}(q^4 - q^5)\right]\cdot\exp\left(-\frac{q_3}{RT}\right), \tag{18}$$

where B combines a number of constants. Assuming, as before, that on passing from one catalyst to another, mainly the values of q_S change, we have

$$q_4 = q'_4 - n_{N_2}q_s,\quad q_5 = q'_5 - n_{N_2O}q_s,\quad q_4 - q_5 = q' + (n_{N_2O} - n_{N_2})\,q_s.$$

In these equations, q'_4, q'_5, and q' combine terms independent of q_S and n_{N_2} and n_{N_2O} are coefficients determined by the number of oxygen–catalyst bonds dissociated in stages (4) and (5). In terms of the approximation employed, q_3 may be regarded as independent of q_S, since in the third stage the oxygen–catalyst bond is both dissociated and formed. We then obtain in place of Eqn. (18)

$$\mu = \mu_0 \exp(\alpha\,\Delta n q_s/RT), \tag{19}$$

where μ_0 is independent of q_S and Δn is

$$\Delta n = n_{N_2O} - n_{N_2}. \tag{20}$$

Fewer oxygen–catalyst bonds are dissociated in stage (4) than in stage (5), so that $\Delta n > 0$; consequently the coefficient μ increases with increase of q_S and so does θ [Eqn. (16)]. The selectivity with respect to N_2 should therefore increase with increase of q_S, tending to unity, while the selectivity with respect to N_2O should fall, tending to zero. Fig. 5 shows that such a relation is indeed observed.

Thus the principal cause of the increase of selectivity with respect to the mild oxidation product as q_S increases is that the formation of this product (the fourth stage) entails the dissociation of fewer oxygen–catalyst bonds than in the formation of the extensive oxidation product (the fifth stage).

This approach can be extended to a more general stage where NH_3 is oxidised to N_2, N_2O, and NO [scheme (IX), Eqns. (11)–(13)]. In this case, the behaviour expected on the basis of the theory is as follows [27,28]: with increase of q_S, the selectivity with respect to the mild oxidation product (N_2) should rise continuously and that with respect to the extensive oxidation product (NO) should fall. This is confirmed qualitatively by the observation that, at fairly high temperatures, platinum exhibits a higher selectivity with respect to NO than palladium, rhodium [9], and other transition metals [1] characterised by higher values of q_S than platinum.

On the basis of the Polanyi relation for the heats of activation and the hypothesis that the higher the degree of oxidation of the product the greater number of oxygen–catalyst bonds dissociated in the stage leading to its formation, one can show [33] that the heat of activation for the reactions under consideration (in the presence of the given catalyst) should increase in the sequence $E_{N_2} < E_{N_2O} < E_{NO}$. The temperatures of the onset of the formation of the corresponding products should therefore increase in the same sequence. This conclusion is confirmed by

---

¶ Since the coefficient $\bar{\nu}$ usually varies within narrow limits, in our discussion it is permissible to disregard this variation of $\bar{\nu}$ with q_S.

the data in Table 1 and by the finding[1] that NO begins to be formed at higher temperatures than N_2O in the presence of each metal.

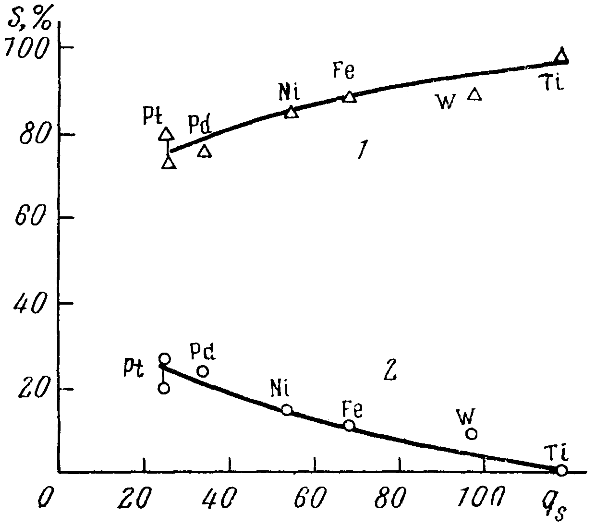

Figure 5. Variation of the selectivity of transition metals at 300°C with q_S (Il'chenko et al.[5]): 1) selectivity with respect to N_2; 2) selectivity with respect to N_2O.

The observed decrease with q_S of both characteristics—the activity r with respect to the overall process and the selectivity S_{N_2O} with respect to the extensive oxidation of NH_3 (see Figs. 4 and 5)—explains the empirical relation noted previously, namely the parallel variation of r and S_{N_2O}.

2. Oxidation of Ammonia in the Presence of Metallic Alloys

In the oxidation of ammonia to NO under industrial conditions, platinum is strongly acted upon by the reaction mixture, under the influence of which the surface of the platinum gauze is loosened, the gauze becomes brittle, and gradually breaks up. The attention of the investigators has therefore been directed to the search for additives to platinum which would improve its strength and stability without reducing its catalytic activity and selectivity. Such requirements are satisfied by platinum–rhodium alloys. In practice, one uses gauze made of 90% Pt–10% Rh alloy (owing to the high cost of rhodium, alloys containing 5–7% Rh are sometimes used). When the reaction is carried out at atmospheric pressure, platinum alloys with 4% Pd and 3.5% Rh, which are somewhat less stable but no less active than the platinum–rhodium catalysts, are employed. Other platinum (and palladium) alloys with transition metals, particularly the platinum alloy with 1% 1% Ir, [1] also exhibit a high activity in the oxidation of ammonia to NO.

Systematic studies yielding information about the specific catalytic activities of alloys and their selectivities under kinetic conditions (particularly at low temperatures) have not so far been made. The kinetics and mechanism of the oxidation of ammonia in the presence of metallic alloys have also been hardly investigated. Presumably the same behaviour should apply here as in catalysis on the pure metals.

It has been shown[34] that the catalytic activity of the 90% Pt–10% Rh alloy increases when ammonia is oxidised by the O_2–O mixture instead of molecular oxygen. The homogeneous oxidation of NH_3 by atomic oxygen was ruled out[34] and it was assumed that acceleration is achieved either owing to the increase of the concentration of adsorbed oxygen or because excited activated species appear in the purely exothermic interaction of O atoms with the surface of the catalyst. The first hypothesis is consistent with schemes (VII)–(IX), because it follows from Eqn. (1) that the rate of reaction is proportional to θ.

3. Oxidation of Ammonia in the Presence of Simple Oxide Catalysts

Quantitative data on the catalytic properties of simple oxides in the oxidation of ammonia have been obtained in a number of studies[13,35,36] (Table 2). Under the conditions of these experiments, the reaction products were N_2 and N_2O and the process occurred in the kinetic region. The steady state was usually attained rapidly, in the course of 5–10 min. A phase transformation of the oxide (with the exception of Ag_2O) was not observed. Table 2 shows that at 230°C the specific catalytic activities of the oxides decrease in the following sequence:

$$Co_3O_4,\ MnO_2 > CuO > CaO_2 > NiO > Bi_2O_3 > Fe_2O_3 > V_2O_5 > TiO_2 > \\ > CdO > PbO > ZnO > SnO_2 > ZrO_2 > MoO_3 > WO_3$$

A similar sequence was obtained in another study[37], according to which the activities of the oxides decrease as follows:

$$Co_3O_4 > Mn_2O_3 > Cr_2O_3 > Fe_2O_3 > CuO > NiO > V_2O_5 > MoO_3 > U_3O_8 > \\ > ThO_2 > WO_3 > SnO_2 > ZrO_2 > ZnO > Nb_2O_5 > Bi_2O_3 > Sb_2O_4 > Ta_2O_5.$$

However, one should note that the activity of Bi_2O_3 observed by Germain and Perez[37] is significantly lower than that found by Il'chenko et al.[36]. According to other data[38,39], lanthanide (La, Ce, Pr) oxides exhibit a low activity in the oxidation of NH_3 and the activities of Al_2O_3 and SiO_2 are very low indeed. The activity of barium peroxide approaches that of Fe_2O_3.[40]

Thus, among the simple oxides, the highest activities in the oxidation of ammonia are shown by the transition metal oxides Co_3O_4, $MnO_2(Mn_2O_3)$, Cr_2O_3, and CuO, the oxides NiO, Fe_2O_3, and V_2O_5 are moderately active, and the activities of the oxides La_2O_3, Pr_6O_{11}, CeO_2, TiO_2, ZrO_2, ThO_2, Nb_2O_5, Ta_2O_5, MoO_3, WO_3, and U_3O_8 are low. The oxides of elements in the main subgroups (except for calcium and barium peroxides) are relatively inactive. A similar behaviour has been observed in the oxidation of hydrogen[41,42], methane, benzene[41], and other inorganic and organic substances.

As in the presence of metals, the oxidation of ammonia in the presence of metal oxides results in the preferential formation of N_2 at low temperatures; on raising the reaction temperatures, nitrous oxide appears in the products, its yield passing through a maximum; at still higher temperatures (400–500°C and above), ammonia is oxidised to an even greater extent—to NO.[1,2,35-40] It has been noted[33] that, in the presence of each catalyst the temperature of the onset of formation of particular products increases in the sequence $N_2 < N_2O < NO$ (see Refs. 36, 38, 40 and Table 2).

At low temperatures and for low degrees of conversion, when only reactions (I) and (II) occur, the selectivity with respect to N_2O in the presence of the majority of oxides increases with temperature[36,40]. In this region, the selectivity with respect to N_2O falls in the sequence

$$CaO_2 > MnO_2,\ NiO > Co_3O_4 > Fe_2O_3 > SnO_2 > CdO > CuO >$$
$$> TiO_2 > ZnO,\ Bi_2O_3,\ PbO,\ ZrO_2,\ MoO_3,\ WO_3$$

(Table 2). Comparison of these data with other results[37,38] leads to the conclusion that the maximum selectivity with respect to N_2O (minimum selectivity with respect to N_2) is shown by the most active oxides (MnO_2, Mn_2O_3, Co_3O_4, CuO, NiO, Cu_2O, and CaO_2), so that the following tendency is observed: the selectivity with respect to mild oxidation varies in general in opposition to the catalytic activity, while the selectivity with respect to extensive oxidation varies in parallel with the activity[36].

Table 2. The oxidation of ammonia in the presence of metal oxides*.[13,35,36]

***The oxide was reduced to the metal during the catalytic reaction.

****S_{N_2O} for NiO at 160°C and to TiO_2 at 290°C.

At high temperatures (700–800°C), reaction (III) proceeds at a high rate. Owing to the marked influence of macrokinetic factors, it is difficult to obtain rigorous quantitative selectivity data in this temperature range. Qualitative characteristics of the selectivity with respect to NO for various oxides at temperatures in the range 700–800°C have been published[43,44]. According to Kurin and Zakharov[43], the yield of NO decreases in the sequence

$$Co_3O_4 > MnO_2 > PbO > Cr_2O_3,\ Fe_2O_3 > CuO > NiO > ZnO >$$
$$> SnO_2,\ MoO_3,\ WO_3,\ TiO_2,\ Al_2O_3;$$

while Morozov et al.[44] obtained the sequence

$$Co_3O_4 > CuO > Cr_2O_3 > Fe_2O_3.$$

Thus, under these conditions too the selectivity with respect to the extensive oxidation products in general varies in parallel with the catalytic activity in relation to the overall process. The most active catalyst (among simple oxides), namely Co_3O_4, exhibits a fairly high selectivity with respect to N_2O at low temperatures and with respect to NO at high temperatures. This catalyst is sometimes used in practice in the oxidation of NH_3 to NO.[1]

The kinetics and mechanism of the oxidation of ammonia in the presence of oxide catalysts (Co_3O_4, MnO_2, CuO, Fe_2O_3, and V_2O_5; see Table 2) have been investigated[13,35,45,46]. The experiments were performed in a differential flow reactor (with conversions not exceeding 20%) and by the flow-circulation method. The reaction was studied at temperatures below 400°C when the products were N_2 and N_2O. The study of the variation of the rate of reactions (I) and (II) with contact time τ in the presence of the most active catalysts (Co_3O_4, MnO_2) showed that, under the chosen conditions, the values of r_i (and hence the selectivity) are independent of τ. This implies that reactions (I) and (II) take place simultaneously and are not inhibited by the products. The variation of the rate of the overall process and of specific reactions with p_{NH_3} and p_{O_2} is represented (for each catalyst) by hyperbolic curves: the reaction is of first order for low values of p_i, and of zero order for high values of p_i.

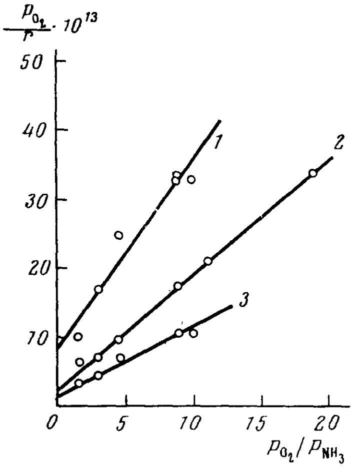

Figure 6. Variation of p_{O_2}/r with p_{O_2}/p_{NH_3} on an MnO_2 catalyst[13,46] at different temperatures (°C): 1) 135; 2) 145; 3) 155.

As in the catalytic reaction on platinum[4], mechanisms of the Langmuir–Hinshelwood type proved to be unsuitable for the interpretation of the experimental data. Scheme (VII) and the kinetic equations (1)–(4) corresponding to it proved to be the most appropriate. Figs. 6 and 7 show that these equations describe satisfactorily the experimental data for the MnO_2 catalyst. A similar result was obtained also for other oxides (Co_3O_4, CuO, Fe_2O_3, and V_2O_5). The rate constants, heats of activation, and entropies of activation for the first two stages of scheme (VII), calculated from the experimental data, have been compiled for the above catalysts[13]. The kinetic data[47] for the oxidation of ammonia in the presence of Cu_2O also agree with Eqns. (1)–(4).

The conclusion that S_{N_2O} increases with increase of θ agrees with the results of a study[40] where it was found that the yield of nitrous oxide increases with increasing concentration of the "excess" oxygen on the surface of transition metal oxides.

According to scheme (VII), the oxygen adsorption stage is irreversible. We shall now consider[45] another extreme case, where adsorption equilibrium is established in the first stage. If such a case does indeed occur, deviations from Eqn. (1) should be observed. The selectivity equations (3) and (4) retain their previous form, but the values of θ involved in them are determined by the oxygen adsorption isotherm and not by Eqn. (2). This means that, at a given temperature, the selectivity should be independent of p_{NH_3} and, for a constant p_{O_2}, it should remain unchanged; in reality, S_{N_2O} decreases with increase of p_{NH_3} (for p_{O_2} = const.), which corresponds to Eqn. (4).

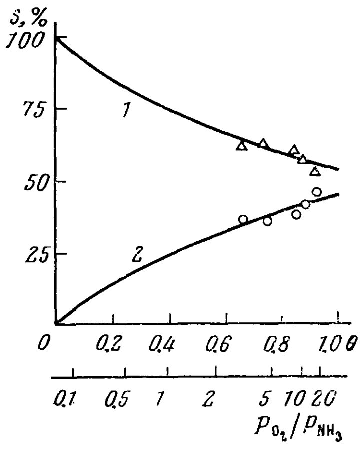

Figure 7. Variation of the selectivity with respect to N_2 (curve *1*) and N_2O (curve *2*) with p_{O_2}/p_{NH_3} and θ at 145°C on an MnO_2 catalyst[13,46] (μ = 1,2; k_1/k_2 = 0.55).

The similarity of the behaviour observed in the catalytic oxidation of ammonia and in the surface reduction of various oxides by ammonia (in the absence of O_2 from the gas phase) constitutes an independent demonstration of the involvement of the (O) species in the process and that their surface concentration θ plays a decisive role in the reaction kinetics. The following observations were made[13,35].

(1) The composition of the products in the catalytic and reduction reactions is the same (see the data of Krauss and Neuhaus[40]).

(2) The rate of the overall conversion of ammonia in the reduction process decreases with increase of the duration of reduction τ'. This result is consistent with Eqn. (1), since θ falls continuously as τ' increases. If the reduction is carried out after treating the catalyst with oxygen, whereupon the catalyst surface is fully oxidised in the initial state (θ is a maximum), then the initial rate of reduction is higher than the steady-state rate of the catalytic reaction. After a specific time τ', the rate of reduction becomes equal to the rate of the catalytic reaction; at this point, the values of θ for the catalytic and reduction reactions are the same. If the reduction is carried out immediately after the catalytic experiment, then the initial rate of reduction is close to the steady-state rate of the catalytic reaction.

(3) In conformity with Eqns. (3) and (4), the selectivity with respect to N_2 increases and that with respect to N_2O falls as τ' increases, i.e. as θ decreases.

The similarity of the characteristics of the catalytic oxidation of ammonia and of the surface reduction of oxides by ammonia shows that, in the interaction of NH_3 with the surface [the second stage in scheme (VII)], electrons are transferred from the ammonia molecule to the catalyst, i.e. NH_3 behaves as an electron donor. This is consistent with the results of studies[47,48] where the catalytic properties of oxides in the oxidation of ammonia were compared with their semiconductor properties.

It is natural to assume that the abstraction of hydrogen from the NH_3 molecule proceeds simultaneously with electron transfer from NH_3 to the catalyst and is completed gradually, in several stages: the formation of the final products from NH_3 and O_2 in a single stage would require the simultaneous collision of many species, which is unlikely. In order to demonstrate the involvement of (NH) and (HNO) species and possibly of other surface complexes in the process, it is necessary to employ physical research techniques. In this connection, we may note that the most probable product of the reaction between NH_3 and the surface oxygen of iron(III) oxide at low temperatures has been shown by infrared spectroscopy to consist of species of the nitroxyl type[49].

It has been shown by ESR[50] that, in the adsorption of ammonia at room temperature on partly reduced vanadium pentoxide deposited on silica gel, the NH_3 molecule enters into the first coordination sphere of the tetrahedrally coordinated V^{4+} ion. This results in a rearrangement of the coordination sphere and in the formation of a shortened vanadium–oxygen bond, characteristic of vanadyl ions. Thus formation of an unstable coordination compound may be the primary step in the activation of NH_3 during the catalytic process, facilitating the next electron transfer stage. This hypothesis appears probable, bearing in mind the tendency of transition metal cations to form complexes with ammonia, a molecule having a lone electron pair.

In the subsequent stages of the catalytic process, the (NH) and (HNO) species behave as electron donors, like ammonia. When these species are converted into the reaction products (N_2, N_2O, and H_2O), electrons are liberated. The reduced form of the catalyst cations M^{n+}_{red}, capable of giving up electrons, therefore corresponds to the free surface sites, appearing as a result of the fourth or fifth stages of scheme (VII).

In the adsorption of electron-accepting oxygen molecules on these centres, electrons combine with the O_2 molecules, forming negatively charged atomic ions (O) bound to the oxidised form of the cations M^{m+}_{ox}. Hence it follows that the surface concentration of the (O) species, equal to θ, is proportional to $[M^{m+}_{ox}]$, while the concentration of free sites ( ), equal to $1 - \theta$, is proportional to $[M^{n+}_{red}]$; the ratio of the concentrations of the oxidised and reduced forms $\gamma = [M^{m+}_{ox}]/[M^{n+}_{red}]$ will be proportional, under steady-stage conditions of the catalytic reaction, to $\theta/(1 - \theta)$. According to Eqn. (2), this implies that γ is proportional to p_{O_2}/p_{NH_3}, i.e. the degree of oxidation of the surface is determined by the ratio of the partial pressures of oxygen and ammonia in the reaction mixture.

The same quantity determines the catalytic selectivity (at a given temperature). The higher the value of p_{O_2}/p_{NH_3}, the higher the degree of surface coverage by oxygen θ. Since the activated complex in the stage leadng to the formation of N_2O incorporates a larger number of oxygen atoms than the activated complex in the stage leading to the formation of N_2 (see the fourth and fifth stages), an increase of p_{O_2}/p_{NH_3} tends to increase the selectivity with respect to the more oxidised product—nitrous oxide.

The kinetics and mechanism of the reaction in the presence of oxides at elevated temperatures have not been investigated. Presumably schemes of types (VIII) and (IX), taking into account the parallel-reaction oxidation of NH_3 to NO and the consecutive-reaction reduction of nitrous oxide by ammonia [here it is also necessary to take into account reactions (V) and (VI)], are valid for these conditions.

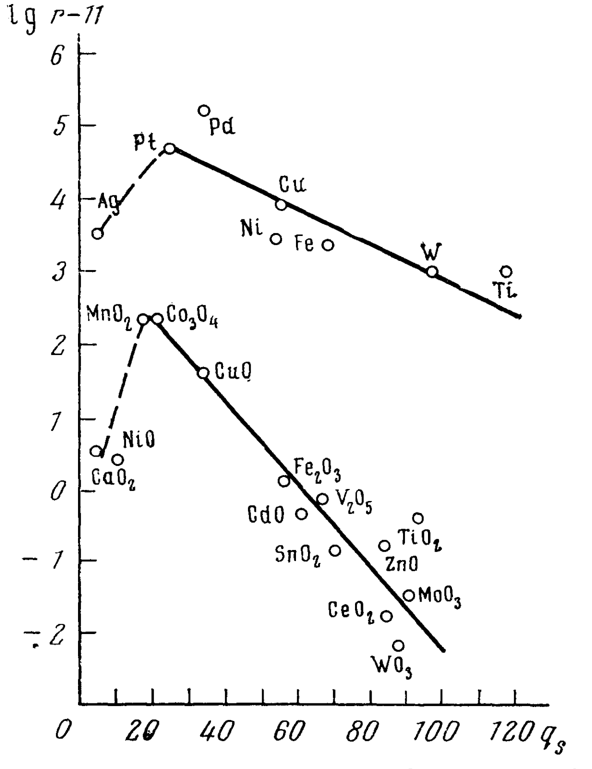

Figure 8. Variation of the specific catalytic activity of metals and oxides in the oxidation of NH_3 at 230°C with q_S; mixture composition: p_{NH_3} = 0.1 atm; p_{O_2} = 0.9 atm.[36]

The results of the theoretical analysis carried out above in relation to metallic catalysts (section II, subsection 1) can be usefully employed in the discussion of the problem of the relation between the catalytic and physicochemical properties of oxide catalysts. Such an examination, which has been carried out in a number of studies[27,28,36], is based on the hypothesis that the oxygen–catalyst bond energy q_S plays a decisive role. Arguments in support of this hypothesis have been obtained[36] by quantum-chemical calculations on complexes simulating the surface compounds of the oxidised and reduced forms of various oxide catalysts with oxygen and the NH species.

Fig. 8 shows that the correlation predicted by Eqn. (15) does indeed occur between q_S and the specific catalytic activity of the oxide. The correlation is analogous to that observed for transition metals. At the same time, it is seen that, under identical conditions, the absolute activity of metals exceeds considerably that of oxides[4,36]. The cause of the difference should probably be sought in the fact that, in the presence of transition metals, the preliminary activation of NH_3 molecules takes place on a metallic surface free from oxygen and leads to the dissociation (or considerable weakening) of the N–H bond (see section II, subsection 1); because of this, the absolute values of k_2 for metals are higher than for oxides[4]. Similar relations between the absolute catalytic activities of metals and oxides have been observed in the oxidation of hydrogen and certain organic substances[30].

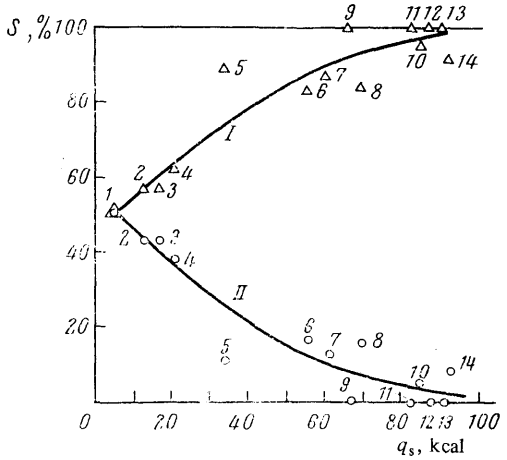

Figure 9. Dependence of the selectivity of oxides with respect to N_2 (curve *1*) and N_2O (curve *2*) on q_S at 230°C: 1) CaO_2; 2) NiO; 3) MnO_2; 4) Co_3O_4; 5) CuO; 6) Fe_2O_3; 7) CdO; 8) SnO_2; 9) V_2O_5; 10) CeO_2; 11) ZnO; 12) WO_3; 13) MoO_3; 14) TiO_2.[36]

Fig. 9 shows that the selectivity of the process with respect to N_2 increases with increase of q_S, while the selectivity with respect to N_2O falls. Such variation of selectivity follows from Eqns. (3), (4), (19), and (20). In addition to the above analysis, we shall consider[27,28] the variation of the rates of formation of N_2 and N_2O with q_S. It can be shown that, when $\theta \simeq 1$, we have

$$\rho_{N_2} = \frac{\partial \ln r_{N_2}}{\partial q_s} = -\frac{\alpha}{RT}\left(1 - \frac{\Delta n}{1+\mu}\right),$$

$$\rho_{N_2O} = \frac{\partial \ln r_{N_2O}}{\partial q_s} = -\frac{\alpha}{RT}\left(1 + \frac{\Delta n\mu}{1+\mu}\right).$$

It is readily seen that ρ_{N_2O} is negative like ρ [see Eqn. (17)]; the type of variation of the rate of extensive oxidation and of the overall rate of the process with q_S should therefore be qualitatively the same. The difference $\rho_{N_2O} - \rho_{N_2} = -\alpha\Delta n/RT$ is likewise negative, which implies that the rate of extensive oxidation should decrease with increase of q_S more rapidly than the rate of mild oxidation. Experiment confirmed this inference (Fig. 10).

The higher the value of q_S, the greater the contribution of r_{N_2} to the overall rate and the higher the selectivity with respect to the mild oxidation product (Fig. 9).

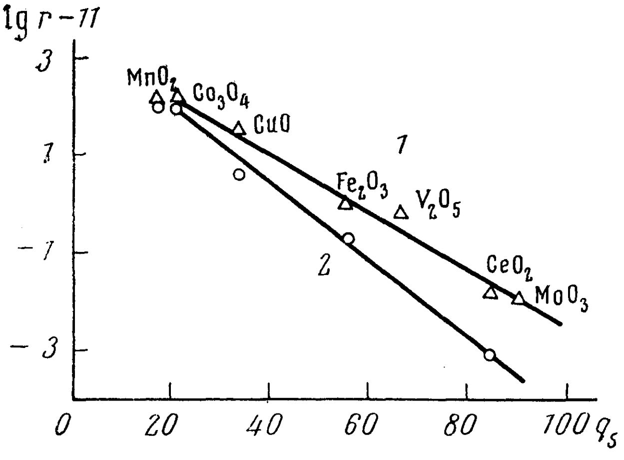

Figure 10. Variation of the rates of formation of N_2 (line 1) and N_2O (line 2) with q_S.[27]

This shows clearly that the principal cause of the increase of the selectivity with respect to the mild oxidation product with increase of q_S is that the formation of this product entails the dissociation of fewer oxygen–catalyst bonds than the formation of the extensive oxidation product[33].

When the above approach is extended to a more general case, where reactions (I)–(III) occur simultaneously, one may conclude that at high temperatures the selectivity with respect to NO should decrease with q_S. Fig. 11 shows that this inference is likewise fulfilled. The observed decrease with q_S of the catalytic activity in relation to the overall process and of the selectivity with respect to the extensive oxidation product explains the empirical observations noted above—the parallel variation of these quantities for a series of oxide catalysts.

The increase of the heats of activation in the sequence $E_{N_2} < E_{N_2O} < E_{NO}$ predicted by the theory[33] also agrees with experiment, since, in the presence of each oxide catalyst, the temperatures of the onset of formation of particular products increase in the sequence $N_2 < N_2O < NO$ (see Table 2 and the data in Refs. 36, 38, 40).

A correlation between the type of conductivity of the oxides and their catalytic properties in the ammonia oxidation reaction has been noted in a number of investigations[2,38,43]. The catalytic activity decreases in the sequence *p*-type semiconductors > *n*-type semiconductors > insulators; the selectivity with respect to N_2O (and NO) increases in the same sequence while that with respect to N_2 diminishes. The above correlation can be explained by the fact that there is a qualitative correspondence between the semiconductor properties of the oxides and the energy of the bond between oxygen and their surfaces[51]; *p*-type semiconductors (MnO_2, Co_3O_4, NiO, and CuO) have the smallest values of q_S, insulators (aluminium, silicon, and other oxides) are characterised by the highest values of q_S, while *n*-type semiconductors (V_2O_5, MoO_3, ZnO, TiO_3, etc.) occupy an intermediate position.

4. Oxidation of Ammonia in the Presence of Complex and Promoted Oxide Catalysts

Complex oxide catalysts based on MnO_2 exhibit a high activity in relation to the low-temperature oxidation of ammonia and at the same time a high selectivity with respect to N_2O. The temperature dependence of the yields of N_2, N_2O, and NO in the presence of these catalysts is of the same type as in the presence of simple oxide catalysts[1,2,40,52]. In the reaction involving the oxidation of NH_3 to N_2O at 200–300°C, MnO_2 with added Bi_2O_3 is extremely effective[2,39,53]. The studies discussed in the preceeding subsection showed that nickel(II) oxide is fairly active in relation to the overall reaction and selective with respect to the formation of N_2O. According to Giordano et al.[48], small amounts of lithium and sodium oxides added to this catalyst increase while added aluminium and iron oxides decrease the activity and selectivity, i.e., in this case, the activity and selectivity in relation to extensive oxidation vary in parallel.

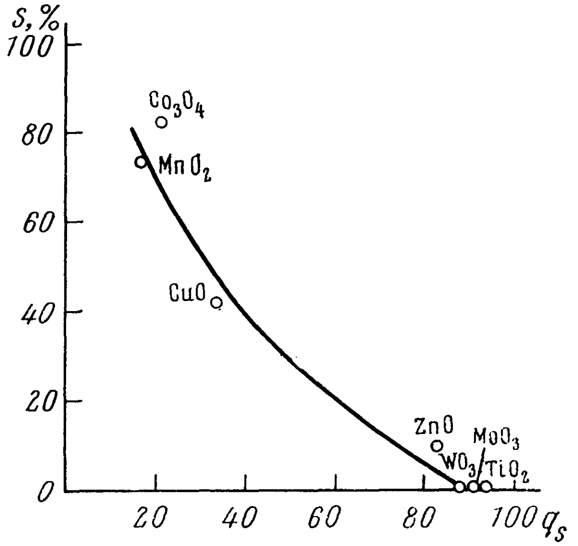

Figure 11. Dependence of the selectivity of oxides with respect to NO on q_S.[27]

In the high-temperature oxidation of ammonia, a high selectivity with respect to NO is shown mainly by complex catalysts, the chemical composition of which resembles that of the effective catalysts of the synthesis of N_2O at low temperatures. It has been shown[44] that, in the presence of cobalt oxide catalysts containing added copper, chromium, zinc, nickel, magnesium, iron, and silver oxides as well as copper and zinc chromites, the yield of NO attained at 700°C is 90–95%; best results are obtained in the presence of pure Co_3O_4. The 85% Co_3O_4–15% Al_2O_3 catalyst is sometimes used in practice[1]. In the presence of manganese oxide catalysts containing added chromium and copper oxides, the yield of NO is 60–80%.[44] The Fe_2O–MnO_2–Bi_2O_3 catalyst is fairly active (but is operation is unstable); complex iron oxide–chromium oxide catalysts are more stable and are used as the second component in two-component catalysts (platinum catalysts are used as the first component)[1].

In contrast to the catalysts based on Co_3O_4, MnO_2, and Fe_2O_3, accelerating the extensive oxidation of ammonia, which were discussed above, complex oxide catalysts based on MoO_3 catalyse, like MoO_3 itself, virtually only the mild oxidation of NH_3 (only to N_2).[54,55] Nitrogen oxides are obtained in very significant amounts in the presence of bismuth molybdate[54] and other molybdates[55]. The activity of such systems decreases in the sequence[55]

$$\text{Bi—Mo—O (Bi : Mo}=1) > \text{Fe—Mo—O} > \text{Mn—Mo—O} > \text{Co—Mo—O} >$$
$$> \text{Bi—Mo—O (Bi : Mo)} = 2) > MoO_3 > \text{Ca—Mo—O, Tl—Mo—O, Pb—Mo—O.}$$

The kinetics and mechanism of the oxidation of ammonia in the presence of complex oxide catalysts and the factors governing their selection have been little investigated. Nevertheless the isolated facts available suggest that this instance constitutes an analogy with catalysis by simple oxides:

(1) The kinetics of the overall process in the presence of MnO_2–Bi_2O_3 catalyst are said to be described[39] by the relation $r = kp_{NH_3}\theta$, i.e. Eqn. (1).

(2) In the presence of complex catalysts, the same relations are observed between the temperatures of the onset of the formation of N_2, N_2O, and NO as in the presence of simple oxide catalysts.

(3) The qualitative composition of the products in the surface reduction of complex oxides by ammonia and in the catalytic reaction is the same[40,55], as for simple oxides.

(4) Since complex catalysts based on Co_3O_4 and MnO_2 have a much lower oxygen binding energy than the catalysts based on MoO_3, presumably the same relations between q_S and the activity and selectivity are valid qualitatively for complex catalysts as for simple oxides: the first group of catalysts (based on Co_3O_4 and MnO_2) are active and selective in relation to the extensive oxidation of ammonia, while the activity of the second group (based on MoO_3) is low, but the catalysts are selective in relation to the mild oxidation. The validity of relations of this kind for complex oxide catalysts too provides a natural explanation of the opposite variation of r and S_{N_2} observed for such catalysts.

Thus, by altering the oxygen–oxide catalyst bond energy as a result of the introduction of additives, it is possible to regulate the activity and selectivity of the catalyst in the oxidation of ammonia.

A fundamentally new method for the selection of a low-temperature catalyst for the synthesis of nitrous oxide from ammonia was used by the present author[19]. The idea is as follows. Since we have seen that a high selectivity with respect to N_2O is achieved on oxides with low values of q_S, oxides such as MnO_2 and Co_3O_4 can be used as a basis for the above catalyst. Next, it is necessary to increase the activity of these without altering q_S, since otherwise the selectivity would fall. Such a method of increasing the activity is provided by the dissimilarity (noted above) of transition metals and their oxides, associated with the higher rate of activation of ammonia on metallic surfaces. When small amounts of platinum or palladium are introduced into the oxide, then q_S for the oxide remains unchanged, but the rate of oxidation of ammonia should increase owing to its activation on the metal. Using this procedure, it was indeed possible to obtain new extremely active and selective catalysts for the oxidation of NH_3 to N_2O (cobalt or manganese oxide promoted by platinum). In the presence of these catalysts at low temperatures (of the order of 200°C), ammonia can be fully converted, the selectivity with respect to N_2O being 60–80%.[19]

The study of the reaction kinetics in the presence of the above promoted catalysts showed that the same Eqns. (1) to (4) are valid for them as for the unpromoted oxides. This demonstrates that the introduction of additives does not cause a fundamental change in the reaction mechanism but there is an appreciable increase of the rate of reaction of ammonia with the surface oxygen of the oxide. This is proved by the observed acceleration of the surface reduction of cobalt and manganese oxides by ammonia in the presence of small amounts of added platinum[19].

A similar promotion effect was demonstrated previously in the oxidation of hydrogen on vanadium pentoxide[56]. We may note that the reactivity of ammonia in its oxidation on metal oxides is close to the reactivity of molecular hydrogen[36].

5. Oxidation of Ammonia on Zeolites Containing Transition Metals

The oxidation of ammonia on a type Y zeolite containing Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Cr^{3+}, and Ag^+ cations has been investigated[57] by a pulse method ($O_2 : NH_3 = 3 : 1$). The cations were introduced into the initial NaY zeolite by ion exchange from solutions of the metal nitrates. The degree of exchange (%) was 70.5 for CuY, 50.0 for FeY, 55 for CoY, 80.4 for CrY, 48.0 for NiY, 56 for MnY, and 51.7 for AgY. After the exchange, the colour of the zeolite corresponded to the colour of the cations in the aqueous solution. The aluminosilicate crystal structure of the NaY specimen was retained in the exchange reaction. It also remained unchanged after the specimens had been heat-treated at temperatures up to 600°C. The only exception was the chromium catalyst in which the formation of a α-Al_2O_3–Cr_2O_3 solid solution was observed.

The catalytic activity was characterised by the degree of conversion of ammonia for the same weight of the metal in the zeolite. The following activity series was established:

$$\text{CuY} > \text{CrY} > \text{AgY} > \text{CoY} > \text{FeY} > \text{NiY, MnY.}$$

The reaction product was molecular nitrogen in the presence of all the above catalysts. A fairly small amount of nitrous oxide was also formed in the presence of the chromium- and silver-zeolites; in the presence of AgY, the selectivity with respect to N_2O at 400°C was approximately 25%. On other zeolites, the selectivity with respect to this product was 1–5%. The authors[57] believe that the process proceeds via a parallel-consecutive reaction mechanism, the N_2O formed being converted into N_2 via reaction (IV). A high rate of this reaction at the temperatures of the catalytic oxidation of ammonia has been demonstrated for the CuY catalyst.

The study of the alternate oxidation of the catalysts by oxygen pulses and of the reduction of the oxidised specimen by ammonia showed that N_2 is formed on reduction in the presence of the FeY, CuY, and CrY zeolites, which absorb O_2; the MnY and CoY catalysts do not absorb oxygen. The adsorption of ammonia on the CuY catalyst at room temperature leads to a change in the colour of the latter, which becomes blue, i.e. is characteristic of the coordination compounds of NH_3 and Cu^{2+}. There is a simultaneous change in the ESR spectrum of the specimen. The adsorbed ammonia is removed by evacuation (at 60°C), whereupon the specimen returns to the initial state. The adsorption of O_2 at 385°C does not change the ESR spectrum of the zeolite. When ammonia is readmitted at 385°C, some of the Cu^{2+} ions are reduced; the copper atoms formed can be reoxidised by oxygen.

A different behaviour is observed in the presence of the MnY zeolite: the ESR spectrum changes only when NH_3 is adsorbed at room temperature. The retention of the ESR signal following the interaction of the zeolite with O_2 and NH_3 at elevated temperatures suggests that in this case the valence state of the manganese in the zeolite remains unaltered. X-Ray diffraction studies of all the zeolites after exposure to a stream of ammonia at 500°C failed to reveal any changes relative to the initial state, which indicates the absence of a metallic phase.

Comparison of the metal cations shows that the above zeolite activity series differs significantly from the corresponding series obtained for oxide catalysts (see subsection 3 of this section). This is evidently associated with the fact that the intermediate chemical interaction in the catalytic process on the zeolite is of the local type and involves a single catalyst cation, while in catalysis on solid oxides collective interactions due to the presence of the crystal lattice also play a significant role.

The authors[57] suggest that a mechanism involving the alternate reduction and oxidation of the catalyst cations is possible on the CuY and FeY zeolites, while in the presence of the MnY, CoY, and NiY zeolites, where the valence state of the metal is stabilised, a mechanism involving the simultaneous interaction of the catalyst with NH_3 and O_2 is probable.

III. THE ANALOGY BETWEEN THE SELECTIVE OXIDATION REACTIONS OF AMMONIA AND ORGANIC SUBSTANCES[27,28]

The oxidation of ammonia is a convenient reaction for the elucidation of the general characteristics of selective catalytic oxidation. In many significant respects, the mechanism of this reaction is similar to that of the oxidation of organic substances. The similarity is manifested in the kinetics. Thus the kinetic equations for the overall oxidation of *o*-xylene[58] and ammonia are analogous. In the oxidation of *o*-xylene[58], but-1-ene[59], and other substances (R), the selectivity with respect to the mild oxidation product increases with increase of the ratio p_R/p_{O_2} in the reaction mixture, as has been observed in the oxidation of NH_3, where the selectivity with respect to nitrogen increases with p_R/p_{O_2}.

The catalytic activity in the oxidation of both ammonia and organic substances is determined primarily by the energy of the bond formed by oxygen with the catalyst surface, the optimum corresponding to low values of q_S. The similarity of the mechanisms of these reactions is responsible for the analogous variation of the catalytic activity as a function of q_S. This explains the finding that the most active catalysts for the oxidation of NH_3 and organic substances are the same (Co_3O_4, MnO_2, and platinum).

The general rule whereby one can understand the nature of the variation of selectivity as a function of q_S is that the formation of the extensive oxidation products (CO and CO_2 in the oxidation of organic substances and N_2O and NO in the oxidation of ammonia) involves the dissociation of a larger number of oxygen–catalyst bonds than the formation of the mild oxidation products (aldehydes, ketones, etc. in organic catalysis and N_2 in the oxidation of NH_3). As a result of this, the selectivity with respect to the mild oxidation products increases and that with respect to the extensive oxidation products decreases with increase of q_S. This implies that a high selectivity with respect to the extensive oxidation products is attained on catalysts with low values of q_S, in agreement with the condition for the highest activity of the catalyst, and explains why the best catalysts for the oxidation of NH_3 to NO and for the complete combustion of organic substances are usually Co_3O_4 and platinum.

Experiments have shown that the optimum values of q_S for the mild oxidation reactions of organic substances is close to the value of q_S for V_2O_5 and for complex catalysts based on V_2O_5 and MoO_3, because the latter are used to accelerate these reactions. The similarity of the mild oxidation reactions of organic substances and ammonia is manifested by the fact that the same catalysts are used also in the mild oxidation of NH_3.

There are also definite differences between the oxidation reactions of organic substances and ammonia. These involve primarily the thermodynamics of the reactions. In the oxidation of organic substances, the extensive oxidation products are thermodynamically more stable than the mild oxidation products, while in the oxidation of ammonia the opposite behaviour is observed (see Section I). In the former case, the mild oxidation product is desired and in the latter the aim is to obtain the extensive oxidation product. This is reasonable, since the advantage of catalysis are reflected in the possibility of obtaining thermodynamically less stable products. The above feature of the thermodynamics of the reactions compared is manifested by the finding that, in the oxidation of ammonia (in contrast to the oxidation of organic substances), an enhanced rate of formation of the mild oxidation product and a reduced observed rate of extensive oxidation correspond to the consecutive reaction scheme.

One must note that the approach used above to establish a relation between the catalytic properties and chemical structures of substances has certain limitations. In a more rigorous treatment, it is necessary to take into account the energy inhomogeneity of the surface oxygen[60], which can play the same role on a given catalyst as the changes in the oxygen binding energy on passing from one catalyst to another. Another simplification is associated with the hypothesis that only the energy of the oxygen–catalyst bond changes significantly from one catalyst to another. In a more exact analysis, one must take into account also the changes in the energies of other bonds formed with the catalyst[32]. Allowance for the energies of other bonds should be understood in a fairly broad sense, including the formation of coordination compounds via π bonding, etc. as well as salt-like surface complexes. In the latter case, the acid–base properties of the catalyst play a significant role[61]. One can also suppose that, in the oxidation of complex organic molecules, the geometrical factor should have a definite importance (the requirement for multipoint adsorption).

It follows from the results discussed that, in the oxidation of ammonia, the acid–base and other properties of the catalysts play an appreciably smaller role than in the oxidation of organic substances, so that the decisive importance of the energy of the bond between oxygen and the surface is shown much more distinctly. In this respect, the oxidation of ammonia is closer to the oxidation reactions of inorganic molecules such as H_2 or CO_2.

IV. CONCLUSION

The analysis carried out in this review has shown that the kinetic method combined with physical research techniques can be employed to establish important features of the mechanism of the oxidation of ammonia under conditions where the oxidation products are nitrogen and nitrous oxide. It follows from the available data that the mechanism is qualitatively similar for metallic and oxide catalysts. The observed differences are largely quantitative and are caused by the specific features of the interaction of the oxidised molecule with the metallic surface. The mechanisms examined, considered in conjunction with the Brønsted–Temkin relation, serve as a fruitful basis for the determination of a relation between the thermodynamic properties of substances and their activities and selectivities in the oxidation of ammonia.

At the same time, one should note many unsolved problems, which include the kinetics and mechanism of the reaction at high temperatures, where NO is formed, the catalytic properties of complex catalysts in the kinetic region, the nature of the intermediate chemical interaction at elevated temperatures, and the role of homogeneous stages in the mechanism of the oxidation of ammonia. The solution of these problems will accelerate progress in the practical selection of new effective catalysts for this most important catalytic reaction.

Organometallic Peroxy-compounds and Their Reactions

G.A.Razuvaev and T.G.Brilkina

Experimental studies on the synthesis and reactions of organometallic peroxy-compounds are reviewed and the reactions of organometallic compounds with oxygen and organic peroxides, leading to the formation of both peroxide and non-peroxide products, are considered. The possible modes and mechanisms of the chemical reactions of organometallic peroxy-compounds are discussed.

The bibliography includes 274 references.

CONTENTS

I. INTRODUCTION

The advances in the chemistry of organic peroxides have been recently widely described in numerous reviews and monographs and have been discussed at All-Union and International Conferences. On the other hand, the problem of the synthesis of organometallic peroxy-compounds (OMPS) and their chemical reactions have so far been little investigated, although these compounds are of undoubted interest both as regards theoretical research and for practical applications. Much attention has been devoted to these problems at the Gorky Institute of Chemistry from different standpoints: systematic research is being carried out on the synthesis and reactions of OMPS and their role in the autoxidation of organometallic compounds (OMC), the mechanisms of the reactions of OMC with various peroxides are being investigated, and the initiating capacity of OMPC and OMC–oxygen and OMC–peroxide systems in free-radical processes are being elucidated.

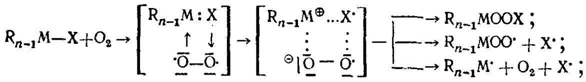
It is useful to examine the fundamental trends in such research, resorting where necessary to data of other investigators. The review does not include information about the peroxy-compounds of boron, phosphorus, and transition metals. There is an extensive literature on these compounds, the consideration of which is impossible within the framework of this article. For boron (R_3B) and phosphorus (R_3P and R_5P) compounds, only the results of a few studies are quoted, confirming the mechanisms of the reactions of their chemical analogues. Attention is concentrated in the review on studies carried out in recent years.

II. REACTIONS OF ORGANOMETALLIC COMPOUNDS WITH OXYGEN AND PEROXY-COMPOUNDS

Many OMC are oxidised by atmospheric oxygen with formation of peroxy-compounds. This process is used as a method of synthesising organic hydroperoxides with primary and secondary organic groups (for example, the oxidation of magnesium and aluminium compounds in ether at a low temperature followed by the hydrolysis of the resulting OMPC). In order to obtain the OMPC in a pure form, the autoxidation of the OMC is not usually employed, since the process is accompanied by secondary molecular and radical reactions of the peroxides.

Some OMC, for example compounds of Group I–III elements, are known to interact readily with oxygen, while others are oxidised only under severe conditions (derivatives of Group IVB elements). Aryl OMC are more resistant to oxygen than the alkyl derivatives. The length and structure of the organic group attached to the metal, the presence of functional groups, etc., are important[1-3]. The oxidation of OMC by oxygen is a complex chemical process. It has now been shown convincingly[4] that the primary reaction in the autoxidation of many OMC is their bimolecular reaction with oxygen. Compounds of Group I–III elements as well as many compounds having an M–M bond react in this way. On the other hand, the autoxidation of the OMC of Group IVB elements[5-7] is initiated by the radicals formed in the spontaneous decomposition of the OMC in the initial stage.

The molecular interaction of OMC with oxygen (or ozone) involves several successive microstages: the coordination of oxygen (or ozone) to the central atom of the OMC via the oxygen p-electrons and the vacant atomic orbitals of the heteroatom and electrophilic attack by the coordinated oxygen on the M–C or M–M bonds followed by electron transfer leading to the formation of either an OMPC or of organic, organometallic, or peroxy-radicals[4,8-12]:

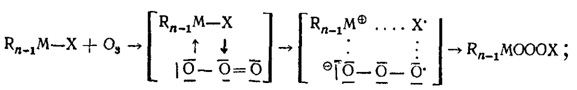


$$R_{n-1}M{-}X + O_2 \rightarrow \begin{bmatrix} R_{n-1}M : X \\ \uparrow \ \downarrow \\ \cdot\underline{\overline{O}}{-}\underline{\overline{O}}\cdot \end{bmatrix} \rightarrow \begin{bmatrix} R_{n-1}M^{\oplus} \ldots X^{\cdot} \\ \vdots \qquad \vdots \\ {}^{\ominus}|\underline{\overline{O}} - \underline{\overline{O}}\cdot \end{bmatrix} - \begin{cases} \longrightarrow R_{n-1}MOOX; & (1) \\ \longrightarrow R_{n-1}MOO^{\cdot} + X^{\cdot}; & (2) \\ \longrightarrow R_{n-1}M^{\cdot} + O_2 + X^{\cdot}; & (3) \end{cases}$$

$X{=}R$, $E'R_m$, $E''(MR_{n-1})_m$;

$M{=}$Li, Mg, Zn, Cd, B, Al, Tl, Si Ge, Sn, or Pb;

E' and $E''{=}$Hg, or Sb



$$R_{n-1}M{-}X + O_3 \rightarrow \begin{bmatrix} R_{n-1}M{-}X \\ \uparrow \ \downarrow \\ |\underline{\overline{O}} - \underline{\overline{O}} = \underline{\overline{O}} \end{bmatrix} \rightarrow \begin{bmatrix} R_{n-1}M^{\oplus} \ \ldots\ldots \ X^{\cdot} \\ \vdots \qquad\qquad \vdots \\ {}^{\ominus}|\underline{\overline{O}} - \underline{\overline{O}} - \underline{\overline{O}}\cdot \end{bmatrix} \rightarrow R_{n-1}MOOOX; \quad (4)$$

$X{=}R$, MR_m, or H; $M{=}$Si, Ge, Sn, or Pb.

The high electron affinity of ozone is responsible for the formation of a reactive OMC–ozone complex by compounds which do not enter into similar reaction with oxygen under the usual conditions. The oxidation by ozone of organic derivatives of Group IVB elements, metal alkyls, dimetal hexa-alkyls, halogen-containing derivatives of tin and lead, trisubstituted organosilanes, and other compounds proceeds at a low temperature (between room temperature and −68° or even −100°C [13−27]).

The OMPC formed via reaction (1) can react under autoxidation conditions with the initial OMC, yielding an alkoxy-derivative or decomposing into radicals with dissociation of O−O or M−O bonds:

$$R_{n-1}MOOR + R_{n-1}MR \rightarrow 2R_{n-1}MOR\ ; \qquad (5)$$

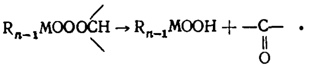
$$R_{n-1}MOOR \rightarrow R_{n-1}MO^{\cdot} + {}^{\cdot}OR\ ; \qquad (6)$$

$$R_{n-1}MOOR \rightarrow R_{n-1}M^{\cdot} + {}^{\cdot}OOR\ . \qquad (7)$$

The radicals formed in the decomposition of the OMC−oxygen complex [Eqns. (2) and (3)] and in the decomposition of the peroxide [Eqns. (5)−(7)] enter into the usual radical reactions in the cage or in the bulk of the solvent. At advanced stages of the autoxidation process, the homolytic substitution of the organic group in the OMC by the peroxy-radical is a very important reaction among these transformations:

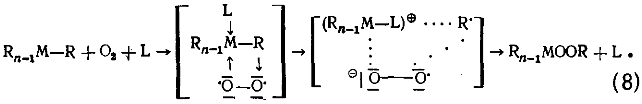
$$ROO^{\cdot} + R_nM \rightarrow R_{n-1}MOOR + R^{\cdot}\ .$$

The trioxide formed via reaction (4), in which X is a primary or secondary alkyl group, decomposes to an OMPC and a carbonyl compound:



$$R_{n-1}MOOO\!\!<\!\!CH \rightarrow R_{n-1}MOOH + \underset{\displaystyle \overset{\|}{O}}{-C-}\ .$$

The bimolecular interaction of an OMC with oxygen or ozone [Eqns. (1) and (4)] is very strongly influenced by the specific solvation of the OMC. The reaction may be catalysed by the introduction of a ligand L, which makes the metal more nucleophilic:



$$R_{n-1}M{-}R + O_2 + L \rightarrow \left[\begin{array}{c} L \\ \downarrow \\ R_{n-1}M{-}R \\ \uparrow \quad \downarrow \\ {}^{\cdot}\bar{\underline{O}}{-}\bar{\underline{O}}{}^{\cdot} \end{array}\right] \rightarrow \left[\begin{array}{ccc} (R_{n-1}M{-}L)^{\oplus} & \cdots\cdots & R^{\cdot} \\ \vdots & & \cdot \\ {}^{\ominus}|\bar{\underline{O}} & \text{——} & \bar{\underline{O}}{}^{\cdot} \end{array}\right] \rightarrow R_{n-1}MOOR + L\ . \qquad (8)$$

When the entire coordination capacity of the OMC is saturated by the ligand species, the coordination of O_2 or O_3 to the heteratom becomes impossible and the OMC exhibits an enhanced resistance to oxidation.

The formation of free radicals in the autoxidation of OMC has been demonstrated by employing labelled compounds (using ^{14}C and D). For example, the oxidation of PhLi and phenyl derivatives R_2M (M = Mg, Zn, or Cd) in labelled benzene proceeds with participation of Ph radicals, which react with the solvent and give rise to half-labelled biphenyl. The phenol isolated from the hydrolysis products in the reaction mixture is formed solely from the OMC.[28−32] The reactions of Ph radicals with other solvents (cyclohexane, chloroform, and carbon tetrachloride) [32−35] and the accelerating effect of additives (ethers) [28, 36−39] have also been noted.

In contrast to Ph_2Cd, whose oxidation proceeds wholly via a free-radical mechanism[35], the reaction of Et_2Cd with oxygen (in n-heptane at −80°C) proceeds without the participation of free radicals. This was confirmed by the autoxidation of Et_2Cd in the presence of effective inhibitors (*o*-phenylenediamine, galvinoxyl, and phenothiazine), used previously to demonstrate the free-radical mechanism of the oxidation of dimethylcadmium and organoboron compounds[40]. In the autoxidation of Et_2Cd in heptane, the reversible formation of an OMC−oxygen complex, which is comparatively stable in solution and is subsequently converted into a peroxy-product, was demonstrated experimentally for the first time[41]:

$$Et_2Cd + 2O_2 \rightleftarrows Et_2Cd \cdot 2O_2\ ;$$

$$Et_2Cd \cdot 2O_2 \rightarrow (EtOO)_2Cd\ .$$

The diethylcadmium−oxygen complex is formed over a wide temperature range (between −80° and 20°C). Its slow conversion into the ethylperoxy-derivative of cadmium can be observed even at room temperature. Substances containing atoms with electron-donating properties catalyse the reversible conversion of the complex into a peroxy-compound.

The replacement of one Ph-group in Ph_2Zn or Ph_2Cd by a Ph_3SiO group has a marked influence on the behaviour of the heterosiloxanes $PhMOSiPh_3$ (M = Zn or Cd) towards oxygen. For example, $PhZnOSiPh_3$ [42] and $PhCdOSiPh_3$ [43] are hardly oxidised by molecular oxygen under the usual conditions; the behaviour of $CH_3CdOSiPh_3$ is the same[43]. The alkyl derivative $EtZnOSiPh_3$ slowly absorbs oxygen but is nevertheless more resistant to O_2 than dialkyl- and diphenyl-zinc. On the other hand, $EtCdOSiPh_3$ is oxidised readily in benzene at room temperature, the organocadmium peroxide being formed in 92% yield[43]:

$$EtCdOSiPh_3 + O_2 \rightarrow EtOOCdOSiPh_3\ .$$

Primary alkyl compounds of mercury (Et_2Hg and n-Pr_2Hg) are resistant to oxygen. On the other hand, compounds with secondary (cyclohexyl and isopropyl) and tertiary (t-pentyl) groups undergo autoxidation via a free-radical mechanism including the bimolecular interaction of the OMC with oxygen in the initial stage [Eqn. (1)] and the formation of an unstable peroxide, which reacts further in accordance with Eqns. (5) and (7).[33,44−51]

Alkylperoxy-radicals $RO_2^{\cdot}$ behave as oxidants:

$$RO_2^{\cdot} + R_2Hg \rightarrow ROH + R_{-H}{=}O + RHg^{\cdot}\ .$$

The $RHg^{\cdot}$ radicals, formed both in the initial stage and at advanced stages of the process as a result of the decomposition of RHgOR,[44,52] decompose in their turn into mercury and the alkyl radical or are oxidised to peroxy-radicals[33,44]:

$$RHg^{\cdot} \rightarrow R^{\cdot} + Hg\ ;$$

$$RHg^{\cdot} + O_2 \rightarrow RHgOO^{\cdot}\ .$$

Like the $RO_2^{\cdot}$ radicals, the latter oxidise the OMC with formation of the final products:

$$RHgO_2^{\cdot} + R_2Hg \rightarrow RHgOR + RHgO^{\cdot}\ .$$

The alkoxy-derivatives of mercury thus formed react with oxygen more readily than the initial R_2Hg, but also in accordance with the free-radical chain mechanism[52].

Dicyclohexylmercury is oxidised by air at an appreciable rate even at room temperature. The main oxidation products in isopropyl alcohol at 60°C are cyclohexanol, cyclohexanone, and metallic mercury[49]. The oxidation products of i-Pr_2Hg in cyclohexane, cyclohexene, and benzene at 50°C are mercury, isopropylmercury isopropoxide, isopropylmercury hydroxide, acetone, isopropyl alcohol, propane, and propene. Apart from the above compounds, small amounts (approximately 5%) of phenyl derivatives have been detected in benzene, namely isopropylphenylmercury, Ph_2Hg, biphenyl, and isopropylbenzene[48]. Solvent involvement has been confirmed by isotopic and mass-spectrometric methods using in the oxidation reaction $(CH_3)_2CHOD$, $(CH_3)_2CDOH$, and isopropyl alcohol or R_2Hg labelled with ^{14}C.[45] The formation of free radicals in the autoxidation of R_2Hg [48−50] has been confirmed experimentally also by the inhibitor method[33,44].

Organoboron compounds are known to be readily oxidised by oxygen with formation of a large number of different products, the proportions of which depend very markedly on the reaction temperature and the solvent. It is suggested[3] that the primary R_3B–oxygen molecular complex is converted into a more or less stable organoboron peroxide in accordance with Eqn.(1). The peroxide is then converted into an alkoxy-derivative in accordance with Eqn.(5) or decomposes with formation of free radicals.

The oxidation of organoaluminium compounds proceeds in the main similarly to the oxidation of boron alkyls. The formation of organoaluminium peroxide was demonstrated for the first time by Sladkov et al.[53] and then confirmed by the low-temperature oxidation of Et_3Al.[54–56] The primary stage of the process is reaction (1). The subsequent interaction of the peroxide with the unoxidised OMC in accordance with Eqn.(5) leads to the formation of the corresponding aluminium alkoxides—the main oxidation products of R_3Al at a moderate temperature. Thus the yield of the peroxy-compound in the oxidation of Et_3Al by dry air in n-heptane at temperatures between −75° and 25°C is higher the lower the initial concentration of Et_3Al and the lower the reaction temperature. In a few instances, the yield of peroxide reaches 50%. At 25°C the peroxide is not detected in the reaction products[55]. As for boron alkyls, there is a succession of stages in the oxidation of the C–Al bond, the rate of oxidation varying appreciably with the number of oxidised alkyl groups. For example, in heptane (at 20–50°C) the ratios of the rates of oxidation of Et_3Al, Et_2AlOEt, and $Et(EtO)_2Al$ are 100 : 25 : 1.[56] Although $Et_3(EtO)Al$ is also oxidised at a high rate, on complete oxidation of Et_3Al under these conditions the yield of $(EtO)_2AlEt$ is low, since the compound exchanges radicals with the initial OMC. This reaction is rapid even at 5–10°C:

$$Et_3Al + (EtO)_2AlEt \rightarrow 2\,Et_2AlOEt\ .$$

In the oxidation of Et_2AlBr (between −30° and 30°C), such exchange does not occur and the reaction is accompanied by the formation of $(EtO)_2AlBr$ only[56].

Ph_3Al is oxidised in benzene, n-hexane, n-nonane, and ethyl ether more slowly and the solvent is involved in the oxidation[30,57,58]. Thus phenol (after hydrolysis) and biphenyl were found in the oxidation of Ph_3Al in benzene, and phenol, acetophenone, acetaldehyde, and alumina were found after the reaction in ether.

Et_3Tl is oxidised without the formation of free radicals. The peroxide produced via reaction (1) shows a smaller capacity for decomposition and isomeric transformations than the aluminium analogue. It was therefore possible to obtain the peroxide $Et_2TlOOEt$ in the oxidation of Et_2Tl in n-octane at −70°C.[59]

The organic compounds R_4M (where M = Si, Ge, Sn, or Pb, and R = alkyl) are in most cases highly resistant to oxygen. They react appreciably with oxygen at a fairly high temperature. The primary reaction in the autoxidation of such OMC as well as symmetrical organobimetallic compounds R_3M–MR_3 is homolytic decomposition of the initial compound at the metal–carbon or metal–metal bond, for example:

$$Et_4M \rightarrow Et_3M^{\bullet} + Et^{\bullet}\ ;$$
$$Et_3M\text{—}MEt_3 \rightarrow 2\,Et_3M^{\bullet}\ (\text{or}\ \ Et_3M\text{—}\dot{M}Et_2 + Et^{\bullet})\ ;$$
$$M{=}Sn,\ \text{or}\ Pb.$$

The development of the free radical chain process is due to the formation and further interactions of the peroxy-radicals:

$$R^{\bullet} + O_2 \rightarrow RO_2^{\bullet}\ ;$$
$$R{=}Et,\ Et_3Sn,\ \text{or}\ Et_3Pb\ .$$

In the case of Et_4Pb (80–130°C, without solvent or in alkanes), degenerate chain branching by the peroxy-product and a number of other side reactions of the latter take place in addition to the reactions of the $RO_2^{\bullet}$ radicals with the initial OMC and their decomposition reactions[6,7,60–62]:

$$EtO_2^{\bullet} + Et_4Pb \rightarrow Et_3PbOOEt + Et^{\bullet}\ ;$$
$$Et_3PbOO^{\bullet} \rightarrow Et_2PbO + EtO^{\bullet}\ .$$

A characteristic feature of the autoxidation of Et_6Sn_2 (60–90°C, without solvent or in alkanes) is the absence of degenerate branching, owing to the high reactivity of the peroxy-compound with respect to the initial OMC:[60,61,63,64]

$$RO_2^{\bullet} + Et_3SnSnEt_3 \rightarrow Et_3SnOOSnEt_3 + R^{\bullet}\ ;$$
$$Et_3SnOOSnEt_3 + Et_3SnSnEt_3 \rightarrow 2\,Et_3SnOSnEt_3\ ,$$
$$RO_2^{\bullet} \rightarrow \text{products}\ ,$$
$$R{=}Et,\ \text{or}\ Et_3Sn\ .$$

The formation of the peroxide in small amounts in the oxidation of Et_6Sn_2 has been demonstrated by infrared spectroscopy[63].

The autoxidation of Et_6Pb_2 (40–90°C, without solvent, in hydrocarbons, or in Et_4Pb) proceeds in the initial stages similarly to the oxidation of Et_6Sn_2 with the preferential dissociation of the Pb–Pb bond[60,61,63–65]. The kinetic process characteristics are more complex, since, as the process proceeds, "limiting" behaviour due to the influence of the reaction products is observed. Nor can one rule out the role of steric factors. For example, the latter explains the higher reactivity of Ph_6Pb_2 with respect to t-$BuO_2^{\bullet}$ radicals compared with that of Ph_6Sn_2.[66]

The photoinitiated oxidation of the compounds R_4M (M = Sn or Pb) with the same and different alkyl groups[67–69] as well as the oxidation of $(Et_3Sn)_2O$[70] proceeds comparatively rapidly at room temperature, while Et_6Sn_2 is oxidised[71] even at temperatures in the range between −30° and 0°C. In the free-radical chain process involving the conversion into peroxy-radicals of the radical pairs formed in the photolysis of the M–C or M–M bonds, there is competition with the photosensitised oxidation of the OMC, the primary product of which is the corresponding OMPC. In many cases, the yield of peroxide reaches 15–25%.[68,69] The radicals are formed as a result of the photochemical dwcomposition of the peroxides at the O–O bond.

An increase of reactivity of the OMC of Group IVB metals towards oxygen is observed when the organic group in R_4M is replaced by groups derived from organic derivatives of the elements of the type EMR_3, where E is an element of Group II or V.[7,61,64,65,72,73] The reactions of such compounds with oxygen proceed under very mild conditions via a bimolecular mechanism without the participation of free radicals[74–79]. Dimetalloxanes are formed in accordance with Eqns.(1) and (5), for example:

$$\begin{gathered}(R_3M)_2Hg + O_2 \rightarrow R_3MHgOOMR_3\ ;\\ R_3MHgOOMR_3 + (R_3M)_2Hg \rightarrow 2R_3MHgOMR_3\ ;\\ R_3MHgOMR_3 \rightarrow Hg + R_3MOMR_3\ ;\\ M{=}Si,\ \text{or}\ Ge;\ R{=}Et,\ \text{or}\ Ph.\ \end{gathered} \qquad (9)$$

When R = Et, the dimetalloxanes produced are responsible for the autocatalytic oxidation of the OMC. However, in the autoxidation of $(Ph_3Ge)_2Hg$, hexaphenyldigermanoxane is catalytically inactive[80].

The interaction of $(Et_3Ge)_2Hg$ and $(Et_3Si)_2Hg$ (0°C, alkanes) with oxygen is accelerated by small amounts of added ligands (NH_3, amines, pyridine, Ph_3P, etc.)[74–77]. The nature of the process and the kinetic parameters correspond to a catalytic reaction with formation of an

OMC–ligand complex [Eqn. (8)]. The peroxide formed is involved in competing catalytic decomposition reactions with the ligand L [Eqn. (10)] and reactions with the initial OMC [Eqn. (9)]:

$$\mathrm{Et_3}M\mathrm{HgOO}M\mathrm{Et_3} \xrightarrow{L} \mathrm{Et_3}M\mathrm{OO}M\mathrm{Et_3} + \mathrm{Hg}\ . \qquad (10)$$

There is also a possibility of the catalytic decomposition of the hydroxy-derivative formed under these conditions[79]:

$$\mathrm{Et_3MHgOMEt_3} \xrightarrow{L} \mathrm{Et_3}M\mathrm{OMEt_3} + \mathrm{Hg}\ .$$

Under certain conditions (high ligand concentration), the reaction proceeds wholly in accordance with the Eqn. (10).[76]

In the oxidation of $(Et_3Ge)_3Sb$ in n-octane at 18°C in accordance with the equation

$$2\,(\mathrm{Et_3Ge})_3\,\mathrm{Sb} + 3\mathrm{O_2} \rightarrow 3\,(\mathrm{Et_3Ge})_2\,\mathrm{O} + \mathrm{Sb_2O_3}\ ,$$

the autoxidation mechanism varies as a function of association of the initial compound from a reaction without the formation of free radicals (for polyassociated species) to a free-radical chain process [for the monomeric form $(Et_3Ge)_3Sb$].[81,82]

$[(i\text{-}Pr)_3Ge]_2Hg$ oxidises via a free-radical mechanism, which distinguishes this compound from the ethyl analogue. The comparatively high oxidation temperature (approximately 50°C) creates conditions for the thermal homolysis of the peroxy- and hydroxy-derivatives formed in the initial stage[83,84]:

$$\mathrm{i\text{-}Pr_3Ge\,HgOOGe\,(Pr\text{-}i)_3} \rightarrow \mathrm{i\text{-}Pr_3GeHg^{\bullet}} + \mathrm{i\text{-}Pr_3GeOO^{\bullet}}\ ;$$
$$\mathrm{i\text{-}Pr_3GeHgOGe\,(Pr\text{-}i)_3} \rightarrow \mathrm{i\text{-}Pr_3GeHg^{\bullet}} + {}^{\bullet}\mathrm{OGe\,(Pr\text{-}i)_3}\ .$$

The addition of an inhibitor reduces sharply the rate of oxidation of the initial OMC.

The formation of triethylsilyl peroxide in the autoxidation of ethyl(triethylsilyl)mercury is explained by radical reactions[85]:

$$2\mathrm{Et_3SiHgEt} \rightarrow \mathrm{Et_2Hg} + \mathrm{Et_3SiHg^{\bullet}} + \mathrm{Et_3}Si^{\bullet}\ ;$$
$$\mathrm{Et_3Si^{\bullet}} + \mathrm{O_2} \rightarrow \mathrm{Et_3}Si\mathrm{O_2^{\bullet}}\ ;$$
$$\mathrm{Et_3SiO_2^{\bullet}} + \mathrm{Et_3SiHgEt} - \left[\begin{array}{l} \rightarrow \mathrm{Et_3}Si\mathrm{OHgEt} + \mathrm{Et_3}Si\mathrm{O^{\bullet}} \\ \rightarrow \mathrm{Et_3}Si\mathrm{OOSiEt_3} + \mathrm{EtHg^{\bullet}}\ . \end{array}\right.$$

A wide variety of products, due to different intermediate and side reactions, are frequently formed in the autoxidation of OMC; particular mention should be made of the processes caused by the reactions of peroxides with OMC. Evidently the knowledge of the nature of these reactions is important for a general understanding of the mechanism of the formation and chemical reactions of OMPC. It is therefore useful to consider in greater detail the reactions of OMC with organic peroxides and the peroxides of organo-element derivatives.

Depending on the nature of the initial compounds and the reaction conditions, the nature of the interaction of OMC with peroxides may vary markedly, the reaction can proceed with or without the formation of OMPC. The mechanism of these processes can be both heterolytic and homolytic and is frequently very complex. An interesting heterolytic reaction of OMC with organic peroxides and peroxides of organo-element derivatives is nucleophilic substitution. It takes place with retention of the O–O bond and is therefore the basis of the principal method for the synthesis of OMPC. The reaction proceeds in accordance with the general equation

$$\mathrm{R}_{n-1}\mathrm{MX} + \mathrm{R'OOY} \rightarrow R_{n-1}\mathrm{MOOR'} + \mathrm{XY}\ , \qquad (11)$$

where $n \geqslant 1$, M = metal, R = alkyl or aryl, R′ = metal, hydrogen, or alkyl, X = OH, NH_2, NR_2, halogen, alkyl, aryl, alkoxy-group, aryloxy-group, or another substituent, and Y = metal or hydrogen. In many cases, reaction (11) is reversible and, in order to displace its equilibrium in the required direction, is carried out in the presence of bases (NH_3, amine, pyridine, etc.) or dehydrating agents (anhydrous sodium or magnesium sulphates).

A wide variety of OMPC have been obtained by reaction (11). For example, when organic peroxides were allowed to interact with lithium, sodium, and potassium halides, the pure peroxides of the alkali metals of the type ROOM [R = t-Bu, $(CH_3)_2PhC$, $(CH_3)Ph_2C$, or Ph_3C] were obtained in a crystalline state, which cannot be achieved in their synthesis by other methods[86–90].

Fully alkylated or arylated organocadmium and organomercury compounds react with hydroperoxides and the hydrocarbon group is substituted. The reactions are complicated both by the ready oxidation of the peroxide derived from the initial OMC, which failed to react, and by the peroxide decomposition reactions. In the case of organocadmium compounds, there is a possibility of the formation of mono- and di-peroxy-derivatives, for example PhCdOOBu-t and $Cd(OOBu\text{-}t)_2$.[91] The mercury compounds R_2Hg (R = n- and i-Pr or Ph) react with t-BuOOH to form the monoperoxy-compound only, which cannot be isolated owing to its further reactions under the conditions of the synthesis (at 70–100°C) in accordance with Eqns. (5) and (7).[92–96] Analogous reactions of the intermediate peroxy-compound occur when $RHgCCl_3$ (R = n- and i-Pr or Ph) reacts with t-BuOOH (80°C).[46] Fairly stable organomercury peroxides were obtained from the sodium salt of cumenyl hydroperoxide and ethyl- or phenyl-mercury chloride[97,98] or the derivatives of the latter XC_6H_4HgCl (X = *p*-Cl or *p*-CH_3O) in toluene solution[99]. The less stable compound $PhCH_2HgOOC(CH_3)_2Ph$[96] and the mercury diperoxide $[Ph(CH_3)_2COO]_2Hg$ were obtained similarly[100].

Fully alkylated or arylated derivatives of aluminium and thallium also readily undergo the substitution of the organic group for the peroxy-group. In the reaction of Ph_3Al with t-butyl or cumenyl hydroperoxides (at room temperature in toluene), the peroxide Ph_2AlOOR was not isolated, since it is readily converted into the aryloxy-derivative[101]. In the reaction of $(EtO)_3Al$ with $Ph(CH_3)_2.COOH$ or of the diethoxy-derivative $(EtO)_2AlCl$ with the salt of this hydroperoxide, the peroxide $(EtO)_2AlOOC.(CH_3)_2Ph$ was isolated and characterised[54,102]. When alkoxy- and alkyl groups are attached to an aluminium atom simultaneously, the alkyl group is substituted by the peroxy-group in the reaction with ROOH:

$$\mathrm{(EtO)_2\,AlEt} + \mathrm{n\text{-}C_8H_{17}\underset{\displaystyle\mathrm{OH}}{\underset{|}{\mathrm{C}}}HOOH} \rightarrow \mathrm{(EtO)_2\,AlOO\underset{\displaystyle\mathrm{OH}}{\underset{|}{\mathrm{C}}}HC_8H_{17}\text{-}n} + \mathrm{EtH}\ .$$

Under the reaction conditions, the peroxide formed is converted into the unstable polymeric peroxide $[-Al(O-)OOCH.(C_8H_{17}O-]n$.[103]

Fairly stable peroxides with a Tl–C bond have been obtained from organothallium compounds by nucleophilic substitution reactions. Depending on the reactant ratio, the reaction of Et_3Tl with pure H_2O_2 can give rise to both Et_2TlOOH (in 50% yield), which exists for several hours at 0–5°C, and the organothallium peroxide $Et_2TlOOTlEt_2$, which is stable at room temperature[104]. The peroxides Et_2TlOOR' [R′ = t-Bu or $Ph(CH_3)_2C$], which are stable under the usual conditions, are formed in high yields (60 to 80%) in the reaction of Et_3Tl with the corresponding hydroperoxides (at 0°C in benzene)[105]. The analogous reaction with triphenylgermyl hydroperoxide gave the organobimetallic peroxide $Et_2TlOOGePh_3$ (80% yield)[104,106]. The hydroperoxide Ph_3SiOOH reacts with Et_3Tl, but the peroxide formed under such conditions rearranges to $Et_2TlOSi(PhO)Ph_2$.[106]

Nucleophilic substitution reactions [Eqn. (11)] have been used particularly successfully for the synthesis of peroxy-compounds of Group IVB elements having the structure R_3MOOR' and the organometallic peroxides $R_3M{-}OOM'R'_3$, both symmetric and asymmetric, with identical and different central metal atoms. Tertiary hydroperoxides and R_3SiX (X = Cl, Br, or NEt_2) gave, in the presence of bases at temperatures between 0° and −5°C, the stable organosilicon peroxides $R_3SiOOCR'R''R'''$ ($R = CH_3$, Et, or Ph and R′, R″, and R‴ = CH_3 or Ph),[107-111] while secondary hydroperoxides gave $R_3MOOCH(CH_3)Ph$ (M = Si, Ge, or Sn; $R = CH_3$, Et, or n-Pr).[112] Hydrogen peroxide and chlorosilanes react in the presence of ammonia to form symmetrical organosilicon peroxides with identical and different groups attached to the silicon atom, namely $R_3SiOOSiR_3$ ($R = CH_3$, Et, n-Pr, or Ph)[113,114] and $R_2R'SiOOSiR'R_2$ ($R = CH_3$ or Ph; $R' = CH_3Ph$, *p*-BrC_6H_4, or *p*-$CH_3OC_6H_4$).[115-117] The asymmetric organosilicon peroxides $Ph_3SiOOSiR_3$ ($R = CH_3$, Et, n-Pr, n-Bu, n-C_5H_{11}, n-C_6H_{13}, or Ph),[110,118,119] and $Ph_3SiOOSi(CH_3)_2R$ (R = n-Bu, Ph, *p*-BrC_6H_4, *p*-$CH_3C_6H_4$, or *p*-$CH_3OC_6H_4$),[115,120] and the organo-dimetallic peroxides $R'R''R'''SiOOGePh_3$ (R′, R″, R‴ = CH_3, Ph, Et, n-Pr, n-Bu, or n-C_5H_{11})[118,121,122] have been synthesised by reaction (11) from hydroperoxides of organic derivatives of the elements and alkyl(aryl)silicon halides.

A series of stable dialkyl(aryl)-t-alkylperoxychlorosilanes have been obtained recently by a novel procedure[123]. They are synthesised by the reaction of $RR'SiCl_2$ with t-alkylperoxymagnesium chlorides in molar proportions of 1 : 1:

$$RR'SiCl_2 + R''OOMgCl \rightarrow RR'Si(OOR'')Cl + MgCl_2\ ;$$

$$R \text{ and } R' = CH_3,\ Et,\ CH{=}CH_2,\ CH_2Cl, \text{ or } Ph;$$

$$R'' = t\text{-}C_4H_9, \text{ or } t\text{-}C_5H_{11}.$$

The substitution of the second chlorine atom takes place with difficulty even in the presence of a considerable excess of $R''OOMgCl$. Peroxides having the structure $RR'Si(OOR'')_2$ are obtained in small amounts under these conditions (approximately 6%). On the other hand, when chloroperoxysilanes are acted upon by alkyl hydroperoxides in the presence of ammonia or pyridine at 0°C, it is easy to obtain diperoxy-compounds derived from silicon and containing identical or different alkylperoxy-groups at the silicon atom[123]:

$$RR'Si(OOR'')Cl + R'''OOH \xrightarrow[(C_5H_5N)]{NH_3} RR'Si(OOR'')(OOR''') + HCl\ ;$$

$$R \text{ and } R' = CH_3,\ Et, \text{ or } Ph;\ R'' = t\text{-}C_4H_9;$$

$$R''' = t\text{-}C_4H_9,\ t\text{-}C_5H_{11}, \text{ or } C(CH_3)_2C_6H_{11}\ .$$

The reaction of the hydroperoxides Ph_3SiOOH and Ph_3GeOOH with the methyl hemiacetal of chloral (at room temperature in CH_2Cl_2 or $CHCl_3$ as solvent) is also interesting from the synthetic standpoint. The reaction gives fairly satisfactory yields of organosilicon and organogermanium peroxy-compounds containing functional groups in the alkylperoxy-group[124]:

$$R_3MOOH + CH_3O\underset{\displaystyle OH}{\underset{|}{C}}HCCl_3 \rightarrow R_3MOO\underset{\displaystyle OH}{\underset{|}{C}}HCCl_3 + CH_3OH\ .$$

When alkoxy or hydroxy-derivatives of alkyltin were used as the starting materials with the corresponding hydroperoxides, the organotin peroxides Et_3SnOOR' [R′ = t-Bu or $Ph(CH_3)_2C$] were obtained by reaction (11) and isolated in high yields (approximately 90%)[125]. The peroxide $Et_3SnOOBu$-s was obtained by the same method[126].

The nucleophilic substitution of an isocyanato-group linked to a Group IV element by an alkylperoxy-group has been demonstrated in the reaction of n-Bu_3MNCO and n-$Bu_2M(NCO)_2$ (M = Ge or Sn) with t-butyl and cumenyl hydroperoxides. The reaction proceeds readily at room temperature, but is complicated by the side reaction of the hydroperoxides with HNCO.[127]

The lead peroxides Et_3PbOOR' [R′ = t-Bu or $Ph(CH_3)_2C$], whose thermal stability is low, are formed from alkoxy-, hydroxy-, or oxo-derivatives of lead and hydroperoxides[128-130]. The solid peroxide $[Et_3PbOO(CH_3)_2C]_2C_6H_4$ was isolated in a fairly pure state after the reaction of Et_3PbOH with the dihydroperoxide derived from *p*-di-isopropylbenzene[128].

OMPC are not formed in the reactions with hydroperoxides of organolead and organotin compounds having M−M bonds. The metal−metal bond is dissociated, for example[131]:

$$(n\text{-}Bu_2Sn)_n + n\,t\text{-}BuOOH \rightarrow (n\text{-}Bu_2SnO)_n + n\,t\text{-}BuOH\ .$$

In the analogous reaction with cumenyl hydroperoxide (at 15−20°C in n-hexane or n-nonane), hexaethyldilead is readily converted into $Et_3PbOC(CH_3)_2Ph$ and Et_3PbOH, which undergo the substitution of their functional groups by the peroxy-group in the presence of an excess of the hydroperoxide[128].

Phenylderivatives of phosphorus(V) and antimony(V) undergo the substitution of one Ph group for the alkylperoxy-group in reactions with hydroperoxides. Pentaphenylantimony (Ph_5Sb) reacts with t-BuOOH and $Ph(CH_3)_2.COOH$ at room temperature in absolute pyridine giving a quantitative yield of the stable peroxides Ph_4SbOOR',[132] which can also be obtained in high yields from the hydroperoxide salts $R'OOM$ [M = Na or Li; R′ = t-Bu, Ph $Ph(CH_3)_2C$, $Ph_2(CH_3)C$, or Ph_3C] and tetraphenylstibonium halides[133]. The reaction of Ph_5P with t-BuOOH in pyridine, dioxan, or ether proceeds in a more complex manner, but its main pathway (80−85%) also involves the formation of an intermediate peroxide which immediately decomposes[132]:

$$Ph_5P + t\text{-}BuOOH \xrightarrow{-PhH} [Ph_4POOBu\text{-}t] \rightarrow Ph_3PO + PhOH + (CH_3)_2C{=}CH_2\ .$$

In the reactions of Ph_5P or benzyloxytetraphenylphosphorus with Ph_3SiOOH and Ph_3GeOOH, peroxy-compounds were not isolated either, because they isomerised to non-peroxy-products at the instant of formation[134]:

$$Ph_4PR + Ph_3MOOH \xrightarrow{-RH} [Ph_4POOMPh_3] \rightarrow Ph_3P(OPh)OMPh_3\ ;$$

$$R{=}Ph, \text{ or } OCH_2Ph;\ M{=}Si, \text{ or } Ge.$$

The same hydroperoxides and Ph_3SnOOH react with Ph_4SbBr in the presence of triethylamine to form the organobimetallic peroxides $Ph_4SbOOMPh_3$ (M = Si, Ge, or Sn), which were isolated in a pure form[135]. The mixed diperoxide of antimony and silicon $Ph_3Sb(OOSiPh_3)_2$ can be obtained by treating a mixture of t-butyl hydroperoxide and Ph_3SiOOH with Ph_3Sb:[136]

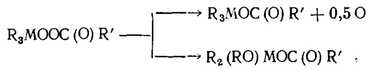
$$Ph_3Sb + t\text{-}BuOOH + 2Ph_3SiOOH \xrightarrow{-H_2O} Ph_3Sb(OOSiPh_3)_2 + t\text{-}BuOH\ .$$

The attempts to synthesise compounds of the peroxyester type by the nucleophilic substitution of alkyl or functional groups in OMC by acyl hydroperoxides were unsuccessful. The peracyl compounds obtained via the reaction

$$R_{n-1}MX + R'CO_3H \rightarrow R_{n-1}MOOC(O)R' + HX$$

(M = Hg, Sn, or Ph; R and R′ = alkyl or aryl, and X = OH, OR″, or $OCOCH_3$; M = Tl, R = Et, R′ = alkyl, and X = Et or OH).

either decompose immediately with liberation of oxygen (organomercury and organothallium derivatives)[104,137-139] or rearrange (organotin and organolead derivatives)[140-143]. Depending on the nature of the group R, for the latter compounds these two pathways can compete[143-146]:



$$R_3MOOC(O)R' \rightarrow R_3MOC(O)R' + 0{,}5\,O_2 \quad ; \quad R_3MOOC(O)R' \rightarrow R_2(RO)MOC(O)R'$$

and, for the diperacyl derivative of diphenyltin, they are equally probable[147]. The intermediate diperoxides formed in the reaction of $Et_2Pb(OH)_2$ and $Et_2Sn(OH)_2$ with percapric acid decompose quantitatively to oxygen and the diethylmetal dicaprate[147,148]. Thus the reactions of OMC with peroxides containing an acid hydrogen atom (with hydroperoxides and peracids) lead to the formation of more or less stable OMPC. The reactions of OMC with other peroxy-compounds—alkyl and acyl peroxides and peroxyesters—are more varied. These reactions are not usually accompanied by the formation of OMPC. Depending on the nature of the peroxy-compound and the metal in the OMC, they can proceed either heterolytically or with intermediate formation of reactive OMC–peroxide complexes, which subsequently undergo both heterolytic and homolytic reactions. Such a mechanism is characteristic of the reactions of peroxides with electron-deficient compounds (those of Groups II and III). Many reactions of OMC with peroxides proceed as free-radical chain processes. In the first stage, the peroxide decomposes to free radicals, which then react with the OMC. The reactions of the above peroxides with OMC of Group IV elements takes place in this way. The peroxides can also act as oxidants, for example, in reactions with organic compounds of metals with free electron pairs [phosphorus(III) and antimony(III)]. The reactions of OMC with peroxy-compounds have been examined fairly completely in our previous reviews[2,149] and here we shall therefore merely give a brief survey of the results of studies by the Gorky group of chemists.

The reactions of organolithium compounds with alkyl peroxides involve the heterolysis of the peroxy-group and depend significantly on the nature of the organic group in the OMC and the peroxide. Alkyl-lithium compounds interact with alkyl peroxides to form asymmetric ethers and lithium alkoxides in accordance with the equation

$$RLi + R'OOR' \rightarrow R'OLi + ROR' \quad . \qquad (12)$$

Kinetic studies on the reactions of RLi (R = Et or n-Bu) with t-butyl and cumenyl peroxides[150,151] confirm the earlier hypothesis[152] that the OMC of Group I metals react with alkylperoxides via an S_N2 mechanism:

$$R^{\ominus} + \underset{R'}{O}{-}OR' \longrightarrow ROR' + OR'^{\ominus} \quad . \qquad (13)$$

However the interpretation of the mechanism of reaction (12) from the standpoint of one-electron transfer and the formation of a radical pair, reacting both within and outside the solvent cage[153], is also supported by some evidence, for example:

$$EtLi + t\text{-}BuOOBu\text{-}t \rightarrow [Et^{\bullet},\ t\text{-}BuO^{\bullet}] + t\text{-}BuOLi \ .$$

In view of the foregoing, the results obtained in the study of the reactions of compounds of the type R_3MLi with organic peroxides and peroxides of organic derivatives of the elements are of interest[154]. In the series of organobimetallic compounds having an M–M bond, the compounds R_3MLi exhibit the greatest polarity of this bond and behave at the same time as weaker nucleophiles than RLi. The reactions of R_3MLi [M = Ge or Sn; R = Et or $(CH_3)_3SiCH_2$] with t-butyl peroxide, benzoyl peroxide, dicyclohexyl percarbonate, and peroxides of organic derivatives of the elements and organometallic compounds proceed under mild conditions and involve nucleophilic attack by the R_3M anion on one of the peroxide oxygen atoms. In asymmetric peroxides of organic derivatives of the elements, the nature of the nucleophilic cleavage of bonds depends on the nature of the nucleophile, the steric effects of the substituents at the peroxy-group, and other factors.

The reactions of R_3MLi with t-butyl peroxide in tetrahydrofuran (THF) proceed in accordance with Eqn.(13) and the products are t-BuOLi and R_3MOBu-t [M = Sn or Ge; R = Et or $(CH_3)_3SiCH_2$]. When M = Ge and R = Et, the yield of Et_3GeOBu-t is low (11%), since the alkoxy-derivative enters in its turn into a nucleophilic substitution reaction with the initial OMC:

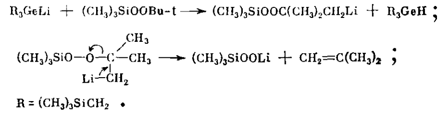
$$Et_3GeOBu\text{-}t + Et_3GeLi \rightarrow Et_3Ge{-}GeEt_3 + t\text{-}BuOLi \ . \qquad (14)$$

The compounds R_3MLi ($R_3M = Et_3Ge$), $[(CH_3)_3SiCH_2]_3Ge$, and $[(CH_3)_3SiCH_2]_3Sn$ are involved in reactions (13) and (14) with bis(trimethylsilyl) peroxide, which is known to be more reactive in relation to nucleophiles than t-butyl peroxide.

In the reaction of $[(CH_3)_3SiCH_2]_3SnLi$ with t-butylperoxytrimethylsilane and t-butylperoxytriphenylgermane, the R_3Sn anion attacks the oxygen atom linked to the t-butyl group in the peroxide[154,156]:

$$R_3SnLi + R'_3MOOBu\text{-}t \xrightarrow{THF} R_3SnOBu\text{-}t + R'_3MOLi$$
$$R = (CH_3)_3SiCH_2;\ R'_3M = (CH_3)_3Si,\ \text{or}\ Ph_3Ge.$$

On the other hand, in the reaction of the germyl analogue R_3GeLi with a silyl peroxide, products, the formation of which is probably due to the metallation of the t-butyl group of the peroxide in the initial stage followed by the elimination of isobutene, were obtained in high yields. The oxygen–oxygen bond does not dissociate under these conditions[154]:

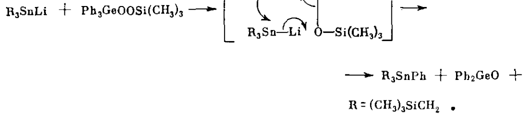


$$R_3GeLi + (CH_3)_3SiOOBu\text{-}t \longrightarrow (CH_3)_3SiOOC(CH_3)_2CH_2Li + R_3GeH \ ;$$
$$(CH_3)_3SiO{-}O{-}\underset{Li{-}CH_2}{\overset{CH_3}{C}}{-}CH_3 \longrightarrow (CH_3)_3SiOOLi + CH_2{=}C(CH_3)_2 \ ;$$
$$R = (CH_3)_3SiCH_2 \ .$$

The reactions of R_3GeLi with $Ph_3GeOOBu$-t and $Ph_3GeOOSi(CH_3)_3$ proceed in accordance with Eqn.(13), the R_3Ge anion attacking the oxygen atom linked to the Ph_3Ge fragment of the peroxide, for example:

$$R_3GeLi + Ph_3GeOOSi(CH_3)_3 \rightarrow R_3GeOGePh_3 + (CH_3)_3SiOLi \ ; \qquad (15)$$
$$R = (CH_3)_3SiCH_2 \ .$$

The reaction of the tin analogue with the latter peroxide leads to the formation of the phenylation product:



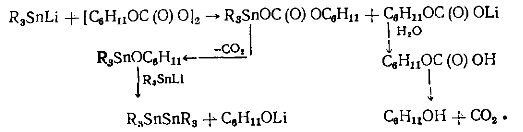
$$R_3SnLi + Ph_3GeOOSi(CH_3)_3 \longrightarrow \left[\begin{matrix} Ph{-}GePh_2{-}O \\ R_3Sn{-}Li \quad O{-}Si(CH_3)_3 \end{matrix}\right] \longrightarrow R_3SnPh + Ph_2GeO + (CH_3)_3SiOLi \ ;$$
$$R = (CH_3)_3SiCH_2 \ .$$

The reaction with the symmetric peroxide $Ph_3GeOOGePh_3$ does not involve phenylation and proceeds in accordance with mechanism (15).

Acyl peroxides (benzoyl peroxide and dicyclohexyl percarbonate) and t-butyl perbenzoate interact with R_3SnLi, the process likewise involving the heterolysis of the peroxy linkage[154]:

$$R_3SnLi + PhC(O)OOR' \xrightarrow{-R'OLi} R_3SnOC(O)Ph \xrightarrow{R_3SnLi} R_3SnSnR_3 + PhC(O)OLi \ ;$$

$$R{=}(CH_3)_3SiCH_2;\ R'{=}PhC(O),\ t\text{-}Bu\ .$$

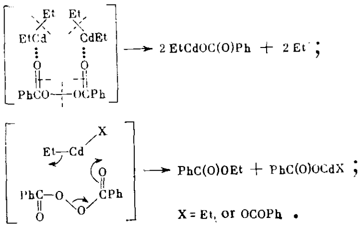


$$\begin{tikzcd}[column sep=small] R_3SnLi + [C_6H_{11}OC(O)O]_2 \arrow[r] & R_3SnOC(O)OC_6H_{11} \arrow[dl, "-CO_2"'] & + & C_6H_{11}OC(O)OLi \arrow[d, "H_2O"] \\ R_3SnOC_6H_{11} \arrow[d, "R_3SnLi"] & & & C_6H_{11}OC(O)OH \arrow[d] \\ R_3SnSnR_3 + C_6H_{11}OLi & & & C_6H_{11}OH + CO_2\ . \end{tikzcd}$$

In the similar reactions of R_2Mg (R = Ph or n-C_5H_{11}) with alkyl peroxides, only one Mg–C bond undergoes heterolytic cleavage[61,157–159]:

$$R_2Mg + R'OOR' \rightarrow RMgOR' + ROR'\ .$$

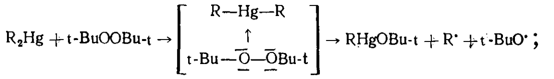
A characteristic feature of the reactions of organocadmium and organomercury compounds R_2M (M = Cd and R = Et or Ph; M = Hg and R = Ph) with benzoyl peroxide is the formation of 1 : 1 and 2 : 1 donor–acceptor complexes, in which there is a possibility of both heterolytic and homolytic cleavage of bonds[91,160]. The reactions involving the 1 : 1 complex take place without the formation of free radicals, while the M–C and O–O bonds undergo homolytic dissociation in the decomposition of the 2 : 1 complex. For example, in the case of cadmium we have



$Ph_3SiOCdR$ (R = CH_3 or Et) react similarly with benzoyl peroxide in benzene. The Cd–C and O–O bonds are dissociated in the coordination complexes formed, while the Si–O–Cd linkage persists[43].

The reactions of the dialkylmercury compounds R_2Hg with benzoyl peroxide lead to the formation of a more complex mixture of products. Free-radical processes also play a significant role in the reaction[96,160,161]. Thus, in the reaction of i-Pr_2Hg, benzoic acid, propane, propene, CO_2, and mercury were isolated in addition to isopropylmercury benzoate.

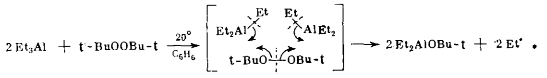
Organomercury compounds react with alkyl peroxides also via OMC–peroxide complexes, which decompose with formation of radicals, initiating the subsequent decomposition of the initial OMC in the reactions of the latter with the solvent[92–94,162]:



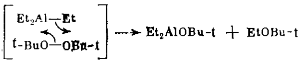
$$R_2Hg + t\text{-}BuOOBu\text{-}t \rightarrow \left[\begin{matrix} R{-}Hg{-}R \\ \uparrow \\ t\text{-}Bu{-}\bar{\underline{O}}{-}\bar{\underline{O}}Bu\text{-}t \end{matrix}\right] \rightarrow RHgOBu\text{-}t + R^{\cdot} + t\text{-}BuO^{\cdot}\ ;$$

$$R{=}n\text{- or } i\text{-}Pr.$$

The reactivity of organic derivatives of Group III elements in relation to alkyl and acyl peroxides is in many respects determined by the nature of the metal. Thus Et_3Al reacts with t-butyl peroxide similarly to organocadmium compounds[163,164]:

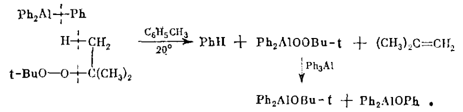


The formation of ether is due to a side reaction involving a heterolytic transformation of the 1 : 1 complex:



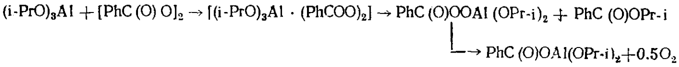
The etherate of triethylaluminium and the complex $Et_3Al.Ph_3P$ do not interact with t-butyl peroxide at room temperature[165]. The low reactivity of the Al–C bond in etherates persists also in the compound $(Ph_3Si)_2AlEt$ with the Si–Al bond[166].

In contrast to alkyl derivatives, Ph_3Al reacts with t-butyl peroxide with the intermediate formation of an organoaluminium peroxide, which then reacts with the initial OMC:[101,163]



Organoaluminium compounds react with acyl peroxides more vigorously than with alkyl peroxides. The reaction of benzoyl peroxide with Et_3Al in solution proceeds even below 0°C.[164,167,168] As for t-butyl peroxide, the reactions proceed with the intermediate formation of donor–acceptor complexes having OMC : peroxide ratios of 2 : 1 and 1 : 1 and decomposing homolytically and heterolytically respectively.

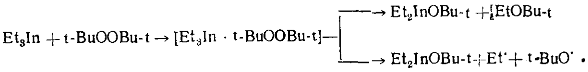
When the alkyl group in an organoaluminium compound is substituted by an alkoxy-group, the probability of heterolytic processes is enhanced. Such behaviour has been noted, for example, in the reaction of dicyclohexyl peroxydicarbonate with $Et_2AlOC_6H_{11}$ and Et_2AlOBu-n and also in the reactions of benzoyl and acetylbenzoyl peroxides with $EtAl(OEt)_2$.[169] However, the reactions of Et_2AlOCH_3 and Et_2AlOBu-s with benzoyl peroxide involve mainly the formation of a 2 : 1 complex, which decomposes homolytically[170]. On the other hand, when aluminium tri-isopropoxide reacts with benzoyl peroxide, the intermediate peroxy-compound is formed[171,172]:



$$\begin{tikzcd}[column sep=small] (i\text{-}PrO)_3Al + [PhC(O)O]_2 \arrow[r] & {[(i\text{-}PrO)_3Al\cdot(PhCOO)_2]} \arrow[r] & PhC(O)OOAl(OPr\text{-}i)_2 \arrow[d] + PhC(O)OPr\text{-}i \\ & & PhC(O)OAl(OPr\text{-}i)_2 + 0.5O_2. \end{tikzcd} \qquad (16)$$

In the reactions of acyl peroxides with the etherate of Et_3Al or the complex $Et_3Al.Ph_3P$ at room temperature, the donor is displaced in the first stage and intermediate 2 : 1 and 1 : 1 complexes are then formed. The ratio of the products of the homolytic and heterolytic decomposition of these complexes depends on the nature of the ligand. Thus $Et_3Al.Ph_3P$ reacts with benzoyl peroxide mainly homolytically, while in the reaction of the etherate the two pathways compete[165]. The complex $(Ph_3Si)_2AlEt.2LiBr.2THF$ reacts with benzoyl peroxide in the same way as with t-butyl peroxide, the process involving the preferential cleavage of the Si–Al bond[166].

Triethylindium and triethylthallium have a reduced electron-accepting capacity. Their reaction with t-butyl peroxide therefore proceeds with much greater difficulty than the reaction of Et_3Al. The reaction of Et_3In with the peroxide begins only at 50°C and Et_3Tl reacts at a still higher temperature (100°C).[173] A complex, which can subsequently decompose heterolytically and homolytically, is also formed in the first stage, for example:



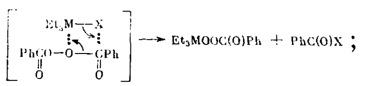
$$Et_3In + t\text{-}BuOOBu\text{-}t \rightarrow [Et_3In\cdot t\text{-}BuOOBu\text{-}t] \begin{cases} \rightarrow Et_2InOBu\text{-}t + EtOBu\text{-}t \\ \rightarrow Et_2InOBu\text{-}t + Et^{\cdot} + t\text{-}BuO^{\cdot}\ . \end{cases}$$

The mechanism of the reaction of Et_3Tl with acyl peroxides is analogous to that of the reaction of Et_3Al.[167,174,175]

When one ethyl group in Et_3Tl is substituted by an isopropoxy-group, the reaction with benzoy peroxide (at approximately 20°C) involves the heterolytic cleavage of the Tl–O bond in the organothallium compound and the C–O bond in the peroxide. As in reaction (16), the perbenzoate formed decomposes with liberation of oxygen[176]. The reaction of benzoyl peroxide with a siloxy-derivative of diethylthallium (at 40–50°C) involves the heterolytic dissociation of the Si–O bond in the OMC–peroxide complex with formation of a peracyl derivative of silicon, which rearranges[176]:

$$\begin{array}{l} \mathrm{Et_2TlOSiPh_3 + (PhCOO)_2 \rightarrow Ph_3SiOOC\,(O)\,Ph + Et_2TlOCOPh} \\ \qquad\qquad\qquad\qquad\qquad\quad \downarrow \\ \qquad\qquad\qquad\qquad\qquad\quad \mathrm{Ph_2\,(PhO)\,SiOC\,(O)\,Ph}\ . \end{array} \tag{17}$$

There is a wide variety of reactions of organic compounds of Group IV elements with alkyl and acyl peroxides. The nature of the reactions is determined both by the nature of the heteroatom and by the structure of the organometallic and peroxy-compounds. There is a possibility of reactions involving the intermediate formation of a reactive complex and, as in the alkoxy-derivatives of aluminium and thallium discussed above, in this complex the heterolytic transformations can occur with retention of the O–O bond and the formation of OMPC:[108,177,178]



$M{=}Sn$; $X{=}OCH_3$, OEt, OC_6H_{11}-cyclo,

OPh, or OCH_2Ph .

$M{=}Si$; $X{=}NEt_2$.

Peresters of organic derivatives of the elements undergo a heterolytic rearrangement (M = Sn or Si) via mechanism (17) and decompose to a slight extent with liberation of oxygen (M = Si). There is also a possibility of the dissociation of the O–O bond in the reaction complex, for example in the reaction of Et_3SnNEt_2 with benzoyl peroxide[108].

The hydrides of Group IV elements having organic substituents (R_3MH) do not react with benzoyl or t-butyl peroxide at room temperature. Their interaction is observed only at the temperature corresponding to the decomposition of the peroxide into radicals. For example, benzoyl peroxide reacts with Et_3SiH in the presence of oxygen and a solvent at 95–97°C. The main reaction products are triethylsilyl benzoate, benzoic acid, and carbon dioxide[179]. Benzoyloxy-radicals decompose or abstract hydride hydrogen from the OMC, forming triethylsilyl radicals $Et_3Si^{\cdot}$:

$$\mathrm{Et_3SiH + PhC\,(O)\,O^{\cdot} \rightarrow PhC\,(O)\,OH + Et_3Si^{\cdot}}\ ;$$

$$\mathrm{Et_3Si^{\cdot} + PhC\,(O)\,OOC\,(O)\,Ph \rightarrow Et_3SiOC\,(O)\,Ph + PhC\,(O)\,O^{\cdot}}\ .$$

The formation of free organosilyl radicals $R_3Si^{\cdot}$ (R = alkyl or aryl) in reactions of silicon hydrides with t-butyl peroxide has been noted[180,181]. Using ESR, it has recently been possible to demonstrate the formation of triorganogermyl radicals R_3Ge in the reaction of R_3GeH (R = alkyl or phenyl) with t-$BuO^{\cdot}$ radicals obtained on photolysis of t-butyl peroxide[182]. The radical mechanism of the reactions of organotin hydrides with alkyl and acyl peroxides has been confirmed by the use of labelled peroxides. It has been established that the reaction involving diacyl peroxide has a chain mechanism and that stannyl radicals ($R_3Sn^{\cdot}$) initiate the decomposition of the peroxide. The reaction of organotin hydrides with t-butyl or t-butylcumenyl peroxide has a radical but non-chain mechanism and organometallic radicals do not initiate the decomposition of the peroxide even at a fairly high temperature (130°C).[183,184]

Tetra-alkyl compounds R_4M (M = Si, Ge, Sn, or Pb) also react with t-butyl, benzoyl, or acetylbenzoyl peroxides and with peresters only at the temperature corresponding to the decomposition of the peroxy-compounds into free radicals[179,185–190]. In these reactions, Et_4Si and Et_4Ge behave as hydrogen donors:

$$\mathrm{Et_4M + R^{\cdot} \rightarrow RH + Et_3M\dot{C}_2H_4}\ ;$$

$M{=}Si$, Ge, Sn; $R{=}CH_3$, Ph, t-BuO, RC(O)O·.

The radicals derived from the peroxides behave in the same way in the reaction with hexaethyldisilane. The Si–Si bond is not dissociated under these conditions[191]:

$$\mathrm{R^{\cdot} + Et_3Si{-}SiEt_3 \rightarrow RH + Et_3Si{-}SiEt_2\dot{C}_2H_4}\ .$$

Secondary organosilicon radicals recombine, while $Et_3Ge\dot{C}_2H_4$ radicals undergo slight decomposition at the M–C bond in addition to dimerisation[185]:

$$\mathrm{Et_3M\dot{C}_2H_4 \rightarrow C_2H_4 + Et_3M^{\cdot}}\ ;$$

$M{=}Ge$, Sn.

The radical $Et_3Sn\dot{C}_2H_4$ does not dimerise and merely decomposes in accordance with the last equation[185,188–190].

The radicals derived from the peroxide do not behave merely as hydrogen acceptors and are capable also of displacing ethyl radicals from the molecule. Only this reaction proceeds with Et_4Pb:[189,190]

$$\begin{array}{c} \mathrm{Et_4M + R^{\cdot} \rightarrow Et_3MR + Et^{\cdot}}\ ; \\ \mathrm{M{=}Sn,\ Pb;\ R{=}t\text{-}BuO,\ PhC\,(O)O}\ . \end{array} \tag{18}$$

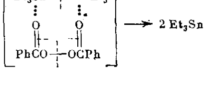
Ethyl radicals disproportionate or react with the initial OMC.

The replacement of the ethyl group in Et_4Sn by a halogen or the benzoyloxy-group does not alter significantly the nature of the interaction with benzoyl peroxide. The formation of all the products detected can be readily accounted for by the free-radical reaction (18). However, this is accompanied by a cryptoradical transformation in the cyclic complex[178,179]. Similar results have been obtained in the reactions of peroxides with tetrapropyl- and tetraisopropyl-tin and in the reaction of t-butyl peroxide with Et_6Sn_2.[189,191]

The reactions of phenyl derivatives of Group IV elements have been hardly investigated. In one of the first studies on these lines[192], it was established that Ph_4Pb does not react with acetyl peroxide, which decomposes and interacts with the solvent. However, in the reaction of $(CH_3)_3SnPh$ with benzoyl peroxide, the bond between the metal and the benzene ring undergoes homolytic cleavage[190]:

$$\mathrm{PhC\,(O)\,O^{\cdot} + (CH_3)_3\,SnPh \rightarrow (CH_3)_3SnOC\,(O)\,Ph + Ph^{\cdot}}\ .$$

The reactions of acyl peroxides with organic derivatives of Group IV metals having metal–metal bonds differ markedly from the reactions of R_4M. Thus the interaction of Et_6Sn_2 with benzoyl and acetylbenzoyl peroxides and dicyclohexyl percarbonate proceeds under very mild conditions and is not characterised by the wide variety of products usually observed in free-radical processes. According to some workers[189,193–197], the reaction proceeds via a stage involving the formation of an unstable cyclic complex, for example:



in which the Sn–Sn and O–O bonds dissociate homolytically without the formation of free-radicals. The absence of any other parallel reactions was confirmed by the determination of the heat of reaction, which proved to be 108 kcal.[198] The cryptoradical mechanism has also been confirmed by the formation of the acetate derivative of the OMC in the reaction with acetylbenzoyl peroxide[195]. Et_6Pb_2 [128,195] and organotin compounds having chains of tin atoms[196,199–202] react similarly with benzoyl peroxide. Polymeric dibutyltin reacts exothermically with benzoyl peroxide, but under these conditions the Sn–Sn bond does not dissociate regardless of the reactant ratio, 1,2-dibenzoyloxy-1,1,2,2-tetrabutyldistannane being formed instead[131].

In the studies on the properties of organobimetallic compounds with M–M′–M groups (M is a Group IVB metal and M′ a metal belonging to another Group), reactions with organic peroxides are also widely investigated in order to be able to compare the behaviour of such compounds and OMC having an M–M bond.

The interaction of $(Et_3Ge)_2Cd$ with t-butyl hydroperoxide in hexane solution (at 0–5°C) proceeds with evolution of heat. The main reaction pathway is the oxidation of the OMC with a side process involving the selective alcoholysis of the OMC by the carbinol formed[203]:

$$(Et_3Ge)_2Cd + t\text{-}BuOOH \rightarrow Et_3GeCdOGeEt_3 + t\text{-}BuOH\ ,$$
$$(Et_3Ge)_2Cd + t\text{-}BuOH \rightarrow Et_3GeCdOBu\text{-}t + Et_3GeH\ .$$

Since $Et_3GeHgOGeEt_3$ is extremely unstable[79] even at temperatures below –20°C, free mercury $(Et_3Ge)_2O$, and t-BuOH were isolated in the analogous reaction of $(Et_3Ge)_2Hg$ with t-BuOOH. The reaction of t-butyl peroxide with $(Et_3Ge)_2Cd$ (at approximately 20°C) led to the isolation of a complex mixture of products, the formation of which can be explained by a mechanism involving one-electron transfer in the complex, where OMC behaves as the electron donor[203]:

$$(Et_3Ge)_2Cd + t\text{-}BuOOBu\text{-}t \rightarrow \begin{bmatrix} Et_3GeCd^{\oplus}\cdot GeEt_3 \\ t\text{-}BuO^{\ominus}\cdot OBu\text{-}t \end{bmatrix} \rightarrow Et_3GeCdOBu\text{-}t + t\text{-}BuO^{\cdot} + Et_3Ge^{\cdot}\ .$$

Triethylgermyl radicals dimerise and recombine with t-BuO˙ radicals. Apart from recombining, decomposing, and abstracting hydrogen, the latter induce the decomposition of the initial OMC:

$$(Et_3Ge)_2Cd + t\text{-}BuO^{\cdot} \rightarrow Et_3GeCdOBu\text{-}t + Et_3Ge^{\cdot}\ .$$

In contrast to the compound examined, its mercury analogue does not react even under the conditions of the photochemical decomposition of the peroxide[72].

Compounds of the type $[R_3M]_nM'$, where M is a Group IV element and M′ a Group II–VI element, react with acyl peroxides vigorously at room temperature, evolving heat, as in the case of Et_6Sn_2, and involving the intermediate formation of active cyclic complexes, decomposing via a cryptoradical mechanism[149,204,205].

The reactions are described by simple stoichiometric equations. When M′ = Cd, the corresponding metal benzoates are formed[206,207]:

$$(Et_3M_2)Cd + 2\,(PhCOO)_2 \rightarrow Cd\,(OCOPh)_2 + 2\,Et_3MOCOPh$$
$$M{=}Si \text{ or } Ge\ .$$

Compounds with Ge–Zn bonds react similarly[208]. In a study of the reaction of bis(triethylgermyl)cadmium with asymmetric peroxides, it was established that the formation of the activated transition complex is preceded by the orientation of the peroxide molecules relative to the polarised Ge–Cd bond[203]:

$$(Et_3Ge)_2Cd + PhC\,(O)\,OOR \rightarrow \begin{bmatrix} Et_3GeCd\text{—}GeEt_3 \\ \vdots\quad\ \vdots \\ PhC(O)\,O\text{—}O\text{—}R \end{bmatrix} \rightarrow Et_3GeCdOC\,(O)\,Ph + Et_3GeOR\ ;$$
$$R{=}CH_3C\,(O) \text{ or } t\text{-}Bu\ .$$

The mercury analogues $(Et_3M)_2Hg$ (M = Si or Ge) react in the same way with benzoyl peroxide and dicyclohexyl percarbonate[72,73,209,210]. The intermediate $Et_3MHgOC(O)R$ decomposes quantitatively under these conditions to metallic mercury and the corresponding derivative $Et_3MOC(O)R$:

$$(Et_3M)_2Hg + (RCOO)_2 \rightarrow Et_3MHgOC\,(O)\,R + Et_3MOC\,(O)\,R$$
$$Hg + Et_5MOC\,(O)\,R \longleftarrow$$
$$R{=}Ph \text{ or } OC_6H_{11}\text{-cyclo}\ .$$

In the analogous reaction of the thallium compound $(Et_3Ge)_3Tl$, the free metal is not liberated and, as for the cadmium compound, the products are the metal benzoates—thallium benzoate and triethylgermanium benzoate[211,212]. The metal M′ is liberated in a free state in the reactions of $(Et_3M)_nM'$ (where M = Si, Ge, or Sn and M′ = Sb, Bi,[213–215] or S, Se, Te [216]) with benzoyl peroxide, the products being the triethylmetal benzoates in accordance with the equations

$$2\,(Et_3M)_3M' + 3\,(PhCOO)_2 \rightarrow 2M' + 6Et_3MOC\,(O)\,Ph\ ;$$
$$M{=}Si,\ Ge \text{ or } Sn;\ M'{=}Sb \text{ or } Bi.$$
$$(Et_3M)_2M' + (PhCOO)_2 \rightarrow M' + 2\,Et_3MOC\,(O)Ph\ ;$$
$$M{=}Si,\ Ge \text{ or } Sn;\ M'{=}S,\ Se \text{ or } Te.$$

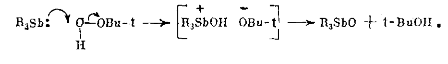
Acetyl peroxide reacts with $(Et_3Si)_2Te$, giving a quantitative yield of elemental tellurium and triethylsilicon benzoate and acetate[216].

The interaction of benzoyl peroxide with ethyl(triethylsilyl)mercury, having a single Si–Hg bond, is described by simple equations[72]:

$$2\,EtHgSiEt_3 + (PhCOO)_2 \rightarrow Et_2Hg + Hg + 2Et_3SiOCOPh\ .$$

This also applies to the reaction with compounds having several atoms of different metals linked to one another, for example $Et_3GeHgSiEt_3$ and $Et_3GeHgSiEt_2SiEt_3$,[73] and with compounds of the type R_3SiSeH.[217]

The reactions of alkyl derivatives of Group V elements with organic hydroperoxides are regarded as oxidation-reduction processes accompanied by the transition of the central element to the highest valence state and the reduction of the hydroperoxides to the corresponding alcohols. The reaction mechanism involves nucleophilic attack on peroxide oxygen by the OMC with the intermediate formation of an ion pair, for example:



$$R_3Sb{:}\ \ \underset{\displaystyle H}{O}\text{—}OBu\text{-}t \longrightarrow \left[R_3\overset{+}{Sb}OH\ \ \overset{-}{O}Bu\text{-}t\right] \longrightarrow R_3SbO + t\text{-}BuOH\ .$$

The deprotonation of the 'onium cation in the ion pair leads to the formation of the oxide of the trialkyl derivative of the element (R_3SbO).[218]

In the reactions of trialkylbismuth R_3Bi (R = CH_3 or Et) with t-BuOOH, an ion pair is also formed in the initial stage. However, since the bismuth(V) state is less stable than the anitmony(V) state, the carbon atom attached to the bismuth atom and not hydrogen is subjected to nucleophilic attack in the bismuthonium ion $R_3\overset{+}{Bi}OH$. Ultimately the organobismuth compound is dealkylated without a change in the valence of bismuth. When $R_3\overset{+}{Bi}OH$ is attacked by the strongly nucleophilic peroxy-anion formed in the reversible reaction

$$t\text{-BuO}^- + t\text{-BuOOH} \rightleftarrows t\text{-BuOH} + t\text{-BuOO}^- ,$$

an asymmetric dialkyl peroxide is produced:

$$t\text{-BuOO}^- \; R-\overset{+}{Bi}(OH)R_2 \longrightarrow t\text{-BuOOR} + R_2BiOH .$$

An ether and a carbinol are formed via similar reactions of alkoxide and hydroxide anions. It has also been established that the heterolytic process is accompanied to a slight extent by a homolytic reaction involving the homolysis of bonds induced by the molecules[218]:

$$R_3Bi + \underset{H}{O}-OBu\text{-}t \rightarrow [R_3Bi \leftarrow \underset{H}{O}-OBu\text{-}t] \rightarrow R^{\cdot} + R_2BiOH + {}^{\cdot}OBu\text{-}t .$$

Phenyl derivatives of phosphorus(III), arsenic(III), and antimony(III) are readily oxidised by t-butyl hydroperoxide to the corresponding oxides Ph_3EO, like the alkyl compounds. The rates of oxidation of Ph_3P and Ph_3Sb are approximately the same, while Ph_3As reacts with the hydroperoxide approximately sixty times more slowly. Such a change in rate has been explained by the presence of two opposed factors: the ability of *d* orbitals to form π bonds with the peroxy-group and the E–O bond energy[219].

In similar reactions with the hydroperoxides Ph_3SiOOH and Ph_3GeOOH, the peroxide oxygen is subjected to nucleophilic attack by triphenylphosphine or triphenylantimony, but, in contrast to alkyl hydroperoxides, the 'onium cation is not deprotonated, a new element–oxygen–element bond being formed[136]:

$$Ph_3E{:} \; \underset{H}{O}-OE'Ph_3 \longrightarrow [Ph_3\overset{+}{E}OH \quad \overset{-}{O}E'Ph_3] \longrightarrow Ph_3E(OH)OE'Ph_3 ;$$

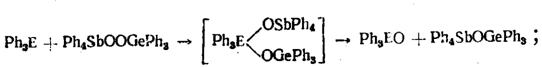
E = P or Sb; E' = Si or Ge.

The symmetrical t-butyl peroxide is less reactive as an oxidant for Ph_3E. Whereas Ph_3P can be nevertheless converted into Ph_3PO at an elevated temperature (110° to 120°C) with formation of di-t-butyl ether, Ph_3As, Ph_3Sb, and Ph_3Bi do not react with t-butyl peroxide under these conditions[155]. Compared with the latter, bis(trimethylsilyl) peroxide is a more powerful oxidant. In the reaction with Ph_3P, Ph_3PO is formed quantitatively after a short time at a temperature as low as 25–60°C.[134,155,220] Ph_3As and Ph_3Sb react just as easily, but with a somewhat lower yield of the oxide product. However, triphenylbismuth is inert with respect to the action of this peroxide too[155]:

$$Ph_3E + (CH_3)_3SiOOSi(CH_3)_3 \rightarrow \left[Ph_3E\begin{matrix}OSi(CH_3)_3\\OSi(CH_3)_3\end{matrix}\right] \rightarrow Ph_3EO + (CH_3)_3Si-O-Si(CH_3)_3 ;$$

E = P or Sb .

The organometallic peroxide $Ph_4SbOOGePh_3$ reacts similarly with Ph_3P [134] and Ph_3Sb, forming two final products:



$$Ph_3E + Ph_4SbOOGePh_3 \rightarrow \left[Ph_3E\begin{matrix}OSbPh_4\\OGePh_3\end{matrix}\right] \rightarrow Ph_3EO + Ph_4SbOGePh_3 ;$$

E = P or Sb .

The foregoing data have shown that the reactions of OMC with oxygen and various peroxides proceed with formation of kinetically independent species having an unpaired electron. Because of this, the OMC–oxygen or OMC–peroxide systems can initiate various chain processes. The initiating capacity of such systems has been studied both in the polymerisation reactions of alkenes and their derivatives and in the reactions of OMC with various substrates. It is impossible to discuss this problem in detail in the present review. As an example, one may quote the initiation of the polymerisation of certain monomers by dialkylmercury or trialkylaluminium in the presence of oxygen[55,221–223] or by a trialkylboron–peroxide system[224] and the initiation of the oxidation of the solvent in the autoxidation of OMC, for example the oxidation of isopropyl alcohol or n-nonane in the reaction involving the oxidation of $i\text{-}Pr_2Hg$.[33,44,45,50] The initiation of the reactions of organomercury compounds of the type R_2Hg (R = alkyl or aryl) with polyhalogenomethanes by oxygen[47], perbenzoic acid[225], t-butyl hydroperoxide and peroxide[93,94], benzoyl peroxide[162,226], and peroxides obtained from cyclohexanone[227] has been noted. Acyl peroxides initiate the reactions of CCl_4 with tetraethylsilane[2,194,228], various organotin derivatives[192,194,195,229–231], and tetraphenyllead[192,230]. The conversion of mercury carboxylates into organomercury compounds, initiated by peroxides, is of interest from the preparative standpoint[232–234].

III. REACTIONS OF ORGANOMETALLIC PEROXY-COMPOUNDS

Organometallic peroxy-compounds are highly reactive. Their chemical reactions can occur in different ways, including both heterolytic and homolytic dissociation of the bonds in the molecule. In many cases, these reaction pathways operate simultaneously. For some peroxy-compounds, the reaction pathway can vary sharply as a function of conditions.

Heterolytic dissociation of the M–O bond in OMPC has been observed in their reactions with H_2O, HCl, and H_2SO_4. Peroxy-compounds of Group I–III elements are very readily hydrolysed by atmospheric moisture[59,88,90,98–100,104,106,235]. Hydroperoxides and organometallic peroxides give rise to the quantitative formation of H_2O_2 in this reaction, for example we have for thallium derivatives[104,106]:

$$\begin{gathered} Et_2TlOOH + H_2O \rightarrow Et_2TlOOH + H_2O_2 ; \\ Et_2TlOOTlEt_2 + 2H_2O \rightarrow 2Et_2TlOH + H_2O_2 . \end{gathered} \tag{19}$$

Alkylperoxy-derivatives gives rise to the corresponding hydroperoxides:

$$R_mMOOR' + H_2O \rightarrow R_mMOH + R'OOH , \tag{20}$$

where M is a Group I–III element. The reaction with hydrogen chloride or its alcoholic solution results in the formation of the corresponding alkyl(aryl) metal halides.

The sensitivity of the peroxides of Group IV elements to hydrolysis depends on the nature of the central metal atom and increases from silicon to lead. The compound Ph_3SiOOH is insensitive to hydrolysis under the usual conditions. In aqueous dioxan in the presence of sulphuric acid, the M–O bond is protolysed both in Ph_3SiOOH [236] and in Ph_3GeOOH and Ph_3SnOOH:[237]

$$Ph_3MOOH + H_2O \xrightarrow{H^+} Ph_3MOH + H_2O_2 ;$$

M=Si, Ge or Sn. .

The acid hydrogen atom in R_3MOOH may be substituted by a fragment comprising an organic derivative of the element in reactions with compounds such as Et_3Tl,[106] Ph_5P, and Ph_4POCH_2Ph,[134] and with Group IV and V metal halides[110,118–122,135,238]. The proton-donating capacity of hydroperoxides decreases in the sequence $Ph_3SiOOH > Ph_3GeOOH > Ph_3COOH > Ph_3SnOOH$ [239] and for triorganosilyl hydroperoxides the sequence is $Ph_3SiOOH > Ph_3COOH > (CH_3)_3.SiOOH$.[240]

Organosilicon peroxides of the type R_3SiOOR' and symmetrical and asymmetric peroxides of the type $R_3SiOOSiR'_3$ are fairly resistant to atmospheric moisture. The peroxide

$Et_3SiOOBu$-t is slowly hydrolysed by water to silanol and t-BuOOH,[107] while in the presence of acids the hydrolysis is faster.

The reaction of $Ph_3SiOOSbPh_4$ with HCl in benzene differs from the usual heterolysis of the Si–O bond[135]:

$$Ph_3SiOOSbPh_4 + HCl \rightarrow Ph_3SiOOH + Ph_4SbCl\ .$$

When this peroxide as well as its germyl and stannyl analogues interact with sulphuric acid, both M–O bonds are cleaved and H_2O_2 is formed[135].

All organotin and organolead peroxides are readily hydrolysable. When R_3MOOR' and R_3MOOMR_3 react with H_2O, acetic acid, or HCl, the Sn–O and Pb–O bonds are heterolysed and organic hydroperoxides or H_2O_2 are formed[23,71,128,129,237,241–244], as in reactions (19) and (20). There are isolated examples of the heterolysis of the O–O bond in certain organometallic compounds. Such cleavage of the O–O bond in organosilicon peroxides has been achieved under the influence of nucleophiles [RLi, EtONa, RMgX, and Ph_3E (E = P, As, or Sb)][155].

More typical reactions of OMPC involving the dissociation of the O–O bonds are the homolytic reactions occurring under the influence of heat, light, or radical initiation. The formation of radicals has been demonstrated in the thermal decomposition of the peroxy-compounds of the elements of all the Groups examined. In n-nonane, *m*-xylene, cumene, and t-butylbenzene solutions, Group I metal peroxides decompose at 80–130°C.[86–89,235,245,246] Thus $Ph(CH_3)_2COOLi$ decomposes to the extent of 80% in 3 h at 90°C [235] and the sodium derivative decomposes to the extent of 35% in 1 h at 80°C. The complex $Ph(CH_3)_2.COONa.Ph(CH_3)_2COOH$ is less stable, losing 80% of peroxide oxygen in 1 h at a temperature as low as 65°C.[89] The complex of potassium cumenyl peroxide with cumenyl hydroperoxide is also relatively unstable[245]. The thermal stability of alkali metal arylalkyl peroxides diminishes with increase of the number of phenyl groups. The peroxides decompose with homolysis of the O–O bond in the initial stage:

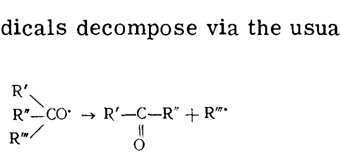
$$\begin{gathered} MOOR \rightarrow MO^{\cdot} + {}^{\cdot}OR\ ; \\ M{=}Li,\ Na\ \text{or}\ K;\quad R{=}t\text{-}Bu,\quad Ph\,(CH_3)_2C\ \text{or}\ Ph_2\,(CH_3)\,C,\ Ph_3C. \end{gathered} \tag{21}$$

The radicals formed dehydrogenate the solvent:

$$MO^{\cdot} + SH \rightarrow MOH + S^{\cdot}\ ; \tag{22}$$

$$RO^{\cdot} + SH \rightarrow ROH + S^{\cdot}\ . \tag{23}$$

The tertiary $RO^{\cdot}$ radicals decompose via the usual mechanism:



$$R'R''R'''CO^{\cdot} \rightarrow R'{-}\underset{\underset{O}{\|}}{C}{-}R'' + R'''^{\cdot} \tag{24}$$

and can give rise to ketones, which in their turn enter into a molecular reaction with the initial OMPC. For example, potassium cumenyl peroxide decomposes to the extent of 60–80% via mechanism (21) and reacts to the extent of 20–40% in accordance with the equation

$$Ph\underset{\underset{O}{\|}}{C}CH_3 + 3\,Ph\,(CH_3)_2COOK \rightarrow PhC\,(O)\,OK + HC\,(O)\,K + 2\,Ph\,(CH_3)_2COH + Ph\,(CH_3)_2COK\ .$$

The thermal stability of mercury monoperoxides $RHgOOR'$ [R′ = t-Bu or $Ph(CH_3)_2C$] decreases in the series R = *p*-ClC_6H_4 > Ph > $PhCH_2$ > *p*-$CH_3OC_6H_4$ > Et > i-Pr.[98,247,248] t-Butylperoxy-derivatives of alkyl- and arylmercury are thermally less stable than the corresponding cumenylperoxy-derivatives. The peroxides decompose above 90°C with homolytic dissociation of the O–O bond and the formation of the oxy-radicals $R'O^{\cdot}$ and $RHgO^{\cdot}$, which, apart from their involvement in reactions (22) to (24), can also initiate the decomposition of the peroxide, for example, we have for $EtHgOOC(CH_3)_2Ph$:[97,248]

$$\begin{gathered} R'O^{\cdot} + EtHgOOC\,(CH_3)_2Ph \rightarrow R'OH + \\ + {}^{\cdot}C_2H_4HgOOC\,(CH_3)_2Ph \\ \longrightarrow C_2H_4 + HgO + Ph\,(CH_3)_2CO^{\cdot}\ ; \\ R' = Ph\,(CH_3)_2C\ \text{or}\ EtHg\ . \end{gathered}$$

Apart from dehydrogenating the solvent, the alkylmercuroxy-radicals decompose via the mechanism

$$EtHgO^{\cdot} \rightarrow Et^{\cdot} + HgO\ .$$

Alkyl radicals recombine and abstract hydrogen from the solvent. Dicumenylperoxymercury decomposes similarly (at 130°C in toluene)[100].

The radical decomposition of OMPC is frequently accompanied by a rearrangement of the peroxides, which can take place at the metal atom or at a tertiary carbon atom in the alkylperoxy-group. The isomeric transformation of the latter type with simultaneous homolytic decomposition has been observed in the photolysis of $EtHgOOC(CH_3)_2Ph$ (λ = 366 nm)[247]:

$$EtHgOOC\,(CH_3)_2Ph \xrightarrow{h\nu} EtHgOC\,(CH_3)_2OPh\ .$$

As already noted, organoaluminium peroxy-compounds, formed in the autoxidation of the alkyl derivatives R_3Al, are very readily converted into the isomeric alkoxy-derivatives when the molecule contains unoxidised groups. Such a possibility is ruled out in the absence of alkyl groups from the aluminium compound.

The compound $(EtO)_2AlOOC(CH_3)_2Ph$ is relatively stable at room temperature. After the hydrolysis of the decomposition products (at 90°C in xylene), $Ph(CH_3)_2COH$, $PhC(O)CH_3$, α-methylstyrene, ethyl alcohol, and aluminium hydroxide were found. It is suggested that these products are formed as a result of a radical reaction of the peroxide[102].

Thallium peroxides constitute an example of OMPC for which the influence of the peroxide structure on the nature of its reaction is a maximum. The decomposition of diethylthallium hydroperoxide is an example of the decomposition of a peroxide with evolution of oxygen. The hydroperoxide, which can be stored at 0–5°C for several hours, decomposes rapidly at room temperature[104]:

$$Et_2TlOOH \rightarrow Et_2TlOH + 0.5\,O_2\ .$$

Peracyl derivatives of thallium also decompose with evolution of oxygen and the formation of the corresponding diethylthallium carboxylates[137,139,249,250]:

$$\begin{gathered} Et_2TlOOC\,(O)\,R \rightarrow Et_2TlOC\,(O)\,R + 0.5O_2\ ; \\ R{=}CH_3,\ n\text{-}C_9H_{19}\ . \end{gathered}$$

The peroxides R_2TlOOR' [R = Et or Ph; R′ = t-Bu or $Ph(CH_3)_2C$] decompose in solution in n-nonane, toluene, cumene, and chlorobenzene at 100°C and above with dissociation of the O–O bond and the formation of radicals which are then involved in competing solvent decomposition and dehydrogenation reactions[105,249,250]:

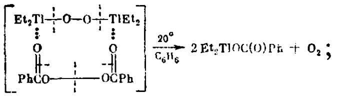
$$R_2TlOOR' \rightarrow R_2TlO^{\cdot} + {}^{\cdot}OR'\ . \tag{25}$$

The rate of decomposition increases with the initial concentration, which indicates the presence of an induced decomposition stage in the breakdown process. Apart from spontaneous homolysis via mechanism (25), autocatalytic decomposition of alkylperoxy-derivatives of diphenylthallium by one of the decomposition products (phenylthallium oxide) has been noted[249,250]. In contrast to tertiary alkylperoxy-derivatives of thallium, $Et_2TlOOEt$ undergoes molecular decomposition in solution in n-octane above 50°C:[59]

$$Et_2TlOOEt \rightarrow Et_2TlOH + CH_3CHO\ .$$

This results in the formation of diethylthallium hydroxide in a high yield (75–80%) and acetaldehyde (30%), which largely condenses under the influence of thallium hydroxide.

The organothallium peroxide $Et_2TlOOTlEt_2$ and the mixed peroxide of thallium and germanium, which are stable at room temperature, undergo an interesting reaction with benzoyl peroxide[104]:



$$Et_2TlOOGePh_3 + (PhCOO)_2 \longrightarrow Et_2TlOC(O)Ph + Ph_3GeOC(O)Ph + O_2\ .$$

The study of the thermal transformation of the latter peroxide showed that it rearranges but only at the germanium atom and not at the thallium atom. It is interesting that, according to kinetic data, the reaction is bimolecular[106]:

$$Et_2TlOOGePh_3 \xrightarrow[80^\circ]{C_6H_5CH(CH_3)_2} Et_2TlOGe(OPh)Ph_2 \xrightarrow{H^+, H_2O} Et_2TlOH + Ph_2Ge(OH)OPh\ .$$

The silyl analogue rearranges similarly already during its preparation from Et_3Tl and Ph_3SiOOH.[106]

For the peroxy-compounds of Group IVB elements as well as thallium peroxides, there is a possibility of all types of reactions: spontaneous free-radical decompositions, including radical-induced stages, rearrangement at the central metal atom, and molecular decomposition, which is comparatively uncommon among OMPC.

The thermolysis of Ph_3SiOOH is known[251] to proceed with the homolysis of the O–O bond in the initial stage:

$$Ph_3SiOOH \xrightarrow[>100^\circ]{C_6H_5OCH_3} Ph_3SiO^\cdot + {}^\cdot OH;\quad Ph_3SiO^\cdot \rightarrow Ph_2(PhO)Si^\cdot;\quad Ph_2(PhO)Si^\cdot + {}^\cdot OH \rightarrow (PhO)Ph_2SiOH\ . \qquad (26)$$

The formation of phenol among the products is explained by the rearrangement of the $Ph_3SiO^\cdot$ radical.

The decomposition of Ph_3SiOOH in chlorobenzene is catalysed by cobalt(II) salts (the stearate and abietate). The reaction proceeds under conditions where the thermal decomposition via mechanism (26) hardly occurs. The decomposition products are Ph_3SiOH, H_2O, and O_2 and there is no phenol[252]. Kinetic data for the influence of inhibitors and spectroscopic study of the valence transformations of the catalyst established that the decomposition under these conditions proceeds via a radical non-chain mechanism, similar to that of the catalytic decomposition of organic hydroperoxides. Cobalt stearate also catalyses the radical decomposition of Ph_3GeOOH, the rate of which is comparable to the rates of decomposition of the silicon analogue and Ph_3COOH.[253] In contrast to these hydroperoxides, the thermolysis of the least stable Ph_3SnOOH in benzene, toluene, dioxan, or acetonitrile at 10–40°C proceeds via two competing pathways:

$$Ph_3SnOOH \xrightarrow{k_1} (Ph_2SnO)_x + PhOH;\qquad Ph_3SnOOH \xrightarrow{k_2} Ph_3SnOH + 0.5\,O_2\ .$$

The ratio of the rates of decomposition varies little in different solvents and the reaction mixture does not catalyse the polymerisation of olefinic monomers[237].

Alkyl triorganosilyl peroxides R_3SiOOR' (R and R′ are alkyl groups) undergo homolytic decomposition on heating to a high temperature (170–200°C).[109,254–256] The dissociation energies of the O–O bond in a series of OMPC, including peroxy-compounds of silicon, have been determined by a thermochemical method[257]. The decomposition of $(CH_3)_3SiOOBu$-t in anisole, isopropylbenzene, n-nonane, and decane is described by the equation for first-order kinetics[254,256] and the rate of decomposition of the compounds $(CH_3)_3SiOOR'$, where R = $Ph(CH_3)_2C$, $Ph_2(CH_3)C$, or Ph_3C, increases steadily with increase of the number of phenyl groups[109,256]. The initial stage of the decomposition is homolysis of the O–O bond:

$$(CH_3)_3SiOOR' \rightarrow (CH_3)_3SiO^\cdot + {}^\cdot OR'\ . \qquad (27)$$

Tertiary alkoxy-radicals react via mechanisms (23) and (24). The radicals $Ph_3CO^\cdot$ and $Ph_2(CH_3)CO^\cdot$, formed via reaction (27) from the corresponding arylalkylperoxysilanes, are not only involved in these reactions but also undergo rearrangement:

$$2\,Ph_3CO^\cdot \rightarrow 2\,(PhO)Ph_2C^\cdot \rightarrow [(PhO)Ph_2C—]_2$$

In contrast to the tertiary alkoxy-radicals $RO^\cdot$, $(CH_3)_3SiO^\cdot$ radicals do not decompose and merely dehydrogenate the solvent:

$$(CH_3)_3SiO^\cdot + SH \rightarrow (CH_3)_3SiOH + S^\cdot\ . \qquad (28)$$

The decomposition of $Et_3SiOOBu$-t in hydrocarbons (nonane, decane) proceeds via a radical mechanism above 140°C, the decomposition products being C_2H_6, C_2H_4, t-BuOH, Et_3SiOH, Et_3SiOR, EtOH, and siloxane[107,258–260]. At 170° to 200°C, the process is complicated by the induced decomposition stage[258,259]. The decomposition of $Et_3GeOOBu$-t proceeds similarly[254].

The thermal stability of organosilicon peroxides R_3SiOOR' depends on the nature of the group R. In the series $(CH_3)_3SiOOCH(Ph)CH_3$, $Et_3SiOOCH(Ph)CH_3$, and n-$Pr_3SiOOCH(Ph)CH_3$, the thermal stability is a maximum for the first peroxide and a minimum for the last (in nonane at 180°C).[112] The thermal stability of the germyl analogues $(CH_3)_3GeOOCH(Ph)CH_3$ and $Et_3GeOOCH(Ph)CH_3$ is higher, the methyl derivative being the most stable[112]. According to kinetic data and the structure of the decomposition products, silyl peroxides incorporating a secondary alkylperoxy-group react simultaneously via three pathways. Apart from the homolytic decomposition in accordance with mechanism (27) and the subsequent reactions of the radicals via mechanisms (23), (24), and (28), the peroxide undergoes a rearrangement at the silicon atom with a synchronous redistribution of bonds in the active cyclic complex:

$$R_3SiOOCH(Ph)CH_3 \rightarrow (RO)R_2SiOCH(Ph)CH_3\ ; \qquad (29)$$

the peroxide also undergoes molecular decomposition to a ketone and silanol[261]:

$$R_3SiOOCH(Ph)CH_3 \rightarrow R_3SiOH + PhC(O)CH_3\ ;$$
$$R = CH_3,\ Et,\ n\text{-}Pr.$$

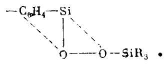
The possibility of the last pathway in the decomposition of the above peroxides has been confirmed by the formation of acetophenone.

The thermal stability of the compounds $Ph_3SiOOCPh_n.(CH_3)_{3-n}$ as well as that of their ethyl analogues decreases as the phenyl groups accumulate in the peroxy-component[110,111]. The peroxide reacts via two simultaneous pathways in accordance with Eqns.(27) and (29); reaction (24) does not occur for $Ph_3SiOOCPh_3$.

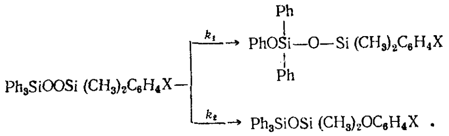
The rearrangements of the OMPC of Group IV elements have been investigated in detail for symmetric and asymmetric organosilicon peroxides and mixed OMPC: $(R_3SiO-)_2$ (R = CH_3, Et, or n-C_6H_{13});[114] $[Ar_n(CH_3)_{3-n}.SiO-]_2$ (Ar = Ph, *p*-$CH_3OC_6H_4$, or *p*-BrC_6H_4);[113,115–117] $Ph_3SiOOSiR_3$ (R = CH_3, Et, n-Pr, n-Bu, n-C_5H_{11}, or n-C_6H_{13});[113,118,119,262,263] $Ph_3SiOOSi(CH_3)_2R$ (R = n-Bu, Ph, $CH_3C_6H_4$, *p*-$CH_3OC_6H_4$, or *p*-BrC_6H_4);[113,115,262,264] $R_3SiOOGePh_3$ (R = alkyl or aryl)[118,121,122]. The thermal decomposition of these peroxides has been investigated in the temperature range 70–100°C and in different solvents. In inert solvents, the peroxides are converted into isomeric non-peroxy-compounds—aryl(alkyl)oxydisiloxanes:

$$R{-}\overset{|}{\underset{|}{Si}}{-}O{-}O{-}\overset{|}{\underset{|}{Si}}{-} \rightarrow RO{-}\overset{|}{\underset{|}{Si}}{-}O{-}\overset{|}{\underset{|}{Si}}{-}\ .$$

The rearrangement is accompanied by the migration of the aryl or alkyl group from the silicon atom to the oxygen atom. The yield of rearrangement products is quantitative. The rate of rearrangement of the peroxides $[Ph_n(CH_3)_{3-n}SiO-]_2$ increases with increase of the number of phenyl groups. The results of kinetic measurements indicate a heterolytic mechanism of the rearrangement. One of the causes of the rearrangement is the effect of the $d\pi - p\pi$ conjugation between the silicon atom and the peroxide oxygen. The electron density deficit at the oxygen atoms increases following the introduction of electron-accepting groups into the moiety attached to silicon. It is noteworthy that the CH_3O and CH_3 groups in the *p*-position in the benzene ring of the peroxides $[p\text{-}XC_6H_4(CH_3)_2.SiO-]_2$ increase the rate constants for the rearrangement, the aryl group migrating, which is due to the more effective interaction of the π-electron cloud of the benzene ring with the *p* electrons of the oxygen atom in the cyclic transition complex:

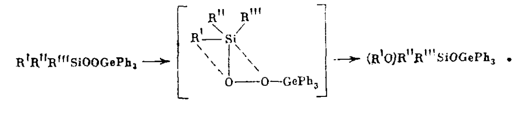


The rearrangement of the peroxides $p\text{-}XC_6H_4(CH_3)_2.SiOOSiPh_3$ is a complex reaction proceeding via two pathways[113,264]:



The relative capacities for migration of the aryl groups attached to different silicon atoms were determined by a kinetic method[113]. The rearrangement of the peroxides $Ph_3SiOOSiAlk_3$ proceeds exclusively via the migration of the Ph group from the silicon to the oxygen atom[113,119,262,263], the thermal stability decreasing with increase of the *I* effect of the alkyl groups in the sequence CH_3 > Et > n-Pr > n-Bu.[119]

On heating in the solid state or in solution above 100°C, the mixed organosilicon organogermanium peroxides $R_3SiOOGePh_3$ (R = CH_3, Et, n-Pr, n-Bu, n-C_5H_{11}, or Ph)[118,121,122] and $(CH_3)_2PhSiOOGePh_3$ [121] are quantitatively converted into a non-peroxy product. This involves the selective migration of the group attached to silicon:



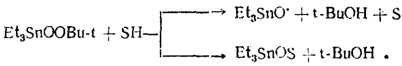
The rate of rearrangement increases with increase of solvent polarity and the number of phenyl groups attached to the silicon atom[118,121]. In terms of the rate of isomerisation, the compounds $Alk_3SiOOGePh_3$ can be arranged in the sequence CH_3 < Et < n-Pr < n-Bu < n-C_5H_{11} < Ph.[122] The factors which determine the pathway and rate of the rearrangement are as follows, as in the case of organosilicon peroxides: (1) electron density deficit at the peroxide linkage; (2) nucleophilic properties of the groups attached to silicon; (3) favourable energy of the cyclic transition state.

The relative basicities of peroxides of the type $R_3MOOM'R_3$ (M and M′ = Si or Ge; R = alkyl or aryl) and the relative migration capacities of the groups have been estimated spectroscopically[265,266] and the different pathways of the rearrangements undergone by these peroxides have been studied.

Peroxy-compounds of tin, such as the organotin peroxides R_3SnOOR' and the organostannyl peroxides $R_3SnOO.SnR_3$, are less stable than the corresponding silicon and germanium peroxides. The nature of the group R′ in the peroxide has an appreciable influence on the decomposition of Et_3SnOOR'. When R′ = Et, the peroxide decomposes comparatively rapidly in solution at room temperature[69,242,260]. The peroxides $(CH_3)_3SnOOBu$-t and $Et_3SnOOBu$-t are stable under the same conditions[254,259,260,267]. The main decomposition products of $Et_3SnOOBu$-t (in n-dodecane at 170°C) are $(Et_2SnO)_x$, $(Et_3Sn)_2O$, $Et_3SnOH.0.5H_2O$, t-BuOH, CH_3COCH_3, CH_4, C_2H_6, C_2H_4, and the dimerisation product of the dodecyl radical. The decomposition proceeds via radical and induced mechanisms: the initial stage involves the homolysis of the O–O bond:

$$Et_3SnOOBu\text{-}t \rightarrow Et_3SnO^{\cdot} + {}^{\cdot}OBu\text{-}t\ . \qquad (30)$$

This is followed by the competing decomposition reactions and the reactions of the radicals with the solvent and the peroxide. Apart from the radical process, the peroxide also undergoes a molecular transformation to $Et_2(EtO).SnOBu$-t similar to the rearrangement undergone by silyl peroxides and there is a competing molecular interaction of the initial peroxide with the solvent[268]:



The peroxide decomposition products at low initial concentrations indicate the absence of free $Et_3SnO^{\cdot}$ radicals. With increase of the concentration of the peroxide and temperature, the yield of products resulting from the radicals formed via mechanism (30) increases. The thermolysis of the peroxide is accelerated by the addition of $(Et_2SnO)_x$ and $(Et_3Sn)_2O$, which are involved in the radical reaction[269].

In connection with the possible formation of peroxides on oxidation of Et_4Sn and Et_6Sn_2, the influence of these compounds on the decomposition of organotin peroxides was studied. The addition of Et_4Sn to a solution of $Et_3SnOOBu$-t in n-decane (at 160°C) hardly alters the rate of decomposition of the peroxide, while the addition of Et_6Sn_2 greatly accelerates the decomposition. The reaction products are the same as in the decomposition of the peroxides in pure decane, but their proportions are altered[267]. In the presence of Et_6Sn_2, the compound Et_3SnOBu-t is formed in addition. The reaction has a radical chain mechanism with initial decomposition via mechanism (30). The radicals attack both the solvent and the OMC molecules, $Et_3SnO^{\cdot}$ radicals reacting preferentially with Et_4Sn, displacing $Et^{\cdot}$ radicals, rather than abstracting hydrogen:

$$Et_3SnO^{\cdot} + Et_4Sn \rightarrow Et_3SnOSnEt_3 + Et^{\cdot}\ .$$

In the decane$-\mathrm{Et_6Sn_2}$ system, the radical decomposition is accompanied by the molecular interaction of the peroxides with the OMC:

$$\mathrm{Et_3SnOOBu\text{-}t + Et_3SnSnEt_3 \rightarrow Et_3SnOSnEt_3 + Et_3SnOBu\text{-}t} \ .$$

The tin peroxide $\mathrm{Et_3SnOOBu}$-s, containing a secondary group, is less stable than the t-butylperoxy-derivative[126] and also less stable than its germanium and silicon analogues. In solution in n-dodecane, the decomposition is a first-order reaction with formation of $\mathrm{(Et_2SnO)_x}$, $\mathrm{(Et_3Sn)_2O}$, $\mathrm{CH_3C(O)Et}$, and $\mathrm{C_2H_6}$. A kinetic study showed that, in n-nonane, isopropylbenzene, and anisole (at 150° to 200°C), a rearrangement and molecular decomposition take place in addition to radical decomposition:

$$\mathrm{Et_3SnOOBu\text{-}s \rightarrow (EtO)\,Et_2SnOBu\text{-}s} \ ,$$
$$\mathrm{Et_3SnOOBu\text{-}s \rightarrow Et_3SnOH + CH_3C(O)Et} \ .$$

Molecular decomposition has also been suggested for the tin peroxide $\mathrm{Et_3SnOOCH_2Ph}$ with a primary alkylperoxy-group, formed in solution on photochemical oxidation of $\mathrm{Et_3SnCH_2Ph}$ by oxygen[67]:

$$\mathrm{Et_3SnOOCH_2Ph \rightarrow Et_3SnOH + PhCHO} \ .$$

Organotin peroxides with tertiary and secondary arylalkyl groups attached to peroxide oxygen, $\mathrm{Et_2SnOOC(CH_3)_2Ph}$ and $\mathrm{Et_3SnOOCH(CH_3)Ph}$, are less stable than the corresponding silicon and germanium derivatives[112,269]. The decomposition of the first peroxide (in octane at 140–170°C) is a first-order reaction. The products are determined by the reactions of the $\mathrm{Et_3SnO^{\cdot}}$ and arylalkoxy-radicals formed via mechanism (30). The peroxide also undergoes the decomposition induced by the solvent radicals[125,260,267,270], for example:

$$\mathrm{Et_3SnOOC(CH_3)_2Ph + S^{\cdot} \xrightarrow{-SH} CH_3\dot{C}HSnEt_2OOC(CH_3)_2Ph \rightarrow}$$
$$\mathrm{\rightarrow C_2H_4 + Et_2SnO + Ph(CH_3)_2CO^{\cdot}} \ .$$

The thermal stability of the phenyl derivative $\mathrm{Ph_3SnOOC.}$ $\mathrm{.(CH_3)_2Ph}$ is also lower than that of the germanium and silicon analogues. The peroxide decomposes at a measurable rate at a temperature as low as 130°C. Whereas homolytic decomposition of $\mathrm{Ph_3MOOC(CH_3)_2Ph}$ (where M = Si or Ge) at the O–O bond is accompanied by the simultaneous isomeric transformation into the phenoxy-derivative $\mathrm{(PhO)Ph_2MOC(CH_3)_2Ph}$, the organotin peroxide does not react under comparable conditions in anisole at 130°C. The radical mechanism includes the formation of $\mathrm{Ph(CH_3)_2CO^{\cdot}}$ and $\mathrm{Ph_3SnO^{\cdot}}$ radicals, the former giving rise to the induced decomposition of the peroxide:

$$\mathrm{Ph_3SnOOC(CH_3)_2Ph + Ph(CH_3)_2CO^{\cdot} \rightarrow Ph_3SnO^{\cdot} + Ph(CH_3)_2COOC(CH_3)Ph} \ ,$$

and the latter being capable of decomposition with ejection of the $\mathrm{Ph^{\cdot}}$ radical, instead of the $\mathrm{Ph_3SiO^{\cdot}}$ and $\mathrm{Ph_3GeO^{\cdot}}$ radicals[271]:

$$x\,\mathrm{Ph_3SnO^{\cdot} \rightarrow (Ph_2SnO)}_x + x\,\mathrm{Ph^{\cdot}} \ .$$

The organostannyl peroxides $\mathrm{R_3SnOOSnR_3}$ are thermally less stable than the peroxides of the type $\mathrm{R_2SnOOR'}$. For example, $\mathrm{Et_3SnOOSnEt_3}$ [61,63,241,243,244,272] decomposes at 0°C in the course of one day and explodes at 60°C. The decomposition in solution in n-nonane (at 20–80°C) proceeds with the quantitative formation of $\mathrm{Et_2SnO}$ and $\mathrm{EtOSnEt_3}$ as the final products. The reaction follows first-order kinetics and is induced by the radicals derived from the peroxide:

$$\mathrm{Et_3SnOOSnEt_3 \rightarrow 2\,Et_3SnO^{\cdot}} \ ;$$
$$\mathrm{Et_3SnOOSnEt_3 + Et_3SnO^{\cdot} \rightarrow Et_3SnOEt + Et_3SnOO\dot{S}nEt_2} \ ;$$
$$\begin{tikzcd}
 & \mathrm{Et_2SnO + Et_3SnO^{\cdot}} \\
\mathrm{Et_3SnOO\dot{S}nEt_2} \arrow[ur] \arrow[dr, "\mathrm{Et_3SnO^{\cdot}}"'] & \\
 & \mathrm{2\,Et_2SnO + Et_3SnOEt} \ .
\end{tikzcd}$$

The peroxide gives rise to the polymerisation of acrylonitrile and methyl methacrylate.

Among all the peroxides of Group IVB elements, the thermal stability of the organolead peroxides is lowest. Thus $\mathrm{Et_3PbOOBu}$-t and $\mathrm{Et_3PbOOC(CH_3)_2Ph}$ decompose slowly even at room temperature and rapidly with evolution of a gas on heating[69,128,129,243]. The decomposition has a radical mechanism and the reaction mixtures catalyse the polymerisation of olefins[69]. The autocatalytic decomposition of $\mathrm{Et_3PbOOBu}$-t has been noted (in hydrocarbons at 90–120°C), the rate of reaction increasing with increase of the initial concentration of the peroxide[254].

The peroxide $\mathrm{Ph_3PbOOC(CH_3)_2Ph}$ is the least stable of the compounds obtained in the $\mathrm{Ph_3MOOC(CH_3)_2Ph}$ series (M is a Group IV element)[271]. Very little benzene has been found in the autocatalytic decomposition products, since the $\mathrm{Ph_3PbO^{\cdot}}$ radicals do not decompose like the $\mathrm{Ph_3SnO^{\cdot}}$ radicals, giving rise to $\mathrm{Ph_3PbOH}$ as a result of the dehydrogenation of the solvent. The autocatalysis is due to the presence of diphenyl-lead oxide, formed as a result of the reactions of the hydroxide:

$$\mathrm{2\,Ph_3PbOH \rightarrow (Ph_3Pb)_2O + H_2O} \ ;$$
$$x\,\mathrm{(Ph_3Pb)_2O} \rightarrow x\,\mathrm{Ph_4Pb + (Ph_2PbO)}_x \ .$$

The addition of the oxide not only shortens the induction period, but also accelerates the decomposition of the peroxide owing to the formation of the less stable oxoperoxide[271]:

$$\mathrm{Ph_3PbOOC(CH_3)_2Ph + (Ph_2PbO)}_x \rightarrow \mathrm{Ph_3Pb(OPbPh_2)}_x\mathrm{OOC(CH_3)_2Ph} \ .$$

Radical and heterolytic reactions are characteristic of the peroxy-compounds of Group V elements, as for the peroxides of Group IV elements already mentioned. The homolytic decomposition of organoantimony peroxides $\mathrm{Ph_4SbOOR'}$ (R′ is a tertiary group) has been achieved under the influence of ultraviolet light[273], for example:

$$\mathrm{Ph_4SbOOBu\text{-}t \xrightarrow{h\nu} Ph_4SbO^{\cdot} + {}^{\cdot}OBu\text{-}t} \ ;$$
$$\mathrm{Ph_4SbO^{\cdot} \rightarrow Ph_3SbO + Ph^{\cdot}} \ .$$

In their interaction with the solvent (toluene and chlorobenzene) via a radical substitution mechanism, the $\mathrm{Ph^{\cdot}}$ and t-$\mathrm{BuO^{\cdot}}$ radicals give rise to benzene, a carbinol, and a mixture of isomeric methylbiphenyls or chlorobiphenyls. The decomposition of the peroxide induced by the solvent radicals has been noted in chlorobenzene as a side reaction. In chloroform, the stages involving the induced decomposition and photolysis of the peroxide at the O–O bond compete: in carbon tetrachloride, the induced decomposition is the main reaction pathway:

$$\mathrm{CCl_4 \xrightarrow{h\nu} Cl^{\cdot} + {}^{\cdot}CCl_3} \ ;$$
$$\mathrm{Ph_4SbOOR' + Cl^{\cdot} \rightarrow Ph_4SbCl + [{}^{\cdot}OOR']} \ .$$

The $\mathrm{{}^{\cdot}CCl_3}$ radicals frequently recombine and frequently interact with the peroxide:

$$\begin{tikzcd}
\mathrm{Ph_4SbOOR' + {}^{\cdot}CCl_3} \arrow[r] & \mathrm{Ph_4SbCCl_3 + [{}^{\cdot}OOR']} \arrow[dr] & \\
 & & \mathrm{Ph_4SbCl + :CCl_2} \ .
\end{tikzcd}$$

The addition of cyclohexene to $\mathrm{CHCl_3}$ or $\mathrm{CCl_4}$ lowers the contribution of the induced decomposition.

Under thermal decomposition conditions (in polar and non-polar solvents at 100°C), the peroxides $\mathrm{Ph_4SbOOR'}$ [R′ = t-Bu, $\mathrm{Ph(CH_3)_2C}$, $\mathrm{Ph_2(CH_3)C}$, or $\mathrm{Ph_3C}$] isomerise quantitatively to a non-peroxy product with migration of one phenyl group from the antimony atom to the oxygen atom[133]:

$$\mathrm{Ph_4SbOOR' \rightarrow Ph_3Sb(OPh)OR' \xrightarrow{2HCl} Ph_3SbCl_2 + PhOH + R'OH} \ .$$

The solvent is not involved in this reaction.

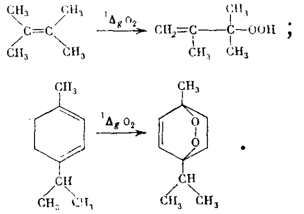
The mixed peroxides involving antimony and a Group IV element behave similarly on heating to 100°C in the solid state or in solution. The rearrangement again takes place at the antimony atom[135]:

$$Ph_4SbOOMPh_3 \xrightarrow{100^\circ} Ph_3Sb(OPh)OMPh_3 \rightarrow Ph_3SbO + Ph_3MOPh\ ;$$
$$M=Si,\ Ge\ \text{or}\ Sn.$$

Molecular decompositions are also possible for the peroxy-compounds of antimony. Bis(triphenylbromoantimony) peroxide $Ph_3(Br)SbOOSb(Br)Ph_3$ is fairly stable at room temperature in the crystalline state, but decomposes rapidly in solution. Two independent reactions then occur: molecular decomposition with elimination of oxygen and a rearrangement with simultaneous cleavage of the O–O bond and the migration of the Ph group from antimony to oxygen:

$$Ph_3(Br)SbOOSb(Br)Ph_3 \rightarrow Ph_3(Br)SbOSb(Br)Ph_3 + 0.5\ O_2\ ;$$
$$Ph_3(Br)SbOOSb(Br)Ph_3 \rightarrow Ph_2(PhO)(Br)SbOSb(Br)Ph_3\ .$$

The contribution of the decomposition of the peroxide via mechanism (31) is greater the higher the concentration of the peroxide in solution. It is of interest that the oxygen evolved is in an excited state and enters into reactions typical of singlet oxygen. In the decomposition of the peroxide in chlorobenzene with added tetramethylethylene or α-terpinene at 70°C, oxygen is hardly evolved, the product being 3-hydroperoxy-2,3-dimethylbut-1-ene or ascaridole respectively[274]:



The above brief review shows that OMPC constitute a very interesting class of compounds. However, in contrast to their formation and thermal decomposition reactions, the chemical reactions of the peroxides have been little investigated. One can state with confidence that new data will be obtained in the immediate future on the reactivities, structures, and the analysis of these compounds, and that practical applications will be suggested.

Chemistry of Extraction by Sulphoxides

Yu.E.Nikitin, Yu.I.Murinov, and A.M.Rozen

The present state of the chemistry of extraction equilibria involving sulphoxides of diverse structure—aliphatic, cyclic, and also mixtures of petroleum origin—is discussed, and results are given for the extraction of inorganic and organic acids and metal salts from aqueous solution. Comparison of the extraction properties of neutral organophosphorus compounds with those of sulphoxides shows a promising future in liquid extraction for cyclic sulphoxides, especially those of petroleum origin. The mechanism of extraction is discussed, and the dependence of extraction properties on the molecular structure of the sulphoxide is considered. A list of 153 references is included.

CONTENTS

I. INTRODUCTION

Methods for the extraction of metals that have been successfully employed in chemical nuclear technology are now beginning to be widely introduced into the industry of rare and non-ferrous metals. The chemistry of extraction has been very intensively studied in connection with the spread of extraction methods for concentrating and separating elements. The variety of approaches and methods of investigation and the great scope of work on the chemistry of extraction equilibria have ensured the solution of many extraction problems. Methods have been found for extracting almost every element.

Nevertheless, the range of extractants used in industry for the extraction of metals has hitherto been narrow (mainly tributyl phosphate, di(2-ethylhexyl) hydrogen phosphate, and amines) and inadequate for technical processes in the hydrometallurgy of rare and non-ferrous metals. The cost of an extractant is an extremely important factor in its application in the technology of such metals. In this connection there is a very pressing need to find and investigate new and powerful extractants possessing high selectivity and chemical stability while being comparatively cheap and suitable for large-scale manufacture. Another acute problem is the search for extractants to remove various organic compounds such as carboxylic and sulphonic acids and also phenols from industrial solutions and sewage.

Among promising extractants must be included sulphoxides, both individual and those of petroleum origin[1]. Resources for production of the latter are almost unlimited. Tens of thousands of tons of sulphoxides a year can be obtained at negligible cost (400–600 roubles per tonne[2]) from a single fraction of diesel fuel from Arlansk petroleum of the Bashkir ASSR (or West Surgut petroleum of Western Siberia). This is possibly why interest in sulphoxides as extractants for metal salts and acids has grown considerably during recent years among both Soviet and foreign scientists. The number of studies on the extraction properties of sulphoxides increases from one year to the next. Work on the chemistry of complexes of sulphoxides with inorganic and organic compounds has even grown considerably more.

The aim of the present Review is to systematise published data and the Reviewers' own results on the extraction equilibria of sulphoxides with metal salts and acids. Consideration is given to the properties both of individual sulphoxides of diverse structure (aliphatic, aromatic, cyclic with different ring sizes, etc.), as well as sulphoxides of petroleum origin.

II. PLACE OF SULPHOXIDES AMONG EXTRACTANTS

Sulphoxides are organic oxides containing an S=O functional group. A quasi-tetrahedral configuration is probable for the molecule, in which one of the orbitals of the tetrahedron is represented by the lone pair of electrons of the sulphur atom. The molecular structure of sulphoxides agrees well with the chemical properties and with the assignment of the vibrational frequencies of the sulphinyl bond in the infrared and Raman spectra. Sulphur and oxygen atoms are joined not only by a σ bond but obviously also by interaction of a $3d$ orbital of sulphur with a $2p$ orbital of oxygen ($2p$–$3d$ hybridisation)[3,4]. Examination of the nature of the sulphur–oxygen bonds in a review[5] led to the conclusion that the electron cloud of an S=O double bond was displaced towards the oxygen atom. Recent studies also confirm a $\sigma + \pi$ bond[6,7].

Interaction of the sulphinyl group with the hydrocarbon substituents attached to the sulphur atom is inductive and electron-accepting in character, without involving conjugation, e.g. with aromatic and unsaturated radicals[8,9]. A carbon atom forming a bond with the sulphur atom is able to act as a donor of electrons (interaction of the lone pair of electrons of the sulphur with π orbitals of the hydrocarbon radical) and also as an acceptor of electrons (interaction of the d orbital of sulphur with π electrons of the hydrocarbon radical). The intramolecular interactions in the sulphoxide molecules and the character of the sulphur–oxygen bond govern the properties of these compounds towards complex formation and extraction. Sulphoxides for which data on these processes have been published are listed in Table 1.

Structure-group analysis of petroleum sulphides[10] indicates that petroleum sulphoxides are mixtures of

Table 1. Properties of most thoroughly studied sulphoxides in complex formation and extraction*.

Sulphoxide	Abbrevn.	Formula	M.p., °C	n_D^{20}	Sulphinyl sulphur, mass %	Ref.

*Different authors have published different melting points, molecular refractions, and other physicochemical constants for sulphoxides. More complete characterisation of the purity of the product would evidently require an indication of the concentration of sulphinyl sulphur determined by potentiometric titration[152].

mono-, bi-, and tri-cyclic thiolans mainly of saturated structure. In order to obtain petroleum sulphoxides sparingly soluble in water (and therefore suitable for extraction) use is made of concentrates of petroleum sulphides or directly distilled fractions of high-sulphur petroleums boiling over the range 260–360°C.[2] The petroleum sulphides are oxidised with hydrogen peroxide[11,12]. A concentrate of petroleum sulphides can be obtained in various ways[13], but preferably by extraction with sulphuric acid[14]. The molecular structure remains almost unchanged when petroleum sulphides are oxidised to sulphoxides, so that the structure-group analysis of the sulphoxides is similar to that of the petroleum sulphides.

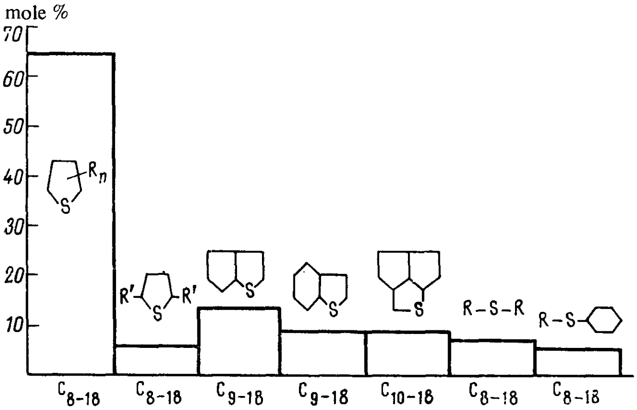

Figure 1. Relative contents of individual structural groups of sulphides and numbers of carbon atoms in molecules of concentrate of sulphides (190–360°C) from Arlansk petroleum.

Fig. 1 illustrates the composition of the most thoroughly studied sulphide concentrate of Arlansk petroleum (190–360°C).[10] Monocyclic and bicyclic thiolans evidently predominate. The composition of the petroleum sulphides is similar for the kerosene–gas-oil fractions of Western Surgutsk[15] and Romashkinsk[16] petroleums. The sulphides present in the kerosene–gas-oil fractions of petroleums confined to Devonian, Carboniferous, and Lower Cretaceous sandstones probably have similar structure-group analyses[17]. It follows from the structure-group composition of petroleum sulphides that the extraction properties of the sulphoxides can be compared with those of individual cyclic sulphides, which serve as model for the petroleum sulphoxides.

Metal salts and acids are usually dissociated and strongly hydrated in aqueous solution. In order to transfer them to an organic phase with a high partition coefficient on extraction it is therefore necessary to use a reagent having a strong tendency to complex formation, sufficient to overcome the bonds between the extractable compounds and water. Hence it is clear that the chemistry of extraction equilibria is closely related to that of complex formation.

The possible information by sulphoxides of complexes with metal salts and acids has been known for a long time. The study, carried out in 1907, of the interaction between iron(III) chloride and a sulphoxide led to isolation of an equimolecular complex[18]. The interaction of sulphoxides with gaseous hydrogen chloride was discovered in 1916.[19] Later the protonation of dimethyl sulphoxide in sulphuric acid was investigated and the basicity estimated[20], which was followed[21] by the preparation of complexes of sulphoxides with perchloric acid. Complex formation by sulphoxides in aqueous and alcoholic media was studied intensively on dimethyl sulphoxide at the beginning of the 1960s.[22–27] The first communications on the possibility of using sulphoxides as extractants date from this time.

Nikolaev et al. formulated general requirements which should be satisfied by extractants, and noted the need to study the class of extractants R_nElO, among which sulphoxides were mentioned[28,29]. The possibility of using sulphoxides as extractants was suggested also by Cotton and Francis[30] in a study of the ligand properties of dimethyl sulphoxide.

The first studies of the extraction properties of sulphoxides were made by Korpak[31–34], but he gave no quantitative interpretation of the extraction equilibria of sulphoxides with metal salts and acids. Nikolaev and his coworkers described the mechanism of extraction by sulphoxides[35–37]. Quantitative characteristics of extraction were obtained by the Reviewers[38–40], in the first investigation of the extractive properties of cyclic sulphoxides, which were found to model those of petroleum sulphoxides[41,42]. Papers giving quantitative characteristics of the mechanism of extraction by sulphoxides appeared also abroad[43–45].

Table 2. Basicity of extractants.

Extractant	p*K*	Ref.	Extractant	p*K*	Ref.
Diethyl ether	0.98	49	Di-isopentyl methylphosphonate	2.74	51
Oxolan	1.26	49	Trimethylphosphine oxide	3.49	49
Acetone	1.18	49	Dimethyl sulphoxide	2.53	49
Butan-2-one	1.18	49	Diphenyl sulphoxide	2.03	51
Cyclohexanone	1.30	49	Dihexyl sulphoxide	2.67	51
Triphenyl phosphate	1.73	49	Dicyclohexyl sulphoxide	2.77	51
Tributyl phosphate	2.56	51	2-Heptylthiolan 1-oxide	2.74	51

Before examining actual experimental results on the chemistry of extraction by sulphoxides, we shall discuss the position occupied by these compounds among oxygen-containing extractants (organic oxides) of type R_nXO. The latter form complexes with metal salts usually by an electronic mechanism of donor–acceptor interaction. The difference in extractive power (and in complex formation) among compounds R_nXO will be determined by the electron density on the oxygen atom†, as well as by the geometrical parameters of the molecules, which largely determine the entropy contribution.

Accurate determination (calculation) of electron density in polyatomic molecules R_nXO (where X = P, S, N, As, Se, etc.) is not yet possible at the present state of development of quantum chemistry, and the best comparative measure of the donor power of oxygen is the basicity of the extractant. This represents the free energy of protonation of the P=O, S=O, N=O, etc. groups[49]. Correlation of basicity with extractive power clearly establishes the position of sulphoxides in the sequence of organic oxides[50,51]. Table 2 indicates that they occur between ketones and phosphine oxides with respect to basicity; they occupy an intermediate position also with respect to extractive power. One reason for the enhanced reactivity of the sulphinyl in comparison with the carbonyl group is that the sulphur atom is larger than the carbon atom ($r_S = 1.04$ and $r_C = 0.77$ Å), and with a consequent diminished energy of bonding with oxygen ($E \propto e^{-m}$, where $m \geqslant 1$) and a smaller force constant k_e(SO).

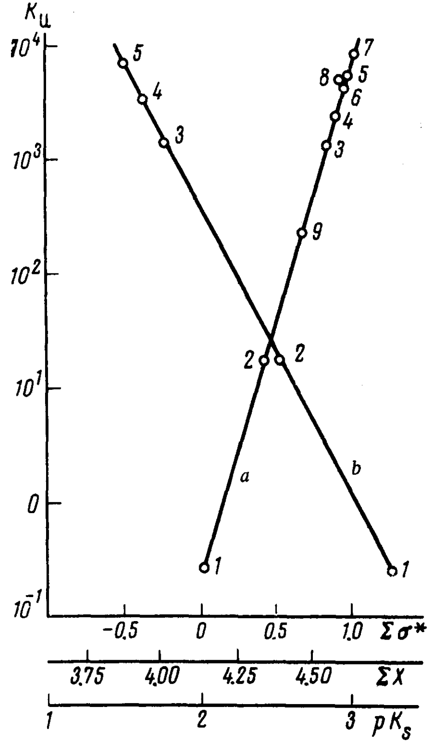

Figure 2. Dependence of extraction constants $\bar{K}_U$ for uranyl nitrate on: *A*) basicity pK_S; *B*) sum of electronegativities ΣX or Taft constants $\Sigma\sigma^*$ of: 1) DPhSO; 2) HPhSO; 3) DHSO; 4) [?]; 5) ChHSO; 6) HTlO; 7) PThO; 8) DPMP; 9) TBP.

The correlation between the basicity of sulphoxides and their extractive power for uranyl nitrate is well described by the equation[51]

$$\lg\bar{K}_U = -11.88 + 5.6\,pK_s \tag{1}$$

which is clearly confirmed by Fig. 2. On passing from dialkyl to cyclic sulphoxides both the basicity of the oxygen atom and the extractive power increase. Values of $\bar{K}_U$ for tributyl phosphate (TBP) and di-isopentyl methylphosphonate (DPMP) fit satisfactorily into the general

---

† The coordination of metals to the sulphinyl oxygen atom has been established from the infrared spectra of the complexes isolated in numerous investigations. An exception is palladium, which is able to coordinate both with sulphur and with oxygen[46–48].

relationship. Dialkyl sulphoxides considerably surpass tributyl phosphate in extractive power, but are somewhat inferior to phosphonates, whereas cyclic sulphoxides are rather better than phosphonates. Cyclic sulphoxides are superior to aliphatic sulphoxides, of course, also in their complexing properties[52]. It must be concluded from the comparison of the extractive power of aliphatic sulphoxides that petroleum sulphoxides (PetrSO), being mixtures of cyclic sulphoxides, will surpass aliphatic sulphoxides and tributyl phosphate in extractive power. This view is supported by many experimental results[41,42,53,54].

The influence of structure is illustrated by Fig. 2, which shows good correlation of extractive power with basicity within a class of sulphoxides, but for open-chain sulphoxides the extractive power may be predicted, as for other neutral extractants[55], from the electronegativities ΣX or the inductive constants σ^* of substituents adjacent to the sulphur atom[51]:

$$\lg \bar{K}_U = 2.34 - 2.54 \sum \sigma^* = 3.04 - 5.23 \sum (X - 2). \quad (2)$$

Equations (1) and (2) give rise to a relation between the basicity of sulphoxides and the electronegativities of substituents:

$$pK_s = 2.54 - 0.47 \sum \sigma^* = 2.67 - 0.94 \sum (X - 2). \quad (3)$$

A similar relation is obtained from a consideration of the extractive power of sulphoxides for nitric acid[56]:

$$\lg \bar{K}_H = -0.64 - 0.92 \Sigma\sigma^*. \quad (4)$$

The extraction properties of sulphoxides are more sensitive than those of neutral organophosphorus compounds to change in the electronegativity of a substituent. Thus replacing one aliphatic group ($X = 2.0$) by phenyl ($X = 2.54$) in the latter type of compound diminishes the extraction of uranium by a factor of 17, but in sulphoxides by a factor of 40.

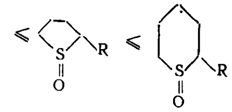
Table 3.

Compound	ν(SO), cm^{-1}	Compound	ν(PO), cm^{-1}
Dimethyl sulphoxide	1069	Tributyl phosphate	1274
Dibenzyl sulphoxide	1056	Triphenyl phosphate	1306
Benzyl phenyl sulphoxide	1054	Tributylphosphine oxide	1160
Diphenyl sulphoxide	1052	Triphenylphosphine oxide	1195

Another characteristic distinction is that extractive power cannot be predicted from the infrared spectra of sulphoxides, unlike those of neutral organophosphorus compounds. The introduction of aromatic substituents leaves the sulphur–oxygen stretching frequency almost unchanged[5,57–59], whereas the phosphorus–oxygen stretching frequency is raised[60] [Table 3]. Nor has the expected fall in absorption frequency ν(SO) been observed on passing to cyclic sulphoxides[59]. The improvement in extractive power on passing from aliphatic to cyclic sulphoxides is due not to an increase in energy of bonding of the resulting complexes but to the entropy factor[40].

From available data it may be concluded that on complex formation sulphoxides are more sensitive to molecular geometry than are neutral organophosphorus compounds. We note in conclusion that sulphoxides can be included in the sequence of neutral organic extractants of increasing extractive power:

$$R_2O < R_2CO < (RO)_3PO < R_2SO < (RO)_2R'PO \leqslant PetrSO \leqslant$$



$< R_3PO < R_3NO.$

III. EXTRACTION OF WATER AND INORGANIC ACIDS

Extraction of Water

Sulphoxides containing >10 carbon atoms are only sparingly soluble in water (0.1–4 g litre^{-1}),[44,61] but cyclic sulphoxides are rather more soluble. The use of salting-out agents during extraction lowers considerably the aqueous solubility of sulphoxides. Solubility is strongly influenced by the nature of the diluent. Thus it decreases by a factor of 200 in the sequence nonane–xylene–chloroform, and e.g. for petroleum sulphoxides in chloroform is 0.02 g litre^{-1}. The melting-point curves for aqueous dibutyl and di-isobutyl sulphoxides exhibit anomalies, but solid hydrates are not detected[62], which indicates weak interaction between the sulphoxides and water.

The extraction of water by sulphoxides can be represented by complex formation according to the equation

$$H_2O + qS \rightleftarrows H_2O \cdot qS, \quad (5)$$

where S is the sulphoxide and q the solvation number. When the activity of water is high ($a_{H_2O} > 0.6$) a monosolvate ($q = 1$) is formed[63]; with $a_{H_2O} > 0.4$ a disolvate appears[58,63]. The decrease in the solubility of water accompanying the decrease in its activity is slower than would be expected from the relation $[H_2O]_{org} \propto a_{H_2O}$. The influence of the diluent on the extraction of water by sulphoxides is analogous to that observed with tributyl phosphate[64]: the effective extraction constant of water K_{H_2O} diminishes in the sequence nonane–benzene–chloroform. The infrared spectra of sulphoxides with water exhibit no significant shift in the absorption frequency of the sulphinyl group, but a slight frequency shift in the symmetrical hydroxyl band (3640 cm^{-1}).[58] All this is evidence of comparatively weak interaction of the sulphoxide with water.

Extraction of Nitric Acid

The heightened interest in the extraction of nitric acid by sulphoxides[33,40] is due to the possible use of the latter as extractants of rare and radioactive elements from nitrate media. A sulphoxide will extract the acid by a solvation mechanism as an unhydrated monosolvate[65–72]:

$$H^+ + NO_3^{2-} + S \rightleftarrows HNO_3 \cdot S. \quad (6)$$

The extractive power for nitric acid diminishes with increase in size of the hydrocarbon group in the dialkyl sulphoxide[45]. That of cyclic sulphoxides[65] is greater than with dialkyl sulphoxides (K_H is ~1 and 0.78 respectively for 2-heptylthiolan 1-oxide and dipentyl sulphoxide, and the latter surpass tributyl phosphate and di-isopentyl methylphosphonate (0.2 and 0.33). The extraction of nitric acid is significantly influenced by the type of diluent of the sulphoxides. Thus K_H has the respective values 1.44 and 1.25 when alkanes[56] and aromatic hydrocarbons are used, whereas the values obtained with tetrachloromethane and chloroform are 0.70 and 0.26.[65] On extraction from concentrated nitric acid the acid concentration in the organic phase exceeds the stoichiometric value[69]. Direct calorimetric measurements of the interaction of nitric acid with various sulphoxides[73] show that the enthalpy of interaction of the second acid molecule with the monosolvate $HNO_3.S$ is considerably smaller than that of addition of the first acid molecule to the sulphoxide, and amounts to ~9 kcal mole^{-1}. The second molecule is probably attached to the anion of the acid in the monosolvate, as with tributyl phosphate. If the enthalpy of complex formation between nitric acid and sulphoxides depends on the groups attached to the sulphur atom, and for diheptyl, benzyl decyl, and diphenyl sulphoxides ΔH decreases from 30 to 28.7 and 24.8 kcal mole^{-1}.

The variation in entropy in this sequence does not exceed 0.8 e.u. The effective extraction constant of nitric acid by sulphoxides correlates with the enthalpy of extraction and is described by the equation[73]

$$\lg \bar{K}_H = -0.079 - 0.866\,\Delta H_{extr}\,. \tag{7}$$

Nevertheless, the extraction constant is almost independent of temperature[65], which indicates that entropy factors are decisive. The relatively large displacement of the sulphinyl absorption band in the infrared spectrum of the solvate of nitric acid to lower frequencies ($\Delta\nu$(SO) = 60 cm^{-1}) indicates a quite stable bond between the sulphinyl oxygen atom and the proton of the acid.

Hydrochloric Acid

In contrast to nitric acid, hydrochloric acid is extracted by a mechanism involving both hydration and solvation[74]:

$$H^+ + Cl^- + h\,H_2O + q\,S \rightleftarrows HCl \cdot h\,H_2O \cdot q\,S. \tag{8}$$

Solvation numbers q determined by various authors[33,63,75,76] vary from 1 to 3, which indicates the presence of mono-, di-, and tri-solvates in the organic phase. The hydration number h also varies, from 3 to 1: i.e. $q + h = 4$, in good agreement with the coordination number 4 generally accepted for the oxonium cation.

Extraction by sulphoxides becomes appreciable only when the concentration of the acid in the aqueous phase exceeds 4 M; the extraction constants are small[45]. When the concentration of the aqueous acid is 6–7 M, the extraction isotherm passes through a maximum (with sulphoxides containing <11 carbon atoms), after which it drops sharply owing to rapid increase in the solubility of the complex in the aqueous phase[75]. The increase in solubility is due to formation of a trihydrate of the monosolvate $HCl.3H_2O.S$. With 10 M hydrochloric acid in the aqueous phase about 50% of sulphoxides enter from the organic phase[75]. On prolonged contact (5–6 h) with the concentrated acid, extensive reaction takes place with the sulphoxides[70,77], as indicated by disappearance of the sulphinyl band from the infrared spectra of the complexes and also by direct chemical analysis for the sulphoxide content.

Hydrofluoric, Hydriodic, and Hydrobromic Acids

Hardly any work has been done on the mechanism of the extraction of these acids by sulphoxides. Monosolvates are formed[70,78,79], which may be hydrated. Hydrobromic and hydriodic acids react chemically with sulphoxides as the acid concentration of the aqueous phase is increased[70]. The hydrohalic acids can be arranged in the sequence

$$HI > HBr > HCl > H_2F_2$$

of diminishing extractability by sulphoxides. The sequence may be connected with the type of hydration of the acid anion.

Extraction of Sulphuric Acid

The mechanism of the extraction of sulphuric acid by sulphoxides involves hydration and solvation[80]:

$$H^+ + HSO_4^- + h\,H_2O + q\,S = H_2SO_4 \cdot h\,H_2O \cdot q\,S. \tag{9}$$

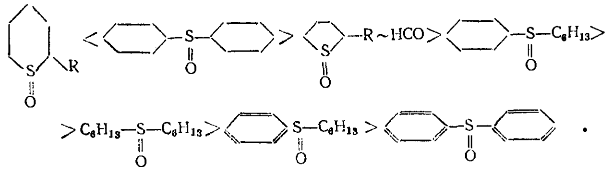
As in the extraction of hydrochloric acid, the solvation and hydration numbers depend on the concentration of acid in aqueous and organic phases. With an aqueous phase containing initially up to 3 M sulphuric acid the latter is present in the organic phase mainly as a dihydrated disolvate $H_2SO_4.2H_2O.2S$; but a trihydrated monosolvate $H_2SO_4.3H_2O.S$ predominates in the organic phase when the acid concentration of the aqueous phase is increased to 5 M, and this complex separates as a third phase; on further increase in the acid concentration it passes into the aqueous phase[80,81]. The displacement of the sulphinyl absorption frequency in the infrared spectra of complexes of sulphuric acid with sulphoxides is about −170 cm^{-1}, which may indicate strong protonation of the sulphinyl oxygen and perhaps transfer of a proton from the acid to this oxygen[45,81] (in concentrated sulphuric acid).

Extraction of Other Acids

Sulphoxides of diverse structure are good extractants for per-rhenic perchloric and boric acids as respectively a disolvate[65], a monosolvate[45,58], and a trisolvate[81]. Sulphoxides—especially those from petroleum—are of practical interest for the extraction of phosphoric acid from sulphuric and nitric acid media, the isolation of boron as boric acid from magnesium chloride solutions, and also the extraction of various heteropolyacids, e.g. molybdophosphoric acid[82].

IV. EXTRACTION OF ORGANIC ACIDS

During recent years several publications have appeared on the use of sulphoxides as extractants for organic acids[83–88]. Monocarboxylic acids are extracted by a solvation mechanism: i.e. unhydrated monosolvates RCOOH.S are formed[81]. The infrared spectra of the solvates show a ν(SO) absorption frequency shift of 20–40 cm^{-1} to longer wavelengths, which indicates formation of a hydrogen bond between the acid proton and the sulphinyl oxygen[89]. As the hydrocarbon group becomes larger, the extraction of the monocarboxylic acid increases, owing to its diminished hydrophilicity and transolvation energy. Extraction of the halogenated acids (such as chloroacetic) is described by Eqn. (6) and also involves formation of unhydrated monosolvates[84,90]. The salting-out effect of cations in the extraction of halogenated carboxylic acids increases with decrease in the ionic radius of the cation and increase in its charge[81]. The heat of extraction of chloroacetic acid by a sulphoxide is ~4 kcal mole^{-1}. The extractive power of sulphoxides for organic acids decreases in the sequence of diminishing basicity of the sulphoxide:



Sulphoxides can be used also to separate organic acids. Thus the partition coefficient of chloroacetic and acetic acids after a single stage of extraction is 20. Most dicarboxylated acids are extracted as anhydrous disolvates—e.g. $(COOH)_2.2S$, $CH_2(COOH)_2.2S$, etc.—produced by hydrogen bonding. Exceptions are phthalic and maleic acids, which form monosolvates on extraction with sulphoxides. The mechanism of the extraction of keto-acids (pyruvic, oxoglutaric) is the same as in the extraction of mono- and di-carboxylic acids. However, the extraction of hydroxy-acids by sulphoxides involves formation of hydrated solvates[86], and the partition coefficient D is smaller than with monocarboxylic acids.

The extraction of organic sulphonic acids by sulphoxides has features in common with that of sulphuric acid: the mechanism of hydration and solvation gives complexes soluble in both aqueous and organic phases, and the sum of hydration and solvation numbers is 4. Sulphuric acid has a strong salting-out effect on the extraction of sulphonic acids. The shift of 80–100 cm^{-1} in the absorption band of the sulphinyl group in the infrared spectra of the complexes of sulphonic acids extracted by sulphoxides indicates stronger protonation of the sulphinyl oxygen by sulphonic acids than by mono- and di-carboxylic acids[81].

Sulphoxides are able to form complexes also with organophosphorus acids. Complex-formation constants $\widetilde{K}$ for di-(2-ethylhexyl) hydrogen phosphate with dihexyl sulphoxide and with 2-pentylthian 1-oxide are larger[91] than with tributyl phosphate (respectively 1.1, 1.8, and 0.65).

Thus the extraction of organic acids by sulphoxides exhibits several regularities. Extraction is greater for monocarboxylic than for dicarboxylic acids, and greater for the latter than for tricarboxylic acids containing the same number of carbon atoms. With increase in molecular mass (i.e. size of the hydrocarbon portion) in each series the introduction of halogens—chlorine, bromine, iodine—leads to an increase in the extraction constants, whereas carboxy-, hydroxy-, and sulpho-groups lower the extraction constant. Thus the extraction equilibrium constants for acids with sulphoxides are determined by the energy of transolvation of the acid on passing from aqueous to organic phases. Extraction entails formation of a hydrogen bond involving the sulphinyl oxygen atom. The extractive power of petroleum sulphoxides exceeds those of tributyl phosphate and phosphonates.

V. EXTRACTION OF METALS

1. Extraction of Metals from Nitrate Media

It is now recognised that sulphoxides are effective extractants for salts of rare metals[92-99]. In all such cases the mechanism remains almost unchanged on passing from tributyl phosphate and its analogues to sulphoxides, when the metal cation is directly coordinated to the sulphinyl oxygen[37].

EXTRACTION OF URANYL NITRATE

As with extraction by tributyl phosphate, sulphoxides extract uranyl nitrate into the organic phase as a disolvate[34,100-105] independently of the type of diluent used:

$$UO_2^{2+} + 2NO_3^- + 2S = UO_2(NO_3)_2 \cdot 2S. \tag{10}$$

In conformity with this equation the extraction constant can be found from the formulae

$$K_U = \frac{y_U \cdot dil}{x_U(2x_H + x_U)^2 (s_0 - 2y_U - y_H)^2 \gamma_\pm^3} = \widetilde{K}_U \cdot \frac{dil}{\gamma_\pm^3} = \overline{K} \cdot dil, \tag{11}$$

where K_U, $\widetilde{K}_U$, and $\overline{K}$ are thermodynamic, concentration, and effective extraction constants, x_U and y_U are the equilibrium concentrations of uranyl nitrate in aqueous and organic phases, x_H and y_H are the equilibrium concentrations of nitric acid (or x_H is the concentration of salting-out agent) in these phases, *dil* is a parameter representing the ratio of the activity coefficients of extracted complex and extractant in the organic phase, $\gamma_\pm$ the mean activity coefficient of uranyl nitrate, and s_0 the initial concentration of the extractant.

With increase in the concentration of nitric acid in the aqueous phase the extraction of uranyl nitrate first increases, passes through a maximum, and then falls[43,44], this decrease being due to competition for the free extractant. At a fixed ionic strength the extraction constant for uranyl nitrate and sulphoxides is almost unaffected by the hydrogen-ion concentration[44,104]. Nor is the extraction constant $\overline{K}$ appreciably affected by the length of the hydrocarbon chain in dialkyl sulphoxides from dipentyl to didecyl. Yet increase in the electronegativity of the groups attached to the sulphur atom lowers the extractive power (Fig. 2), which increases appreciably on passing from dialkyl to cyclic sulphoxides[39,105]. Among cyclic sulphoxides that have yet been studied 2-alkylthian 1-oxides possess the greatest extractive power. The properties of the extracted complexes of cyclic sulphoxides with uranyl nitrate change when the alkyl substituent is moved from the α to the β or γ position relative to the sulphur atom. This is apparent in stronger hydration of the complexes and a considerable diminution in their solubility in organic solvents[76]. When an α-alkyl group in thiolan 1-oxide is replaced by cyclohexylmethyl, the solvation number changes, and uranyl nitrate is extracted as a monosolvate $UO_2(NC_3)_2.S$, apparently owing to steric factors[39]. Complexes of uranyl nitrate with di-isopentyl sulphoxide also show a limited solubility in organic diluents[106], which may be due to polymerisation or to different lattice energies of complexes formed with sulphoxides of differing structure. The variation of the properties of the complexes and especially their solubility require separate investigation.

The extractive power of sulphoxides diminishes considerably with rise in temperature. Heats of extraction calculated from the dependence of $\overline{K}$ on $1/T$ remain almost unchanged on passing from dialkyl to cyclic sulphoxides. As mentioned above, the Reviewers attribute the enhanced extractive power of cyclic sulphoxides to entropy factors[40].

The effect of the solvents for the sulphoxides is well described by the parameter *dil* in Eqn. (11), as in the extraction of uranyl nitrate by neutral organophosphorus compounds. The extractive properties of sulphoxides deteriorate in the sequence heptane–benzene–tetrachloromethane–chloroform. The reason for the impairment in the case of chloroform is its strong solvating action resulting from strong hydrogen bonding with sulphoxides[107].

EXTRACTION OF OTHER METALS

Zirconium and hafnium nitrates are extracted by sulphoxides as disolvates[108], and rare-earth metals (lanthanides) as trisolvates, perhaps partly hydrated in the organic phase[109]. Thorium nitrate is able to form with sulphoxides two solvates—a trisolvate in the presence of a large excess of free extractant[110], and a disolvate in other cases[108].

Gold(III), mercury, silver, and palladium(II) also are extracted by sulphoxides from nitric-acid solutions[36,37]. In contrast to other complexes, however, the last may involve coordination of the sulphinyl group at both sulphur and oxygen atoms, as is indicated by displacement of the sulphinyl absorption band to higher frequencies in the infrared spectrum[48].

Since sulphoxides surpass tributyl phosphate in extractive power, they extract several hydrolysed species of metal salts from nitrate and weakly acid media[111], according to the equation

$$M^+ + (z-m)\,A^- + (h+m)\,H_2O + q\,S \rightleftarrows M(OH)_mA_{z-m}\cdot H_2O\cdot q\,S + m\,H^+. \qquad (12)$$

Hydrolysed species of bismuth(III), iron(III), copper, cobalt, and nickel are well extracted from nitrate media by sulphoxides, and to a less extent those of zirconium and hafnium. The solvation numbers are 3 for copper and bismuth[112] and 4 for iron[111]. In the extracted complexes the metal is coordinated by the sulphinyl oxygen atom (except in the case of bismuth[112]) through a water molecule, as is indicated by the small shift (10–15 cm^{-1}) in the absorption frequency ν(SO).

The action of sulphoxides on many elements has been studied by reverse-phase paper chromatography with the sulphoxides as stationary phase and nitric acid as mobile phase[113–115]. The low R_f values for many elements indicate the possibility of effective extraction of several metals by sulphoxides, as well as their use in the analytical separation of metals in industry. Good separation of the metal pairs zirconium–hafnium, uranium–thorium, zinc–cadmium, iron–copper, etc. can be effected by means of sulphoxides.

2. Extraction of Metals from Chloride Media

By analogy with tributyl phosphate sulphoxides may be able to extract metal chlorides by two mechanisms[116]—as coordinatively solvated compounds (solvates)

$$M^{z+} + z\,A^- + q\,S \rightleftarrows MA_z\cdot q\,S \qquad (13)$$

and as complex anions present in ionic aggregates (as metal-complex acids)

$$M^{z+} + m\,H^+ + (z+m)\,A^- + q\,S \rightleftarrows H_mMA_{z+m}\cdot q\,S. \qquad (14)$$

Extraction by the second mechanism often involves the participation of water, i.e. hydration and solvation.

By the first mechanism (at hydrochloric acid concentrations below 5 M) sulphoxides extract as disolvates the chlorides of palladium[117–121], zinc[63], tellurium[108,122,123], thorium[124,125], uranium[34], zirconoium[126,127], hafnium[126], scandium[128], and perhaps lanthanides; and as monosolvates mercury[129] and silver[130] chlorides. All other metals, as well as most of the above with increase in the concentration of hydrochloric acid, are extracted as metal-complex acids by the second mechanism (14).

During extraction by the first mechanism the metals are coordinated directly to the sulphinyl oxygen (palladium is coordinated through the sulphur atom). In the second mechanism extraction is due to interaction of the proton of the metal-containing acid with the sulphinyl oxygen atom. As the concentration of hydrochloric acid in the aqueous phase is increased, the extraction of metals by sulphoxides passes in most cases through a maximum, independently of the mechanism of extraction. The decrease in partition coefficients with increase in the concentration of hydrochloric acid is due both to its coextraction and to formation of highly charged anions of the metal-containing acids, which are extracted less strongly than are anions having a lower charge or neutral[117] species.

Decrease in the extraction of metals is due to the enhanced solubility of the complexes they form with sulphoxides in concentrated hydrochloric acid. Ruthenium(II) chloride behaves rather unusually in comparison with other salts. With increase in the concentration of hydrochloric acid its extraction by sulphoxides diminishes, passes through a minimum (at 2–3 M HCl), and increases afresh. The descending part can be explained by poor extractability of the anionic complexes.

The composition of the complexes formed during extraction by the first mechanism has been established most reliably—$TeCl_4.2S$,[122] $PdCl_2.2S$,[117–121] $UO_2Cl_2.2S$,[34] $ZrCl_4.2S$,[127] $HfCl_4.2S$,[126] $MoO_2Cl_2.2S$,[131] $WO_2Cl_2.2S$,[131] and $SeCl_3.2S$.[128]

In the analysis of extraction equilibria from aqueous hydrochloric acid the most difficult task is to establish the composition of the complexes formed by mechanism (14). The difficulty is to determine the concentration of the free extractant, since hydrochloric acid may be extracted by sulphoxides as three solvates differing in degree of hydration. It is difficult also to allow for the possible extraction of metal-containing acids differing in the composition of the anionic portion (e.g. $CuCl_3^-$, $CuCl_4^{2-}$, etc.). Direct elementary analysis of the complexes obtained by saturation does not always give an unambiguous answer, since higher solvates may also be present in solution.

Knowing the composition of the complexes extracted, confirmed by infrared, Raman, and proton magnetic resonance spectral data, we can confidently accept that the metal-containing acids—$HGaCl_4\cdot H_2O.3S$, $H_2CuCl_4\cdot 3H_2O.2S$, $HFeCl_4.2H_2O.2S$, $HInCl_4.2H_2O.2S$, and $HInCl_4.H_2O.S$ (on saturation)—are extracted by a hydration–solvation mechanism[63]. Thallium is extracted as the acid $HTlCl_4.2S$ by a solvation mechanism.

From the results of reverse-phase chromatography (with hydrochloric acid as eluant) and the low R_f values for most elements[113,114] it may be concluded that sulphoxides will find application for the extraction of noble metals and certain non-ferrous and rare metals. Large separation factors have been obtained by the use of sulphoxides for the elements selenium–tellurium, molybdenum–tungsten[131], iron–cobalt–nickel[132], tantalum–niobium[133], palladium–rhodium, platinum, etc.

Summarising the results for the extraction of metals from aqueous hydrochloric acid by sulphoxides, we must emphasise that extraction equilibria for this system are still difficult to describe quantitatively—in the sense of interpreting the mechanism of extraction and the formation of extractable complexes—because the aqueous phase may contain several complexes of the same metal, differing in composition and extracted by different mechanisms.

3. Extraction of Metals from Mixed Media and by a Mixture of Extractants

Zirconium, hafnium, uranium[76,134], and thorium are well extracted by sulphoxides from mixed aqueous hydrochloric and nitric acids. As when tributyl phosphate is used, the partition coefficient for zirconium and hafnium is greater from the mixed solutions than from either acid separately[38]. This effect can be explained by enhanced extraction of a mixed complex of the type $ZrCl_n(NO_3)_{4-n}.2S$.[135]

From aqueous sulphuric acid containing a fluoride tantalum and niobium are effectively extracted by sulphoxides[53,136–147] as fluorotantalic and fluoroniobic acids. In most cases these metals form on extraction monohydrated trisolvates of the types $HTaF_6.H_2O.3S$ and $H_2NbOF_5.$ $.H_2O.3S$. Concentration extraction constants of petroleum sulphoxides for tantalum and niobium are respectively 10 and 2.5. These sulphoxides can be used to separate the metals by extraction[53].

Tellurium is extracted as a chloride complex from aqueous sulphuric acid containing a chloride, but the mechanism of extraction has not yet been studied in detail.

Sulphoxides in synergistic mixtures. Comparison of the general laws of the extraction of metals by sulphoxides and by neutral organophosphorus compounds suggests that sulphoxides should have an enhancing effect as donor additions to synergistic mixtures of extractants. Indeed, constants for addition of the first and second molecules of dibutyl sulphoxide to europium tris(2-thenoyltrifluoroacetone) [$Eu(TTA)_3$] [148] are closely similar to or slightly higher than those for tributyl phosphate. In the extraction of uranium by an equimolecular mixture of a sulphoxide and bis-2-ethylhexyl hydrogen phosphate[149] three types of complex—$UO_2A_2.2HA$, $UC_2A_2.2S$, and $UO_2A_2.HA.S$, where A is the anion of the acid HA, and S is the sulphoxide—are present in the organic phase. The main reaction responsible for synergism in the extraction[150,151] can be regarded as

$$UO_2^{2+} + H_2A_2 + 2S \rightleftarrows UO_2A_2 \cdot 2S + 2H^+. \qquad (15)$$

The synergistic effect increases with the basicity of the sulphoxide. Partition coefficients of the metal are considerably higher with sulphoxides than when tributyl phosphate is used as the synergistic additive.

It follows from the above discussion that sulphoxides resemble organophosphorus compounds in the mechanism of complex formation during extraction, but differ in a greater tendency to polymerisation (association) in the organic phase. For example, the extraction constants for uranyl nitrate increase with the metal concentration, which indicates at least dimerisation. This difference is apparently due to the highly polar character of sulphoxide molecules (dipole moment ~4, and for tributyl phosphate ~3) and diminished steric hindrance to association (two groups present instead of the three in neutral organophosphorus compounds). The extracted sulphoxide complexes usually dissolve preferentially in organic solvents of high dielectric constant, are less soluble in aromatic solvents, and exhibit limited solubility in alkanes. It is advisable to use aromatic and chlorinated solvents with sulphoxides as extractants for acids and metal salts.

Study of the chemistry of extraction has shown that sulphoxides—especially those from petroleum—are promising extractants for many radioactive, rare, trace, and non-ferrous metals, as well as inorganic and organic acids. Cyclic sulphoxides (thiolan and thian homologues) possess the strongest complexing power. Since research on the extraction and coordination chemistry of these compounds has only just begun, valuable new data may be expected on the properties of cyclic sulphoxides.

Complexes of Organosilicon Compounds Containing a Siloxane Bond

M.G.Voronkov, V.P.Mileshkevich, and Yu.A.Yuzhelevskii

The ability of various classes of organosilicon compounds containing a siloxane (Si-O) bond to form intra- and inter-molecular complexes, by hydrogen bonding and otherwise, is surveyed, and several physicochemical properties of the complexes are discussed. A list of 264 references is included.

CONTENTS

I. INTRODUCTION

Compounds containing a siloxane bond occupy an important place in the chemistry of silicon. Several monographs and reviews[1-3] have dealt with the physical and chemical properties of these compounds, as well as aspects of their practical use. Nevertheless, no survey has yet appeared of the tendency of various classes of such organosilicon compounds to form complexes, with a discussion of their properties. A probable reason is that most studies of complexes of oxygen-containing silicon compounds have appeared during the past decade, although the first compounds of this type were obtained as early as the beginning of the present century[4-6]. Not only are complexes of organosilicon compounds containing a siloxane bond of obvious theoretical interest but attention has recently been paid to them as products of practical promise. Several of them are specific catalysts[7], biologically active compounds[8,9], or intermediates in the production of siloxane oligomers and polymers[10-12].

In contrast to a carbonyl bond, both atoms forming a siloxane bond can act as centres of complex formation. The presence on the silicon atom of five vacant $3d$ orbitals is responsible for the possible existence of five- and six-coordinated silicon compounds. Of the five d orbitals only the d_γ orbitals ($3d_{z^2}$ and $3d_{x^2-y^2}$) are used for the formation of σ bonds, probably for steric reasons. In five-coordinated silicon compounds, which have a trigonal bypyramid structure, p orbitals of other atoms are bonded with the d_{z^2} orbital of the silicon atom (hybridisation of the latter sp^3d). In six-coordinated complexes, with an octahedral structure, the silicon atom has sp^3d^2-hybridised orbitals[13,14].

Besides σ bonding, the d orbitals of the silicon atom (d_e orbitals) can be used to form $p_\pi{-}d_\pi$ bonds with π systems or with atoms having unshared p electrons (halogens, oxygen, nitrogen, etc.) The latter type of bonding is very characteristic of the siloxane bond itself[2], but this does not prevent several compounds containing this bond from forming intra- and inter-molecular complexes by additional $p_\pi - d_\pi$ interaction, as will be shown below.

The oxygen atom acts as another centre of complex formation by the siloxane bond. Owing to $p_\pi - d_\pi$ interaction with the adjacent silicon atom the basicity of a siloxane oxygen atom is usually weak. The degree of $p_\pi - d_\pi$ interaction depends significantly on the structure of the molecule containing the siloxane bond. In the series of compounds CH_3OCH_3, SiH_3OCH_3, SiH_3OSiH_3, for example, the El–O–El′ angle (El, El′ = C, Si) is respectively 111.43°, 120.6°, and 144°, so that the hybridisation of the oxygen atom in methoxysilane can be assessed as intermediate between sp^3 and sp^2, and that in disiloxane as intermediate between sp^2 and sp. In the latter case both lone pairs of electrons of the oxygen atom may take part in $p_\pi - d_\pi$ interaction with d orbitals of the two attached silicon atoms[2]. These compounds, of course, exhibit different tendencies to complex formation both with electron acceptors and with electron donors, as well as with compounds containing active hydrogen or deuterium. One of the main tasks of this Review will be to examine such regularities.

II. COMPLEXES WITHOUT HYDROGEN BONDING

1. Intramolecular Complexes

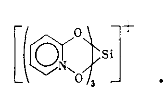
The first intramolecular oxygen-containing organosilicon compounds were obtained in 1903 by Dilthey[4,5], who found that silicon tetrachloride acted on acetylacetone and its methyl derivative to form crystalline substances, which were regarded as "siliconium salts"

$$\{[RCOCH{=}C(CH_3)O]_3Si\}Cl \cdot HCl$$

containing a sexivalent silicon atom (R = CH_3 (I), C_2H_5). These compounds were converted further into salts $[A_3Si]^+M^nCl_{n+1}$, where M = Sn^{2+}, Fe^{3+}, Au^{3+}, Pt^{5+} and A = $RCOCH:C(CH_3)O$.[4-6] Corresponding derivatives of other β-diketones were obtained later[6,15-17]. The octahedral structure of compound (I) has been proved by resolving its racemate into optically active stereoisomers[15,18]. The chelate structure of (I) has been indicated also by its infrared spectrum, from which the carbonyl band in the region of 1700 cm^{-1} is absent, and has been replaced by a wide band at 1555 cm^{-1}.[19] Absorption in the range 1500–1600 cm^{-1}, which is characteristic of all chelate acetylacetonates of metals, is due to stretching vibrations of $C\overset{\cdots}{=}C$ bonds, and in some cases also $C\overset{\cdots}{=}O$ bonds[20-24].

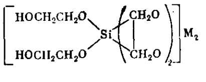
In the proton magnetic resonance spectrum of (I) the signals from protons attached to carbon atoms are displaced down-field relative to the enolic form of pure pentane-2,4-dione, which was initially interpreted as proof of benzoid resonance in the chelate ring[25]. It was shown later, however, that an analogous shift occurs on passing from chelate diketonate cationic complexes of various metals (as well as silicon) to the corresponding neutral diketonates[26,27]. Thus this phenomenon does not indicate the development of aromatic structure in acetylacetonates, and can be satisfactorily explained as an effect of the electric field produced by the charge on the ion[26].

Reports have appeared also of other β-diketonate cationic complexes, having the structure $[\mathrm{SiRdik_2}]^+[\mathrm{M^nCl_{n+1}}]^-$, where $\mathrm{M = H^+}$, $\mathrm{Fe^{3+}}$, $\mathrm{Sn^{4+}}$, and R is a hydrocarbon group[19,24,28], as well as non-ionic compounds $\mathrm{dik_2SiX_2}$, where X is an organic substituent[19], chlorine[19,23,24,29], or an acyloxy-group[21,22,30], and also $\mathrm{dikSiR_3}$, in which R is a hydrocarbon group[21,31-33]. The valency of the silicon atom depends on the composition of the β-diketonates. Chelate rings are present in the cationic complexes $[\mathrm{dik_3Si}]\mathrm{X}$ and $[\mathrm{dik_2SiR}]\mathrm{X}$, as well as in those of types $\mathrm{dik_2SiX_2}$ and $\mathrm{dik_2SiRX}$ (where X represents chlorine on an acyloxy-group)[21-24,28-30,34,35]. Under ordinary conditions stable chelate rings are not formed when two or three organic substituents R are attached to the silicon atom[19,31-33]. Thus expansion of the electron octet with the formation of additional σ bonds occurs only when a sufficient number of electronegative substituents are attached to the silicon atom. In chelate compounds having two diketonate ligands silicon is quinquevalent (trigonal–bipyramidal structure) in the case of ionic compounds, or sexivalent (octahedral structure) when all bonds in the molecule are covalent in character. With dika $\mathrm{SiR_3}$ a chelate structure may merely be intermediate in a *cis–trans* rearrangement[31,32]. A similar structure to cationic β-diketonates is possessed also by siliconium ions having tropolonato-ligands $[(\mathrm{C_7H_5C})_3\mathrm{Si}]^+$ [36,37] and the trispyridine-1,2-dioxysiliconium ion[34]

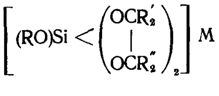


Several other stable ionic complexes are known in which the electron octet of the silicon atom is expanded by the formation of additional SiO bonds. The central silicon atom is attached only to electronegative atoms or in an extreme case may be attached to a single organic group. Typical complexes of this type are derivatives of arylene-o-diols having the structure $[(\mathrm{C_6H_4O_2})_3\mathrm{Si}]\mathrm{M_2.H_2O}$ (where $\mathrm{M = NH_4}$ [38,39], K, $\mathrm{C_5H_5NH}$ [38], $\mathrm{CN_3H_6}$ [40]), $[(\mathrm{C_6H_4O_2})_3\mathrm{Si}]\mathrm{H_2}$ or $[\mathrm{RSi(O_2C_6H_4)_2}]\mathrm{H}$ and their alkali-metal salts[41], $[(\mathrm{C_6H_4O_2})_2\mathrm{Si}]\mathrm{Mg.9H_2O}$ and $[(\mathrm{C_6H_4O_2})_3\mathrm{Si}]\mathrm{Mg}$ [40], $[\mathrm{RSi(O_2C_6.H_4)_2}]\mathrm{NR'_4}$ [34,42,43], and $[\mathrm{RSi(O_2C_6H_{4-n}R'_n)_2}]\mathrm{PR''_4}$.[7] When an organic substituent is attached, the silicon atom is in a five-coordinated state, but in other cases it is six-coordinated. The molar conductance of aqueous solutions of silicon(V) complexes indicates that they are salts formed by a univalent anion and a cation[44].

In 1929 Meerwein discovered[45] that orthosilicic esters of glycols and glycerol on titration with caustic alkalis give salts of intramolecular alkoxo-acids, for which a structure of type

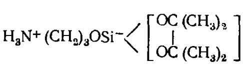


was suggested. Later other complexes of similar type



$$\left[(\mathrm{RO})\mathrm{Si}<\begin{pmatrix}\mathrm{OCR'_2}\\ | \\ \mathrm{OCR''_2}\end{pmatrix}_2\right]M$$

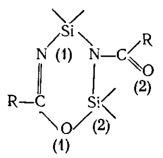
were obtained, in which R, R′, R″ = H, Alk and M represents an alkali metal or an ammonium cation[46,47], compounds of corresponding structure with biscyclohexane-1,1-dioxy- and bistetramethylethylenedioxy-substituents attached to the silicon atom[48], and several alkylammonium zwitterions derived from 1,2-diols[49], e.g.



$$\mathrm{H_3N^+(CH_2)_3OSi^-}<\begin{bmatrix}\mathrm{OC(CH_3)_2}\\ | \\ \mathrm{OC(CH_3)_2}\end{bmatrix}_2$$

All complexes of the above type are sparingly soluble in non-polar organic solvents. Several of them are very stable (e.g. the above zwitterion melts at 190°C); others decompose even at 100°C. The formation of complexes is favoured energetically, and often takes place with the evolution of heat. Salts of similar structure have been obtained also from orthosilicic esters of α-hydroxycarboxylic acids[50].

Crystalline adducts of derivatives of monohydric alcohols with five-coordinated silicon, e.g. $[(\mathrm{CH_3O})_5\mathrm{Si}]\mathrm{K}$, $\{[(\mathrm{CH_3O})_4\mathrm{Si}]_2\mathrm{O}\}\mathrm{K_2}$, are stable only at low temperatures[51]. Other examples of intramolecular complex formation by means of additional silicon–oxygen bonds are cyclobisbenzamidodimethylsilane



in which the distance between the $\mathrm{Si_{(2)}}$ and $\mathrm{O_{(2)}}$ atoms is 2.613 Å,[52] and also 2,2,5-trimethyl-5-nitro-2-sila-1,3-dioxan, the chair structure of which is assumed to be stabilised by transannular Si ← O interaction[53].

Thus, despite the well defined tendency of the siloxane bond to $p\pi - d\pi$ interaction, leading to diminished electron unsaturation of the silicon atom, the presence of such bonds in the molecule does not prevent involvement of *d* orbitals of the silicon atom in the formation of intramolecular coordinate bonds with oxygen or nitrogen atoms.

A typical example of intramolecular complexes of the latter type is silatrane

$$\mathrm{HSi(OCH_2CH_2)_3N}$$

with its derivatives

$$\mathrm{XSi(OCH_2CH_2)_3N}$$

where X = Alk, Ar, Hal, etc.[54-80]. These compounds are usually crystalline solids with high-melting points (153 °C for silatrane), although several liquid silatranes have been obtained recently[72,74,75]. The presence of a transannular Si ← N bond in the molecules has been proved by measurements of dipole moments[59-62,81,82], determinations of nuclear magnetic resonance[58,64,65,83,84] and ultraviolet[84] spectra, quantum-chemical calculations[81], and X-ray structural examination[85,86]. According to the latest estimates the transfer of electron density from the nitrogen to the silicon atom in a silatrane molecule is relatively small (0.1–0.2e).[81,82] X-Ray examination indicates that the phenylsilatrane[86] and *m*-nitrophenylsilatrane[85] molecules contain the silicon atom at the centre of a distorted trigonal bipyramid with three equatorial oxygen atoms, whil the axial positions are occupied by the group X and the nitrogen atom. The Si ← N bond lengths in the two derivatives are respectively 2.193 and 2.116 Å, much shorter than the sum of the van der Waals radii of the silicon and nitrogen atoms (~3.5 Å), but exceeding appreciably the length of a normal silicon–nitrogen single bond (~1.83 Å).

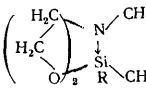
A dative bond Si ← N is formed also in *C*-substituted silatrane derivatives $XSi(OR)_n(OR')_{3-n}N$, where $n = 0-2$, $R = CH_2CH_2$, $R' = CH(CH_3)CH_2$ [60,75,82,87], etc.[75], substituted triphenoxysilatranes

$XSi(OC_6H_4)_3N$ [75, 88, 89]

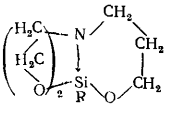
and other related heterocyclic sytems

$XSi(ZCH_2CH_2)_3N$

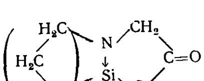
(Z = S or NH)[90].



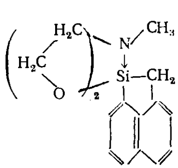
60,64,83,91,



90,

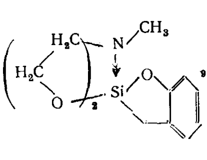


92,



93,

(II)



93

(III)

Available X-ray data indicate that the Si ← N bond length has the values 2.336, 2.344, 2.263, and 2.297 Å respectively for the compound[91]

$CH_3Si(OCH_2CH_2)_2(CH_2)_3N$

for triphenylene-phenylsilatrane[89], and for the above methylbishydroxyethylamine derivatives (II) and (III).[93]

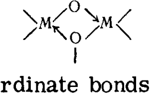
The presence of the Si ← N dative bond is assumed also in phthalocyanine derivatives of siloxanes[94-97].

Transannular Si ← N interaction is almost completely absent from alkyl-2-aminoethoxysilanes $R_nSi(OCH_2CH_2.NR'_2)_{4-n}$.[98-101]

2. Intermolecular Complexes

When dissolved in non-polar solvents the overwhelming majority of compounds containing siloxane bonds (other than silanols) show little tendency to associate or to undergo donor-acceptor interaction with the solvent. This is indicated by numerous determinations of molecular weight and other physicochemical results.

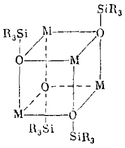
Many heterosiloxanes—compounds containing "foreign" atoms in the siloxane chain—exhibit systematic departures from this rule. Intermolecular coordination of such compounds is due to dative interaction of oxygen atoms with the heteroatoms. The stability of the autocomplexes of heterosiloxanes varies between wide limits. In several cases this type of complex formation is not clearly evident, and is apparent only from some increase in molecular weight. The nature and the valency state of the heteroatom are of decisive importance in the molecular association of heterosiloxanes. Sometimes, however, other substituents attached to the heteroatom and to the silicon atom have an appreciable effect. For example, compounds of the types $[R_3SiOMX_2]_2$ (where R represents H or an organic radical, X = Hal, H, or an organic radical, and M = Al, Ga, In) [102-111] and $[(R_2SiO)_3M]_2$ (R represents an organic radical and M = Al, Ga, Fe) [112-115] form stable dimers having the almost planar four-membered ring



.

The stability of the coordinate bonds is indicated by that of the ring in $[(CH_3)_3SiOAlCl_2]_2$ (up to 200°C).[108]

An analogous cyclic structure is suggested for $[(CH_3)_3.SiOAu(CH_3)_2]_2$,[116] $[(CH_3)_3SiOTl(CH_3)_2]_2$,[117] and $\{[(CH_3)_3.SiO]_4Zr\}$.[118,119] The presence of three bonds involving the bridging oxygen atoms in the dimers diminishes the strength of $p_\pi - d_\pi$ interaction between silicon and oxygen atoms and confers a coordinatively unsaturated character on the systems. With silanolates of alkali and pseudo-alkali metals, therefore, the above compounds form salts of type $[(R_3SiO)_4M]M'$, whose molecules contain only uncoordinated oxygen atoms, while the heteroatoms M retain their high coordination number[112,114,115,120-125]. The compounds $(CH_3)_3POM[OSi(CH_3)_3]_3$ and $(CH_3)_3NOM[OSi(CH_3)_3]_3$ (M = Al, Ga) probably have the zwitterion structure $\gtrdot\bar{M}-O-\overset{+}{P}\lessdot$.[123] In the crystalline phase potassium, rubidium, and caesium trimethylsilanolates resemble $[(CH_3)_3COM]_4$ in being tetrameric, with the Si–O–M angle 123 ± 2°[126]; trialkylsiloxy-derivatives of mercury, zinc, and cadmium have an analogous structure:



,

where M = K, Rb, Cs[126] or HgR, ZnR, CdR.[119]

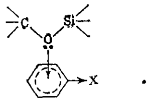
Potassium, rubidium, and caesium trimethylsilanolates are almost insoluble in organic solvents[127-129]. Sodium and lithium silanolates are associated in organic solvents, the degree of association increasing with decrease in the dielectric constant of the medium[128-134]. Potassium trimethylsilanolate dissolves immediately on addition to a solution of lithium or sodium trimethylsilanolate. Pure crystalline double salts $K\{M[OSi(CH_3)_3]_2\}$ (where M = Na, Li), having a narrow melting range, can be isolated from the resulting solutions[127].

Several permethylsiloxy-derivatives of metals have higher molecular weights in solution (degree of association usually $\not>$1.5–1.7). When the methyl groups are replaced by ethyl, however, the degree of association falls to 1.0, probably owing to steric factors[132]. This is typical of compounds of type $U(OSiR_3)_5$ [132], $Zr(OSiR_3)_4$ [118,132], and $Ti(OSiR_3)_4$ [118,133]. Whereas trialkylsiloxy-derivatives of boron, phosphorus, and arsenic are monomeric, the unusual viscosity properties of siloxane polymers containing atoms of these elements suggest that they form unstable donor-acceptor association complexes, which decompose completely on dissolution[134-138].

Besides the above aggregates, complexes of siloxanes with several foreign ligands are also known. The formation of such complexes has been studied systematically by various physicochemical methods (mainly refractometrically)[139-160]. Compounds containing an Si–O–Si group show little tendency to form complexes either with donor or with acceptor solvents. The tendency to complex formation by alkoxysilanes $R_{4-n}Si(OR')_n$ depends on the number and structure of the substituents R and R'. In general the ability of alkoxysilanes to form labile complexes with ligands of any type falls with increase in the number of alkoxy-groups in the molecule and also as their structure becomes more complicated. The weakening of the electron-donating properties of the oxygen atoms observed with increase in *n* in the alkoxysilanes is due to diminished steric accessibility and mainly to diminished polarity of the Si–O(C) bonds caused by the introduction of new electronegative alkoxy-substituents into the molecule. The latter effect is associated with simultaneous increase in $p_\pi - d_\pi$ interaction in the silicon–oxygen bonds. The weakening of the bonds of alkoxysilanes with electron-donating ligands as *n* increases is probably caused mainly by the more difficult steric accessibility of the silicon atom.

Phenoxysilanes, in which substituents more electronegative than alkoxysilanes are attached to silicon, exhibit a greater tendency to complex formation with organic bases, and less tendency with acids [141,146,155]. Oxalyldioxysilanes form stable complexes (up to 80–100°C) with oxolan, dioxan, and pyridine of general formula $[Si(C_2O_4)_2.2X]_n$, and with dioxan also $[C_6H_5Si(C_2O_4H)C_2O_4.1.5diox]_n$. [161]

Alkoxysilanes associate with several benzene derivatives of type C_6H_5X. The stability of such complexes increases with the electron-accepting properties of the aromatic ring in the C_6H_5X molecule. Consequently the oxygen atom of the alkoxy-group acts as donor in the charge-transfer complexes formed, and the aromatic compound as acceptor [141,144,146,162]:



Various physicochemical methods have been used to establish the formation of complexes by alkoxysilanes with the tetrachlorides of tin [157,163–168], titanium [169,170], and silicon [171], but not with phosphorus halides [172,173]. Heats of complex formation *q* per donor–acceptor bond in complexes of tin(IV) chloride with $R'Si(OR)_3$ correlate satisfactorily with the sum of the Taft polar σ^* constants of the substituents R′ [166,167]:

$$q = 7.849 - 1.03\,\Sigma\sigma^*;\ r = 0.95\ . \qquad (1)$$

Increase in the +*I* effect of substituents attached to the silicon atom leads to a decrease in the heat of complex formation. The same tendency is evident in the systems formed by titanium(IV) and tin(IV) chlorides with alkoxychlorosilanes $Cl_{4-n}Si(OR)_n$, in which complex formation becomes less marked as *n* decreases [164,166,170]. Silatranes

$RSi(OCH_2CH_2)_3N$

form 1 : 1 and 2 : 1 complexes with titanium(IV) chloride, and an equimolecular complex with aluminium bromide. These complexes are assumed to have an octahedral structure [174].

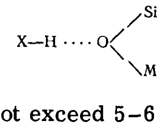
Labile complexes are formed by the interaction of $(CH_3O)_4SiSO_3$, [175] $(C_6H_5O)_4Si$, [176] and $(R_3SiO)_3PO$ (where R = CH_3, C_2H_5, C_6H_5) [177] with dioxan, of alkoxysilanes with iodine [141,156,178], and of alkylalkoxy- and acetoxysilanes with tris-(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dionato)europium and other paramagnetic shift reagents [179]. Complex formation by aminoalkoxysilanes [180–182] and alkoxyaminosilanes [183,184] with metal halides [181–184] and with silthianes [180] involves the nitrogen atoms, not oxygen.

Donor–acceptor interaction involving a phosphoryl group develops in mixtures of tristrialkylsilyl phosphates with tin(IV) and tellurium(IV) chlorides [185,186] and also with chloroform [177, 186].

III. HYDROGEN BONDING

1. Intermolecular Association of Siloxanes and Alkoxysilanes with Proton Donors

The energy of the hydrogen bond in the associated complexes



(M = Si or C) does not exceed 5–6 kcal $mole^{-1}$. Hydrogen bonds of this type have been studied by infrared spectroscopy [187–220], nuclear magnetic resonance [221], refractometry [140,141,146,152,155,170,199], dielectric measurements [199, 220,222,223], and viscosimetry [140,220]. The proton donors used have been phenol [187–212], pyrrole [188,189,198,212,215], chloroform [141,221,223] or deuterochloroform [214,217], alcohols [140,141, 146,198–200,215,220,222], and other compounds containing mobile hydrogen [141,144,211,216].

Table 1. Shifts in hydroxyl-stretching band of phenol on hydrogen bonding with organo-silanes and -siloxanes.

*The basic properties of the oxygen atom do not develop under the conditions of the determination.

Infrared spectroscopy is the most sensitive method for studying a hydrogen bond, whose strength is assessed from the shift $\Delta\nu_{X-H}$ in the X–H or X–D stretching vibrations (X = O, N, etc.) due to interaction of the hydrogen (or deuterium) atom with the siloxane oxygen. According to the absolute frequency shift $\Delta\nu_{X-H}$ proton donors can be arranged in the sequence[189] *p*-bromophenol > phenol > 2,3-dimethylphenol > indole > benzyl alcohol > pyrrole. In interpreting the infrared spectra, however, we must bear in mind that proton donors can form a hydrogen bond not only with the siloxane oxygen atom but also with π-electron systems (aromatic rings, multiple bonds) and halogen atoms present in the proton acceptor[188,224].

Selected values of $\Delta\nu_{O-H}$ for the systems formed by phenol with siloxanes are given in Table 1 together with comparative data for some isostructural organic compounds. Alkoxysilanes are evidently weaker bases than the corresponding dialkyl ethers, and siloxanes are still weaker bases. Thus the oxygen compounds of silicon are much less basic than might be expected from the induction effect of the silicon atom, which is less electronegative than carbon. This is explained by the presence of a donor–acceptor π bond, which diminishes the basicity of the siloxane oxygen atom.

Table 2. Values of $\Delta\nu_{C-D}$, $\Delta\nu_{O-H}$, and $\Delta\nu_{N-H}$, in systems comprising a base and a proton (deuteron) donor, accompanying the hydrogen bonding of compounds of subgroup IV*b* elements with deuterochloroform[214], phenol[216], and pyrrole[215].

General formula	$\Delta\nu_{C-D}$, cm^{-1}				$\Delta\nu_{O-H}$			$\Delta\nu_{N-H}$, cm^{-1}	
	C	Si	Ge	Sn	Si	Ge	Sn	Si	Ge
$(CH_3)_3MOCH_3$	—	—	—	—	153	245	329	163	258
$(CH_3)_3MOC_2H_5$	29	21	38	56	—	—	—	—	—
$(CH_3)_3M]_2O$	33	13	55	84	73	274	—	76	285

Table 2 illustrates the basicity of isostructural oxygen-containing compounds of elements in subgroup IVb. The shifts $\Delta\nu$ are minimal for compounds in which M = Si, owing to the substantial contribution by $p_\pi - d_\pi$ conjugation. Yet the variation in electronegativity of the atom M would suggest that the basicity should increase regularly from carbon to tin. The fall in basicity from compounds in which M = C, Ge, Sn to the isostructural silicon compound is especially large in the $[(CH_3)_3M]_2O$ series.

The departure from this rule observed with n = 3, 4 in the series $R_{4-n}M(OC_2H_5)_n$, where M = C, Si, and R = CH_3 (No. 23, 24, 30, and 31 in Table 1) must be attributed to the great steric hindrance to hydrogen bonding presented by the ethoxy-groups in compounds in which M ≠ C.[198]

Depending on the nature of the compounds the basicity of siloxane oxygen falls in the sequence (Table 1)

$$C_{Alk}OSi > C_{Ar}OSi > SiOSi > SiOSiOSi\ ,$$

which is probably governed by increasing electronegativity of the substituents attached to the oxygen atom and increasing degree of $p_\pi - d_\pi$ interaction in the molecules. A noteworthy feature is the unexpected enhanced basicity of cyclotrisiloxanes (No. 57–62 in Table 1), which is confirmed by nuclear magnetic resonance data[221]. The cause is the lower degree of $p_\pi - d_\pi$ conjugation in the strained planar molecules[188], as well as the greater steric accessibility of the oxygen atoms in them than in higher cyclosiloxanes or linear siloxanes[192].

In series of compounds with the same number of siloxane bonds in the molecule the induction effect of groups attached to the silicon atom has a decisive influence on the basicity. Statistical treatment of experimental data for trialkylethoxysilanes, alkyltrialkoxysilanes, and hexa-alkyldisiloxanes by means of the Taft equation

$$\Delta\nu_i = \Delta\nu_0 + a\Sigma\sigma_i^* \qquad (2)$$

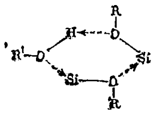
gave the results listed in Table 3. A good linear dependence of $\Delta\nu_i$ on $\Sigma\sigma_i^*$ was shown graphically[207] for phenol complexes of compounds of general formula $(CH_3)_{2-m}(X_nC_6.H_{4-n})_mSi(OC_2H_5)_2$. The variation in the parameter a (Table 3) suggests that the induction effect of the substituents has the greatest influence on the basicity of trialkylethoxysilanes, and the least on that of alkyltrialkoxysilanes, with disiloxanes occupying an intermediate position. Hence the ability of the silicon atom to transmit the induction effect of substituents to oxygen diminishes with increase in the number of siloxane bonds in the molecule. Study of the hydrogen bonding of phenol and pyrrole with compounds of general formula $R_{4-n}M(OC_2H_5)_n$ (where R = CH_3, C_3H_7, n = 1–4, and M = C, Si, Ge) has established that the $\Delta\nu_i$–n lines have smaller slopes for the silicon derivatives than for the carbon and germanium compounds, where p_π–d_π conjugation is either absent or slight[198]. Thus there are grounds for supposing that the diminution in sensitivity to the induction effect of substituents on passing from ethers or alkoxygermanes to alkoxysilanes, or with increase in the number of siloxane bonds in the molecule, is due to increase in $p_\pi - d_\pi$ conjugation in the same sequence[205].

Table 3. Parameters in the Taft equation (2) for complexes of phenol with alkoxysilanes and disiloxanes.

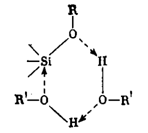
Formula	$\Delta\nu_0$	a	Correlation coefficient	Ref.
$R_3SiOC_2H_5$	275±2	−61.3±3.9	0.980	205
$RSi(OC_2H_5)_3$	237	−24.7	0.992	212
$RSi(OCH_3)_3$	266	−31.8	0.965	212
$(R_3Si)_2O$	162±3	−42.9±3.2	0.954	205

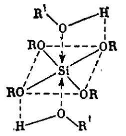
The steric effect of substituents is quite clear in the hydrogen bonding of phenol with siloxanes[189,192,204]. On passing from alkoxysilanes to disiloxanes the influence of steric factors on association with phenol is apparent also in a decrease in the number of hydrogen-bonded hydroxy-groups[192,204]. Differences in tendency to hydrogen bonding depending on steric features of substituents in siloxanes and alkoxysilanes have been revealed also by refractometry[139,141,144] and n.m.r. spectroscopy[221].

Depending on the nature of the components siloxanes and alkoxysilanes may form with proton donors 1 : 2, 1 : 1, and 2 : 1 complexes[145,199,213,220,223]. For example, tetra-alkoxysilanes give only 1 : 2 complexes[220] with the corresponding alcohols, methyltrialkoxysilanes and dimethyldialkoxysilanes 2 : 1 and 1 : 1,[199,213,220], and ethoxytrimethylsilane forms a 2 : 1 complex[195,213]. An ordinary hydrogen bond is undoubtedly present in the 1 : 1 complexes. In other cases silicon atoms may also be involved in complex formation, with an increase in their coordination number to 5 or even 6. For example, a 2 : 1 complex is assigned the structure[199]



and a 1 : 2 complex the structure





.

The latter structure is supported by the ability of complexes of tetra-alkoxysilanes with alcohols to dissociate as very weak monobasic acids[199]:

$$Si(OR)_4 \cdot 2\,ROH + ROH \rightleftarrows [Si(OR)_6H]^- + ROH_2^+ \quad .$$

Energetic characteristics published for the hydrogen bond between proton donors and oxygen-containing silicon compounds have been few and contradictory[190,191,195]. Table 4 gives existing values for the enthalpy of formation of the hydrogen bond. A linear relation exists between the frequency shift of the absorption by phenol and the enthalpy of formation of the hydrogen bond, the latter calculated from the association equilibrium constant[190]†:

$$-\Delta H(\pm\,0.5\ \text{kcal mole}^{-1}) = 0.016\ \Delta\nu_{OH} + 0.63 \quad . \qquad (4)$$

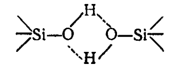
2. Hydrogen Bonds formed by Silanols

Silanols are associated by hydrogen bonding even in very dilute solutions[225-228], so that complete absence of association can be expected only in the gas phase[225,229]. The hydroxyl-stretching frequencies in the infrared spectra of dilute solutions of silanols in relatively inactive solvents (carbon disulphide and tetrachloride) lie in the range 3670–3695 cm^{-1}, being little affected by the nature of the substituents attached to the silicon atom[201,225,229-238]. Absorption by a free hydroxy-group occurs at frequencies 60–80 cm^{-1} higher in silanols than in alcohols[230,239], and is thus closer to the region of vibrations by the hydroxide ion (4200 cm^{-1})[240]. Together with the greater intensity of the band due to a silanol than to a carbinol hydroxyl[238] this indicates that the oxygen–hydrogen bond is more stable in silanols than in their carbon analogues. Hydroxy-groups in gaseous trimethylsilanol[225], as well as those in Aerosil and glass[241-244], absorb at 3735–3749 cm^{-1}. The infrared spectra of concentrated solutions, liquids, or crystals of silanols show a frequency shift to ν_{OH} = 3200 to 3300 cm^{-1},[225,226,229,238,245]. This band due to hydrogen-bonded hydroxysilyl groups has considerable width and greater integral intensity than in the corresponding carbinols.[228] The frequency shift due to association is $\Delta\nu_{OH}$ = 200–400 cm^{-1}, considerably larger than in carbinols, and caused by the enhanced acidity of silanols[187,225,230,231,235,238-240,245]. The absorption frequencies of free and associated OD groups in the infrared spectra of deuterosilanols R_3SiOD are respectively 2710–2730 and 2435–2455 cm^{-1}.[225,229,246]

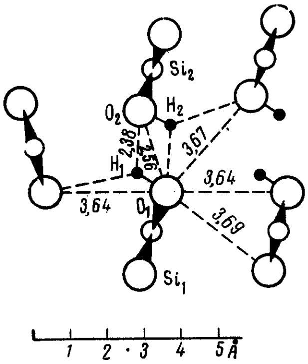
An interesting example of association due to the hydrogen bonding of silanol groups is heptacyclohexyltricyclo-[7,3,3,1]heptasiloxane-3,7,14-triol, which forms a strongly associated dimer having K_{diss} = 0.0037. This dimer is soluble in benzene and in tetrachloromethane. Its infrared spectrum does not show vibrations of free hydroxy-groups, but contains a broad band with its maximum at 3230 cm^{-1}. It is assumed that all six hydroxyls of the two associated molecules of this triol are hydrogen-bonded in pairs[226].

Still stronger hydrogen bonds are present in the crystals of many inorganic hydrosilicates[241,247-251].

The infrared spectra of crystalline and liquid silanols contain only one wide band due to hydrogen-bonded hydroxysilyl groups[228,235,238,239,245,252], which indicates the cyclic character of the molecular association, in which almost all the hydroxy-groups are involved[228,252]:



.



Schematic arrangement of hydroxy-groups in the structure of diethylsilanediol.[255]

X-Ray[253,254] and electron[255] diffraction indicates that crystalline dialkylsilanediols $R_2Si(OH)_2$ (where R represents ethyl or allyl) consist of layers and chains of molecules joined by hydrogen bonds. The accompanying diagram shows schematically the arrangement of hydroxy-groups in diethylsilanediol molecules. The Si-O(H) distance is comparable with the siloxane bond length in polysiloxanes. Some contraction of the $O_{(1)}-O_{(2)}$ bond (2.56 Å) in comparison with the sum of the van der Waals radii can be attributed to the formation by dipoles of a group having a fixed hydrogen bond[225].

---

†Values given[191] for ΔH differ substantially from the probably more reliable values in Ref. 190 and from those calculated by means of Eqn. (4).

The infrared spectra of dilute solutions of certain trialkylsilanols containing π-type proton acceptors (phenyl, vinyl) and of all dialkylsilane- and siloxane-diols contain two or more overlapping bands in the region of absorption by hydroxy-groups[232-235,245,252,256]. Their presence can be explained satisfactorily in terms of rotational isomerism[233-235]. The staggered isomers predominate over the gauche isomers (the higher-frequency bands are usually more intense than those at lower frequencies) in $HO[SiR_2O]_nH$ molecules in which $n = 1, 2$ and $R = CH_3$, C_2H_5, whereas with $R = C_6H_5$, $CH_2:CH$ the predominant gauche structure is stabilised by weak interaction of one of the hydroxy-groups with the π electrons of the R substituents. The existence of rotational isomers leads to a certain restriction of freedom of rotation in siloxanediol molecules. The most stable intramolecular bond in hexaphenyltrisiloxane-1,5-diol is due to the steric effect of the phenyl groups, which promote the formation of cyclic, but not linear, molecules. Intermolecular association of polydialkylsiloxanediols is governed by the dimensions of the substituents, and in the case of di- and tri-siloxane-$\alpha\omega$-diols diminishes in the sequence

$$(CH_3)_2 > CH_3(C_6H_5) > CH_3(CH_2:CH) > (C_6H_5)_2.$$

Silanols not only associate but also form complexes with other proton-donating compounds—phenol[187,231,232,257], alcohols[242,243], and water[242,244]—as well as with several electron donors—ethers and esters[200,201,218,219,230-232,257,258], amines[10-12,243,248,258], benzene derivatives[218,219,242,243], dimethyl sulphoxide[201,259,260], ketones[219,243], and others[218,219,242,261,262]—among which study of the complexes with diethyl ether and with phenol gave valuable information on their acid-base properties. Table 5 lists experimental data for the most representative series of silanol complexes. Formation of the complexes with ether and similar compounds undoubtedly involves the hydroxyl hydrogen atom of the silanol, so that their stability is directly dependent on the degree of protonation of the latter. It follows from Table 5 that silanols are significantly stronger acids than analogous hydroxy-derivatives of carbon, germanium, and tin. Similar results have been obtained from a study of complexes formed by these compounds with dimethyl sulphoxide and with oxolan.[200,231] The abnormally high acidity of silanols indicates $p\pi - d\pi$ conjugation between silicon and oxygen atoms with enhancement of the polarity of the oxygen–hydrogen bond[187,196,200,201,230,231,251,263].

The variation of the frequency shift $\Delta\nu_{OH}$ accompanying the hydrogen bonding of silanols with ether indicates that the acidity of the silanols decreases with increase in the $+I$ effect of substituents attached to the silicon atom (e.g. with the lengthening of alkyl groups), but increases with increase in the $-I$ effect. For disubstituted silanediols $R_2Si(OH)_2$ (R = Alk, Ar) the logarithm of the ratio of $\Delta\nu_{OH}$ for the diol–ether to that for the dimethylsilanediol–ether complex is linearly dependent on the Taft σ constants, which confirms the comparatively small contribution by conjugation for most substituted diphenylsilanediols.[257]

The stability of the ether complexes increases somewhat on passing from trialkylsilanols to the corresponding dialkylsilanediols, which is consistent with replacement of an organic radical by the more electronegative hydroxy-group. Passing from the disubstituted silanediols to the corresponding siloxane-1,3-diols causes little or no (for the methyl or phenyl derivatives respectively) increase in acidity, which remains almost constant on further lengthening of the siloxane chain. These results suggest that the total induction and mesomeric effects of R_2SiO groups ($R = CH_3$, C_6H_5) in the series of compounds $HO[SiR_2O]_nH$ (n = 1–5) are close to zero[232].

Values of $\Delta\nu_{OH}$ for adducts of phenol with hydroxylated compounds (Table 5) indicate that the oxygen atom in the hydroxysilyl group is only slightly less basic than that in a carbinol group, although silanols are significantly stronger acids than are the corresponding alcohols. Triphenylgermanol and triphenylstannol are appreciably stronger bases than is triphenylsilanol, in conformity with the arrangement of the elements in Group IV of the Periodic System. Thus here, too, data for silicon compounds are not consistent with the general rule, probably because of $p\pi - d\pi$ conjugation[201]. In the association of phenol with trialkylsilanols increase in the length of an alkyl group attached to the silicon atom causes an increase in basicity of the hydroxysilyl oxygen atom and hence an increase in the phenolic $\Delta\nu_{OH}$ shift. Replacement of alkyl by more electronegative groups (phenyl, benzyl) leads to diminished basicity. Hence in this series of compounds the more acidic silanols are weaker bases, as might have been expected.

Table 5. Values of $\Delta\nu_{OH}$ in the spectra of silanols (and some of their analogues) in the presence of ether or phenol.

No.	Formula	$(C_2H_5)_2O$		C_6H_5OH	
		$\Delta\nu_{M-OH...O}$, cm^{-1}	Ref.	$\Delta\nu_{C_6H_5OH...O}$, cm^{-1}	Ref.
1	2	3	4	5	6
1	$(CH_3)_3COH$	122	230	271	187
2	$(CH_3)_3SiOH$	238	230	216	230
3	$(C_2H_5)_3SiOH$	230	230	216 228	230

24	$(C_3H_7)_2Si(OH)_2$	270	257	—	—
25	$(C_6H_5CH_2)_2Si(OH)_2$	302	257	169	257

On the introduction of new siloxane bonds into silanols the basicity of the latter is not inversely proportional to their acidity, as is always observed with alcohols[257,264]. Thus replacing methyl or phenyl in a trisubstituted silanol by hydroxyl yields the more acidic silanediols, which, however, also possess greater basicity. Acidity remains roughly constant in the series $HO[SiR_2O]_nH$, while basicity increases from n = 2 to n = 3 (Table 5). The shift $\Delta\nu_{OH}(C_6H_5OH)$ suggests that the hydrogen bonding involves hydroxysilyl oxygen atoms, since the shifts produced by the association of phenol with Si–O–Si bonds do not exceed 150–160 cm^{-1}. These results were interpreted in terms of multicentre $p\pi - d\pi$ conjugation, whose development with growth of the siloxane chain may lead to weakening of $p_\pi - d_\pi$ interaction of the hydroxyl oxygen atoms with the terminal silicon atoms[232,257]. However, the unusual apparent relations between the acidity and the basicity of siloxane-$\alpha\omega$-diols may be due to variation in the acidity of phenol itself, resulting from coordination of its oxygen atom with the hydroxy-groups of the siloxane-diol, which are more strongly acidic than phenl itself (Table 5):

Electrohydrodynamic Atomisation of Liquids

V.I.Kozhenkov and N.A.Fuks

A critical analysis is given, with a list of 68 references, of the main problems facing the investigation and the application of the electrohydrodynamic atomisation of a liquid.

CONTENTS

I. INTRODUCTION

The production of highly dispersed monodisperse aerosols of similar charge is of great interest both scientifically and for several branches of industry. The vigorous attack on this problem has been due primarily to the use of charged disperse materials in the electronic–ionic industry and to the development of colloidal rocket propellents. Several processes are available for obtaining such aerosols, one of the most promising being the electrohydrodynamic atomisation of liquids, a particular case of electrostatic atomisation. The term "electrohydrodynamic atomisation of a liquid" appeared comparatively recently in certain foreign papers[1-3]. The customary term "electrostatic atomisation of a liquid" covers in essence a number of processes, which can be grouped under three main types of atomisation having characteristic fields of application.

1. Electrostatic atomisation with large mass flows of the liquids (up to ~ 50 cm^3 s^{-1}), with the liquid fed under pressure, and with very high voltages (up to 100 kV and over). The process is accompanied by the formation of a coarsely dispersed polydisperse aerosol. This mode of atomisation has found its greatest application in industrial electrostatic painting.

2. Electrostatic atomisation with minute liquid flows (10^{-9}–10^{-3} cm^3 s^{-1}) and relatively lower voltages (up to 10 kV) in a vacuum. Under such conditions many liquids (from pure dielectrics to molten metals) can be atomised to highly dispersed aerosols of particles having a high ratio of charge to mass ($\geqslant 10^3$ C kg^{-1}). The first account of the production of monodisperse aerosols by vacuum atomisation is that of Semple and Bollini[4]. This process has been applied in rocket technology to produce colloidal propellents and also in microelectronics in the manufacture of printed circuits.

3. Electrostatic atomisation under normal atmospheric conditions with small liquid flows (10^{-8}–10^{-4} cm^3 s^{-1}) and with relatively low voltages on the liquid (3–8 kV). Under certain conditions this process yields a monodisperse aerosol from many liquids over a wide range of droplet sizes (0.1–1000 μm) and with charges on the drops comparable with the limit permitted by the Rayleigh relation for the stability of a charged spherical drop. This is the type of atomisation to which the term "electrohydrodynamic atomisation of a liquid" is mainly applied.

A characteristic feature of the electrohydrodynamic process is that the small mass flows of liquid and the relatively low voltages create identical conditions of formation for all droplets, merely by drops reaching the Rayleigh instability relation $Q^2 = 16\pi r^3\gamma$ (where Q is the surface charge of the drop, r the drop radius, and γ the surface tension of the liquid), which ensures the production of a monodisperse aerosol. This excludes the drawing-out of long continuous liquid filaments (with not too viscous liquids), which in the electric field would disintegrate into separate drops under the influence not only of Coulombic but also of hydrodynamic and gravitational forces, with consequent formation of a polydisperse aerosol. Production of a monodisperse aerosol in the electrohydrodynamic process is superficially analogous to the mechanism of its formation in disc atomisation with extremely small liquid flows.

A considerable number of papers on the investigation and the utilisation of the electrohydrodynamic process have recently been published both here and abroad. The only survey known to the Reviewers is that by Bailey[5]. However, his analysis of published information is insufficiently critical, and he ignores much published work, both recent and earlier, which would give an idea of the state of and prospects for research on the process. We now review and briefly analyse published results on this question.

The first mention of the effect of an electric charge on a liquid dates from 1745, when Bose[6] observed that the rate of cavitation of a liquid in a narrow capillary increases on application of an electric potential. This phenomenon was later explained by the action in a liquid drop of electric forces opposing those of surface tension. When the charge on the drop reaches a certain value, the electric forces become stronger than those of surface tension, and the drop becomes unstable. A criterion of the stability of a spherical drop of an ideally conducting liquid was first established by Rayleigh[7]. The stability of a charged spherical drop in an electric field was investigated by Zeleny[8-10], who evaluated the critical field strength at which the drop still remains spherical. In experimental studies of a corona discharge from a liquid apex[10] he observed that a liquid filament was drawn out from the narrow capillary, and then broke down into separate drops. This can be regarded as the first attempt to investigate the mechanism of the formation of an aerosol by the electrohydrodynamic atomisation of a liquid.

II. MECHANISM OF THE FORMATION OF AN AEROSOL BY THE ELECTROHYDRODYNAMIC ATOMISATION OF A LIQUID

Experimental results indicating the possibility of obtaining a highly dispersed monodisperse aerosol by the electrohydrodynamic method were first published in 1952–1953 by Vonnegut and Neubauer[11,12]. They atomised such liquids as water, sugar solution, lubricating oil, alcohol, suspensions of fine inorganic colorants in poorly conducting liquids, etc., using both direct and alternating voltages of 6–10 kV. The degree of monodispersity and the size of the droplets were assessed from the presence of bright colours in the higher-order Tyndall spectra. Vonnegut and Neubauer determined experimentally for several liquids the upper conductivity limit at which a highly dispersed monodisperse aerosol could still be formed, and stated that a monodisperse aerosol can be obtained even from more highly conducting liquids, but considerably larger drops (of diameter $\geqslant 25\ \mu m$) were then produced. However, these results were not related to the conditions and are of limited value. The authors stated also that a monodisperse aerosol could not be obtained at negative potentials, but offered no explanation. Nor did they attempt to explain the formation of uniform particles, i.e. the mechanism of formation of a monodisperse list, but nevertheless took[11,12] the first step in a theoretical examination of the break up of the initial volume of charged liquid, by adopting an energetic approach to the problem. They put forward the hypothesis of the minimum energy of the system, on the basis that a charged spherical drop (or other finite volume of liquid) tends to a state in which the total energy of the system (the surface energy and the energy of Coulombic interaction of surface charges) is minimal. Such an energy state should correspond to the ensemble of droplets formed when a primary drop breaks up. Examination of the equation for the total energy of the system enables the equilibrium specific charge on the droplets to be determined. For many authors this hypothesis served as starting point in a theoretical investigation of the electrohydrodynamic process[13-15].

The problem of the mechanism by which aerosol particles—in particular a monodisperse aerosol—are formed is undoubtedly basic for an understanding of the physics of the electrohydrodynamic process. It is not surprising, therefore, that many investigators have been concerned with this question. Thus it was suggested[16] that, at the critical potential for the start of fine atomisation (i.e. formation of a monodisperse aerosol), the electric forces of repulsion exceed the forces of surface tension, and the main filament stretching out from the capillary breaks down into a multitude of symmetrically arranged fine filaments, which become unstable and immediately disintegrate into very fine charged drops. Other workers[17,18] have expressed a similar view on the mechanism. The paper on the electrohydrodynamic production of uniform emulsions using an earthed liquid counter-electrode gives photographs of the atomisation process, on which liquid filaments emerging from the capillary can be seen[18]. However, the fairly long exposure in photographing such a rapid process makes unconvincing the authors' statement that aerosol formation occurs by the rupture of filaments extending from the capillary. Furthermore, the comparatively large masses of liquid consumed in the experiments, the conclusion that a highly dispersed monodisperse aerosol can be obtained from non-polar liquids (such as tetrachloromethane), and finally the fact that it was not an aerosol but an emulsion formed by immersing the particles in a liquid that was investigated—in general cast doubt on the reliability of these results.

Some confusion has hitherto existed in many publications concerned in some measure with the mechanism of electrohydrodynamic atomisation and in particular with the formation of a monodisperse aerosol by this process. Thus electrostatic atomisation with large mass flows of liquid has been investigated theoretically and experimentally[19-25]. The high rate of flow, like high viscosity, results in the formation of a stable and relatively long (ten times the drop size) liquid filament, whose subsequent behaviour in the electric field (bending, cleavage into segments, and breakdown of the latter into individual drops) is governed to comparable extents by electrostatic forces and by hydrodynamic and gravitational forces. Yet the results of these investigations have been compared with those obtained for the electrohydrodynamic atomisation of a liquid. Results for atomisation with large mass flows and with very small flows of liquid—the latter involving purely electrohydrodynamic atomisation—should be discussed separately. It is significant that workers who used the latter régime[11,16,17] concluded that a stage in which a liquid filament extends from the tip of the capillary is essential to the formation of a highly dispersed monodisperse aerosol.

In only one paper[26] has the mechanism of the formation of a highly dispersed aerosol by electrohydrodynamic atomisation been regarded as the detachment of single drops from a liquid apex at the tip of the capillary. However, no experimental data were given to support this mechanism. High-speed photomicrographs of the breakaway of a drop and its movement near the capillary showed[27] large drops under a "dropping" atomisation régime with an exposure time lasting milliseconds, so that it is impossible from this paper to assess the formation and the behaviour of the highly dispersed aerosol obtained by electrohydrodynamic atomisation.

The production of monodisperse droplets of size $r = 5-20\ \mu m$ and the formation of an aerosol jet during the electrohydrodynamic atomisation of various liquids (dibutyl phthalate, ethanol, and their 50% solution) have been investigated[28] by high-speed photomicrography using a powerful pulsed laser (20 MW for 35 ns). The experiments showed that formation of a monodisperse mist in this process results from the emission of single droplets from a liquid apex or from the tip of a small liquid cylinder: it is not produced by the stretching out and rupture of a liquid filament, as had been stated earlier[11,16-18,29]. The picture of the process is analogous to the formation of a monodisperse aerosol by disc atomisation with a small supply of liquid.

One of the main problems in the physics of the electrohydrodynamic atomisation of a liquid is to test experimentally the Rayleigh instability relation for a charged spherical drop, as well as to investigate theoretically and experimentally the charges on aerosol particles obtained by this process. A charged electrically conducting spherical drop should retain its size and shape until $Q^2 = 16\pi r^3\gamma$. This relation has been confirmed theoretically[30]. Several workers[31-33] undertook experimental verification by similar methods, consisting in suspending a charged spherical drop in a vertical electric field and observing the moment at which a number of fine droplets were expelled from the surface of the initial drop. This phenomenon was observed in 1926 by Macky[34] in experiments on drops of water placed in a strong electric field. More recently Doyle et al.[31] made a similar experiment on volatile drops. During evaporation the ratio of the surface charge to the mass of the drop increases, and when the Rayleigh relation is reached a cloud of daughter droplets is emitted. These workers found that the charge on the drop at the instant of disruption of its stability agreed quite well with that calculated from the Rayleigh relation.

A second important result from this work was that the charges on the daughter droplets were very roughly measured as half the Rayleigh value, or at least did not exceed the latter. This work[31] was later developed by Abbas and Latham[33]. The application of an original method[35] to measure the size and charge of drops (30–200 μm) of n-octanol obtained by electrohydrodynamic atomisation confirmed also that the drop becomes unstable on attaining the Rayleigh relation and that the ratio of mass and charge lost by the drop also corresponded to this relation. Schweizer and Hanson[32] have shown with almost the same measuring apparatus that the Rayleigh relation is satisfied to at worst 4%, while the losses of mass and charge by the initial drop as a consequence of the emission of daughter droplets are respectively 23% and 5%.

A series of theoretical and experimental studies of the subdivision of a charged drop in an electric field were regarded by Ryce et al.[1,36–39] as applying to electrohydrodynamic atomisation. They were related to the mechanism of the formation of a monodisperse aerosol during atomisation, since they solved the problem of the symmetrical and unsymmetrical splitting of the initial drop as a function of the closeness of its approach to the Rayleigh relation. A theoretical solution was based on the hypothesis of minimum energy[11] with the postulates[36–38] that (i) the resultant droplets do not interact, (ii) the initial drop is able to divide when $Q^2 < 16\pi r^3\gamma$, and (iii) conduction by the surrounding medium is isotropic, i.e. division of the drop is unaffected by the space charge. The solution leads to the conclusion that drops are able to undergo symmetrical cleavage when $Q^2 > 16\pi r^3\gamma$, and unsymmetrical cleavage when $Q^2 \leqslant 16\pi r^3\gamma$. The experimental model involved a large drop of water (d = 2 mm) with addition of a surface-active agent in stearin oil. Since the behaviour of a liquid drop in a gaseous medium differs significantly from its behaviour in a liquid, such a model is quite obviously too remote from the actual process of electrohydrodynamic atomisation. Thus the simplifying postulates in the theoretical solution and the evident incompatibility of the experimental model with the electrohydrodynamic atomisation of a liquid diminish the value of these studies for determining the true mechanism.

Although many investigators have adopted the minimum energy hypothesis for the theoretical assessment of atomisation results, some authors reject it completely. Thus Krohn[2] obtained droplet charges exceeding half the Rayleigh value for the atomisation of Wood's alloy. On the basis of these experimental results and an analysis of the work of Vonnegut, Ryce, Hendricks, and Doyle[31], who employed the hypothesis, he asserts that the minimum energy principle cannot be used to obtain quantitative results and that the droplet charges close to the equilibrium value (i.e. half the Rayleigh charge) found by Hendricks and his coworkers are obviously due to the poor conductance of the liquids employed. He publishes his experimental results, but does not give the method for measuring the parameters of the aerosol obtained, so that it is difficult to judge the reliability of these results.

Until recently the magnitude of the charge on the droplets obtained by electrohydrodynamic atomisation has remained an open question. The most interesting work has been done by Hendricks[40], Pfeifer[3,41], and Semple and Bollini[42]. Experiments by Hendricks et al. on the atomisation of octoil and glycerol showed that the individual charges on drops measured by means of a Faraday cage and a flight-path charge spectrometer agreed quite satisfactorily with the theoretical equilibrium charges and never exceeded them. Semple and Bollini used distilled water as working liquid in their experiments, but accomplished the process under a so called "dropping" régime with monodisperse drops of size 140–420 μm formed with a frequency of 350–950 s^{-1}. As in the above work[40] the charges on these drops were quite close to the equilibrium values, but somewhat exceeded the latter. This result was obviously due to errors of technique, e.g. in the measurement of drop parameters consequent on the difficulty of allowing for evaporation of the drops. The Reviewers have recently shown[43] that the individual charges on monodisperse droplets (5–15 μm) of dibutyl phthalate—a liquid of high boiling point, which eliminates effects due to vaporisation and condensation—are close to the calculated equilibrium value, and at least do not exceed the latter.

Thus, in view of the absence of an exact theory of the electrohydrodynamic atomisation of a liquid, the minimum energy hypothesis can be regarded for the present as a convenient basis for examining (with quite good approximation) qualitative aspects of the phenomenon.

III. POSSIBILITY OF QUANTITATIVE ASSESSMENT OF THE PROCESS

The publication discussed above were devoted to a qualitative examination of the underlying physics of electrohydrodynamic atomisation, but a new line of research—a quantitative appraisal of the possibilities of the method, the relation between the process parameters and the characteristics of the resulting aerosol, and hence the range of possible variation of the process parameters with the aim of controlling the aerosol characteristics—was required for the successful application of the process in colloidal rocket propellents. A physical model for the process must, of course, be chosen before the process can be described quantitatively. We shall therefore consider a few models suggested by different authors.

As mentioned above, the model of a charged spherical drop in an electric field suggested by Ryce is too far from the actual process of electrohydrodynamic atomisation. A model involving periodic variation of the form of a liquid hemispheroid under the influence of an electric field at the tip of a capillary was suggested by de Schon and Carson[44]. Assuming a Poiseuille flow of liquid in the capillary, these authors obtained the dependence of the form factor of the liquid hemispheroid on the time and the parameters of the process—the internal radius and length of the capillary, the height of the hydrostatic column of working liquid, the viscosity of the liquid, and the electric potential applied to the liquid—but neither the electrical conductivity of the liquid nor the size of the droplets obtained was considered. Furthermore, the whole work related to pulsating generation of the aerosol, so that the model cannot be used to describe the production of a monodisperse aerosol, since a pulsating régime does not yield monodispersity[43].

Semple and Bollini[42] describe the production of a collimated beam of monodisperse water drops carrying charges of the same sign. The experimental results gave the dependence of the process on the capillary diameter, the hydrostatic pressure of liquid, and the applied voltage. However, large drops (d = 140–420 μm) were generated, when not only Coulombic forces but also gravity played a significant part ("dropping" régime), so that the model cannot be extended to electrohydrodynamic atomisation.

The most noteworthy papers are those by Hogan and Hendricks[40] and by Pfeifer and Hendricks[41]. In the latter[41] theoretical and experimental investigation of the dependence of the specific charge of the droplets obtained by electrohydrodynamic atomisation on the process parameters the starting point was the minimum energy hypothesis and the authors' model of the mechanism of the emission of droplets of a dielectric liquid from the tip of a capillary in a strong electric field. Both régimes with and those without allowance for the effect of the space charge in the region of atomisation were considered. A formula was obtained[41] for determining the specific charge on the particles from the parameters of the liquid and the process (viscosity, dielectric constant, surface tension, electric potential on the liquid, mass consumption of liquid, geometry of the capillary, and distance from capillary to counter-electrode). Experiments on the atomisation of glycerol yielded an empirical formula for the specific charge on the droplets, which agreed quite well with the theoretical formula. In the deduction of the latter, however, the radius of the liquid tip was equated to that of the capillary in the expression for the strength of the electric field between a liquid point and a plane, which is possible only in the limiting case of an ideal dielectric. In the other limiting case (an ideally conducting liquid) the radius of the tip must obviously be equated to that of the droplet emitted from the liquid tip. This would introduce a correction into the proposed[41] formula.

IV. ROLE OF THE ELECTRIC POTENTIAL AND THE CORONA. NEUTRALISATION OF THE CHARGES ON DROPLETS

Among the main characteristics of electrohydrodynamic atomisation are the initial atomisation potential and the critical potential. The former corresponds to the appearance of instability in the liquid meniscus and the start of atomisation. The critical potential represents the development of the process with increase in the voltage applied to the capillary, and the transition to steady emission of droplets from the liquid point. It has been shown theoretically and experimentally[45,46] that with rise in potential the liquid meniscus is stretched to a cone having a vertical angle of ~ 100°, after which the surface breaks down with the emergence of a liquid filament or with the detachment of droplets from the tip of the cone. The Reviewers have been unable to confirm a theoretical formula obtained[40] for the initial atomisation potential. This formula obviously represents only a particular case of atomisation, and disregards a variety of process parameters and properties of the atomised liquid.

The most interesting characteristic of the generation of a monodisperse aerosol by electrohydrodynamic atomisation is the critical potential[30,43], corresponding to the transition from pulsating generation with formation of a polydisperse aerosol to steady generation of a monodisperse aerosol. The nature of the critical potential can be explained by the variation in the conductivity of the liquid under the influence of the electric field[41], but it is difficult at present to evaluate this potential theoretically.

Since electrohydrodynamic atomisation takes place in strong electric fields, it is accompanied under certain conditions by the development of a corona discharge from the liquid point or liquid filament. Two main problems—the effect of the corona on atomisation as a function of the sign of the applied potential and its effect on the atomisability of the liquid—have been examined in the many studies[2-11,29,35,46-48] of such a discharge from a liquid drop and its effect on electrohydrodynamic atomisation. All experiments on the effect of a corona have been made with potentials of at least 4 kV. A highly dispersed monodisperse aerosol can be generated electrohydrodynamically at the relatively low potentials of 3–4 kV.[28] The process then occurs in the absence of a corona, whether the potential on the liquid is positive or negative.

The liquid droplets formed by electrohydrodynamic atomisation carry a very high charge, approximately half the Rayleigh value, and therefore possess high electric mobility. The rate of electrostatic leakage is then so large that a stable cloud cannot be produced from such an aerosol, while it is difficult to control its transport and formation of an aerosol flux, which entail large losses on the walls of the tubes. In some cases, therefore, the charge and hence the mobility of the droplets must be lowered, sometimes removed completely, or more precisely the aerosol must be brought to an equilibrium charge distribution. An aerosol bearing charges all of the same sign can be neutralised by electrostatic coagulation with oppositely charged particles in the presence or in the absence of an electric field. Such coagulation is more intense only from a certain critical field E_{cr}, which increases with increase in the individual charges on the coagulating particles[49]. Since the individual droplet charges obtained electrohydrodynamically are extremely large, it is pointless in this case to apply an external field to accelerate coagulation.

Several studies of the neutralisation of droplets have used gaseous ions from a corona discharger or a thermal ioniser. Thus the corona discharge with a point–plane electrode system was used[18] to neutralise a cloud of droplets of a polymer solution bearing charges of the same sign. An earthed grid was placed between the corona-displaying point and the capillary to eliminate the effect of the field due to the corona on the field at the end of the capillary. A thermal ioniser—an incandescent tungsten wire—was used[50] to neutralise a flux of charged particles of a water–glycerol mixture, representing the working medium of a colloidal propellent. In this case electrostatic coagulation takes place in the absence of a field.

V. PRODUCTION OF MONOMOBILE AEROSOLS

The need to produce monomobile aerosols—having charges of like sign with a narrow particle distribution function with respect to electrical mobility—arises in many fields of aerosol research as well as in certain special applications of electronic–ionic technology. There is no sharp boundary between mono- and poly-mobile aerosols, as in the case of mono- and poly-disperse aerosols. What aerosol is regarded as monomobile depends on specific requirements. Application possibilities for monomobile and monodisperse aerosols are analogous—calibration of charged-particle counters and spectrometers, investigation of physical processes in charged aerosols, directed deposition of particles in an electric field, etc. Monomobile aerosols located in different mobility ranges are usually obtained by different methods, the chief of which are outlined below.

1. The charging of monodisperse[51] aerosols in the field of a corona discharge (shock charging)[52,53] or in an ionising atmosphere in the absence of an external field (diffusion charging)[54,55]. Many dischargers suitable for the generation of monomobile aerosols have been described[56-62]. Measurement of the particle mobility distribution function

by means of an instrument of high resolving power is the most interesting[62]. Charging by gaseous ions will yield monomobile particles over a fairly wide range of mobilities (0.05–0.0002) with a comparatively high aerosol concentration.

2. The vibrating capillary method with application of a potential to the liquid or induction of charge on the surface of the liquid at the outlet from the capillary. Coarsely dispersed monomobile particles ($d = 120\ \mu m$) were obtained[63], but no quantitative data were given on their mobility.

3. Preparative spectrometry of charged aerosols. Strictly monomobile latex particles were obtained[64], bearing one or more elementary charges.

4. Electrohydrodynamic atomisation to produce a monodisperse aerosol. This provides a very wide range of particle sizes (~ 0.2–700 μm). The individual charges on the particles are very large, around half the Rayleigh limit. The only reported[43] measurement of the mobility of such particles, in which a modified UT 7003 aspiration ion-counter was applied to a monodisperse dibutyl phthalate aerosol of particle size $r = 5–20\ \mu m$, showed that a monodisperse aerosol obtained by electrohydrodynamic atomisation is also extremely monomobile, with the particles of this size range having mobilities of ~ 0.2–0.5 $cm^2\ V^{-1}\ s^{-1}$.

VI. APPLICATION OF THE ELECTROHYDRODYNAMIC ATOMISATION OF LIQUIDS

The possibility of using electrohydrodynamic atomisation to obtain monomobile aerosols having like charges from many liquids—including solutions of organic and inorganic substances, volatile and non-volatile liquids, suspensions, and even melts—guarantees a wide range of applications for the method. Discussion is already proceeding on the possibility of using the process in such fields as colloidal rocket propellents[20,40,41,50], microencapsulation[65], microdosage of very toxic substances[66], preparation of emulsions[17,67], demonstration of electrophysical experiments[68], and, in combination with hydraulic[22-24] and disc[25] atomisation, in electrostatic painting. This method shows great promise for (*a*) obtaining very homogeneous, thin coatings from solutions of polymers, oligomers, and also salts and electrolytes, (*b*) calibrating aspiration counters and ion spectrometers, flow-type charge spectrometers, aerosol classifiers, counters of condensation nuclei, photoelectric aerosol counters, and other aerosol instruments, and (*c*) obtaining and investigating individual polymer molecules by the highly dispersed monodisperse atomisation of extremely weak solutions of the polymers.
