Electron-donating additives (PyH, NH_3, THF, etc.) have a marked influence on the properties of catalysts; a limited influence of PyH and Et_3N on the yield and proportions of the final products in the polymerisation of ethynylferrocene has been noted[286]. A decrease of the yields and molecular weights of the PA [283,287,294] and p-iodophenylacetylene[77] polymers have been observed when modified systems comprising Et_3Al with $Fe(DMG)_2.2D$ (where D = PyH or NH_3) and $TiCl_3.D_n$ (where D = PyH and n = 1 or 2) were used. The use of δ-$TiCl_3$ (this modification contains up to 27% $AlCl_3$) instead of α-$TiCl_3$ in the complex with Et_3Al leads to an appreciable increase of the yield of cyclic trimers[294]. The activity of the complex falls with increase of the coordinating capacity of the electron-donating additive[287]. In this connection it is interesting to note that, when the catalytic complex is prepared under appropriate conditions, the acetylenic monomer may form part of the complex as an electron-donating additive[295].

The virtually constant activity of iron, cobalt, and nickel chelate complexes in the polymerisation of acetylenic compounds (regardless of the structure of the ligand) and the influence on the process of the electron-donating additives bound to the catalyst show that the coordination of the monomer or the polymer to the transition metal atom is a significant factor in polymerisation in the presence of Ziegler–Natta catalysts[283,287].

The ratio of the components of the catalytic system is very important for the specific synthesis of linear and cyclic products. This is not surprising, since the formation of the active catalytic complex is associated primarily with alkylation and the change in the valence state of the transition metal[296,297]. Thus, in polymerisation in the presence of the $R_3Al–TiCl_4$ catalytic system, the maximum yield of the cyclotrimerisation products derived from a number of alkynes was noted for the molar ratio Al:Ti = 1–3 (with R = iso-Bu),[276] 3 (with R = Et),[298] 3 (with R = iso-Bu),[282,291,292,299,300] and 2–4 (with R = Et).[274] Whereas in the polymerisation of PA in the presence of $Et_3Al–TiCl_4$ the maximum yield of linear polymers was reached for Al:Ti > 4,[274] in the presence of $(iso\text{-}Bu)_2AlCl–TiCl_4$ linear polymers were not obtained for any Al:Ti ratios in the range from 1/3 to 8;[284] in the presence of $Et_2AlCl–TiCl_4$ with Al:Ti = 3–7 the yield of triphenylbenzenes falls sharply and the main reaction product is a linear polymer[273]. On the other hand, other investigators believe that the optimum ratio for the formation of linear polymers is Al:Ti = 1–3.[269,301–303] In the presence of the $R_3Al–Ti(OBu)_4$ system where R = Et or iso-Bu, no changes were observed in ethynylferrocene for the molar ratio Al:Ti = 1. For higher Al:Ti ratios, up to 20, mainly a linear polymer is formed. On passing from R_3Al to Et_2AlCl and for the molar ratio Al:Ti = 5, only a cyclic trimer is formed[286]. Poly-α-ethynylnaphthalene and polyPA have been obtained in the presence of $Et_3Al–Ti(OBu)_4$ for Al:Ti ratios of 2.86 [288] and 4 [285] respectively. The replacement of $TiCl_4$ by $TiCl_3$ increases the activity of the system in linear polymerisation reactions over a wide range of Al:Ti ratios (from 1 to 10),[75,77,268,272,283,304–309] the use of δ-$TiCl_3$ resulting in an increase of the polymerisation rate constant approximately by a factor of 5 compared with α-$TiCl_3$.[308]

When the nature of the transition metal is altered, the optimum ratio of the catalytic system components for the preferential formation of linear or cyclic products changes. This is mainly because of the ease of reduction of a particular metal. Indeed vanadium halides react with aluminium alkyls much more readily than do titanium halides[296]. In conformity with this finding, the optimum ratios in the polymerisation of hex-1-yne in the presence of $(iso\text{-}Bu)_3Al–TiCl_4$ and $(iso\text{-}Bu)_3Al–VOCl_3$ are respectively Al:Ti = 3 and Al:V = 1.5. With increase of the latter ratio, the yield of the linear polymer rises sharply for an overal conversion of 100%.[291] However, as in the case of olefins[297,298], there are no unambiguous data concerning the valence state of the transition metal in the catalytic complex in the polymerisation of acetylenes. For example, it is believed that the maximum activity of the system with respect to cyclotrimerisation corresponding to Al:Ti = 3 is determined by Ti^{2+} [274] or Ti^{3+}.[292]

The data concerning the influence of solvents on the structure of the reaction products are also contradictory. Donda et al.[274] believe that aromatic solvents promote the cyclisation of PA in the presence of $Et_3Al–TiCl_4$. According to the results of Reikhsfel'd and coworkers[282,310], the nature and amount of the solvent, which is inert with respect to the catalyst (benzene, n-heptane, cyclohexane, n-octane, and isooctane), do not influence the overall yield and the proportions of the 1,2,4- and 1,3,5-trisubstituted benzenes formed in the polymerisation of a number of alkynes in the presence of (iso-Bu)$_3$Al–TiCl$_4$. In the presence of the same catalytic system, no difference was observed between the polymerisations of α-ethynylanthracene in n-heptane and toluene[53]. On the other hand, the yield of cyclic trimers in the polymerisation of PA in the presence of Et$_3$Al–TiCl$_3$ is determined by the type of solvent employed[308]: other conditions being equal, mainly linear polymers (in yields of 84–98%) are formed in aromatic solvents (benzene, toluene, and *o*-dichlorobenzene), while in aliphatic solvents (n-heptane, cyclohexane, and dichloroethane), the products are cyclic trimers (23–90%).

The range of monomers polymerised in the presence of Ziegler–Natta catalysts is fairly extensive: propyne[272,290,295,298], but-1-yne[298 304 311], pent-1-yne[75], hex-1-yne[268,282,284,291,292,304–306,311,312], dodec-1-yne[311], 3,3-dimethylbut-1-yne[299], 3-methylpent-1-yne[313], 4-methylhex-1-yne[306], vinylacetylene[284,300,301], isopropenylacetylene[273], PA,[170,274,283,285,287,295,307,308,314,315], *o*- and *p*-nitro, -chloro-, and -methyl-phenylacetylenes[214], phenyldeuteroacetylene[316], α- [288] and β-ethynylnaphthalenes[303], 9-ethynylanthracene[53], ethynylferrocene[286], cyanoacetylene[317], α-furylacetylene[300], isobutoxyacetylene[318], phenoxyacetylene[302], trimethyl- and triethyl-silylacetylenes[319,320], but-2-yne[298], dec-5-yne[298], methylphenylacetylene[316], and β-iodophenylacetylene[75,77]. Propargyl bromide and 5-ethynyl-2-methylpyridine do not polymerise—the former monomer decomposes the catalyst, while in the presence of the latter the catalyst is not deactivated. According to Makovetskii et al.[300], the pyridine substituent weakens the capacity of the triple bond for coordination. Disubstituted acetylenes show a greater tendency towards the formation of cyclic trimers than monosubstituted derivatives[276,294,316], which can probably be explained by the greater steric hindrance in the formation of the linear polymer chain. When the temperature was reduced, a decrease of the conversion of the monomers[269,283,284,286,291,302,307] and an increase of the relative content of cyclic trimers in the reaction products[294,316] were observed. The yield of cyclic trimers also increases with increase of the degree of conversion of monomers[294,316].

It is known[296,297] that not only the ratio of the components of the catalytic complex but also the state of aggregation of the catalyst and its degree of dispersion in the solvent have a major influence on the structure and properties of the products obtained. In their turn, these parameters depend in many respects on the conditions in the preparation of the catalytic complex (the order in which the components are introduced, the rate of stirring, the temperature and duration of interaction, the absence or presence of a solvent, the absolute amounts of the components, etc.). Thus in the polymerisation of PA in the presence of Et$_3$Al–α-TiCl$_3$ the order in which the components of the catalytic system, the solvent, and the monomer are mixed has hardly any influence on the rate of reaction. However, when δ-TiCl$_3$ is used, a change in the order in which the reactants are introduced (a change from the sequence TiCl$_3$ + Et$_2$Al solution + monomer to the sequence TiCl$_3$ + monomer + Et$_3$Al solution) alters sharply the polymerisation kinetics[316]. In the latter case the monomer is probably actively involved in the formation of other catalytic active centres. This may be promoted by the AlCl$_3$ present in relatively large amounts as an impurity in δ-TiCl$_3$. Similarly the purity of the metal alkyl has a definite influence on the degree of reduction of the transition metal (for example, one must take into account the virtually unavoidable admixture of the highly reducing aluminium hydride in the initial aluminium alkyl component). It is extremely probable that the contradictory nature of many of the data discussed is in fact in many respects determined by the different conditions used in the preparation of the catalyst components and the catalytic complexes based on them as well as different process conditions.

5. Other Catalysts

The linear polymerisation and cyclotrimerisation of acetylenes is catalysed by many systems comprising Group VIII transition metal compounds (with the exception of iron) or their complexes, for example NiCl$_2$, CoBr$_2$, PbCl$_2$, Ru(SCN)$_2$, OsCl$_2$, [Ni(C$_2$H$_4$CN)$_3$.P]$_2$, PdCl$_2$.[P(Bu-n)$_3$]$_2$, and NiCl$_2$.[P(Pr-n)$_3$]$_3$ in combination with hydrides of Group I–IV elements (NaBH$_4$, KBH$_4$, LiH, LiAlH$_4$, B$_2$H$_6$, SiH$_4$, SnH$_4$, etc.)[224,241,321–326].

The systems comprising cobalt, platinum, palladium, and osmium proved to be the most active in the polymerisation of hept-1-yne. The valence of the metal is unimportant, but the effectiveness of the organometallic complex is greater than that of an inorganic salt. At high temperatures the process is catalysed even in the absence of a reducing agent[326].

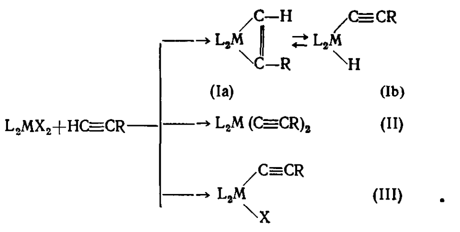
Acetylenes also polymerise under the influence of palladium on charcoal[327] and catalytic systems consisting of an iron halide (FeX$_n$, where X = Cl or Br, and *n* = 2 or 3), and alkali metal acetylide, and a ketone[328,329].

6. The Mechanisms of the Polymerisation Reactions of Acetylenes in the Presence of Transition Metal Compounds

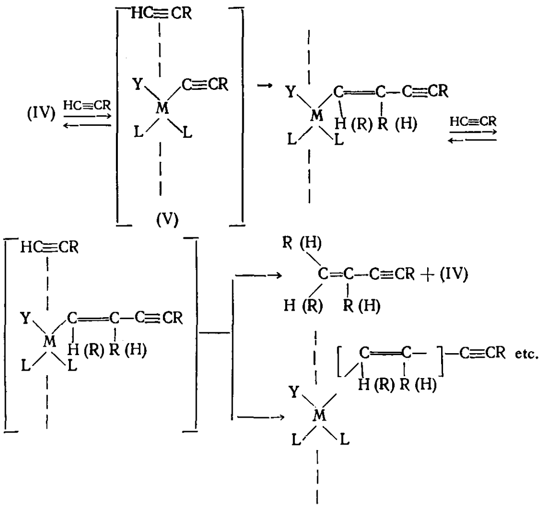
Several mechanisms have been proposed for the cyclic oligomerisation and linear polymerisation of acetylenes, which reflect primarily the wide variety of the catalytic systems employed. However, the contradictory nature or lack of some data on the kinetics and mechanisms of the processes, frequently caused by experimental difficulties (the high rates and heats of reaction[240,330]), make these mechanisms merely hypothetical.

Despite the wide variety of transition metal compounds which catalyse the polymerisation of acetylenes, the first stage in the linear polymerisation and cyclotrimerisation is believed to be coordination of acetylenes to the transition metal of the π-complex type[15,25].

According to Meriweather et al.[240], when Ni(CO)$_2$.(PR$_3$)$_2$ is used, the actual catalyst of the polymerisation of acetylenes is the complex  $(R_3P)_2Ni\left\langle\begin{matrix}C{-}H\\ \Vert\\ C{-}R'\end{matrix}\right.$, in equilibrium with the hydride acetylide (R$_3$P)$_2$Ni(H)C≡CR′. The advantages and disadvantages of this mechanism have been discussed in detail in the literature[14,15,25]. Whereas intermediate acetylides have not been detected in the case of nickel catalysts, a number of acetylides have been isolated in the presence of the less active triphenylphosphine complexes of platinum[236–238]. Possibly the formation of acetylides determines the induction period in polymerisation[234]. The "organometallic" mechanism based on these data can be represented as follows[112,226,236]:

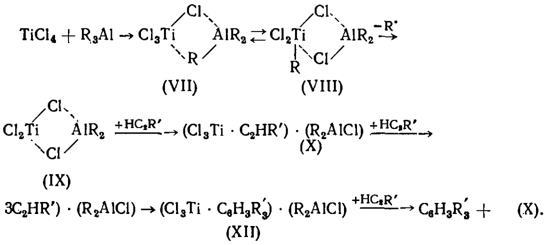


We put (Ib) = (II) = (III) = $L_2M\langle^{C\equiv CR}_{Y}$ = (IV), where M = metal, L = ligand, R = alkyl or aryl, Y = H or C≡CR, and X = Cl, Br, I, or SCN.



The reaction of the phosphine complex of the metal with the alkyne results in the formation of one of the active intermediate products (I)–(III) or their mixture, (IV). Then (IV) reacts rapidly and reversibly with another alkyne molecule to form (V). In the π-complex (V), the triple bond interacts with the p_z orbital of the bivalent metal in such a way that the z axis passes through the centre of the triple bond and the alkyne is disposed parallel to the plane of the complex. The presence in the system of a new π-linked acetylenic unit (V), acting as a kind of Lewis base, compensates the weak shift of the π-electron cloud of the σ-linked acetylenic unit and leads to the formation of (VI). The growth of the polymer chain takes place via the insertion of the coordinated monomer molecule in the ≡C–M bond.

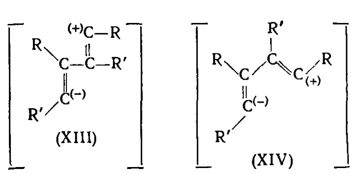
On the basis of the investigations made, Reikhsfel'd and Makovetskii suggested[14,282] that, regardless of the type of catalyst used, the cyclotrimerisation of acetylenes proceeds via a coordination mechanism similar to that proposed earlier for the formation of benzene or cyclooctatetraene derivatives in solutions of nickel complexes[15]. When account is taken of later refinements[292], the proposed mechanism is as follows. When the alkyne RC≡CH molecule interacts with the Ti^{3+} ion, forming part of the two-metal complex with aluminium in proportions of 1 : 1, the complex (VII) is formed with a bridge bond via the R group. The presence of this bond is necessary for the reversible alkylation of titanium to the complex (VIII). The alkylation of titanium is promoted by the fact that the bridge bond via the chlorine atom is energetically more favourable than the bridge bond via the alkyl group. The complex (VIII) contains the extremely unstable Ti–R bond, which dissociates with formation of the complex (IX). The latter reacts with an alkyne molecule to form a new complex (X), which contains, like complex (IX), a coordination-unsaturated titanium atom. In the attack on the complex (X) by two alkyne molecules, an octahedral complex (XI) is produced. According to kinetic data (the second order of the cyclotrimerisation reaction with respect to the monomer[313]), the last stage determines the rate of the entire process. The next stage is the intramolecular exchange of the chlorine atom for the alkyne with a nearly coplanar disposition of all three alkyne molecules and subsequent formation of a benzene ring from them. This liberates two coordination sites in the octahedron, which rearranges back to a square form (XII) with a molecule of the benzene derivative as the ligand. The latter is displaced by a new alkyne molecule with formation of the initial complex (X):



The mechanism discussed above is based primarily on the independence of the cyclotrimerisation reaction (observed by the authors) in different solvents and the identical reactivities in this process of acetylenes with substituents having the opposite effects on the electron density of the triple bond. On the other hand, the mechanism does not explain the simultaneous formation of linear as well as cyclic oligomers and the influence of the nature of the solvent on the ratio of the cyclic and linear products noted in many instances[274,294,308]. The formation of asymmetric 1,2,4-trisubstituted benzenes, the yield of which is sometimes equal to or greater than that of the symmetrical 1,3,5-isomer[277,278,294,308], is also difficult to account for in terms of the "coordination" mechanism. The first order (with respect to the monomer) of the PA cyclotrimerisation reaction[294,308] in the presence of the $Et_3Al-TiCl_3$ system is not consistent with the many-centre character of the "coordination" mechanism.

Many investigators have developed the anionic-coordination mechanism of cyclotrimerisation and linear polymerisation of acetylenes, proposed for the first time by Natta et al.[332]

According to Lutz[14,298], the alkyne is polarised after chemisorption on the catalyst surface. Chain propagation proceeds via the Al–C bond and the direction of the reaction is determined by the configuration of the intermediate complex—(XIII) or (XIV); a linear polymer is formed in the presence of the former and a cyclic trimer in the presence of the latter:

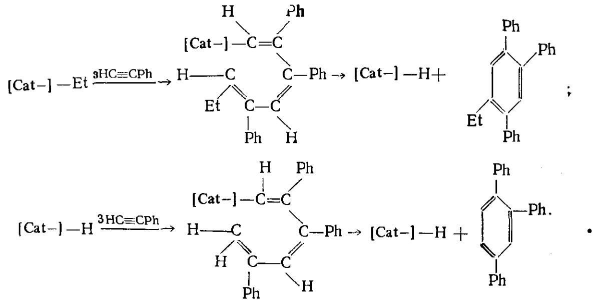


The high selectivity of the cyclisation of disubstituted acetylenes is associated with steric factors. However, this mechanism does not explain the cyclotrimerisation of monosubstituted acetylenes occurring in many instances with high yields.

A study of the reaction of acetylene in the presence of the $Et_3Al-TiCl_4$ system established[333] that ethylbenzene is formed together with benzene. A control experiment showed that the former is not a product of the direct alkylation of benzene under the influence of Et_3Al. This suggested that the cyclotrimerisation proceeds with participation of the M–C bond and the intermediate formation of linear products.

There is no doubt that, as in the polymerisation of olefins in the presence of Ziegler–Natta catalysts, the reactions of acetylenes are initiated by the insertion of the monomer molecule in the M–C bond of the complex catalyst. It has been established by NMR for the $Me_2AlCl-(C_5H_5)_2TiCl_2$ catalytic system[334] that PA is inserted in the Ti–Me bond. The monomer, activated on formation of the π-complex[15], undergoes the *cis*-dissociation of the triple bond during the addition to the M–C bond, as shown by the chain structures of the polyenes synthesised[335–337]. Measurements of the electrical conductivities of reaction mixtures with different compositions have shown that the PA polymerisation reactions in the presence of many Ziegler catalysts are ionic[285].

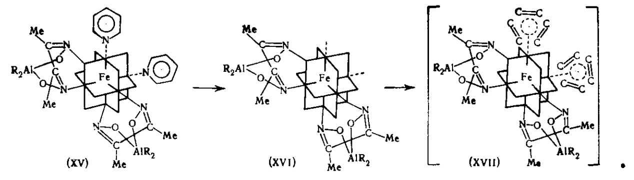
Data obtained in two investigations[294, 308] on the polymerisation of PA in the presence of $Et_3Al-TiCl_3$ are consistent with the anionic-coordination mechanism. The independence of the rate constant for the polymerisation of PA in n-heptane of the yield of cyclic trimers and the first order of the reaction with respect to the monomer show that the mechanism of the formation of cyclic products in the polymerisation of PA in the presence of Ziegler systems is determined by the abstraction of the linear trimer from the catalystic centre with ring closure and not by the simultaneous step involving the interaction of three monomeric units:



The presence of the ethyl group in triphenylbenzenes confirms this mechanism. The preferential formation of cyclic products when the polymerisation is carried out in aliphatic hydrocarbons and of linear polymers in aromatic solvents is associated with the donor–acceptor interaction of the aromatic solvents with the growing chain, which hinders the formation of a conformation suitable for cyclisation. Furthermore, one cannot rule out the possibility of the formation of complexes by aromatic solvents with the titanium component of the catalyst[49, 338–341], which would also hinder cyclisation. The strong inhibiting effect of Et_3Al on the cyclisation process may be explained as follows: by the capture of the end of the polyene chain due to the counteraction by the free Et_3Al on the $TiCl_3$ surface; by the donor–acceptor interaction of Et_3Al with the polyene chain; by the possibility of the formation of Et_3Al as an agent transferring to the chain the secondary active centres [Cat–]–Et, on which the growing chains have an "alkyl" tail which sterically hinders cyclisation.

However, one should note that the homogeneous catalytic system $R_3Al-NiCl_2$ is formed in both aliphatic and aromatic solvents, while polarisation takes place only in the latter[288]. The aromatic solvent probably plays in this case the role of a ligand with π-donor properties, increasing the possibility of dative interaction between the transition metal and acetylene.

Simionescu et al.[226] consider the complex $Fe(DMG)_2.2PyH$ as an octahedral chelate system, which gives rise to a new complex (XV) by reaction with R_3Al. The formation of (XV) was confirmed experimentally by the detection of the RH produced. The aluminium in (XV) decreases the electron density of the Fe–N chelate linkage, which is enhanced by the π-electron system of PyH. In this connection, one should consider the above activity series of aluminium alkyl components[226, 287, 288]. On heating (90°C, 15 min), the complex (XV) is converted into the polymerisation catalyst (XVI) proper. The electron deficiency of the Fe–N linkage is compensated in (XV) by the six alkyne molecules forming two three-unit aromatic systems of type (XVII). The subsequent dissociation of the triple bond leads to the formation of the polyene:



In contrast to the polymerisation mechanisms already examined, where chain propagation takes place (by analogy with vinyl polymerisation) as a result of the addition of the triple bond to the active terminal bond, in the presence of $RhCl.(PPh_3)_3$ PA behaves as a bifunctional monomer. C≡C and ≡C–H behaves as functional groups. Chain propagation is the result of the successive addition of the ≡C–H bond in one monomer molecule to the C≡C bond in another under the coordinating influence of rhodium, as shown by the formation of *trans*-1,4-diphenylbutenyne[223].

The catalytic activity of π-allyl compounds is apparently in many respects determined by their stability, which depends on the nature of the metal and the ligands linked to it[254]. The presence of π-allyl groups is not an obligatory condition for the activity of the complex; the creation of a specific state of the transition metal and a definite degree of its stabilisation are important[257]. The oligomerisation of acetylenes on π-allyl halides is described by first-order kinetic equations with respect to the monomer. The reaction order with respect to the catalyst varies as a function of its nature: it is 0.5 in cyclotrimerisation on π-crotylnickel chloride and unity on the monomeric π-pentenylnickel iodide[257]. The acetylenic monomer initially displaces the allyl ligand from the catalyst (identification of diallyl) with formation of formally univalent (from π-allylmetal halides)[260, 261] or zerovalent nickel[256, 257]. Linear polymerisation takes place via the insertion of the monomer in the M–C σ bond and subsequent chain transfer to the monomer[257, 260] or via insertion in the metal hydride linkage[261].

The hypothetical mechanism of catalysis by a Group VIII transition metal salt and a hydride reducing agent presupposes the reduction of the ion to the lowest valence state with formation of the metal hydride, which in its turn gives a complex with two and more monomer molecules[325]. In this complex the metal atom behaves as an agent transferring hydrogen from one monomer molecule to another.

In the light of recently published interesting data on the polymerisation of a number of acetylenes in the presence of Group VIB arenemetal tricarbonyls[242,243], the "cyclobutadiene" mechanism[15], which has not apparently been considered for the explanation of the linear polymerisation of acetylenes, has attracted attention. An intermediate ladder compound having the cyclobutane structure, which is rapidly and quantitatively converted into linear polyPA following the addition of the catalyst, has been isolated from the products of the initial stage of the polymerisation of PA. Dewar hexamethylbenzene has been detected in the reaction medium in the polymerisation of but-2-yne[242,243]. These findings suggested that a series of consecutive [2 + 2] cycloadditions initially result in the formation of ladder polymers, which are then converted into higher-molecular-weight linear products, probably via a series of metathetical reactions of the olefins with subsequent isomerisation of the electronic structures of the final compounds.

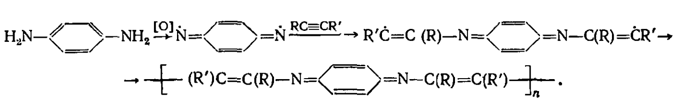
V. COPOLYMERISATION OF ACETYLENES

The copolymerisation of various acetylenic monomers with one another is closest to the homopolymerisation of acetylenes as regards the process mechanism and the properties of the products. As in homopolymerisation, in the copolymerisation of alkynes in the presence of radical initiators[38], cationic catalysts[342], homogeneous and heterogeneous Ziegler–Natta catalysts[343], and catalytic systems comprising Group VIII transition metal compounds and the hydrides of Group I–IV elements[323,324], only copolymers with a low molecular weight have been obtained regardless of reaction conditions. Possibly alternating copolymers are formed in the copolymerisation of *p*-chlorophenylacetylene with *p*-methoxyphenylacetylene and of cyanoacetylene with phenoxyacetylene[38].

The thermal copolymerisation of mono-,and di-acetylenes (PA and *p*-diethynylbenzene) in the range 150–300°C leads to infusible insoluble, and thermally stable copolymers with low electrical resistivities[32–34]. In the catalytic copolymerisation of mono- and di-ethynyl derivatives, the structure of the product is determined by the nature of the diacetylene monomer and the reaction conditions. Whereas the copolymers of PA with *p*-diethynylbenzene contain polyene sections (polyenisation process) together with polyphenylene sections (polycyclotrimerisation process)[26,330,344–348], hepta-1,6-diyne copolymerises with PA under the same conditions via the C≡C bond of the intermediate hept-1,6-diyne dimer, namely 5-(pent-1-ynyl)indane[330,346–349]. Unusual copolymers consisting of polyene or polyene and acene fragments are formed in the homopolymerisation of propargyl propiolate in the presence of $Ni(CO)_4$ [246] or on thermal homopolymerisation of conjugated diynes[26].

The product of the radiation-chemical reaction obtained on irradiation of an acetylene–carbon tetrafluoride mixture by fast electrons at room temperature is apparently a polyvinylene in which some of the hydrogen atoms in the chain have been substituted by fluorine atoms[350]. The fluorine content in the polymer increases with increase of the CF_4 concentration in the initial mixture and varies from 14 to 40 wt.% when the $CF_4 : C_2H_2$ ratio changes from 1 : 1 to 50 : 1 respectively.

The introduction of acetylenic monomers into the reaction system where aromatic compounds undergo polycondensation via a radical mechanism leads to the formation of soluble coloured paramagnetic copolymers. Thus macromolecules containing aromatic and acetylenic units have been obtained by the reduction of aromatic bisdiazonium salts with titanium trichloride in the presence of phenylacetylene, propargyl alcohol, and acetylenedicarboxylic acid[351–353]. The oxidation of aniline and *p*-phenylenediamine by cerium(IV), iron(III), and vanadium(V) salts in the presence of propargyl alcohol, acetylenedicarboxylic acid and its dimethyl ester gives rise to a copolymer via the mechanism[354]

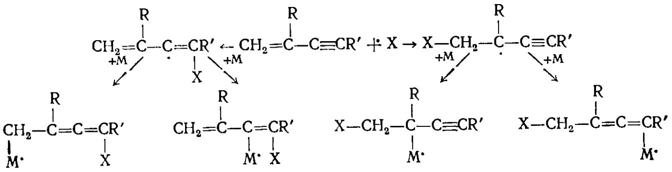


Copolymers containing polyphenylene and polyvinylene fragments are formed when the acetylenic monomer is introduced into the lithium–*p*-dichlorobenzene system in THF solution[355].

The block copolymerisation of polyvinylenes (polyacetylene, polyPA, and polytolane) with electron-accepting vinyl monomers (maleic anhydride, fumaronitrile, and acrylonitrile), occurring in solution and in the melt at 180–200°C, has been investigated[356–360]. A reaction mechanism has been proposed, consisting in the thermal excitation of the charge-transfer complex of the polymer and the monomer to a triplet state at the initiation stage followed by the decomposition of the complex with hydrogen transfer and the formation of polymeric radicals activated by paramagnetic centres and behaving as centres for the growth of macrochains. When polyarylvinylenes are added to vinyl monomers in catalytic amounts, the homopolymerisation of the latter is initiated[361–363].

However, the copolymerisation of acetylenes with olefinic monomers is of greatest theoretical and practical interest. The theoretical interest arises primarily from the determination of the causes of the deactivation of the growing centre on polymerisation of acetylenes and the practical interest is due to the creation of new types of polymeric materials combining the properties of conjugated (high thermal stability and resistance to thermal oxidation, semiconducting properties) and saturated polymers (solubility, fusibility, etc.). It has been noted[364–366] that the set of properties characteristic of polyconjugated systems is manifested to a much greater extent when the conjugated blocks in the macromolecule are separated by fairly long non-conjugated sections. It has been suggested that the copolymers of dicyanoacetylene with vinyl monomers be used in articles where both semiconducting properties and thermal stability are needed (thermoelectric devices, transistors, solar batteries, the casings of rockets, etc.)[367] and that the copolymers of polyvinylenes with ethylene and propene be used for the manufacture of synthetic paper[368].

Studies on the synthesis of rubbers with unsaturated units to facilitate their vulcanisation have been made for a long time[369–371]. The aim of many, particularly the early investigations of the copolymerisation of ethynyldimethylvinylmethanol with dienes[372–377], vinylpyrrolidinone, vinylcaprolactams[378], and 2-methyl-5-vinylpyridine[379] has been to obtain the final products. Price and McKeon[156] proposed the following mechanism for the copolymerisation of vinylacetylenes with acrylonitrile, styrene, isobutene and 2-vinylpyridine (M):



(XVIII) (XIX) (XX) (XXI)

R=R′=H; R=H, R′=Et; R=Me, R′=H; R=Me, R′=Et.

The polymerisation takes place mainly with formation of structures of type (XX), but the monomers with R = Me and R′ = H are partly converted also into structures of type (XIX) or (XXI) [(XVIII)] respectively.

The radical copolymerisation of isoprene with vinylacetylene takes place preferentially and with trimethylvinylethynylsilane exclusively via the double bond of the acetylenic monomer[380]. According to infrared spectroscopic data, isopropenyl- and vinyl-acetylenes are combined into ternary copolymers with ethylene and propene as a result of the dissociation of the triple bond when the reaction is carried out in the presence of $EtAlCl_2$–$VOCl_3$ (or VCl_4). [381, 382] According to the available data on the cationic polymerisation of vinylacetylene[158–161], the copolymerisation of vinylacetylene with isobutene in the presence of BF_3 [369] also probably proceeds via the triple bonds of the acetylenic monomer.

Thus the problem of the structures of the copolymers of the vinyl- and isopropenyl-acetylene series is controversial. As for the data on the homopolymerisation of monomers of this type discussed above, the formation of soluble products is attributed both the the involvement in the reaction of only double or triple bonds of one molecule of the acetylenic monomer[130, 126] and of the triple bond of one molecule and the double bond of another[130, 378]. In the former case linear and in the latter cyclolinear copolymers should be formed.

The copolymerisation of *p*-ethynylstyrene with styrene[113, 383] or of propargyl esters of acrylic, methacrylic, and itaconic acids with *N*-vinylpyrrolidinone and *N*-vinylcaprolactam[89, 384, 385] in the presence of radical initiators probably proceeds preferentially via the double bonds. The number of triple bonds involved in the reaction increases with increasing temperature of the synthesis and at advanced stages of the reaction, which results in the formation of cross-linked products. Under the same conditions, 1,4-di-*p*-chlorophenoxybut-2-yne does not copolymerise with styrene[82].

The explosive copolymerisation of ferrocenylacetylene with chloroprene which could not be prevented by the addition of hydroquinone and which was accompanied by the liberation of iron and HCl, has been observed at 85–90°C. Under the same conditions, ferrocenylacetylene and isoprene failed to react. It is suggested[386] that the degradative processes are associated with the intermediate formation of an unstable α-chlorovinylferrocene.

Dehalogenation of dihalogenomaleic anhydride in the presence of vinyl monomers can serve as a method for the preparation of copolymers with the acetylenedicarboxylic anhydride units[79]. The synthesis of ternary copolymers has been described: acetylene–ethylene–propene[387, 388], acetylene–methylacetylene–propene[389], ethynyldimethylvinylmethanol–butadiene–styrene (or acrylonitrile)[370, 390], $CH_2{=}C(R)C{\equiv}CH$ (where R = H, alkyl, cycloalkyl, or aryl) with 1-mono-olefins[381, 382] and other similar systems[391], hex-1-yne–cyclohexane–sulphur dioxide[392], and PA–cycloheptene–sulphur dioxide[392].

In the statistical copolymerisation of acetylenes, the preferential interaction of the vinyl monomer is usually noted[388, 393–396], which is due to the different reactivities and coordination capacities of the comonomers. Possibly the formation of the copolymer only at a high concentration of the Ziegler catalytic system is associated with the latter factor[397]. However, PA is more active in radical copolymerisation with vinyl chloride[398], vinylidene chloride[399, 400], acrylonitrile[401], and maleic anhydride[402].

The alternating copolymerisation of PA [403] and its *p*-dimethylamino-derivative[50, 404] with maleic anhydride presupposes, like the alternating copolymerisation of vinyl monomers, the preliminary formation of donor–acceptor complexes of the comonomers. The change in the composition of the copolymer as a function of the proportion of the monomers in the initial mixture shows, according to the author[402], that maleic anhydride does not form a stable complex with PA. On the other hand, thermochemical studies and ESR, NMR, and infrared spectroscopic data have shown[360, 405, 406] that the copolymerisation of PA with maleic anhydride proceeds with formation of polyphenylene blocks. One cannot rule out the possibility that the first reaction stage consists mainly in the formation of poly-PA with subsequent addition of maleic anhydride units.

The block copolymers of acetylenic monomers can be obtained in different ways. When PA was added to live polyisoprene with a molecular weight up to 500 000, a block copolymer with the molecular weight of the polyene block up to 10 000 was obtained[407]. The opposite sequence is also possible: the addition of monomers to live polyacetylene chains[192]. When ethylenic and acetylenic monomers were introduced alternately into the reactor containing complex initiators, it was possible to obtain copolymers containing up to 10% of acetylenic hydrocarbons[388, 389]. Block copolymerisation can occur also with simultaneous supply of the comonomers to the catalyst, as happens in the interaction between acetylenes and olefins in the presence of Et_3Al–$TiCl_3$ [408] or (iso-Bu)$_3$Al–$VOCl_3$.[409–411] The intense colour of the copolymer after the complete separation of the ferrocenylacetylene homopolymer suggests the possible block copolymerisation also of the ferrocenylacetylene–isoprene pair in the presence of radical initiators and (iso-Bu)$_3$Al–$TiCl_4$. [397, 412] The possibility of the formation of block copolymers of olefins with acetylenes even at a low concentration of the latter is due, according to Matkovskii[413] primarily to the preferential adsorption of acetylenes by the active centres and the difference between the rate constants for the homopolymerisation of the comonomers. Dimethyl- and ethylmethyl-ethynylmethylamines deactivate the active centres much more markedly than PA, probably owing to the additional involvement of the amino-group in the reaction[411]. An increase in the content of the acetylenic comonomer in the initial mixture reduces the rate of copolymerisation, the yield of the copolymer, and its molecular weight[409–411].

The ability of cyanoacetylene to polymerise under the influence of amines[189] has been used to synthesise graft copolymers. The reaction was carried out by adding cyanoacetylene to a solution of the polymeric initiator, which consisted of a homopolymer of 2-vinylpyridine or the copolymers of 4-vinylpyridine and 2-dimethylaminoethyl methacrylate with vinyl monomers[184].

Thus, despite the inhibiting properties of acetylenic monomers in radical[401, 414, 415] and ionic[409–411, 413] polymer-

Table 1. Conditions governing the preparation of binary acetylenic copolymers.

[a] There is a possibility of the copolymerisation of acetylene with mono-olefins at 40–150°C in DMF under the influence of catalytic systems, consisting of inorganic and organic cobalt or nickel salts and alkali metals or their acetylides[416], and also of the copolymerisation of acetylene or other alkynes with dienes in hydrocarbon solvents at 50°C under pressure in the presence of catalysts of the Ziegler–Natta type[417].

[b] Transition metal halides mixed with lithium and aluminium alkyls, aluminium halide alkyls, or aluminium hydrides can serve as catalysts[389].

[c] Copolymers of hept-1-yne have also been obtained under these conditions[419,420].

[d] Copolymers of non-1-yne, cyclohexylpropyne, and pentadec-1-yne have also been obtained under these conditions[421].

[e] The copolymerisation with other monomers under the influence of radical or ionic initiators is also possible[367].

isation of vinyl monomers, it has been possible to obtain different types of copolymers of acetylenes with olefins (Table 1).

From kinetic studies of the radical polymerisation of styrene and methyl methacrylate in the presence of PA and its derivatives, Higashiura and Oiwa[424,426] regard acetylenes as highly effective inhibitors and not as comonomers. The inhibiting activity of acetylenes is associated primarily with the resonance stabilisation of the terminal growing chain radical and the activity of the acetylenic radicals should decrease sharply with increase in the size of the conjugated block to which the active centre is linked. Bearing in mind that the probability of the formation of radicals of this type should depend on the concentration of the acetylenic monomer in the reaction mixture and on the corresponding reaction rate constants, Uzbekova and Razumovskii investigated the radical copolymerisation of *p*-diethynylbenzene[435] and PA [425] with styrene and methyl methacrylate using reaction mixtures with a low content of the acetylenic monomer. Their data show that the acetylenes investigated can be regarded as comonomers with a weak inhibiting activity.

Zaitsev et al. proposed an equation for the determination of the composition of the copolymer[436], taking into account the characteristics of the radical copolymerisation of acetylenes noted above, i.e. the difference between the reactivities of the radicals $-CH{=}\dot{C}R$ and $-CH{=}C(R)-\dot{C}H{=}CR$:

$$\frac{d[M]}{d[X]}=\frac{r_X[X]/[M]+r_Xr_M+r_M[M]/[X]+1}{2r_X[X]/[M]+1}, \tag{1}$$

where $r_M = k_{MM}/k_{MX}$, $r_X = k_{XX}/k_{XM}$, and M and X are respectively the vinyl and acetylenic monomer. Table 2 shows (the copolymerisation conditions are indicated in Table 1) that the copolymerisation constants r_M calculated from the classical equation and from Eqn. (1) on the basis of the same experimental data hardly differ, while the values of r_X differ appreciably, as was to be expected.

Table 2. The copolymerisation constants for acetylenic and vinyl monomers.

[a] Calculated by Zaitsev et al.[436] from the data of Uzbekova and coworkers[425,435].

[b] r_M was calculated from the differential equation for the composition of a copolymer of bifunctional monomers[437].

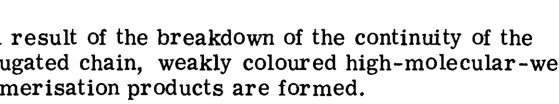
VI. THE STRUCTURES AND ELECTROPHYSICAL PROPERTIES OF ACETYLENIC POLYMERS

The data on the kinetics of the polymerisation of a number of acetylenes discussed above indicate a monomolecular mechanism of chain termination and the independence of the molecular weight of the conditions of the synthesis. Regardless of the chemical nature of the acetylenic monomers and the methods used to polymerise them, polymers with low molecular weights are usually obtained ($\overline{M}_n$ does not exceed 1000–5000). These facts demonstrate the inactivation of the reactive centre during the polymer chain propagation process.

On the one hand, the active centre of the growing chain is linked directly to the conjugated system, so that the reactivity must be evidently influenced by factors which determine the mobility and degree of delocalisation of π electrons. Indeed theoretical calculations based on models involving a conjugated reaction centre[201,212–214,438] confirmed that the delocalisation of the charge or the radical over the conjugation chain with increasing length of the polymeric molecule are the cause of the kinetic deactivation of the active centres. On the other hand, the active radical formed, for example, on dissociation of the triple bond is located in the p_{xy} orbital in the plane perpendicular to that of the conjugated p_z orbitals. In this case the active radical must be appreciably localised in the last unit of the growing chain owing to the weak overlapping of the electronic wave functions and its reactivity should not therefore depend on the chain length.

Thus the mechanism of the delocalisation of the unpaired electron of the growing polymeric radical in radical polymerisation or of the ionic charge in the ionic polymerisation of acetylenes is not self-evident. Therefore, the possibility of the intermolecular inactivation of the reactive centre is postulated together with the intramolecular inactivation[23].

The breakdown of the continuity of the conjugation chain may lead to a growth of the polymer chain which virtually rules out the inactivation of the growing macroradical. Thus the polymerisation of alkylacetylenes containing mobile hydrogen atoms in the α-position relative to the triple bond is accompanied by hydrogen transfer from the alkyl side group to the main chain and the formation of alkylidene side groups[268,305,439,440]:



As a result of the breakdown of the continuity of the conjugated chain, weakly coloured high-molecular-weight polymerisation products are formed.

Long conjugation chains with a coplanar disposition of the C=C bonds are probably unfavourable on thermodynamic and kinetic grounds. The conjugated fragments of macromolecules tend to assume an arrangement relative to one another at an angle in the range $0° < \theta < 90°C$. The macromolecules formed are not planar: they can have different steric conformations in which the exchange interaction of the π electrons diminishes with increase of $\cos^2\theta$. Therefore, in order to estimate the conjugation chain lengths in the macromolecules, the concept of "effective conjugation" or of "block conjugation" has been introduced; it is conventionally expressed in terms of the number of conjugated structural elements having a coplanar arrangement and an electronic absorption or luminescence spectrum analogous to that of the corresponding polymeric homologue as regards the position of the maximum[23,336]. The size of the conjugated block depends on the conditions of the synthesis, but changes little with increase in the length of the macromolecule. The conjugated blocks in polyPA, obtained by thermal polymerisation in bulk at 150°C and in the presence of the $Et_3Al–TiCl_3$ catalytic system in benzene at 70°C, consist of 3–5 and 4–8 units respectively[336,441,442].

The monomeric units in polyPA are combined "head-to-tail"[443–445]. Polyenes obtained under different conditions differ from one another by the position of the substituents both in relation to the double bond and in relation to the chain itself[19,40,224,336,337,446,447]. Four types of chain conformation are possible for polymers of the polyPA type: *trans*-*s*-transoid, *trans*-*s*-cisoid, *cis*-*s*-cisoid, and *cis*-*s*-transoid. For a free rotation of 180° about the single bond, there is a possibility of a transition from the *s*-transoid form to the *s*-cisoid form and converseley. It was found experimentally[336] that polyPA obtained by thermal polymerisation has mainly the *trans*-*s*-cisoid conformation (the angle of rotation about the single bond is $\varphi = 120°C$) with an admixture of the *cis*-structure. The fractions of the polyPA obtained in the presence of $Et_3Al–TiCl_3$ can have the *cis*-*s*-cisoid and *cis*-*s*-transoid conformations ($\varphi = 140–150°$ and $<80°$ respectively). According to calculated data[447], the *cis*-*s*-cisoid conformation ($\varphi = 110°$) is energetically favoured for polyPA. The discrepancy between the calculation and experiment in the last two instances has been attributed by the author[447] to intermolecular interaction. The benzene-soluble polyPA and poly-(α-ethynylnaphthalene) fractions, obtained in the presence of $Fe(DMG)_2.2PyH + Et_3Al$, have the *cis*-*s*-transoid conformation, while block polymerisation of PA and α-ethynylnaphthalene leads to products having the *trans*-transoid structure[337].

Molecules with the *cis*-*s*-cisoid conformation can give rise to close packing of the same type as in molecular crystals. The distances between the molecules are then still so large that intermolecular delocalisation cannot be appreciable. The macromolecules with the *cis*-*s*-transoid conformation are more close packed. Accordingly, Ziegler polyPA is characterised by the presence of crystalline formations (degree of crystallinity about 30%), while thermal polyPA is amorphous[40,448]. Together with the soluble Ziegler polyPA having the *cis*-*s*-transoid conformation and a yellow colour, which has already been considered, a small amount (about 5%) of a red product with a high degree of crystallinity (>70%) and insoluble in organic solvents at room temperature is formed. This product is an assembly of macromolecules with the *cis*-*s*-cisoid structure firmly fixed to the surface of the catalyst. The helical molecular chain contains three monomeric units per repeat period with benzene rings slightly inclined relative to the chain axis. The crystal lattice consists of chains located one above the other without displacement; the packing coefficient is 0.8.[449]

Possibly all the isomeric polyene structures discussed above exist in the helical form and are characterised by a greater (for the *cis*-form) or smaller (for the *trans*-form) packing density. Helical chain conformations impart an ordered structure to the macromolecules, which enables them to be distributed in crystal matrices[337]. The helical structure of the linear conjugated polyhexafluorobut-2-yne is probably responsible for the white colour of this polymer[450].

It has been suggested on the basis of the number and intensity of the diffraction lines and in view of the identity of their periodicities[337] that more ordered packing of the macromolecules is achieved at lower temperatures of the synthesis and that the packing in crystalline matrices depends more on the structure of the main polymer chain than on the nature of the substituent.

The non-stereospecificity of anionic polymerisation noted above can be attributed both to the non-stereospecificity of the addition of the anion to the triple bond and to the isomerisation of the growing anion or the macromolecules when they are isolated and investigated. It is known[224,446,447] that heat treatment or treatment with solvents causes the isomerisation of polyPA. The *cis*–*trans* isomerisation of polyacetylene has been observed on decomposition of catalysts of the Ziegler–Natta type by a mixture of methanol and hydrochloric acid[451] and as a result of the heat generated by a laser source in the recording of Raman spectra[452]. The ratio of the *cis*-transoid and *trans*-transoid structures apparently depends primarily on the temperature of the addition of the first monomeric unit to the catalyst, i.e. on the formation of the complex (XVII). If the transition (XVI) → (XVII) takes place at a low temperature (–78°C), then fully *cis*-transoid poly-(α-ethynylnaphthalene) is formed not only at –78°C but also at a polymerisation temperature of 25°C.[226]

Thus the configuration of the polyene is determined mainly by the composition of the catalyst and the temperature of the synthesis; a *cis*-transoid configuration presupposes the *cis*-dissociation of the triple bond in the polymerisation process. On the other hand, according to electron microscope data, the supermolecular structure of polyenes changes very little with the temperature of the synthesis and is almost independent of the type of the catalyst and its concentration[337,451].

Regardless of the nature of the aromatic substituent, all the polyenes investigated form only globular structures with dimensions up to 300–700 nm. More complex morphological formations in the form of rods or other structures have not been observed even for *cis*-transoid polymers with the highest degree of crystallinity[337,453,454]. The characteristics of the molecular, the supermolecular, and the electronic structures of acetylenic polymers discussed above determine their semiconducting properties[22,112,120,226,455-458].

The dark and photoelectric conductivities of soluble polyvinylenes do not usually exceed $10^{-12}\ \Omega^{-1}\ cm^{-1}$ regardless of the nature of the initial monomer and the polymerisation conditions. The mobility is of an electronic type; as a rule, one is dealing with *p*-type conductivity with a mobility of $10^{-4}\ cm^2\ V^{-1}\ s^{-1}$.[456,459] When a polymer–electron acceptor heterophase system is formed, it is possible to increase greatly the photoconductivity of the system relative to the level of the photoconductivity of both the polymer and the acceptor[460-465]. Not only the corresponding low-molecular-weight compounds but also polymeric compounds, for example the products of the nitration of PA and tolane polymers, can be used as electron acceptors even under the conditions of electrophotography. In the presence of polymeric acceptors, the system exhibits film-forming properties and an improved thermal stability in addition to the enhanced photosensitivity[466,467].

Possibly the increase of photoelectric sensitivity is associated with the spectral sensitisation of the acceptor by the polyene system. Since the spectral sensitisation constitutes the most important procedure for varying the spectral photosensitivity and increasing the integral photosensitivity of silver halides in photography and of zinc oxide in electrophotography, the spectral sensitisation of the photoconductivity of inorganic semiconductors by conjugated polymers is of great interest[468-471]. The electrical conductivity of polymers is defined by the relation[455]:

$$\sigma = q\mu n = q\mu N e^{-E/2kT} \quad ,$$

where q is the elementary charge of the current carriers (electrons), μ the mobility of the carriers, n the number of carriers per unit volume, N the concentration of π electrons, and E the activation energy for conduction (the gap between the valence and conductivity bonds under the conditions of the band mechanism of conduction).

The activation energy is determined mainly by the electron–electron repulsion in the polymer chain; it amounts to 2.5 and 2.4 eV respectively for PA and tolane polymers[472]. The gap may be reduced only when the electron–electron interaction in the polymer chain is weakened, which involves the withdrawal of electrons from the chain under the influence of, for example, electron-accepting side groups[473]. With increase of the degree of conjugation of the cyclic benzene side groups with the main chain, which is achieved by the high-temperature sublimation of the polymer (500°C, 10^{-5} mmHg), the mobility of the holes in the sublimed films of PA and tolane polymers increases from 2×10^{-4} to 0.1 and from 2×10^{-4} to 0.3 $cm^2\ V^{-1}\ s^{-1}$ respectively, while the activation energy for conduction diminishes to 1.4 and 1.3 eV.[472,474,475]

The activation energies for conduction and the mobilities obtained for the sublimed polyphenylvinylene films are probably close to the theoretical limit. Indeed, with decrease of the electron–electron repulsion in the polymer chain under the influence of electron-accepting side group substituents, the concentration of carriers also falls, i.e. the compensation effect comes into force[456].

The mobility of the charge carriers is determined by the intermolecular transitions of these carriers between the conjugated regions. Their low mobility in conjugated polymers in the acetylenic series is due primarily to the low degree of overlapping of the atomic wave functions at the sites corresponding to the breaks in conjugation. Branching and cross-linking in macromolecular chains should therefore lead to a decrease of the activation energy for conduction and to an increase of the mobility of the carriers. Ladder and graphite-like structures can be regarded as limiting cases of the structures of regularly cross-linked polymers.

---o0o---

The data examined demonstrate an extremely vigorous development in recent years of research on the polymerisation processes of acetylenic compounds. This is associated primarily with efforts directed towards the creation of new organic semiconducting materials. A number of mechanisms have been proposed for the thermal and catalytic polymerisation of acetylenes, which may be regarded as merely hypothetical in view of the contradictory nature or lack of convincing data for the kinetics and mechanisms of the processes. An unambiguous answer to the question of the causes responsible for the deactivation of the growing active centre in the polymerisation of acetylenes has not yet been obtained. There is no doubt that further study of the copolymerisation of alkynes is of interest from both theoretical and practical points of view. We share Myl'nikov's view that "together with the importance of seeking new semiconducting organic polymers there is an urgent necessity for a more detailed investigation of the specific physical structure as solids with a simultaneous development of methods for their purification and for the determination of the impurities"[458]. However, the activation energies for conduction and charge carrier mobilities greater than about 1 eV and about 1 $cm^2 V s^{-1}$ respectively should not probably be expected even for well ordered polyvinylene systems with a linear structure. Studies involving both the synthesis of regular ladder and graphite-like systems and an increase in the photoconductivity of organic semiconductors under the influence of electron acceptors are possibly the most promising in this sense.

Magnetic Effects in Chemical Reactions

A.L.Buchachenko

The Review discusses in what elementary chemical reactions the intrinsic angular momentum of electrons and nuclei is conserved and in what reactions it is not conserved, how weak electron-nuclear magnetic interaction and an external magnetic field influence the conservation of angular momentum and what are the consequences of this effect, and what magnetic effects occur in chemical reactions, as well as the conditions for their development and detection. Conditions are formulated for the non-conservation of the intrinsic angular momentum of electrons and nuclei in chemical reactions. The bibliography contains 36 references.

CONTENTS

I. INTRODUCTION

Chemical processes, i.e. transformations of some molecules into others, are always accompanied by regrouping of nuclei and rearrangement of electron shells. The most important characteristic of such transformations is their energy. In the analysis of chemical processes and the reactivity of reactant species, therefore, it is right to pay maximum attention to the energy aspect. However, it must always be borne in mind that electrons and many nuclei possess intrinsic angular momenta, and the laws of their conservation can exert a marked influence on the direction of chemical reactions and hence on their energetics. Wigner's rule on the conservation of the total electron spin of a reactant system was formulated comparatively long ago, but it is not always satisfied.

The angular momentum of electrons and nuclei is conserved in elementary chemical reactions involving substitution, dissociation, recombination, addition, disproportionation, and electron transfer. If, however, long-lived states, in which transitions are possible between states differing in spin multiplicity, are established in chemical reactions, the angular momentum of electrons and nuclei is not conserved. This leads to the remarkable consequences of magnetic effects in chemical reactions, the most striking of which—chemical polarisation of nuclei, enrichment of magnetic isotopes in chemical reactions, and the effect of a magnetic field on the rates of chemical reactions—are discussed in the present Review.

II. ORIGIN OF MAGNETIC EFFECTS

In most molecules the intrinsic angular momenta (spins) of the electrons balance: i.e. the electrons are coupled. Chemical reactions may take place either without change of spin in the electron-pairs or with uncoupling of the electrons. In the former case the spins in the electron-pairs remain balanced; in the latter case unbalanced individual electron spins appear. The former reactions are classified chemically as heterolytic, and the latter as homolytic or radical.

Magnetic effects must obviously be sought in reactions of the second type, because they involve the production of magnetic moments of electrons, which interact strongly among themselves, with the magnetic moments of the nuclei, and with external magnetic fields. Under certain conditions all these interactions lead to non-conservation of the electronic and the nuclear spin of the reactant system, to the appearance of magnetic effects in chemical reactions. We shall now consider what these effects are and under what conditions they develop.

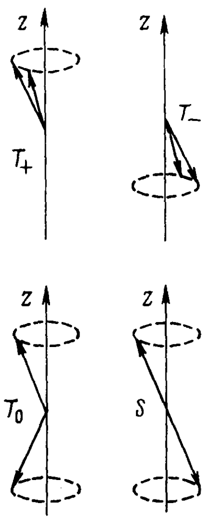

Figure 1. Orientation and precession of electron spins of a radical-pair in an external magnetic field in the z-direction.

In order to understand the origin of magnetic effects in radical reactions it is sufficient to consider as model a simple radical-pair ($HR^{1\cdot}$, $R^{2\cdot}$) in which one radical $HR^{1\cdot}$ contains only one magnetic nucleus (the proton), while the other radical $R^{2\cdot}$ has none. Let the g-factor of the first radical be g_1, and that of the second radical g_2: i.e. the Zeeman energies of the electrons of these radicals in a magnetic field H are $g_1\beta H$ and $g_2\beta H$. We suppose that hyperfine magnetic interaction between electron and proton also occurs in the radical $HR^{1\cdot}$, its energy being am, where $m = \pm\frac{1}{2}$ is the projection of the spin of the proton in the direction of the external magnetic field and a is the electron–proton hyperfine interaction constant. Finally, non-magnetic exchange interaction J occurs between the unpaired electrons of the radical-pair; it forms part of the electrostatic interaction, and is distinguished from the usual Coulombic interaction only in its dependence on the electron spin. Exchange electrostatic forces which depend on the spin of the electrons must be postulated in order to satisfy one of the fundamental principles of quantum mechanics—the Pauli principle.

The spins of the two unpaired electrons in a radical-pair may be oriented in such a way that their vectors must be either added or subtracted, to give a total spin of either unity or zero. Because of the occurrence of exchange interaction the energies of these two states are not the same but differ by the amount J. The state with zero spin is a singlet (S); the state with unit electron spin is termed a triplet (T), since the total electron spin may be oriented in a magnetic field in three different ways with projections of +1, 0, and −1 for the total spin vector in the field direction. These three substates T_+, T_0, and T_- differ in their Zeeman energies, which are respectively $g\beta H$, 0, and $-g\beta H$, where $g = \frac{1}{2}(g_1 + g_2)$. The scheme of orientation of electron spins in a radical-pair is shown in Fig. 1, and the energy levels of the states corresponding to these orientations are indicated in Fig. 2.

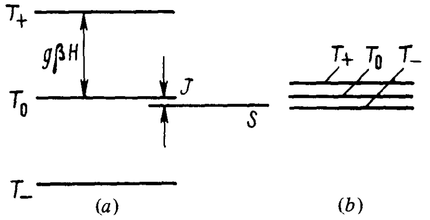

Figure 2. Energy levels of a radical-pair in a magnetic field: a) strong; b) weak.

We shall now suppose that the radical-pair is in a triplet state. Such a pair must undergo a transition to a singlet state before it is able to recombine to give the reaction product. Thus the probability of recombination (or disproportionation), with the formation of molecular products having zero total electron spin, is proportional to the probability of triplet–singlet transition. The latter probability is proportional to the square of the matrix element calculated from the spin wave functions of state S and T and the spin Hamiltonian $\mathscr{H}$ of the pair:

$$p_{T\text{-}S} \sim |\langle T|\mathscr{H}|S\rangle|^2. \tag{1}$$

The Hamiltonian $\mathscr{H}$ defines the interactions of electrons and nuclei in the pair:

$$\mathscr{H} = \beta H(g_1S_1 + g_2S_2) - J(^1/_2 + 2S_1S_2) + aIS_1\,, \tag{2}$$

where the first term represents the Zeeman interaction of the electrons, the second term the exchange interaction, the third term the hyperfine interaction between electron and proton in the $HR^{1}\cdot$ radical, S_1 and S_2 are the spins of the first and second electrons, and I is the spin of the proton. The matrix element for the transition T_0–S is

$$\langle T_0|\mathcal{H}|S\rangle = {}^1/_2(\Delta g\beta H + am) \tag{3}$$

in which $\Delta g = g_1 - g_2$ and $m = \pm\frac{1}{2}$ (for the proton). The matrix elements for transition from states T_+ and T_- to state S are

$$\langle T_+(-{}^1/_2)|\mathcal{H}|S(+{}^1/_2)\rangle = -({}^1/_8)^{{}^1/_2}a, \tag{4}$$

$$\langle T_-(+{}^1/_2)|\mathcal{H}|S(-{}^1/_2)\rangle = ({}^1/_8)^{{}^1/_2}a. \tag{5}$$

(The procedure for calculating such matrix elements will be found in greater detail in Ref. 1).

The expressions $(\pm\frac{1}{2})$ in Eqns. (4) and (5) denote the projections of the spin of the proton; triplet–singlet transitions from states T_+ and T_- are obviously allowed only in the presence of hyperfine electron–nuclear interaction, and are necessarily accompanied by reorientation of the nuclear spin: $T_+(-\frac{1}{2}) \to S(+\frac{1}{2})$ and $T_-(\frac{1}{2}) \to S(-\frac{1}{2})$. Thus it is important for transitions from T_+ and T_- states to the S state that hyperfine interaction should involve a single electron–nucleus system; the change in electron spin accompanying the triplet–singlet transition will then be balanced by a change in the nuclear spin.

Thus a triplet–singlet transition is accompanied by a change in the total electron spin and is therefore forbidden. However, if the unpaired electrons attached to the components of a radical-pair differ in their Zeeman energy and if hyperfine interaction links electronic and nuclear spin systems, the prohibition on such a transition is partly removed. This partial elimination of spin prohibitions is the cause of the magnetic effects.

Before analysing magnetic effects we note that the mean exchange interaction is small in radical-pairs in a liquid, and the exchange energy can be neglected (proofs of this statement will be given later). Therefore in strong magnetic fields, when the Zeeman energy $g\beta H$ is large, the T_+ and T_- levels are remote from S, and the main contribution to triplet–singlet mixing is made by transitions between contiguous T_0 and S levels. In weak magnetic fields $g\beta H$ is small, all three levels T_+, T_0, and T_- are situated close to the level of the singlet state, and transitions from all the triplet substates are important for triplet–singlet mixing (Fig. 2). We shall now enumerate the principal magnetic effects.

(i) It follows from Eqns. (3)–(5) that the probability of triplet–singlet transitions and hence the probability of reaction depend on the nuclear spin of the radical. As a consequence the recombination products are enriched (or impoverished) in nuclear spins of a certain orientation: i.e. a non-equilibrium population of Zeeman nuclear levels is produced in the reaction products. Such non-equilibrium population or pumping of Zeeman levels results in a non-equilibrium orientation or polarisation of nuclei in the molecules generated from the radical-pairs. This phenomenon of chemically induced magnetic polarisation of nuclei was discovered by Fischer and Bargon and independently by Ward and Lawler in 1967, and has become widely known[2,3].

(ii) It follows also from Eqns. (3)–(5) that the probability of recombination depends on the hyperfine electron–nuclear interaction energy. Isotope effects should be observed in the rates of recombination of the components of radical-pairs, since the nuclei of isotopes possess different magnetic moments and hence have different hyperfine interaction constants.

(iii) The dependence of the probability of recombination of radicals on the hyperfine interaction energy (or on the magnetic moment of the nuclei) makes possible the selection and enrichment of magnetic isotopes in chemical reactions. This effect is purely magnetic in origin, so that a method of isotope enrichment that can be based on it differs fundamentally from other methods (e.g. the selective dissociation of chemical bonds by laser illumination, which utilises the isotope effect on vibration frequencies due to the difference in mass between isotopes[4]).

(iv) Another consequence of Eqn. (3) is that the probability of recombination of the radicals forming a pair depends on the strength of the external magnetic field (provided that the radicals have different g-factors, i.e. that $\Delta g \neq 0$). This gives rise to quite definite and soundly based ideas on the causes and the physical mechanisms of the influence of an external magnetic field on the direction and the rates of chemical reactions. In the case of radical reactions a magnetic field affects the rate of triplet–singlet conversion and changes the probability of recombination. This mechanism is readily generalised to cover any reactions involving species in higher spin states, with a larger number of unpaired electrons (e.g. iron and copper ions, molecular oxygen, etc.). In such cases the magnetic field also influences the probabilities of intersystem transitions between states differing in spin multiplicity (doublets, triplets, quartets, quintets, etc.) in reactant-pairs, and consequently changes the probabilities of chemical reactions.

Each of these four effects will be discussed further. Before proceeding to their detailed analysis, however, we can usefully extend the key equations (3)–(5) to cover any pair of radicals with any number of nuclei. The spin Hamiltonian of such a generalised pair is

$$\mathcal{H} = \beta H(g_1S_1 + g_2S_2) - J({}^1/_2 + 2S_1S_2) + \sum_i a_iS_1I_i + \sum_j a_jS_2I_j \quad , \tag{6}$$

where I_i is the spin of the ith type of nucleus in the first radical, I_j is the spin of the jth type of nucleus in the second radical, and a_i and a_j are the corresponding hyperfine interaction constants. The matrix element of triplet–singlet mixing for a transition from the T_0 state is

$$\langle T_0|\mathcal{H}|S\rangle = {}^1/_2\left(\Delta g\beta H + \sum_i a_im_i^a - \sum_j a_jm_j^b\right) , \tag{7}$$

where the m_i^a are the projections of nuclear spins of the ith kind in the first radical, the m_j^b are the projections of nuclear spins of the jth kind in the second radical, and the summation covers all nuclei in both radicals. The three terms in Eqn. (7) are respectively the difference in the Zeeman energies of the electrons, the sum of the hyperfine interaction energies in the first radical, and the corresponding sum in the second radical of the pair. The matrix elements of triplet–singlet mixing from states T_+ and T_- are

$$\langle T_+, m_i - 1|\mathcal{H}|S, m_i\rangle = -({}^1/_8)^{{}^1/_2}a_i[I_i(I_i + 1) - m_i(m_i - 1)] , \tag{8}$$

$$\langle T_-, m_i + 1|\mathcal{H}|S, m_i\rangle = ({}^1/_8)^{{}^1/_2}a_i[I_i(I_i + 1) - m_i(m_i + 1)] . \tag{9}$$

As with the model one-proton radical-pair (Eqns. 4 and 5), triplet–singlet transitions from states T_+ and T_- are obviously allowed only in the presence of hyperfine electron–nuclear interaction, and are accompanied by reorientation of the nuclear spin of the ith kind: in a T -S transition the nuclear spin increases $(m_i - 1 \to m_i)$; in a T_--S transition the nuclear spin diminishes $(m + 1 \to m_i)$.

The probabilities of all these transitions are proportional to the squares of the matrix elements (7)–(9). It is readily seen that Eqns. (3)–(5) are particular cases of the general equations (7)–(9): they are obtained with $m_i = \pm\frac{1}{2}$, i.e. for a one-proton radical-pair.

III. CHEMICAL POLARISATION OF NUCLEI

1. Physical Mechanisms of the Chemical Polarisation of Nuclei

The chemical polarisation of nuclei has acquired great popularity, with accounts of its theory and chemical applications in several books and reviews[2,3,5-7]. For this reason only a brief discussion will appear here of the evolution of ideas in this field, of the current state of the theory, and of chemical applications of the phenomenon.

We shall first discuss the mechanisms by which nuclear polarisation is produced. As noted above, the main contribution to triplet–singlet conversion of a radical pair is made in strong magnetic fields by transitions from the T_0 state. Equation (3) shows that, if $\Delta g > 0$ and $a > 0$, the probability of triplet–singlet transition is greater in a radical-pair having $m = +\frac{1}{2}$ than in a pair having $m = -\frac{1}{2}$. This means that pairs having a proton oriented in the direction of the field undergo triplet–singlet conversion more rapidly and hence recombine more rapidly: i.e. the products of recombination (or disproportionation) are enriched with positively polarised nuclei. On the other hand, radicals that have avoided recombination in the radical-pair and have escaped into space contain an excess of protons oriented against the field, and these radicals confer on their conversion products a negative nuclear polarisation. Thus T_0–S transitions in radical-pairs involve a selection of radicals according to their nuclear spins: chemical reactions lead to selection, to a sorting of radicals (and hence of molecules produced from them) according to their nuclear-spin states.

It is readily seen that, if the sign of Δg or a is changed in Eqn. (3), the sign of the nuclear polarisation also changes. For the same reason the sign of the polarisation is reversed if the precursor of the molecules is not a triplet but a singlet pair, when the reverse singlet–triplet conversion of the pair takes place. It is easy to predict from Eqn. (3) the sign of the chemical polarisation of nuclei as a function of those of Δg and a and the spin state of the radical-pair. Kaptein[8] suggested for this the convenient form

$$\Gamma = \mu\varepsilon\,\Delta g a \tag{10}$$

known as Kaptein's rule, in which $\mu = +1$ if the precursor of the molecule is a triplet pair, $\mu = -1$ if the precursor is a singlet pair, $\epsilon = +1$ for a product of recombination or disproportionation, $\epsilon = -1$ for conversion products of radicals outside a pair, Δg and a determine the signs of these quantities $\Gamma > 0$ corresponds to positive polarisation (A, absorption in the nuclear magnetic resonance spectra by molecules having polarised nuclei), and $\Gamma < 0$ corresponds to negative polarisation (E, emission in the n.m.r. spectra).

Integral polarisation of a given group of nuclei arises only when $\Delta g \neq 0$. If $\Delta g = 0$, an unusual type of polarisation often appears, which is characteristic of groups of nuclei having spin–spin interaction. In this case the components of the spin multiplet, appearing at high and low fields, correspond to polarisation of different signs; this type of polarisation is termed the multiplet effect or multiplet polarisation.

It is easy to show that multiplet polarisation is produced by the same mechanism as is integral polarisation, i.e. by the dependence of the rate of triplet–singlet transitions in radical-pairs on the nuclear spin of the radicals. Let us consider a simple pair of radicals

each of which contains one proton; the pair is initially in a triplet state, and also has $\Delta g = 0$. Equation (7) then simplifies to

$$\langle T_0|\mathscr{H}|S\rangle = {}^1/_2\,(a_1m^a - a_2m^b). \tag{11}$$

If $a_1 < 0$ and $a_2 < 0$, pairs having proton orientations $m^a = \frac{1}{2}$, $m^b = -\frac{1}{2}$ and $m^a = -\frac{1}{2}$, $m^b = \frac{1}{2}$ will obviously pass into the singlet state more rapidly, so that

molecules, in which the two protons have opposite spin orientations, will predominate in the product of recombination. The scheme of population of nuclear-spin levels in such a molecule is shown in Fig. 3, where the arrows denote n.m.r. transitions, which lead to a multiplet effect AE (the components of the spin multiplet correspond to positive polarisation at low field, and to negative polarisation at high field).

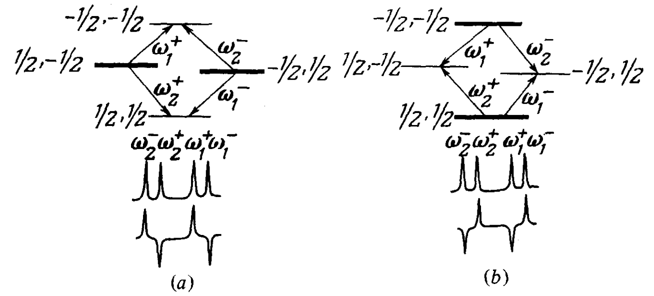

Figure 3. Multiplet effect in a fragment $>$CH–CH$<$ of a molecule generated from a triplet pair: a) AE; b) EA.

It is readily seen from Eqn. (11) also that, if the sign of one of the hyperfine interaction constants is changed (e.g. $a_1 > 0$, $a_2 < 0$), the populations of the levels and the sign of the multiplet effect are changed (Fig. 3b). These properties are readily predicted from Eqn. (7) for any case. A convenient formula for such prediction was proposed by Kaptein[8]:

$$\Gamma_{\rm ME} = \mu\varepsilon a_i a_j J_{nn}\sigma_{ij}\,, \tag{12}$$

where μ and ϵ have the same significance as in (10), a_i and a_j are hyperfine interaction constants, J_{nn} is the spin–spin interaction constant of the nuclei in the molecule (only the signs of these quantities are important here), $\sigma_{ij} = 1$ if the nuclei i and j are present in the same radical of the pair, and $\sigma_{ij} = -1$ if they belong to different radicals. The multiplet effect has the sign of EA when $\Gamma_{ME} > 0$, and that of AE when $\Gamma_{ME} < 0$.

Thus Eqns. (3) and (7) define the signs of the integral and multiplet polarisation produced in strong fields when transitions from the T_0 state are mainly responsible for the triplet–singlet conversion of the pair. These equations have been obtained by quantum-mechanical calculation. It is not difficult to show that the same result—the dependence of the rate of triplet–singlet conversion on the nuclear spin—can be obtained from classical physics.

We shall demonstrate this on the model one-proton pair ($HR^{1}\cdot$, $R^{2}\cdot$). The orientations of the electron spin vectors of the pair are indicated in Fig. 1. These vectors are known to precess about the z-axis (the direction of the external magnetic field). In order that the transition $T_0 \rightarrow S$ should occur the vectors must be "unwound" relative to each other by 180°: i.e. it is necessary that the difference of phase in the precession of the two electrons should be π. The frequency of precession of the first electron is $g_1\beta H \pm \frac{1}{2}a$ depending on whether the spin of the proton is directed with or against the field. That of the second electron is $g_2\beta H$. The corresponding frequency differences between the two electrons are $\Delta g\beta H \pm \frac{1}{2}a$. In order that the transition $T_0 \rightarrow S$ should take place it is necessary that

$$(\Delta g\beta H + {}^{1}/{}_{2}a)\, t_\alpha = \pi \ \text{(proton with the field)}$$
$$(\Delta g\beta H - {}^{1}/{}_{2}a)\, t_\beta = \pi \ \text{(proton against the field)}\ ,$$

where t_α and t_β are the transition times in a pair having nuclear spins α and β. If Δg and a have the same sign, we obviously obtain $t_\alpha < t_\beta$: i.e. radical-pairs in which the proton is oriented in the direction of the field pass into the singlet state and recombine more rapidly. The triplet–singlet conversion of pairs in which the proton is oriented against the field lags behind, and such pairs have a greater chance of dissociating. The result is the selection of radicals according to nuclear-spin states—in agreement with the quantum-mechanical equations (3) and (7).

From the classical picture of a triplet–singlet conversion it is not difficult to estimate the conversion time

$$t_{T_0-S} \simeq (\Delta g\beta H + am)^{-1}$$

for a one-proton pair, or in general

$$t_{T_0-S} \simeq \Big(\Delta g\beta H + \sum_i a_i m_i^a - \sum_j a_j m_j^b\Big)^{-1} \quad . \tag{13}$$

With the usual values of the g-factors and the hyperfine interaction constants in organic radicals this time amounts to $\sim 10^{-9}$–10^{-8} s.

In weak magnetic fields the contribution by T_0–S transitions to the integral polarisation becomes negligible, because the difference $\Delta g\beta H$ between the Zeeman energies is small in weak fields. This is accompanied by increased contributions to the polarisation by T_+–S and T_-–S transitions, which entail reorientation of nuclear spins—in conformity with Eqns. (4), (5) and (8), (9).

In contrast to T_0–S transitions, in which the z-component (projection) of the total electron spin remains unchanged, so that the nuclei do not change their orientation, T_+–S and T_-–S transition are accompanied by a change in the z-component of the electron spin and reorientation of the nuclear spins. In fact, T_0–S transitions in radical-pairs involve merely a sorting-out of nuclear spins according to orientation, whereas in T_+–S transitions a fresh orientation of the nuclei is established. For this reason the chemically induced polarisation of nuclei shows considerable differences between weak and strong magnetic fields (for greater detail see Refs. 2, 3, 5, and 6).

2. Main Stages in the Development of the Chemical Polarisation of Nuclei

The discovery of the phenomenon itself must be regarded as the first stage in the development of the chemical polarisation of nuclei; as already stated above, it was made simultaneously and independently by two groups of investigators. It is surprising that this occurred accidentally in both cases: the actual investigations in which the new phenomenon was discovered were on an extremely trivial plane, which is quite instructive from a methodological point of view.

The first attempt to explain the phenomenon in terms of the Overhauser effect was unsuccessful. The four chief experimental criteria of the chemical polarisation of nuclei—the dependence of polarisation on the type of chemical reaction, establishment of the phenomenon in the products of cage recombination, unusually large polarisation coefficients, and finally the multiplet effect—do not fit into the framework of the Overhauser effect.

The second stage began in 1969, when Kaptein and Oosterhoff[9] and independently Closs[10] almost simultaneously suggested that chemical polarisation of nuclei appeared in radical-pairs on triplet–singlet transitions, whose probability depends on the nuclear spin. This idea and the qualitative explanation of the phenomenon based on it have been examined above. We shall now consider the quantitative theory of the chemical polarisation of nuclei.

The probability that a molecule will be formed in the nuclear spin state ab is the integral of the product of three probabilities:

$$P_{ab} = \int_0^\infty \varepsilon\, |c_{S,ab}(t)|^2\, \mathrm{f}(t)\, \mathrm{d}t \quad . \tag{14}$$

Here $|c_{S,ab}(t)|^2$ is the probability that the pair will pass into a singlet state by time t (if the initial state of the pair were a triplet) or remain in the singlet state by this time (if the initial state of the pair were a singlet), i.e. the probability that the pair will be by time t in a singlet state and will be ready for recombination. The function $\mathrm{f}(t)$ represents the lifetime distribution of the pairs: $\mathrm{f}(t)dt$ is the probability that the pair will survive to time t and be destroyed by time $t + dt$. The coefficient ϵ denotes the probability that a pair that has survived from time t and is by then in a singlet state, i.e. completely prepared for recombination, will finally recombine (or disporportionate).

The quantity $|c_{S,ab}(t)|^2$ is obtained by solving the time-dependent Schrödinger equation with the time-independent Hamiltonian of the pair (6). It is supposed that only the spin functions of the pair vary with time, these being produced by the superposition of the wave functions of singlet and triplet states. The quantity $c_{S,ab}(t)$ is essentially a coefficient of the singlet component of the spin function of the pair, and its square a contaminant of the singlet state. If the pair were initially in a triplet state, in strong magnetic fields we have

$$|c^T_{S,ab}(t)|^2 = (\mathscr{H}^2_{ab}/D^2_{ab}) \sin^2 D_{ab}t, \tag{15}$$

where

$$\mathscr{H}_{ab} = \langle T_0 | \mathscr{H} | S \rangle = \frac{1}{2}\Big(\Delta g\beta H + \sum_i a_i m_i^a - \sum_j a_j m_j^b\Big) \tag{16}$$

is a matrix element of T_0–S mixing (Eqn. 7) and

$$D_{ab} = (\mathscr{H}_{ab}^2 + J^2)^{1/2} \; . \tag{17}$$

If the initial state of the pair is a singlet, then

$$|c_{S,ab}^S(t)|^2 = \frac{1}{n} - \frac{\mathscr{H}_{ab}^2}{D_{ab}^2} \sin^2 D_{ab} \; . \tag{18}$$

The subscript ab denotes the nuclear spin state of the pair, where a and b represent the sets of nuclear spins of the first and second radicals respectively and n is the total number of nuclear spin states of the radical-pair (and of the molecule generated from the pair). Equation (18) is obtained from the condition for normalisation: the total probability of finding the pair in the nuclear spin state ab is $1/n$, independently of whether the pair exists at the given moment in a singlet or a triplet state.

The theory was originally based on a static model of the pair, in which

$$\mathrm{f}(t) = \frac{1}{\tau} \exp(-t/\tau), \tag{19}$$

where τ is the lifetime of the radical-pair. From Eqn. (14) together with (15) and (19) we find that the probability of formation of a molecule in the nuclear spin state ab from a triplet pair is in this case

$$P_{ab} = 2\varepsilon\mathscr{H}_{ab}^2\tau^2/(1 + 4D_{ab}^2\tau^2). \tag{20}$$

This quantity is essentially the population of the state ab in the molecule: the coefficient of nuclear polarisation in the transition ab–$a'b'$ is the difference between those of states ab and $a'b'$ related to the equilibrium, Boltzmann difference between the populations of these states. Similarly, it is easy to calculate the populations in molecules generated from singlet pairs, by substituting Eqns. (18) and (19) in (14), a variant known as the Closs–Kaptein–Oosterhoff theory.

With reasonable lifetimes $\tau \simeq 10^{-12}$–10^{-11} s for the pairs this theory gave calculated polarisations that were too small. Experimental values far exceeded those predicted theoretically (examples of calculations will be found in Ref. 4). The reason for such a discrepancy is obvious: as shown above (§III, 1) the duration of a triplet–singlet transition is 10^{-9}–10^{-8} s, in comparison with which the lifetime of a pair is too short and insufficient for triplet–singlet conversion of the pair and the accompanying selection of radicals according to nuclear spins.

The third stage in the development of the theory of the chemical polarisation of nuclei was initiated by the publications of Adrian[11–13], who suggested a dynamic model of a radical-pair, in which the radicals are able to diffuse into space, diverge, and again return to the initial pair after completing diffusion migrations. The probability of return gradually diminishes with increase in length of the diffusion path, so that the probability of the radicals meeting again decreases with increase in this length and hence in the duration of diffusion. However, a longer path entails a longer time of triplet–singlet evolution and hence greater efficiency of selection of radicals according to nuclear spins. In the dynamic model

$$\mathrm{f}(t) = mt^{-3/2} \tag{21}$$

a function used by Noyes[14] to interpret the kinetics of liquid-phase reactions. It has recently received direct experimental support from flash photolysis in the picosecond range[15].

From Eqns. (21) and (14) we find that the population of the nuclear spin state ab in a molecule generated from a triplet pair is

$$P_{ab}^T = \pi^{1/2}\varepsilon m (\mathscr{H}_{ab}/D_{ab})^2 |D_{ab}|^{1/2} \; . \tag{22}$$

In order to calculate the population in a molecule generated from a singlet pair we must bear in mind that the majority of the pairs recombine immediately after formation (primary recombination), and radicals separate only from the remaining pairs, diffusing away, returning, and again meeting (secondary recombination). Only pairs that have undergone secondary recombination are subject to singlet–triplet evolution, and only in them is nuclear polarisation produced. For the population of the nuclear spin state ab in a molecule generated from a singlet pair we can therefore write

$$P_{ab}^S = \frac{\alpha}{n} + (1-\alpha)\int_0^\infty \varepsilon |c_{S,ab}^S(t)|^2 \mathrm{f}(t)\,\mathrm{d}t \; . \tag{23}$$

The first term in (23) represents the probability of primary recombination, and the second term the population produced in pairs that have undergone secondary recombination. It is noteworthy that α and ϵ are similar in physical meaning and probably in magnitude (~0.5–0.8); the slight difference between them is that α relates to a primary pair, in which the radicals may be separated by foreign molecules (e.g. in the decomposition of acyl peroxides $R^1CO.O.O.CO.R^2$ a CO_2 molecule separates the pair of radicals $R^1\cdot$ and $R^2COO\cdot$), whereas ϵ defines the probability of recombination in a contact pair. Substituting (18) in (23), we obtain the population

$$P_{ab}^S = \frac{\alpha}{n} + (1-\alpha)\left[\frac{1}{n}\int_0^\infty \varepsilon\,\mathrm{f}(t)\,\mathrm{d}t - \pi^{1/2}\varepsilon m (\mathscr{H}_{ab}/D_{ab})^2 |D_{ab}|^{1/2}\right] . \tag{24}$$

The first two terms are not well defined, but this has no significance, since only the difference between the populations is important for calculating the polarisation, and these terms do not enter into this difference.

If a molecule is produced by chance encounters of independently generated radicals, its precursor is a pair whose initial state may equally probably have been singlet or triplet T_0 (such pairs are said to be uncorrelated). Some of the singlet pairs undergo primary recombination, and the remainder singlet–triplet evolution and secondary recombination. All those pairs that have been in a T_0 state undergo the reverse, triplet–singlet evolution. The nuclear polarisation produced in these pairs is the net result of such complicated evolution and can be calculated without difficulty[3] (for uncorrelated pairs $\epsilon = \alpha$).

The introduction of a dynamic model of a pair into the chemical polarisation of nuclei immediately solved several theoretical difficulties. Quantitative agreement between theory and experiment improved markedly. The physically unreal model of a static pair, in which the radicals were fixed at a definite distance for an unnaturally long time, became unnecessary. Quantitative calculations were simplified, for it became clear that the greatest contribution to the polarisation was made by long diffusion paths with the long time required for successful T–S evolution. It is on such paths that the radicals diverge far apart, so that the exchange energy of the electrons J can be neglected with good approximation. It is easily seen that Eqns. (22) and (24) then simplify to

$$P_{ab}^T = \pi^{1/2}\varepsilon m |\mathscr{H}_{ab}|^{1/2} \; , \tag{25}$$

$$P_{ab}^S = \frac{\alpha}{n} + \frac{(1-\alpha)}{n}\int_0^\infty \varepsilon\,\mathrm{f}(t)\,\mathrm{d}t - (1-\alpha)P_{ab}^T \; . \tag{26}$$

It immediately became possible to dispense with (which was entirely justified physically) a fairly inconvenient and indeterminate theoretical parameter.

Even with a dynamic model of the pair, however, difficulties remained in the theory of the chemical polarisation of nuclei. Firstly, the function f(t) does not take into account the finite lifetime of the radicals (more correctly, it assumes that the radicals exist for an indefinite time). Secondly, theory does not reproduce the dependence of the polarisation on the magnetic interaction energy: it predicts that the polarisation will be proportional to $|\mathcal{H}_{ab}|^{\frac{1}{2}}$—see Eqns. (25) and (26)—whereas proportionality both to $|\mathcal{H}_{ab}|^{\frac{1}{2}}$ and to $\mathcal{H}^2_{ab}$ has been found experimentally. The overcoming of these difficulties constituted the fourth stage in the development of the chemical polarisation of nuclei, which characterises the current state of the theory.

3. Current State of the Theory

In order to correct defects in the dynamic model of a pair the modified function

$$\mathrm{f}(t) = m t^{-3/2} \exp(-t/\tau) \tag{27}$$

has been suggested[16,17], where τ is the characteristic lifetime of the radical, the time of its conversion into another radical (by decomposition or substitution), as a result of which the initial pair disappears and is replaced by a new pair. The function f(t) in the form (27) describes an exponential distribution of diffusion paths with respect to length (and duration).

Substituting (27) in (14) and calculating the difference between the populations of the nuclear spin states ab and $a'b'$ in a molecule generated from a triplet pair, we obtain

$$\begin{aligned} P^T_{ab} - P^T_{a'b'} = \pi^{1/2}\varepsilon m \Big\{ &[(2\mathcal{H}_{ab})^2 + \tau^{-2}]^{1/4} \cos\frac{\arctan(2\mathcal{H}_{ab}\tau)}{2} - \\ &- [(2\mathcal{H}_{a'b'})^2 + \tau^{-2}]^{1/4} \cos\frac{\arctan(2\mathcal{H}_{a'b'}\tau)}{2}\Big\} = X(\tau) \ . \end{aligned} \tag{28}$$

It can readily be shown that in the two limiting cases—short-lived radicals ($\tau \ll \mathcal{H}^{-1}_{ab}, \mathcal{H}^{-1}_{a'b'}$) and long-lived radicals ($\tau \gg \mathcal{H}^{-1}_{ab}, \mathcal{H}^{-1}_{a'b'}$)—Eqn. (28) leads to the formulae

$$P^T_{ab} - P^T_{a'b'} = \pi^{1/2}\varepsilon m \tau^{3/2} (\mathcal{H}^2_{ab} - \mathcal{H}^2_{a'b'}) \ , \tag{29}$$

$$P^T_{ab} - P^T_{a'b'} = \pi^{1/2}\varepsilon m (|\mathcal{H}_{ab}|^{1/2} - |\mathcal{H}_{a'b'}|^{1/2}) \ . \tag{30}$$

Thus with short-lived radicals the polarisation is proportional to the difference between the squares of the matrix elements of triplet–singlet mixing (as in the static model). With long-lived radicals the polarisation is proportional to the difference between the square roots of the matrix elements (as in Adrian's dynamic model). Hence Eqn. (28) is a general expression for the difference in populations, from which the equations of the Closs–Kaptein–Oosterhoff and Adrian theories are obtained as particular, asymptotic solutions.

Nor is it difficult to deduce expressions for the difference between the populations of nuclear spin states in a molecule generated from a singlet pair or from an uncorrelated pair:

$$P^S_{ab} - P^S_{a'b'} = -(1-\alpha) X(\tau) \tag{31}$$

$$P^U_{ab} - P^U_{a'b'} = {}^1/_2 \alpha X(\tau) \ , \tag{32}$$

where $X(\tau)$ has been given by Eqn. (28). It follows also from these equations that the polarisation of molecules generated from triplet and uncorrelated pairs has the same sign but is opposite to the polarisation of molecules from a singlet pair (in agreement with earlier, qualitative predictions). The polarisations from these pairs are in the proportions $1 : \frac{1}{2}\alpha : -(1-\alpha)$ and depend on the probability of primary recombination; in particular, when $\alpha = 0.8$ the proportions are $1 : 0.4 : -0.2$.

An important stage in the development of the chemical polarisation of nuclei and its application to chemistry and chemical kinetics was the establishment of a kinetic theory linking the kinetics of the polarisation with that of chemical reactions[4,18]. The principal equation is

$$\frac{\mathrm{d}I}{\mathrm{d}t} = E\frac{\mathrm{d}I_0}{\mathrm{d}t} - \beta(I - I_0), \tag{33}$$

where I is the nuclear magnetisation (or n.m.r. signal) during the reaction and I_0 is the corresponding equilibrium magnetisation (or equilibrium n.m.r. signal). The first term defines the rate of chemical pumping, the rate of establishment of polarisation; while the second term is the rate of its destruction, the rate of relaxation of the non-equilibrium magnetisation to its equilibrium value $\beta = T_{1n}^{-1}$, in which T_{1n} is the nuclear relaxation time in the molecule. Solutions describing the kinetics of chemical reactions occurring under various régimes were obtained from Eqn. (33).[4] The kinetic parameters of the reaction, the nuclear relaxation times, and the polarisation coefficient E could be obtained by comparison with experiment.

This last parameter is of especial interest for the theory; it shows the factor by which the non-equilibrium nuclear polarisation of a molecule at the instant of its generation from a radical-pair exceeds its equilibrium, Boltzmann polarisation (in particular, $E = 1$ for molecules having the equilibrium polarisation). In other words, the coefficient of nuclear polarisation is the ratio of the non-equilibrium difference in population of nuclear spin states to its equilibrium value:

$$E = \langle P_{ab} - P_{a'b'} \rangle / (P^0_{ab} - P^0_{a'b'}) \ , \tag{34}$$

where

$$P^0_{ab} - P^0_{a'b'} = p^0_n = \tan\mathrm{h}\,\frac{\hbar\gamma_n H}{2kT} \ .$$

The coefficient E is determined experimentally from the kinetics of the chemical polarisation of nuclei and applies to a molecule, a molecular group, or a certain nuclear spin transition between states ab and $a'b'$ in the molecule. Populations are calculated and normalised per single radical-pair. In order to determine the polarisation parameters from experimental polarisation coefficients E, therefore, the relation between the coefficient and the populations of nuclear spin states must be established.

Molecules for which the polarisation coefficient has been determined experimentally are generated in various nuclear spin states, with various population differences; some of them contain no excess polarisation at all (e.g. those formed from singlet pairs in primary recombination). For this reason the experimental polarisation coefficient for the ab–$a'b'$ transition is an average value:

$$E_{ab-a'b'} = \sum_i E_i p_i, \tag{35}$$

where E_i is the partial polarisation coefficient for the ith molecular species and p_i the fractional content of these molecules. For example, the mean polarisation coefficient of the transition for a molecule generated from a triplet pair is

$$E^T_{ab-a'b'} = \frac{P_{ab} - P_{a'b'}}{P^0_{ab} - P^0_{a'b'}} \cdot \frac{P_{ab} + P_{a'b'}}{\sum\limits_{ab} P_{ab}} + \frac{P^0_{ab} - P^0_{a'b'}}{P^0_{ab} - P^0_{a'b'}} \left(1 - \frac{P_{ab} + P_{a'b'}}{\sum\limits_{ab} P_{ab}}\right). \tag{36}$$

The first term gives the contribution to the total polarisation by those molecules that have been generated in the nuclear spin states *ab* and *a'b'*; all the remaining molecules are generated in other nuclear spin states, so that they contribute the equilibrium polarisation to the given transition *ab*–*a'b'*. The first of the multipliers in the terms in (36) correspond to the partial polarisation coefficients of these molecules, and the second of the multipliers to their partial fraction; $\sum_{ab} P_{ab}$ is the total probability of generation of a molecule summed over all nuclear spin states. The second term is obviously negligibly small, so that from (28) we have

$$E^{T}_{ab-a'b'} = \frac{X(\tau)}{p^{0}_{n}} \Phi^{T}, \tag{37}$$

where

$$\Phi^{T} = \frac{(P_{ab} + P_{a'b'})}{\sum\limits_{ab} P_{ab}}$$

is the fraction of molecules that have been generated in states *ab* and *a'b'*. It can easily be deduced that e.g. for a pair with one proton $\Phi^{T} \simeq 1$, and for a two-proton pair $\Phi^{T} \simeq \frac{1}{2}$. In general, for a polyproton system containing *m* protons in the pair $\Phi^{T} \simeq 2^{1-m}$. Values of P_{ab} and hence of Φ^{T} can in principle be calculated for any specific system.

Similarly, formula (35) can readily be used to express the experimental polarisation coefficient for the *ab*–*a'b'* transition in a molecule generated from a singlet pair:

$$E^{S}_{ab-a'b'} = -\frac{(1-\alpha) X(\tau)}{p^{0}_{n}} \Phi^{S}, \tag{38}$$

where

$$\Phi^{S} = \frac{P^{S}_{ab} + P^{S}_{a'b'}}{\sum\limits_{ab} P^{S}_{ab}}$$

$$\sum_{ab} P^{S}_{ab} = \alpha + (1-\alpha)\int\limits_{0}^{\infty} \varepsilon f(t)\,dt - (1-\alpha)\sum_{ab} P^{T}_{ab}\ .$$

The exact expression for Φ^{S} is more cumbersome than that obtained with a triplet pair; however, it can be accepted approximately that $\Phi^{S} \simeq 2/n$. If the molecule contains *m* protons, for example, we have $\Phi^{S} \simeq 2^{1-m}$. In the same way expressions can be obtained for the polarisation coefficient of a molecule from an uncorrelated pair.

The meaning and purpose of these equations lie in the theoretical calculation (in terms of population differences) of nuclear polarisation coefficients and hence, from a comparison of the results with experimental values, determination of the parameters of chemical nuclear polarisation (magnetic parameters of the pair, lifetimes of the radicals). This approach to a quantitative analysis of the phenomenon has several advantages over the simulation of n.m.r. spectra of molecules with polarised nuclei. The chief advantage is that we can disregard relaxation effects in the molecules and their distorting effects on the populations of levels and the chemical nuclear polarisation spectra; the difficulties entailed in allowing for relaxation in the simulation of the spectra led to several errors in the analysis of the chemical polarisation of nuclei (for further details see Ref. 4).

All the theoretical approaches discussed here are essentially semi-empirical, since they involve two hypothesis. Firstly, it is assumed that the spin Hamiltonian of a radical-pair is independent of time, i.e. that the exchange interaction of electrons in the pair is independent of time and hence of the distance between the radicals. Secondly, the molecular dynamics of the pair, described by the distribution of diffusion paths of the radicals and the probability of the latter meeting again after their diffusion separation, is described by the Noyes semi-empirical function, which depends on a power of the time $t^{-\frac{3}{2}}$. These assumptions enable spin dynamics (i.e. the dynamics of the singlet–triplet evolution of the pair) and molecular dynamics (i.e. the dynamics of diffusion displacements) to be treated separately, independently. As has been shown above, the result of their combined action, leading to nuclear polarisation, can be presented in comparatively simple analytical form, convenient for the analysis of experimental data, physically clear, and easily interpreted.

However, the hypothesis that spin and molecular dynamics are independent is in general incorrect. The diffusion of the radicals in the pair modulates the mutual orientation of and the distance between the radicals, and consequently modulates the exchange potential. The latter in turn influences the rate of triplet–singlet evolution. Through the exchange potential the molecular dynamics thus has a strong influence on the spin dynamics and hence on the polarisation produced.

A rigorous, non-empirical theory should consider spin and molecular dynamics together, i.e. should solve the problem of the singlet–triplet evolution of a pair with a time-dependent spin Hamiltonian, which in turn controls the molecular dynamics and is a random function of time. Such a non-empirical approach has recently been developed by Freed and Pedersen[19], who have obtained an exact solution of the problem of the $S-T_0$ evolution of a pair and have calculated both nuclear and electron polarisation. It is significant that these authors have used the physically most real model, in which the energy of exchange interaction depends exponentially on the distance between the radicals, while the time dependence of the inter-radical distance is determined by random diffusion and is described by Liouville's stochastic equation. Numerical solution gave polarisation coefficients as functions of various parameters (diffusion coefficients, hyperfine interaction energies, differences in Zeeman energies, parameters of the exchange potential). The problem of the influence of the Coulombic and exchange potential on molecular-diffusion dynamics and on the polarisation has also been solved.

The results of the Freed–Pedersen theory are important in all respects, in particular for the chemical polarisation of nuclei, as the rigorous theory has confirmed the main principles and physical ideas of the semi-empirical theory. Moreover, it has shown that the postulated independence of spin and molecular dynamics does not present a difficulty and does not distort at all seriously the true physical picture of the phenomenon. The physical reason for the insensitivity of the spin dynamics to the exchange potential is that the singlet–triplet evolution is a slow process, so that during its progress the radicals of the pair are able to separate to considerable distances, at which their exchange energy can be neglected. In other words, the main contribution to the singlet–triplet evolution of a pair and to the consequent nuclear polarisation is made by long diffusion paths, on which the exchange potential is negligible. This constitutes an important difference between nuclear and electron polarisation: the former is produced in long-range diffusion paths, whereas short-range spin dynamics makes the major contribution to the establishment of electron polarisation.

The practical (or rather technical) advantage of the semi-empirical theory is that it will give more reliable results, which are simple to interpret physically. The semi-empirical theory contains several parameters (such as the coefficient m in the Noyes function, the probability of recombination in a contact singlet pair ϵ, and the fraction of primary recombination α), of course, but the number of such empirical parameters in the non-empirical theory is no less and even greater. Comparison of the two theories indicates that the semi-empirical theory describes satisfactorily the physics of the phenomenon of chemically induced polarisation of nuclei and gives quite reliable quantitative results. However, this theory requires further development, the empirical parameters must become more accurate, and fresh experiments must be undertaken aimed at further improving and refining the theory.

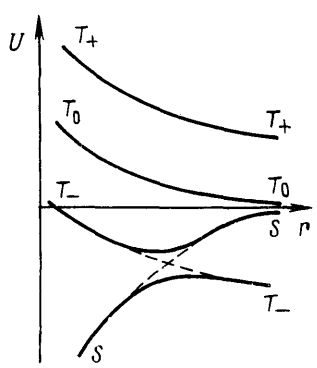

Figure 4. Dependence of energy of spin states of a radical-pair on the inter-radical distance. Full curves show adiabatic reaction paths for recombination (or dissociation) with change in the electron spin; the broken lines represent non-adiabatic paths with conservation of spin.

Besides establishing the physical mechanisms of the non-equilibrium pumping of Zeeman nuclear levels, the chemical polarisation of nuclei has also presented several fundamental results relating to the chemical physics of elementary chemical processes. Firstly, it has confirmed the concepts of the primary and secondary recombination of radicals in a pair and the molecular dynamics of a pair. The quantitative agreement between experiment and theory shows that the function f(t) reproduces quite well the dynamic behaviour of a pair.

Both quantitative agreement with theory and direct experimental results have demonstrated that the intrinsic angular momenta are preserved in elementary radical reactions involving the transfer of atoms (substitutions) and electrons, as well as in the addition of radicals: i.e. such reaction take place with complete conservation of electron and nuclear spins. This is indicated also by the maintenance of spin multiplicity in the transformation of pairs occurring on the decomposition of one of the radicals or on substitution: the resulting new radical-pair retains the spin multiplicity of the old pair. These direct experimental facts, together with the quantitative agreement between theory and experiment, show that the contribution by acts of dissociation and of actual recombination (i.e. "collapse" of the pair) to the establishment of nuclear polarisation is infinitesimal: i.e. these acts occur with conservation of the spins of electrons and nuclei. The behaviour of the energy levels of the dissociating molecule (or, what is the same, the collapsing radical-pair) is shown in Fig. 4. The conservation of the spins of electrons and nuclei as the system moves along the reaction coordinate of dissociation (with increase in the distance r) or recombination (in the opposite direction) shows that the region of quasi-intersection of T_- and S levels (in which $J \simeq g\beta H$) is traversed rapidly, non-adiabatically. For this reason adiabatic effects are insignificant in producing nuclear polarisation[3].

Finally, it must be noted that the spin correlation of electrons, a kind of spin "memory", is preserved in radical-pairs in a liquid for a long time ($\sim 10^{-6}-10^{-7}$ s). The spin correlation is lost in the time interval during which the state of the pair passes into those of the individual radicals. This time is found to be sufficiently long for the radicals to separate to great distances, while retaining the spin "memory" and phase relations of the initial pair[3].

The quantitative agreement between theoretical and experimental results shows that the chief interactions responsible for the singlet–triplet evolution of radical-pairs are hyperfine and Zeeman. These are the "strongest" interactions, responsible for the non-conservation of electron and nuclear spins in radical-pairs; all other interactions (spin–orbit, spin-rotation, etc.) usually play a subordinate role (although, as we shall see later, these interactions are sometimes extremely significant).

4. Chemical Applications of the Chemical Polarisation of Nuclei

The detection of chemical nuclear polarisation has become a new and powerful method for investigating the mechanisms of chemical reactions, a new and sensitive method of detecting radicals and radical processes, on which much has already been written[3,7,20] and which has made the phenomenon widely known and popular in chemistry. However, it must be clearly understood that the observation of nuclear polarisation in a reaction still does not mean that a radical mechanism is fundamentally involved. Several recent experimental results indicate that the phenomenon often arises either entirely in side-reactions or in a process resembling the main process but constituting only a small part of the latter. Thus investigation of the chemical nuclear polarisation in the thermal isomerisation of 2-alkoxyquinoline N-oxides has shown[21] that the proportion accounted for by a radical mechanism is 0.2–0.7.

Chemical nuclear resonance of phosphorus-31 has shown that organic phosphites react with hydroperoxides by two competing mechanisms—radical and non-radical (molecular or ionic)—where the former reaction path, which induces polarisation of phosphorus-31 nuclei, constitutes only a minute fraction ($10^{-2}-10^{-4}$).[22] In the corresponding reactions catalysed by transition-metal ions it has also been established that the radical path is secondary[23]. Application of the same technique to the reactions of ozone with organic phosphites indicates that radical ozonolysis amounts to only about 5%, the main reaction probably involving biradical states in which nuclear polarisation is not produced[24]. Investigation of the chemical polarisation of nuclei in the products of the fairly unusual reaction of tetra-alkylammonium salts with carbon tetrachloride suggests[25] that it has either an ionic or a nucleophilic mechanism and is accompanied by the formation of unstable intermediate compounds, which initiate secondary radical reactions in which the observed polarisation is produced.

Analysis of the chemical polarisation of carbon-13 in the reaction of quinone diazide with cyclohexylamine reveals strong polarisation of the nuclei in an unstable intermediate triazen[26]. It is concluded that this is formed in non-radical stages of the reaction, and that is polarisation results from subsequent reversible decomposition of the triazen by a radical mechanism.

A common feature of the above examples is that the radical mechanism leading to nuclear polarisation either does not predominate or plays an altogether subordinate part. An entirely new aspect of this technique is the separation of radical and non-radical mechanisms, and sometimes even frank discrediting of radical stages and their role in the reactions.

Chemical nuclear polarisation is the only kinetic method which will distinguish competition between radical and non-radical mechanisms, especially if they yield the same products. It becomes possible not only to distinguish these mechanisms but also to estimate their competition. Thus, if a given product is formed by two paths with constants k_1 and k_2 and polarisation coefficients E_1 and E_2, the observed polarisation coefficient is

$$E = (E_1k_1 + E_2k_2)/(k_1 + k_2) = E_1p_1 + E_2p_2 \ , \tag{39}$$

where p_1 and p_2 are the fractions of the two reaction paths. If the second path is non-radical, $E_2 = 1$ and the second term can be neglected. Having calculated E_1 theoretically, we can then easily find p_1 and p_2 (for greater detail see Ref. 3).

An important role in the mechanisms of radical reactions is often played not only by radicals (and hence radical-pairs) but also by biradicals. It is sensible to distinguish between biradicals having dynamic exchange, in which the exchange interaction is usually weak, from radical centres joined by flexible molecular bridges, so that they are able periodically to move together and apart. As a consequence, such biradicals often behave in chemical reactions like radical-pairs. Biradicals with static exchange, on the other hand, usually have a rigid molecular frame, so that the exchange interaction in them is not modulated by molecular movements and remains constant. The Table shows what nuclear polarisation can in principle be expected in strong and weak fields for reactions involving radicals and biradicals.

Character of nuclear polarisation in radical-pairs and biradicals.

Field	Radical-pairs, and biradicals with dynamic exchange	Biradicals with static exchange
Strong	$S-T_0$ (integral and multiplet)	$S-T$ (integral, with $g\beta H \approx J$)
Weak	$S-T_0$ (multiplet) $S-T$ (integral)	

In order that $S-T_-$ transitions should make a significant contribution to nuclear polarisation it is necessary that the S and T_- levels should have approximately the same energy, i.e. that $g\beta H \simeq J$. Hence it follows that their contribution arises in shorter diffusion paths than that by $S-T_0$ transitions. In biradicals with static exchange, where the exchange energy J is fixed, the polarisation has a "resonance" character and appears in a magnetic field corresponding to the condition $g\beta H \simeq J$. It is thus possible by means of chemical nuclear polarisation to measure the energy of exchange interaction in biradicals having different structures. Interesting examples of this type have been given in Closs[6].

In conclusion let us consider in what reactions chemical nuclear polarisation can be observed and whether any predictions can be made. No definite answer can be given, but several considerations may be adduced. First of all, it is necessary that radicals should be generated in the reaction, either in the main or in a secondary reaction path. "Chemical" intuition is necessary to predict this, but experience shows that this is not infallible: the phenomenon is often observed unexpectedly, where radical mechanisms have not been suggested.

Further, high rates of chemical pumping, comparable with the rates of nuclear relaxation, are necessary for the certain observation of chemical nuclear polarisation. It is good if the reaction takes 3-5 min, and still better if it occurs within seconds. However, this condition is desirable but not necessary: even in slow reactions such polarisation can be observed provided that the polarisation coefficients are sufficiently large. In the decomposition of acyl peroxides, for example, intense polarisation has been observed for an hour and more without additional supply of reactant. A quite strict condition can be formulated: in order that a maximum should be observed on the kinetic curves of chemical nuclear polarisation (and this is the clearest and most unambiguous criterion of detection), the condition

$$|E|k - \beta > 0 \quad \text{or} \quad |E|kT_{1n} > 1$$

must be satisfied. Furthermore, these three fundamental parameters—the polarisation coefficient, the reaction rate constant, and the nuclear relaxation time in the molecule—determine the detectability of the polarisation, while the above relation among them is a criterion of its experimental observation.

IV. ISOTOPE EFFECTS IN RECOMBINATION

As shown in Section III, the probability of triplet-singlet conversion in a radical-pair depends on the energy of hyperfine electron-nuclear interaction. For this reason isotope effects should be observed in the recombination of radicals in pairs. Their magnitude can easily be calculated by means of Eqns. (14) and (23).

We shall consider as illustration the simple example of the recombination of hydrogen and deuterium atoms with the trichloromethyl radical. We suppose for simplicity that the initial states for recombination are triplet pairs and assume that the lifetime of the radicals $\tau \gg \mathcal{H}_{ab}^{-1}$. The probability of recombination can then be calculated from Eqn. (25). We compute the ratio of probabilities as

$$\frac{P_{\mathrm{CHCl_3}}}{P_{\mathrm{CDCl_3}}} = \frac{\sum\limits_{ab} \pi^{1/2}\varepsilon m\,|\mathcal{H}_{ab}^{\mathrm{H}}|^{1/2}}{\sum\limits_{ab} \pi^{1/2}\varepsilon m\,|\mathcal{H}_{ab}^{\mathrm{D}}|^{1/2}} \ . \tag{40}$$

The summation covers all states having $m_{\mathrm{H}} = \pm\frac{1}{2}$ for hydrogen and $m_{\mathrm{D}} = 0, \pm 1$ for deuterium, while

$$\mathcal{H}_{ab} = \langle S|\mathcal{H}|T_0\rangle$$

is defined by Eqn. (7). In weak magnetic fields, when $\Delta g\beta H \ll a$, we find from Eqn. (40) with $a_H = 506$ and $a_D = 77$ oersteds that

$$P_{CHCl_3}/P_{CDCl_3} \simeq 1.75\ .$$

In general, when $\Delta g\beta H$ is comparable with the hyperfine interaction, the effect should depend on the strength of the magnetic field.

Isotope effects in the recombination of any radicals from any pair of precursors can readily be calculated in a similar manner. The largest effects must be expected in recombination from triplet pairs, and the smallest from singlet pairs. It would be interesting to compare predicted and experimental effects if any exist.

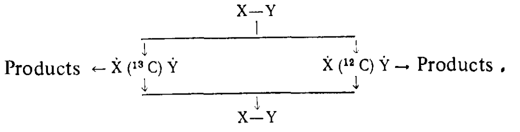
V. ENRICHMENT OF MAGNETIC ISOTOPES IN CHEMICAL REACTIONS

As has been shown earlier—Eqns. (3)-(5) and (7)-(9)—the probability of triplet-singlet transitions in a radical-pair, and hence the probability of recombination, depend on the energy of hyperfine interaction. It depends also on the magnetic moment of the nucleus, since this energy is unambiguously linked with the magnetic moment of the nucleus by the well known Fermi relation

$$a = \frac{8\pi}{3}\mu_e\mu_n\,|\,\psi(0)\,|^2,$$

where μ_e and μ_n are the magnetic moments of the electron and the nucleus, while $|\psi(0)|^2$ is the density of electrons on the nucleus. Thus the probability of a chemical reaction should depend on the magnetic moment of the nucleus, so that chemical reactions can be used for the selection and enrichment of magnetic isotopes, as well as their isolation from non-magnetic isotopes.

This idea can easily be illustrated by a simple example in which triplet pairs are generated chemically (by thermal or photochemical dissociation) from a molecule X-Y:



We suppose that one of the radicals (e.g. X·) contains a carbon nucleus. Radical-pairs containing the magnetic carbon-13 isotope will undergo more rapid triplet-singlet conversion than will pairs containing the non-magnetic carbon-12 isotope. Therefore the former pairs will become singlets more rapidly and recombine more rapidly with the formation of the original X-Y molecules, whereas the triplet-singlet conversion of the latter pairs will lag and such "non-magnetic" pairs will have less chance of recombining. Thus molecules of the initial substance X-Y will be enriched with the magnetic isotope, while the conversion products will be depleted of this isotope.

It is easy to suppose that, if singlet pairs are generated from X-Y, the reverse singlet-triplet evolution of the pairs will result in depletion of the magnetic isotope from the initial molecules, and enrichment of the decomposition products. However, this process will be far less efficient in selecting isotopes, since the majority of the singlet pairs recombine without singlet-triplet conversion (primary recombination), and only a small proportion of singlet pairs undergo singlet-triplet evolution leading to selection of the isotopes. The recombination of triplet pairs is always preceded by triplet-singlet conversion, so that such pairs are most effective in selection. Uncorrelated pairs, formed by the chance encounters of independently generated radicals, occupy an intermediate position with respect to efficiency of isotope selection.

Considering now the quantitative theory of isotope enrichment for the same model pair from X-Y, we suppose that the pair (X·, Y·) is initially in a triplet state and that transitions from the T_- state make the major contribution to its triplet-singlet conversion. The content of the magnetic carbon-13 isotope in the molecule formed from the pair will then be

$$\delta_{S-T_-} = \frac{P^{^{13}C}_{S-T_-}\delta_{^{13}C}}{P^{^{13}C}_{S-T_-}\delta_{^{13}C} + P^{^{12}C}_{S-T_-}\delta_{^{12}C}}\ , \tag{41}$$

where $P^{^{13}C}_{S-T_-}$ and $P^{^{12}C}_{S-T_-}$ are the probabilities of $S-T_-$ transitions in pairs containing carbon-13 and carbon-12 respectively, while $\delta_{^{13}C}$ and $\delta_{^{12}C}$ are the contents of these isotopes in the initial molecules that have not yet undergone chemical change. The numerator of (41) is the probability of formation of X-Y molecules from pairs containing carbon-13; the denominator defines the total probability of the generation of X-Y molecules both from "magnetic" and from "non-magnetic" pairs; and their ratio is the isotopic content of carbon-13 in X-Y molecules formed after recombination. The probabilities of $S-T_-$ transitions are proportional to the squares of the matrix elements of these transitions (Eqns. 5 and 9). On substituting them in (41), we obtain

$$\delta_{S-T_-} = \frac{\delta_{^{13}C}\left[\sum\limits_i \langle T_-|\mathcal{H}|S\rangle_i^2\right]_{^{13}C}}{\delta_{^{13}C}\left[\sum\limits_i \langle T_-|\mathcal{H}|S\rangle_i^2\right]_{^{13}C} + \delta_{^{12}C}\left[\sum\limits_i \langle T_-|\mathcal{H}|S\rangle_i^2\right]_{^{12}C}}\ , \tag{42}$$

where

$$\left[\sum_i \langle T_-|\mathcal{H}|S\rangle_i^2\right]_{^{13}C}$$

is the sum of the squares of the matrix elements over all nuclear spin states of the "magnetic" radical-pair; the second term in the denominator is the corresponding sum for the "non-magnetic" pair.

Considering a numerical example, we suppose a triplet pair (~·C=O, ·CH$_2$~), in which $a_{^{13}C} = 150$ (acyl radical) and $a^H_{CH_2} = 16$ oersteds, with initially the natural isotope content $\delta_{^{13}C} = 0.01$ and $\delta_{^{12}C} = 0.99$. Computing with these values the matrix elements by means of Eqn. (5) or (9) and substituting them in (42), we obtain

$$\delta_{S-T_-} = \frac{[(150/8^{1/2})^2 + 2\,(16/8^{1/2})^2]\cdot 1\cdot 10^{-2}}{[(150/8^{1/2})^2 + 2\,(16/8^{1/2})^2]\cdot 1\cdot 10^{-2} + [2\,(16/8^{1/2})^2]\cdot 0.99} \simeq 0.32$$

i.e. the carbon-13 content in the carbonyl group in the ~CO.CH$_2$~ molecules formed after recombination should have increased more than thirtyfold.

We shall now estimate the contribution of $S-T_0$ transitions to the enrichment of magnetic isotopes. In this case the content of carbon-13 in a molecule generated from a triplet pair by $S-T_0$ transitions is

$$\delta_{S-T_0} = \frac{P^{^{13}C}_{S-T_0}\delta_{^{13}C}}{P^{^{13}C}_{S-T_0}\delta_{^{13}C} + P^{^{12}C}_{S-T_0}\delta_{^{12}C}}\ . \tag{43}$$

Again replacing the probabilities of these transitions by the corresponding matrix elements, we obtain

$$\delta_{S-T_0} = \frac{\left[\sum\limits_i \langle T_0|\mathcal{H}|S\rangle_i^2\right]^{^{13}C}\delta_{^{13}C}}{\left[\sum\limits_i \langle T_0|\mathcal{H}|S\rangle_i^2\right]^{^{13}C}\delta_{^{13}C} + \left[\sum\limits_i \langle T_0|\mathcal{H}|S\rangle_i^2\right]^{^{12}C}\delta_{^{12}C}}\ . \tag{44}$$

Each of the items in this formula has the same meaning as in Eqn. (42); the sole difference is that the matrix elements are calculated for $S-T_0$ transitions by means of Eqn. (3) for a one-proton pair, or in general by means of Eqn. (7).

However, as we have seen earlier (in analysing the chemical polarisation of nuclei), the probability of an $S-T_0$ transition is proportional to the square of the matrix element only for short-lived radicals: for long-lived radicals the probability is proportional to the square root of the matrix element. This means that Eqn. (44) applies only to short-lived radicals. For long-lived radicals we find from (43) that

$$\delta_{S-T_0}=\frac{\delta_{^{13}\mathrm{C}}\left[\sum_i \langle T_0|\mathscr{H}|S\rangle_i^{1/2}\right]^{^{13}\mathrm{C}}}{\left[\sum_i \langle T_0|\mathscr{H}|S\rangle_i^{1/2}\right]^{^{13}\mathrm{C}}\delta_{^{13}\mathrm{C}}+\left[\sum_i \langle T_0|\mathscr{H}|S\rangle_i^{1/2}\right]^{^{12}\mathrm{C}}\delta_{^{12}\mathrm{C}}}\,. \qquad (45)$$

This equation defines the content of the carbon-13 isotope in a molecule generated by an $S-T_0$ transition from a triplet pair of long-lived radicals.

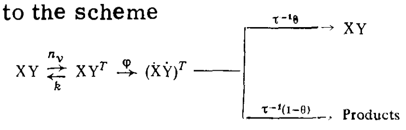
Let us again estimate the contribution made by $S-T_0$ transitions to isotopic enrichment for the same pair ($\sim\!\cdot\mathrm{C{=}O}$, $\cdot\mathrm{CH_2}\!\sim$). Substituting the parameters of this pair in Eqn. (7) and confining our attention to weak fields (i.e. neglecting the term $\Delta g\beta H$), we obtain $\delta_{S-T_0}\simeq 0.29$ for short-lived radicals and the value 0.04 if the lifetime of the radicals in the pair $\tau \gg \mathscr{H}_{ab}^{-1}$.

Enrichment should be most efficient in weak fields, where the contribution to triplet–singlet conversion arises from all three triplet substates; in strong fields only the contribution from T_0-S transitions remains. However, this conclusion must not be regarded as generally applicable: situations may occur in which $\Delta g\beta H$ is large, and then in a strong field $S-T_0$ transitions can play an even greater role in the selection of isotopes than do all three transitions taken together in a weak field.

It is easy also to deduce rigorous equations of isotopic enrichment for cases of recombination in uncorrelated pairs as well as in singlet pairs. It must be borne in mind merely that in singlet pairs primary recombination takes place without isotopic enrichment, so that the isotope content must be averaged over molecules formed by primary and by secondary recombination. Clearly, the greater the probability of primary recombination the smaller the mean isotopic enrichment. For this reason, as has already been noted, the efficiency of selection of isotopes is low in singlet pairs compared with triplet pairs of the same structure.

The above numerical estimates of isotope enrichment apply to cases in which each initial X–Y molecule has undergone only one chemical change, only one act of decomposition. We shall term this the first stage of enrichment. Molecules that have passed through the first stage and are enriched with the magnetic isotope can obviously undergo fresh chemical change and become still more enriched in a second stage; and so on. In fact, with increase in the degree of chemical conversion the quantity of substance X–Y remaining will diminish, but its isotope content will continually increase in proportion to the extent of conversion.

To calculate this effect we suppose that X–Y decomposes at a constant rate (e.g. on photochemical initiation) according to the scheme



.

The excited triplet state of the molecule XY breaks down at a constant rate φ to form the triplet pair $(\mathrm{X}\cdot,\ \mathrm{Y}\cdot)^T$, which either recombines again to XY or breaks down and is converted into products; n_ν is the number of quanta absorbed, k the rate constant for deactivation of the triplet state, and $\tau^{-1}\theta$ the constant representing "collapse" of the pair to the original molecule; and θ denotes that fraction of the rate constant that depends on magnetic interactions in the pair. The scheme for conversion of the same molecule XY* containing a magnetic isotope is of the same form, except that the corresponding "collapse" constant is $\tau^{-1}\theta^*$. From the above equations it is easy to express their ratio in terms of the matrix elements of singlet–triplet mixing. If $T_{-}-S$ transition make the major contribution to enrichment, for example, we have

$$\theta^*/\theta=\left[\sum_i \langle T_-|\mathscr{H}|S\rangle_i^2\right]^{^{13}\mathrm{C}}\Big/\left[\sum_i \langle T_-|\mathscr{H}|S\rangle_i^2\right]^{^{12}\mathrm{C}}.$$

Analysis of the kinetic scheme for the concentration variation of "magnetic" molecules XY* and "non-magnetic" molecules XY yields the equations

$$[\mathrm{XY}^*]=[\mathrm{XY}^*]_0-\frac{n_\nu\delta_{^{13}\mathrm{C}}\varphi}{k+\varphi}(1-\theta^*)\,t, \qquad (46)$$

$$[\mathrm{XY}]=[\mathrm{XY}]_0-\frac{n_\nu\delta_{^{12}\mathrm{C}}\varphi}{k+\varphi}(1-\theta)\,t\,. \qquad (47)$$

Since $\theta^*>\theta$, it follows by formal kinetics that a mixture of XY and XY* molecules is enriched with the "magnetic" molecules XY*. The degree of enrichment can be defined as the ratio

$$\delta=\frac{[\mathrm{XY}^*]}{[\mathrm{XY}]+[\mathrm{XY}^*]}\,.$$

Substitution from (46) and (47) yields

$$\delta(t)=\frac{\delta_{^{13}\mathrm{C}}[\mathrm{XY}]_0-\dfrac{n_\nu\delta_{^{13}\mathrm{C}}\varphi}{k+\varphi}(1-\theta^*)\,t}{[\mathrm{XY}]_0(1+\delta_{^{13}\mathrm{C}})-\dfrac{n_\nu\delta_{^{13}\mathrm{C}}\varphi}{k+\varphi}(1-\theta^*)\,t-\dfrac{n_\nu\delta_{^{12}\mathrm{C}}\varphi}{k+\varphi}(1-\theta)\,t}\,. \qquad (48)$$

The extent of conversion χ is defined as

$$\chi(t)=1-\frac{[\mathrm{XY}]+[\mathrm{XY}^*]}{[\mathrm{XY}]_0+[\mathrm{XY}^*]_0}\,.$$

The degree of enrichment will then be related to the extent of conversion by the formula

$$\delta(t)=\frac{\delta_{^{13}\mathrm{C}}[\mathrm{XY}]_0-\dfrac{n_\nu\delta_{^{13}\mathrm{C}}\varphi}{k+\varphi}(1-\theta^*)\,t}{[\mathrm{XY}]_0(1+\delta_{^{13}\mathrm{C}})[1-\chi(t)]}\,. \qquad (49)$$

Clearly, the greater the extent of conversion $\chi(t)$ the higher the isotope content $\delta(t)$, in agreement with qualitative predictions.

Equation (49) holds only when the extent of conversion is not too large, since it takes no account of enrichment in the second, third, etc. stages: i.e. it disregards variation in the initial content of the isotope. For this reason Eqn. (49) gives an incorrect asymptotic approximation as $\chi(t)\to 1$. In principle, however, exact kinetic equations can be deduced for isotope enrichment. The corresponding kinetic parameters n_ν, φ, and k or their combinations can be determined from the kinetics of the consumption of the substance, quantum yields, etc., i.e. from the usual kinetic measurements.

The enrichment of magnetic isotopes in chemical reactions, predicted here and given a theoretical basis, has been detected experimentally[27] in the photolysis of an aliphatic ketone, which becomes enriched with carbon-13. The degree of enrichment increases with the extent of conversion (in conformity with theoretical predictions). This novel principle of isotopic enrichment differs significantly from all other known principles: in none of the latter are magnetic effects in chemical reactions used for enrichment.

The principle of the enrichment of magnetic isotopes in chemical reactions formulated here is quite general and applicable to the sorting of nuclei not only in the carbon-13-12 system but also in other systems (oxygen-17-16, uranium-235-238, boron-10-11, etc.). The efficiency of enrichment is determined mainly by three factors—firstly the convenience of the chemical system (it is extremely desirable that the system should generate triplet radical-pairs), secondly the magnitude of the hyperfine electron-nuclear interaction (it is desirable that the chemical system system should generate radicals having large hyperfine interaction constants), and thirdly the electronic and nuclear relaxation times in the radicals, which should be sufficiently long. If such relaxation is rapid (occurring in times less than or comparable with the duration of triplet-singlet evolution of the pair), spin correlation in the pair is lost rapidly, and the pair remains all the time in an uncorrelated state. In other words, rapid relaxation leads to phase randomisation of the electrons, and prevents the triplet-singlet evolution of the pair from being controlled by hyperfine interaction. As a result, the efficiency of the reaction in selecting magnetic isotopes diminishes. Rapid relaxation in radicals may be caused by strong spin-orbital or spin-rotational interaction (for electrons) and also by quadrupole interaction (for the nuclei).

VI. EFFECT OF A MAGNETIC FIELD ON CHEMICAL REACTIONS

A fourth remarkable consequence of non-conservation of the angular momentum of electrons is that the probability (and the rate) of a chemical reaction depend on the strength of a steady magnetic field. This relation is predicted for radical reactions by Eqns. (3) and (7), according to which a magnetic field changes the probabilities of triplet-singlet transitions in radical-pairs. The effect of a field can be estimated by means of the equations deduced for calculating the chemical polarisation of nuclei.

The probabilities of the generation of molecules from triplet, singlet, and uncorrelated pairs are given by the equations

$$P^T = \sum_{ab} \pi^{1/2}\varepsilon m\,|\mathcal{H}_{ab}|^{1/2} \tag{50}$$

$$P^S = \alpha + (1-\alpha)\int_0^\infty \varepsilon\,\mathrm{f}(t)\,\mathrm{d}t - (1-\alpha)\sum_{ab}\pi^{1/2}\varepsilon m\,|\mathcal{H}_{ab}|^{1/2} \tag{51}$$

$$P^U = \frac{1}{2}\alpha + \frac{1}{2}(1-\alpha)\int_0^\infty \varepsilon\,\mathrm{f}(t)\,\mathrm{d}t + \frac{1}{2}\alpha\sum_{ab}\pi^{1/2}\varepsilon m\,|\mathcal{H}_{ab}|^{1/2}. \tag{52}$$

Equations (50) and (51) have been obtained by generalising (25) and (26). Since we are now interested not in nuclear polarisation but in the aggregate probability of the generation of molecules in all nuclear spin states, the summations in (50) and (51) have been made over all such states. The deduction of (52) will be found in Ref. 3.

A magnetic field obviously accelerates triplet-singlet evolution and increases the probability of recombination in a triplet pair (provided, of course, that $\Delta g \neq 0$). However, the field accelerates equally the reverse, singlet-triplet evolution, so that the probability of recombination in a singlet pair is diminished. Equation (51) shows that this decrease is greater for smaller α, i.e. the smaller the proportion of primary recombination and the greater the proportion of pairs undergoing secondary recombination, in which singlet-triplet conversion takes place. It follows from Eqn. (52) that recombination in uncorrelated pairs is accelerated by a magnetic field.

In estimating the dependence on a magnetic field of the probability of formation of a molecule we can for simplicity neglect hyperfine interaction and assume that

$$\mathcal{H}_{ab} = \frac{1}{2}\Delta g\beta H .$$

Since we have thus postulated that radicals do not contain nuclear spins, the summation in Eqns. (50)-(52) no longer makes sense in this approximation. For a numerical estimate of the effect we consider only uncorrelated pairs, the most general case in chemistry. With $\alpha = \epsilon = 0.8$ and $m = 10^{-6}$ s$^{\frac{1}{2}}$ we find from Eqn. (52) that

$$(P - P_0)/P_0 \simeq 10^{-3}\,|\Delta gH|^{1/2}, \tag{53}$$

where F_0 and P are the probabilities of recombination in the absence and in the presence of a field respectively. Equation (53) defines the relative effect of a magnetic field. Values of $H = 10^4$ and $\Delta g = 10^{-2}$ (the latter is typical of pairs of organic radicals) lead to $(P - F_0)/P_0 = 10^{-2}$, about 1%, which is, of course, small. An appreciable effect of a field can be expected only in the recombination of radicals having markedly different g-factors, i.e. in exceptional cases.

It would appear at first glance that weak magnetic fields should have no effect, for $\Delta g\beta H$ is small. However, in such fields a significant contribution to the triplet-singlet conversion of a pair is made by transitions from T_+ and T_- substates induced by hyperfine interaction with a probability proportional to a^2. With increase in field strength the T_+ and T_- levels diverge, with an accompanying decrease in the contribution to triplet-singlet conversion made by transitions from them. Therefore the effect of a weak magnetic field on reactions is due to elimination of degeneracy from the triplet levels. This mechanism is significant only when the hyperfine interaction and the contribution of T_+ and T_- states to recombination are large.

The influence of a magnetic field exerted by this mechanism was first observed by Sagdeev et al. in the reaction between perfluorobenzyl chloride and n-butyl-lithium[28-30]. This reaction involves $\cdot CF_2C_6F_5$ radicals, in which the energy of hyperfine interaction with fluorine-19 nuclei is large and the contribution by T_+ and T_- states to triplet-singlet conversion of radical pairs is considerable. No effect of the field has been detected in the corresponding reaction of benzyl chloride, since hyperfine interaction with the protons in the $\cdot CH_2C_6H_5$ radical is weak, and therefore the contribution of T_+ and T_- states to recombination small. For the same reason no effect of a magnetic field has been detected on the photosensitised decomposition of benzoyl peroxide[31].

Thus the influence of a magnetic field on the probability of the recombination of radicals can operate by two mechanisms. Firstly, the relative contributions by S-T_0 and S-$T_\pm$ transitions to triplet-singlet conversion of a pair changes on passing from weak (or zero) to strong fields. If the precursor of the recombination product is a singlet radical-pair, the probability of recombination increases as the field becomes stronger. If the precursor is a triplet or an uncorrelated pair, the probability of recombination diminishes with increase in the field. This mechanism operates only when considerable electron–nuclear hyperfine interaction is present in the radicals. Secondly, if Δg is large in the radical-pairs, the probability of recombination increases in proportion to $|\Delta g\beta H|^{\frac{1}{2}}$ for triplet and uncorrelated pairs, but decreases in proportion to $|\Delta g\beta H|^{\frac{1}{2}}$ for singlet pairs. This mechanism is far more important and will be extended to other reactions.

Both these effects can be calculated theoretically in each case, and the dependence of the probability of recombination on the intensity of the magnetic field can be predicted. In the reactions of organic radicals, however, considerable effects can be expected (cf. the above numerical estimates), because values of Δg are usually small in pairs of organic radicals. Considerably greater effects may be expected in reactions involving transition-metal ions and organic molecules or radicals, when Δg may be considerable. Thus in the pair (Fe^{2+}, O_2), which probably precedes the electron-transfer reaction

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^-$$

for example, $\Delta g \simeq 2$, and with $H = 10^4$ oersteds the effect of the magnetic field may reach ~10%.

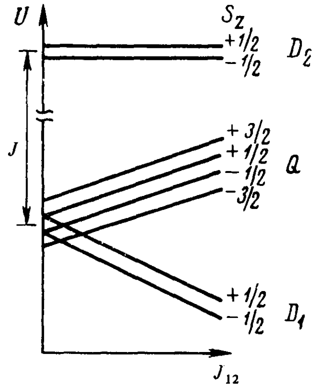


Figure 5. Energy levels and spin states of a triplet–doublet pair (*T*, *D*).

In more complicated reactions involving species in higher spin states (triplets, quartets, etc.) a magnetic field induces transitions between states differing in spin multiplicity. For example, a "triplet + doublet" reaction (an example is the interaction of oxygen in a triplet state with a radical in a doublet state) is preceded by a (*T*, *D*) pair containing three unpaired electrons. Such a pair may exist in states of total spin $\frac{3}{2}$ and $\frac{1}{2}$, corresponding to a quartet and two doublet states (Fig. 5). One of the doublet states (D_2) corresponds to singlet oxygen and is situated at a great height, so that it will be of no interest to us. A magnetic effect arises from the mixing of quartet and doublet states Q and D_1, of substates of Q having $S_z = \pm\frac{1}{2}$ with the corresponding substates of D_1, i.e. of states having the same z-components of the total electron spin. The physical meaning of quartet–doublet mixing is the same as for triplet–singlet mixing in radical-pairs.

A calculation has been made of the effect of a magnetic field in such a system[32]. Since reaction occurs only in the doublet state D_1, it should be accelerated by a magnetic field which induces additional quartet–doublet transitions. Fig. 5 shows that the exchange interaction J_{12} between the electrons of the components of the pair removes the degeneracy of the miscible levels D_1 and Q and slows down the quartet–doublet evolution (just as exchange interaction retarded triplet–singlet evolution in a radical-pair). However, if it is accepted that the molecular dynamics of the pair (*T*, *D*) is the same as for a radical-pair, the exchange interaction J_{12} can be neglected, and the effect of the field is then proportional to $|\Delta g\beta H|^{\frac{1}{2}}$.

The influence of a magnetic field on other, more complicated reactions has been discussed in Ref. 3, where numerical estimates are given of the effects to be expected.

The influence of a magnetic field on biological systems and processes, reported in many papers on magnetobiology, may be due to molecular mechanisms of the above type. Such mechanisms should operate in biochemical reactions involving species having unpaired electrons (e.g. processes involving the transfer of electrons along the chain of cytochromes and the associated reactions of oxidative phosphorylation, many enzymic reactions, the oxidation of non-haemin iron by oxygen, certain stages of photosynthesis, etc.). Experimental results summarised in several monographs of magnetobiology[33-36] show that the effect of a field is most significant in these particular biochemical systems (or in those organelles, e.g. in mitochondria, where these processes take place).

Thus there are clear and soundly based physical reasons for the influence of a magnetic field on the rates of chemical reactions. They are due to the influence of the field on the probabilities of intersystem transitions between states of different spin multiplicities in the reactant-pairs. Even within the framework of this general mechanism, however, the effects of a magnetic field may be extremely diverse, for several reasons.

Firstly, a magnetic field should have no effect if $\Delta g = 0$ in the reactant-pair.

Secondly, the magnitude of the effect is strongly dependent on the molecular dynamics of the reacting pair. Thus in a radical-pair in a liquid the dynamics is described by the function $f(t) = mt^{-\frac{3}{2}}$, so that the field effect is proportional to $|\Delta g\beta H|^{\frac{1}{2}}$. If the dynamics of the pair is described by an exponential function, the effect is proportional to $(\Delta g\beta H)^2$.[3] With reaction between charged species diffusion in the pair takes place in a Coulombic field, and the function $f(t)$ has a completely different form[3]. Magnetic effects may be expected in principle even if the reactant centres are fixed in certain structural units (e.g. in mitochrondrial membranes), and reaction between them (electron transfer) occurs by a tunnel mechanism. Such a mechanism is often assumed in biochemical systems.

Thirdly, exchange interaction between electrons in the reactants forming a pair has a significant influence on transitions between spin states in the pair: the greater this interaction the smaller the effects to be expected. Different situations may arise, of course, in different (especially biochemical) systems: in some cases exchange interaction may be negligible, and in others considerable (as e.g. in the reaction of oxygen with deoxyhaemoglobin to form diamagnetic oxyhaemoglobin). For this reason threshold phenomena are possible, or even a change in sign of the effect with change in intensity of the magnetic field.

Fourthly, the observation of magnetic field effects requires that intersystem transitions between states of different spin multiplicities in the reacting pairs should be induced by a difference in Zeeman energies $\Delta g\beta H$, and this requires that the electronic relaxation times of the components of the pair should be sufficiently long: otherwise, rapid electronic relaxation will lead to randomisation of the precession phases of the electrons and disrupt evolution of the pair from one spin state to another. Such loss of spin correlation in a pair because of rapid electronic relaxation would lead to a loss of magnetic effects. (As shown in Section V, the efficiency of selection of magnetic isotopes in chemical reactions decreases markedly for the same reason.)

The problem of the effect of a magnetic field on chemical and biochemical processes has a long and rich history; much and often contradictory information has been obtained on magnetobiology and magnetomedicine. Examination shows that much of it is naive and physically unsound, and often it is erroneous. However, there is also a considerable proportion of reliable results, showing convincingly that magnetic effects in chemical and biological processes are real and frequently significant. It would be interesting to consider such data from the viewpoint of the molecular mechanisms discussed here, test several predictions following from these mechanisms, and also set up experiments at a molecular level.

VII. CONCLUSION

The intrinsic angular momentum of both electrons and nuclei is conserved in elementary chemical reactions involving substitution, dissociation, recombination, electron transfer, addition, disproportionation, etc: i.e. these elementary processes take place without change in the spins of electrons and nuclei. This conclusion applies equally to homolytic and to heterolytic reactions, as is directly indicated by results for the chemically induced magnetic polarisation of electrons and nuclei.

The reason for the conservation of spin in elementary chemical processes is that their duration is extremely short, around 10^{-14}–10^{-13} s. This is considerably less than the reciprocal of the rates for all the interactions that are able to induce change in the spin of an electron or a nucleus during a chemical process.

If in a chemical reaction, however, long-lived states are established, in which transitions are possible between levels differing in spin multiplicity, the intrinsic angular momentum of electrons and nuclei is not conserved in such states. A clear example is provided by the radical-pairs that precede chemical acts of recombination or disproportionation. Their lifetime (10^{-11}–10^{-8} s) is sufficiently long for transitions between states differing in spin multiplicity (triplet and singlet), accompanied by changes in electron and nuclear spins. This time is already comparable with the reciprocal of the interaction that induces transitions between singlet and triplet. (Quite weak interaction, e.g. an external radio-frequency field H_1, is able to change the angular momentum of electrons and nuclei. The energy of interaction of the field with an electron or a nucleus is γH_1, where γ is the gyromagnetic ratio for the electron or the nucleus. However, a longer time, of the order of $(\gamma H_1)^{-1}$, is now required to change the spin. Thus with $H_1 = 1$ oersted the time necessary for reorientation of an electron or a proton is respectively $\sim 4 \times 10^{-7}$ and 3×10^{-4} s. Such a change in spins is the essence of the phenomena of electron spin resonance and nuclear magnetic resonance.)

A long period of existence of radical-pairs (or reactant-pairs in general, with a set of electron-spin states) is not the sole condition ensuring the non-conservation of spin. Another important condition is that the exchange interaction between the electrons of the components of the pair should be sufficiently weak. Strong exchange interaction stabilises the angular momentum, maintains the electron spin of the system, and suppresses the evolution of the pair from one spin state to another.

Finally, a third condition is an interaction that induces transitions between spin states and alters the angular momentum. As shown above, the most important of this type are Zeeman and hyperfine interactions. The latter is especially important in weak fields, where the bonding between electron and nucleus is stronger than that of electrons and nuclei with the external magnetic field. Electron and nucleus then behave as a single spin system, change in the electron spin being balanced by a simultaneous change in the nuclear spin.

If all three conditions are satisfied, the angular momentum of the electrons and nuclei in a chemical system may not be conserved. This leads to magnetic effects in chemical reactions, the most striking of which are the chemical polarisation of nuclei, the enrichment of magnetic isotopes in chemical reactions, and the effect of a magnetic field on the rates of chemical reactions.

Reactions in Frozen Multicomponent Systems

G.B.Sergeev and V.A.Batyuk

Results of research on chemical reactions in frozen multicomponent systems are summarised. Transition of a system into a peculiar solid state leads to the appearance of several characteristic features, which can be explained on the basis of a structural-kinetic model. A list of 104 references is included.

CONTENTS

I. INTRODUCTION

Investigations on the kinetics and the mechanism of chemical reactions in ordered systems, in particular at low temperatures, constitute a new and rapidly developing branch of chemistry. The attention and interest of world science was directed to this field mainly by Soviet scientists, primarily Academician N. N. Semenov. In his contributions to the International Symposium on Macromolecular Chemistry at Moscow in 1960[1] and to the Eighteenth International Congress of Pure and Applied Chemistry at Montreal in 1961[2] he summarised experimental results, obtained by that time by several Soviet scientists, on low-temperature polymerisation, formation and destruction of free radicals, and rapid chain reactions in the photochemical hydrobromination of alkenes.

Semenov had studied chemical reactions in the solid phase at low temperatures as early as the 1920s. When sulphur and cadmium vapours produced deposits on a surface cooled in liquid air, explosive formation of cadmium sulphides was observed when the layer reached a certain thickness[3,4]. The method of molecular beams, proposed in these papers for the study of reactions at low temperatures, has since been successfully applied to the investigation of polymerisation[5-7] and the halogenation of alkenes[8].

At the end of the 1950s Semenov, with his ever present sense of the novel, gave active support to investigations, begun in the Department of Chemical Kinetics directed by him at Moscow State University, on the chemical reactions of halogens and hydrogen halides with various substances at temperatures close to the boiling point of nitrogen. This work revealed that in some cases lowering the temperature may favour a chemical process, and a reaction that does not take place at room temperature may be accomplished at low temperatures. It was discovered that certain chemical processes occurred spontaneously and rapidly at low temperatures, that chain reactions could take place in the solid phase, and that phase transitions and unstable molecular complexes of donor-acceptor type played a special role in effecting chemical changes at low temperatures. The results have been summarised in reviews[9-12]. These investigations, combined with studies of initiated and non-initiated polymerisation at low temperatures, and the formation and conversion of free atoms and radicals, established the foundations of a new branch of chemical physics—cryochemistry.

The accomplishment of chemical changes in the solid phase at low temperatures considerably extends our views on the elementary act in a chemical process. Transition of a reacting system from the gaseous to the liquid and solid states is accompanied by the intensification of intermolecular interactions, which begin to play an important part. Unstable reactive species can be investigated at low temperatures. Cryochemistry opens the way to obtaining and studying unstable intermediates involving radicals, ions, and reactive molecules, a path to the synthesis of new chemical compounds that are difficult or quite impossible to obtain in other ways.

The reaction having the lowest activation energy is most likely to occur at low temperatures. Hence a kind of energy selection may occur, leading to the formation of only one chemical product in a series of parallel processes. This will permit the establishment of a new chemical technology, characterised by the controlled synthesis of required products. At low temperatures substances can be obtained in a high degree of purity, uncontaminated by side-products and without poisoning the environment.

Until not long ago attention was paid mainly to photochemical and radiation-chemical processes in the study of chemical reactions at low temperatures. These aspects were analysed by Semenov[1,2] and in several other monographs and reviews[13-15].

Two periods—from the end of the nineteenth century to the middle of the 1950s and from the end of the 1950s to the present time—can be traced quite clearly in the investigation of chemical reactions at low temperatures. Mainly haphazard and qualitative work was undertaken during the first period; it has been surveyed in monographs[16,17]. Systematic investigation of different chemical reactions at low temperatures began during the 1950s, after it had been established that active atoms and radicals are stabilised at the temperature of liquid helium[16,17].

At the end of the 1950s research on low-temperature polymerisation was begun both here and abroad[1]. At the same time studies were begun in Moscow University on the addition of halogens to double bonds at temperatures close to 77 K.[18] It was discovered in the early 1960s that chemical and biochemical processes can occur in frozen solutions at temperatures below the melting point of the solvent[19]. The conversion of various monomers at low temperatures, the generation and transformation of radicals in solids, and low-temperature reactions of halogens and halogen hydrides with alkenes and cyclic compounds are being investigated in many Soviet institutes and laboratories. A systematic study of such processes has been made in Moscow University.

Research during recent years has shown increasingly clearly that detailed knowledge of the phase condition of ordered systems is necessary for an understanding of the mechanism of chemical changes occurring in them. It is extremely important to examine the formation and the development of defects in solids and to establish the relation between these processes and change in the reactivity of the system. The effect of the heterogeneity of a specimen on the occurrence of chemical reactions in it should be most clearly evident in multicomponent systems.

Research at Moscow University during recent years has shown that many kinetic rules governing chemical processes occurring in frozen multicomponent systems can be understood if the liquid phase is considered to constitute the defects responsible for the chemical reactions. Conditions for the formation of such a phase may be produced in multicomponent systems during preparation of the specimens or at the instant of reaction.

The study of solid multicomponent systems, in particular frozen solutions, is of great practical interest. This is connected primarily with problems in the low-temperature preservation of food products and of biological and medical preparations.

The present Review surveys several chemical and biochemical reactions occurring in multicomponent systems, especially in frozen solutions. These belong to an important class of solid-phase processes possessing several specific features.

II. TYPES OF REACTIONS AND PROCESSES

Investigators working at low temperatures are faced with several difficulties. Analysis of the reaction products must usually be carried out after the system has warmed up to room temperature. This involves a phase transition, during which the mobility of the molecules increases and various processes can easily occur[1,2], which must be taken into account. Douzou et al. have shown[20,21] that fall in temperature is accompanied by abrupt changes in such macroscopic properties of the system as its dielectric constant, viscosity, and hydrogen-ion concentration.

The first investigations of reactions involving at least two substances were usually made in vacuum equipment with layer-by-layer freezing of the reactants. The progress of the reaction was followed thermographically, and various chemical and physicochemical methods of analysis were applied after warming to room temperatures[10,22]. However, reactions under such conditions yield insufficiently homogeneous mixtures, so that it is difficult to obtain quantitative results.

The method of molecular beams[8,23] enables homogeneous multicomponent mixtures to be obtained at low temperatures. Combining it with spectral or calorimetric measurements gives information on the composition of the products and on the effective activation energy[11,24]. Condensation in molecular beams and the method of matrix isolation are used also to investigate photochemical processes[25]. Special designs of cuvettes and cryostats together with spectral methods of analysis enable the composition of the products to be studied, and in several cases also the kinetics of their formation, directly at low temperatures[26]. Inert vitrifying solvents can conveniently be used here.

Experimental studies of reactions in frozen solutions are usually made[27] by running together solutions of the reactants and freezing rapidly in liquid nitrogen. The specimens are then placed in a cryostat at the experimental temperature, with allowance for the effect of establishment of the temperature in the specimen and occurrence of the reaction during warming up. In a kinetic study chemical or physicochemical analyses of a series of specimens are made at definite time intervals. Electron spin resonance can be employed for processes involving stable radicals, to give data on reaction kinetics directly at the experimental temperature, without heating of the specimen[28]. Fig. 1 shows as example the temperature dependence, obtained by the above technique, of the rate of reaction of 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl with hydrazobenzene.

Table 1 gives experimental results for various chemical and biochemical reactions occurring in multicomponent systems at low temperatures. Polymerisation, photochemical and radiation-chemical reactions, and processes involving stabilised radicals are not included, since they fall outside the scope of the present Review. It is evident that the most diverse types of processes can be accomplished at low temperatures in frozen solutions, with and without solvents.

III. KINETIC FEATURES

Analysis of experimental results obtained for various chemical processes at low temperatures will reveal several of their common and most characteristic features. The temperature dependence of reaction velocity illustrated in Fig. 1 is typical of the frozen multicomponent systems listed in Table 1. Reaction occurs below the freezing point of the solvent, and takes place formally in the solid phase. Several experiments have shown that a process is more rapid in frozen solutions than e.g. in supercooled liquid solutions at the same temperature[28]. Fig. 1 shows the extremal temperature dependence of reaction velocity in frozen solutions. The rate of reaction in a solid matrix at a lower temperature is greater than in the liquid phase. Thus transition of a system from the liquid phase to the frozen state is accompanied by increase in the rate of a process: i.e. the phenomenon of a negative temperature coefficient is observed.

The most characteristic feature of reactions in binary systems, which have been investigated at low temperatures mainly in the absence of a solvent, is the influence of phase transitions. Most of the mixture usually reacts when one of the starting materials melts. If the reactants undergo phase transitions below the melting point of the mixture, reaction may take place in the solid phase. In the cyclohexene–chlorine system, for example, reaction occurs at −170°C, at the instant of transition of cyclohexene from a vitreous to a crystalline state[8,23].

In the absence of solvents, chemical reactions occur readily at low temperatures, at high rates, and usually give a single product in nearly theoretical yield[10]. In order to elucidate the mechanism several reactions between halogens and alkenes have been studied in non-polar solvents over a wide temperature range. The characteristic kinetic feature under such conditions is a negative temperature coefficient[12,29]. Increase in rate with fall in temperature has recently been observed for the reaction of nitrosyl chloride with α-oxides[30] and in those between halogens and phenylcyclopropanes[31].

Table 1. Chemical reactions in frozen solutions and at low temperatures.

No.	Process	Reaction, substance (catalyst)	Solvent	t, °C	Ref.
1	Halogenation of alkenes and aromatic compounds	 ethylene, propene, isobutene, cyclohexene, hex-1-ene halogens: chlorine, bromine	none	—45——196	9, 18, 84
		bromination of hex-1-ene	cyclohexane, benzene	0——110	42
		bromination of toluene 	none	—70——142	9
2	Reaction of alkenes with NO_2	alkenes: propene, isobutene, but-1-ene, hex-1-ene, cyclohexene, cyclopentadiene, buta-1,3-diene; main products: dinitroalkanes, nitroalkyl nitrites and nitrates	none	0——90	9
3	Inorganic addition and exchange substitution	$2NO+Cl_2 \longrightarrow 2NOCl$ $HBr+Cl_2 \longrightarrow HCl+ClBr$ $2NO+O_2 \longrightarrow 2NO_2$	none	—116——165 —105——182 —95	9
4	Hydrohalogenation of alkenes	 Hal=Br, Cl, I	none	—100——190	9
5	Hydrolysis	acetic anhydride  *p*-nitrophenyl acetate  *β*-propiolactone (catalyst: imidazole) 	water	—10	85
		δ-thiovalerolactone and γ-thiobutyrolactone (morpholine)	water	-10 to 45	85, 86
		penicillins G and V, 6-aminopenicillanic acid (imidazole, histidine, histamine, carnosine, OH^-)	water	to -78	19
6	Hydroxylaminolysis	formamide, acetamide, propionamide, asparagine, glutamine, 2,5-diketopiperazine, cytosine, acetylcholine; esters of glycine, serine, tyrosine, phenylalanine, and glutamic acid 	water	to -23	60, 65, 87, 88
		ethyl ester of lysine, methyl esters of lysine and arginine (trypsin)	water	—18	89
7	Inhibition by structural analogues (in hydroxylaminolysis)	esters of phenylalanine, serine, lysine, tyrosine, and glutamic acid; other cpd.	water	—18	90
8	Decomposition	hydrogen peroxide ($CuCl_2$, $FeCl_3$) $H_2O_2 \rightarrow H_2O + \frac{1}{2}O_2$	water		91
		t-butyl peroxyformate (2,6-lutidine, pyridine) $HC(O)OOC(CH_3)_2 \rightarrow HOC(CH_3)_3+CO_2$	*p*-xylene	to —70	92, 93
9	Menshutkin reaction	$CH_3I+(C_2H_5)_3N \rightarrow [(C_2H_5)_3NCH_3]I$	benzene, nitrobenzene, dioxan, CCl_4, water	to —196	42, 94 44, 61—64
10	Formation of epoxides	2-chloroethanol (reaction with NaOH)	water	to —15	95
11	Mutarotation	glucose (HCl)	water	—7	96
12	Dehydration	5-hydro-6-hydroxyuridine 	water	—10	72
13	Electron transfer	$Fe^{3+} \rightleftarrows Fe^{2+}$	water	to —196	97
14	Polymerisation	anhydrides of *N*-carboxyamino-acids 	dioxan	to —26	98
		6-aminopenicillanic acid 	water	to —28	99
		adenosine cyclic 3′,5′-phosphate,	water	—15	100
		oligo(2′-*O*-methylinosine 3′-phosphate) (on poly-C matrix)	water	—15	101

Table 1 (Cont'd.)

No.	Process	Reaction, substance (catalyst)	Solvent	*t*, °C	Ref.
15	Oxidation	hydrazobenzene 	dioxan	to —196	42, 44
		ascorbic acid 	water	—30 to 40	42
16	Enzymic oxidation	phosphoric esters of quinols (peroxidase) 	water	—30 to 50	65
17	Nucleophilic substitution	fluoro-2,4-dinitrobenzene with glycylphenylalanine (hexadecyltrimethylammonium bromide) 	water	—30 to 30	83
18	Chemical inactivation of enzymes	trypsin with imidazole α-chymotrypsin with urea	water water	—18 to —70	102 103
19	Denaturation of DNA	in solutions buffered at various pH	water	—13 to 25	104

Reactions with halogens are characterised by the formation of unstable intermediate donor–acceptor complexes of diverse composition and structure. The role of such complexes has been discussed in great detail[12], as well as the participation of complexes in the formation of radicals[32]. A negative temperature coefficient can be regarded as kinetic evidence that molecular complexes are involved in the chemical reaction. The participation of unstable donor–acceptor complexes will explain the main features of chemical reactions occurring at low temperatures in the absence of a solvent or in a non-freezing solvent. This concept is also extremely useful for analysing the mechanism of reactions of many different organic compounds[33].

Various hypotheses, usually without adequate experimental support, have been adduced to explain the features of chemical reactions in frozen multicomponent systems. The acceleration of chemical processes in frozen solutions has been attributed to change in the reaction mechanism, catalysis by the surface of the solid phase, the occurrence of phase transitions, the presence of various defects, the concentrating of reactants in non-freezing regions of the solvent, the existence of molecular compounds, a favourable spatial arrangement of the reactants, and an increase in the mobility of protons in ice. In the Reviewers' opinion the decisive role belongs to structural inhomogeneity and the consequent high mobility of the reactant molecules.

IV. STRUCTURAL AND PHASE INHOMOGENEITY

The variety of chemical processes occurring at low temperatures and the similarity of their inherent features indicate that the course of chemical reactions in frozen solutions is influenced by quite general factors. The occurrence of a reaction requires a certain degree of mobility of the molecules; it is impossible to understand the reasons for the acceleration of chemical changes and to elucidate their mechanism without knowledge of the structure and the phase constitution of the frozen solutions. Unfortunately, the structure of frozen solutions has not been adequately studied, and hardly any data are available on the phase state and the molecular mobility in such systems under the reaction conditions.

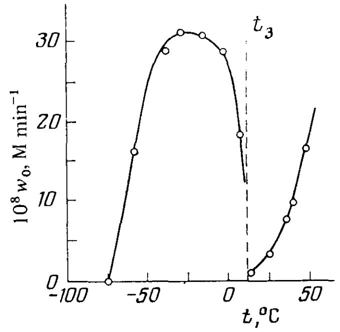

Figure 1. Temperature dependence of rate of reaction of 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl (R) with hydrazobenzene (Hab) in liquid and frozen dioxan solutions, with $[R]_0 = [Hab]_0 = 10^{-4}$ M.

Structural heterogeneity of frozen aqueous solutions was detected in the investigation by electron spin resonance of the distribution of paramagnetic ions—VO_2^{2+}, Mn^{2+}, and Gd^{3+}—at the temperature of liquid nitrogen[34-38]. Analogous results were obtained in a study of solid solutions of organic compounds by the method of stable radicals[39,40]. In solid solutions of sulphuric acid of concentration > 3.5 M the distribution of vanadyl ions is almost uniform, whereas in specimens that freeze as polycrystals a non-uniform distribution of these ions is observed.

The phase constitution of about ten binary systems has been studied by e.s.r.[28,41-43] with the stable 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl radical as tracer, varying in concentration from 10^{-7} M to 2×10^{-4} M. Analysis of the structure was based on the difference between the spectra of the radical in solution and in the solid state. Binary and ternary solutions of various compositions were examined over a wide temperature range, from 40 to −196°C. Solutions consisted either of the solvent and the tracer radical or of solvent, additive, and radical. The solvents used were water, dioxan, benzene, nitrobenzene, hexane, cyclohexane, etc. Substances having freezing points both above and below that of each solvent were chosen as additives—other solvents and also iodomethane, triethylamine, hydrazobenzene, azobenzene, hex-1-ene, ascorbic acid, inorganic salts, and other substances.

In all the systems investigated the e.s.r. spectrum of the tracer radical at −18°C is a triplet. The correlation times τ suggest that the mobility of the radical in frozen solutions at this temperature is comparable with its mobility in the liquid phase. As example Fig. 2 shows the spectra in three systems. The combined results indicate that frozen multicomponent systems are heterogeneous with respect to structure and, what is especially important, phase. Such systems are characterised by the coexistence of two phases—solid and liquid—over a very wide temperature range. One of these phases has been termed[44] a liquid microphase, to emphasise the abnormally high molecular mobility in this phase.

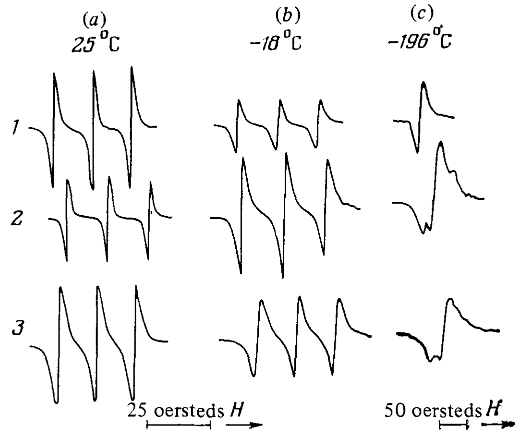

Figure 2. Spectra (e.s.r.) of 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl in: *a*) liquid; *b*), *c*) frozen 10^{-5} M solutions in various solvents: 1) dioxan (m.p. 11.8°C); 2) water (0°C); 3) cyclohexane (6.5°C). Correlation times ($10^{12}\tau$, s): 1*a*) 3.3; 1*b*) 66; 2*a*) 23; 2*b*) 130; 3*a*) 5.0; 3*b*) 16.

The existence of regions of high mobility has since been detected in an investigation of electronic spin–lattice relaxation times T_1 and e.s.r. spectra of frozen aqueous solutions of paramagnetic ions[45]. In aqueous (0.5 M) manganese(II) nitrate solutions high mobility is preserved down to −50°C. In this system the relaxation time T_1 increased sharply when the temperature changed only slightly, from 4.1×10^{-9} to $\sim 3 \times 10^{-8}$ s between −50 and −57°C.[45] Cooling from one temperature to the other was obviously accompanied by freezing of the liquid microphase, when the whole specimen became in fact solid.

The e.s.r. spectrum of diphenylpicrylhydrazyl shows a sharp increase in line width near the setting temperatures of solutions in toluene[46]. This is due to displacement of the hydrazyl radicals into uncrystallised regions and increase in their local concentration. The bell-shaped temperature dependence of the intensity ratio of e.s.r. spectra due to radical-pairs having a transition $\Delta M_S = 2$ and to radicals having the transition $\Delta M_S = 1$ in frozen solutions (10^{-3} M) of the stable 2,2,6,6-tetramethylpiperidino-oxyl radical in cyclohexane is also caused by structural heterogeneity of the system and the formation of liquid microregions on freezing[47].

Recent results have indicated the existence, on the surface of ice below 0°C, of a quasi-liquid layer in which the coefficient of self-diffusion of water molecules is as much as 10% of the value in liquid water under normal conditions[48]. Abnormally high mobility of water molecules is observed in frozen solutions of biopolymers, and is usually attributed to a special state of water in the hydrate sheath[49,50].

Electron spin resonance enables only a paramagnetic component to be followed. More complete information on the composition of the liquid microphase is obtained by nuclear magnetic resonance[42,44], the theory of which indicates[51] that absorption lines in solids are broader than those in the liquid phase and are not recorded in high-resolution n.m.r. spectra. If a liquid microphase is formed in a frozen solution, in which reactants are concentrated, narrow resonance lines must be expected to appear in the high-resolution n.m.r. spectra of such solutions, corresponding to reactants that retain their mobility and to part of the solvent. Comparatively narrow resonance signals due to solutes and solvent are indeed observed in frozen solutions[28,52].

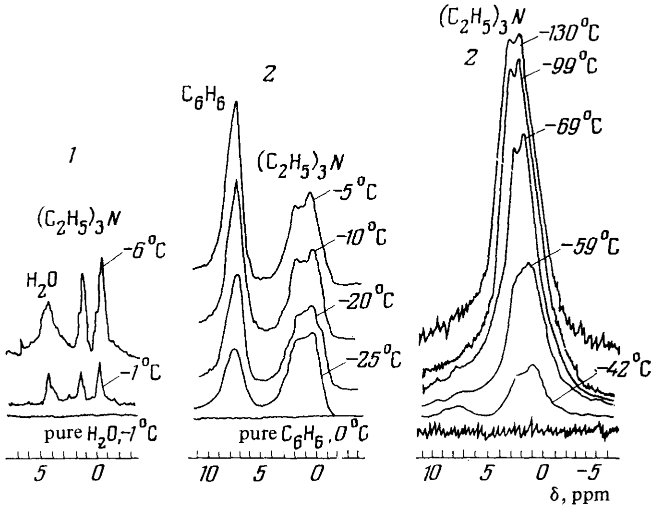

Figure 3. Spectra (n.m.r.) at various temperatures for frozen pure solvents and solutions of triethylamine: 1) 0.04 M; 2) 0.4 M.

Fig. 3 shows as example high-resolution n.m.r. spectra for frozen solutions of triethylamine in water and in benzene. It is evident that the pure solvents do not give such spectra when frozen. The spectra of the frozen solutions contain absorption bands corresponding to triethylamine and to the solvent. A frozen solution is found to contain highly mobile triethylamine molecules down to −130°C.

Integration of the n.m.r. spectra has enabled the temperature variation of the composition of the liquid microphase to be traced. The temperature dependence obtained for the ratio of the numbers of moles of iodomethane and benzene $P_{CH_3I}/P_{C_6H_6}$ in the liquid microphase of frozen benzene solutions and in the liquid solution (0.4 M CH_3I) is given in Table 2. The absolute numbers of moles of various substances in the liquid microphase have been calculated by comparing the results of integrating their spectra and those of a standard, a sealed capillary containing a concentrated solution of sulphuric acid. It is found (see also Fig. 3) that a liquid microphase, consisting of part of the solvent and solutes, is present in frozen solutions down to several tens of degrees below the melting point. Fall in temperature is accompanied by decrease in volume of the liquid microphase, as solvent freezes out and the concentration of the solutes increases.

Table 2.

t, °C	25	−29	−47	−59	−80
	liquid solution		frozen solutions		
$P_{CH_3I}/P_{C_6H_6}$	0.036	1.6	3.3	4.4	15.4

The composition of the microphase depends on the temperature, the proportion of solute increasing with fall in temperature. Table 2 shows that the ratio of the quantity of iodomethane to that of benzene in the liquid microphase of frozen solutions changes by factors of 8.5 and 370, relative to the liquid solution at 25°C, when the temperature falls to −29 and −80°C respectively. In this case we may consider that benzene is dissolved in iodomethane in the liquid microphase, since this contains far more of the latter than of the former.

The composition of the liquid microphase at a given temperature remains unchanged when a specimen is cooled from room temperature to −130°C and then allowed to warm up until the solution has completely thawed out. When the specimen is cooled to −196°C, the liquid microphase gradually disappears: i.e. molecules in the microheterogeneities lose their high mobility. The liquid microphase reappears when the specimen warms up. Comparison of specimens that have first been frozen in liquid nitrogen with those that have not been immersed in it but have been frozen in the resonator of the spectrometer at the specified temperature has shown that formation of the liquid microphase is independent of the method of freezing: it has the same composition in the two cases.

The temperature range of existence of the liquid microphase, the degree to which solutes are concentrated in it, and its volume at a given temperature are determined by the quantity of solutes and by the physicochemical properties of the system, of which the most important are the cryoscopic properties of the solvent and the ability to form eutectics.

The complete reversibility of the variation in the e.s.r. and n.m.r. spectra with temperature shows that the state of frozen multicomponent systems obtained with rates of cooling < 100 deg min^{-1} is close to thermodynamic equilibrium. Hence the volume V_L of microregions of high molecular mobility will be determined by the equation of state of the system. This volume decreases with fall in temperature: i.e. $\partial V_L/\partial T > 0$. To each temperature corresponds a microphase volume in which chemical reaction will occur (if its components are able to interact). When the drop in temperature is sufficient, reactions will cease owing to the increase in viscosity, the decrease in molecular mobility, and the Arrhenius law.

Fig. 4 shows as example the variation in the volume of the liquid microphase during the reaction of triethylamine with iodomethane in frozen benzene. The initial volume of the specimen is $V_0 = 0.36$ ml. Increasing extent of reaction, with decrease in the number of moles, is evidently accompanied by a decrease in V_L. At the same time the total concentration of solutes in the liquid microphase c_L remains constant (Fig. 5). This concentration increases with fall in the temperature, and hardly changes on introduction of the additive. At a given temperature and with a given initial concentration of starting materials, the composition of the liquid microphase depends mainly on the cryoscopic properties of the solvent. The total concentration of solutes in the liquid microphase can be found from the formula

$$c_L = (T_0 - T)/\Delta,$$

where T_0 is the melting point of the solvent and Δ (in deg M^{-1}) is its cryoscopic constant. Table 3 shows quite good agreement between experimental values and those calculated by means of this constant. The result indicates that the state of a slowly frozen multicomponent system is close to thermodynamic equilibrium.

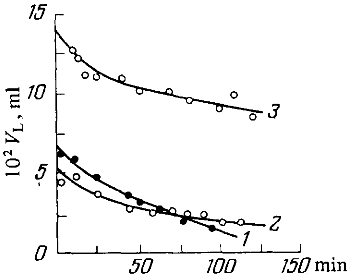

Figure 4. Variation in volume of liquid microphase in reaction of iodomethane with triethylamine (initially 0.2 M) in frozen benzene solutions: 1) at −5°C; 2) at −10°C; 3) with 0.4 M cyclohexane at −5°C; $V_0 = 0.36$ ml.

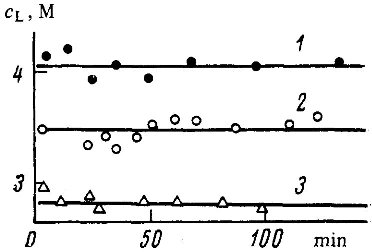

Figure 5. Variation in total solutes concentration c_L in liquid microphase during reaction of triethylamine with iodomethane (both initially 0.2 M) in frozen benzene at: 1) −10°C; 2) −5°C with 0.4 M nitrobenzene; 3) −5°C.

The reason for the formation of a liquid microphase in frozen solutions is that the inclusion of solutes in the crystal lattice of a solid solvent requires a greater quantity of energy than that consumed in the rise in chemical potentials accompanying increase in the concentration of components in the liquid microphase. The origin of microheterogeneities is clear also when eutectics are formed: the concentrating effect accompanying freezing may lead to a composition corresponding to a eutectic mixture. Data on the composition of the liquid microphase obtained by the n.m.r. method show that solutes constitute ~ 20–30% of the total volume of the liquid microphase at temperatures 10–15 deg below the freezing point of the solution.

Table 3. Total concentration of solutes in liquid microphase c_L and observed rate constants k_{exp} in reaction of triethylamine with iodomethane in frozen solutions in benzene, with initial reactant concentrations of 0.2 M.

Additive, 0.4 M	t, °C	$10^4 k_{exp}$, s^{-1}		c_L, M

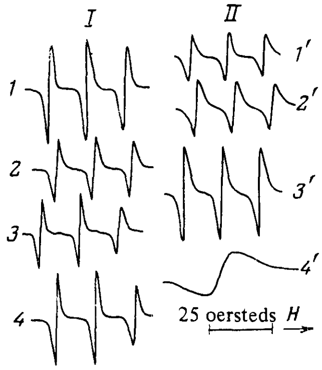

Figure 6. Spectra (e.s.r.) of 10^{-5} M 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl in: I) dioxan (m.p. 11.8°C) at −18°C; II) naphthalene (m.p. 80.1°C) at 25°C in the presence of 0.5 M additions of (correlation time $10^{11}\tau$, s): 1) t-butyl alcohol (13); 2) tetrachloromethane (4.4); 3) water (21); 4) azobenzene (29); 1') dioxan (4); 2') t-butyl alcohol (15); 3') nitrobenzene (26); 4') no addition.

Structural heterogeneity and phase non-uniformity are typical not only of frozen solutions but also of many other multicomponent systems. Fig. 6 shows as example e.s.r. results indicating the existence of a liquid microphase (at 25°C) in solid naphthalene (m.p. 80.1°C) when various additives are introduced[42]. In the absence of an additive the spectrum of the iminoxyl radical in naphthalene is a singlet, which is typical of frozen solutions in other solvents at the temperature of liquid nitrogen. This is converted into a triplet on addition of dioxan, t-butyl alcohol, or nitrobenzene. Thus additive concentrations of 0.5 M or less increase the mobility of the radical by several powers of ten, while the correlation time τ

changes from $< 10^{-5}$–10^{-6} to 4×10^{-11} s. Such a change in mobility is due to the formation, in the matrix of solid naphthalene, of regions of high molecular mobility, which is preserved at a temperature 55 deg below the melting point.

More and more results have appeared recently on molecular mobility in polymers. They indicate that polymer matrices with fillers behave as two-phase systems. The polystyrene–benzene system is characterised over the range −100 to 100°C by two nuclear magnetic spin–spin relaxation times T_2. Protons of benzene are responsible for the "phase" with the longer relaxation time T_{2a}, and protons of the macromolecules for the "phase" with the shorter time T_{2b}.[52] With fall in temperature the population density of the former "phase" diminishes. A sharp decrease in T_{2a} relaxation times is observed in the region of the melting point of benzene. This is evidence of partial crystallisation of benzene and that it in considerable measure determines the composition of this phase. Strictly speaking, the molecular motion of benzene in polystyrene is described by a spectrum of correlation times, and estimates show that the relaxation of benzene molecules in a polystyrene matrix is due mainly to rotational motions[52].

The plasticisation of a polymer by compounds of low molecular weight leads to an increase in molecular mobility. This conclusion is based on the variation in the e.s.r. spectra of radicals and the increase in their rate of conversion[53-55].

Interesting results have been obtained on the behaviour of liquid inclusions in potassium chloride crystals in the field of a temperature gradient[56]. The rate of movement depends on the size of the inclusions and on the applied temperature gradient.

The structure of solid multicomponent systems obtained from the liquid state depends significantly on the setting conditions, primarily on the rate of cooling. Such experiments have been made mainly on alloys. Rates of $\sim 10^3$–10^7 deg s^{-1} lead to extension of the range of solid solutions and a considerable decrease in the liquation of impurity elements, ultimately yielding a homogeneous alloy. Metastable phases and amorphous structures can be obtained with the above rates of cooling[57].

Little if any study has been made of the influence of rate of cooling on the structure of frozen organic-solvent solutions. The thermodynamic disequilibrium of the resulting systems can reasonably be expected to increase with the rate of freezing, which would influence significantly the kinetics of reactions occurring in them. The composition of supersaturated solid solutions formed in the *p*-chloronitrobenzene–*p*-bromonitrobenzene system depends on the rate of crystal growth[58].

It has recently been established that structural inhomogeneity is characteristic not only of crystallising but also of vitrifying systems, e.g. inorganic glasses[59].

Thus available experimental results indicate that multicomponent systems formed from the liquid state with fall in temperature possess both structural and phase heterogeneity. Such systems contain phases differing in composition, physicochemical properties, and degree of molecular mobility.

V. STRUCTURAL–KINETIC MODEL

The phase constitution of multicomponent systems has been examined, and kinetic data on chemical reactions have been obtained for the first time, directly in frozen solutions by application of the e.s.r. and n.m.r. methods. The former has been used to study a reaction involving a stable iminoxyl radical, 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl, and the latter to investigate the Menshutkin reaction[44]. Microwave spectrometry has permitted simultaneous observation of the phase state of the system and the kinetics of the reaction, as well as elimination of the possible effect of thawing, which occurs when specimens are analysed by other methods. Comparison of results obtained by different methods has in turn yielded necessary information on the role of freezing–unfreezing processes. Values obtained by different methods showed good mutual agreement (Table 3). Thus the phase transition connected with thawing out and the method of freezing have hardly any effect on kinetic results for spontaneous chemical reactions.

Let us consider the requirements that should be taken into account in any model intended to describe reactions in frozen solutions. The fundamental kinetic laws discussed in Section III are observed with chemical processes of the most diverse types. Hence the proposed model should be generally applicable and be based on principles taking into account the physicochemical properties common to all frozen systems. On the other hand, the chemical specificity of each individual process should appear in the model.

No-one has hitherto attempted to consider together reactions involving active species (e.g. radicals stabilised in matrices at low temperatures by the action of various types of radiation) and spontaneous chemical reactions occurring in solid matrices. In the Reviewers' opinion these kinetically dissimilar processes are actually most closely interconnected, and form the basis for the same general rules.

Our results on the kinetics of chemical reactions in frozen solutions and their phase condition suggest a structural–kinetic model for chemical reactions in solid matrices[44]. Frozen multicomponent systems have been shown to be heterogeneous with respect to phase. To a first approximation they can be imagined to consist of regions differing in composition and hence with different physicochemical properties. Solutes are preferentially concentrated in some regions, and the solvent is concentrated in others.

Phase heterogeneity may arise also by the action of various types of radiation and other physical agents. Even monocrystalline specimens become inhomogeneous under the influence of γ-rays, with maximum heterogeneity in the vicinity of active species stabilised at low temperatures. We can thus speak of the amorphisation of structure around stabilised radicals.

The actual occurrence of chemical reactions in solid matrices is made possible by the emerging phase heterogeneity (under the influence of freezing, radiation, or some other factor). This brings together the reactants, and thereby satisfies an important condition for reaction to occur. Thus chemical reaction takes place in certain regions of a frozen system. Molecular mobility varies significantly within a region, and shows differences in temperature variation in regions differing in composition. Study by e.s.r. and n.m.r. of the phase condition of frozen binary and ternary systems has shown that the freezing of solutions (in the usual solvents) of substances differing in chemical nature concentrates the latter in regions of enhanced molecular mobility. Over a wide temperature range, extending several tens of degrees below the freezing point, this is closely similar to the mobility in the liquid phase. To a first approximation these regions can be regarded as a liquid microphase located in a solid matrix.

The kinetics of chemical reactions in frozen systems can be explained on the basis of certain fundamental principles. (i) Multicomponent systems are characterised by structural and phase inhomogeneity. The components are non-uniformly distributed in a matrix of the main substance. (ii) Phases having different degrees of molecular mobility coexist over a wide range of conditions. The molecular mobility of reactants in frozen systems over a wide temperature range is closely similar to the mobility in a liquid phase. (iii) Freezing is accompanied by a change in the physicochemical properties of the system, which differ significantly for different phases and cannot be obtained simply by extrapolating data for a homogeneous system. It must especially be noted that, even if the totality of microregions in which reaction mainly occurs are regarded as a liquid microphase, this differs markedly in physicochemical properties from the initial liquid solution and even from its supercooled state if the latter could be obtained.

The frozen system may not in general be necessarily in thermodynamic equilibrium. The function describing its true phase condition can then be found only experimentally. Yet solution of the main kinetic problem—to find the law governing the variation of reactant concentrations with time—is impossible in analytical form without knowledge of this function. Two limiting régimes, corresponding to two possible structural states of the system, can be distinguished for chemical reactions.

Firstly, reaction cannot occur to an appreciable extent during transition of the system from liquid to frozen states with a rate of cooling not exceeding 100 deg min^{-1}, which is frequently the case according to the experimental results. The phase condition of the system is then at or close to thermodynamic equilibrium. Such a régime may be termed *kinetic*. The condition $v < w_{12}$ then holds, where v is the rate of chemical reaction, e.g. in the liquid phase at the melting point, and w_{12} the rate of transition of the system from the phase state at temperature t_1 (at or above the melting point) to the state at temperature t_2 (below the melting point).

The second group of conditions, which we may term a *relaxation régime*, will apply to rapid reactions, when $v > w_{12}$, with rapid quenching of the system, e.g. rates of cooling of $\sim 10^3 - 10^7$ deg s^{-1}. The process will then be governed by the rate of the phase transition. It is especially significant that, with high rates of cooling, the state will not correspond to thermodynamic equilibrium. Transition to a non-equilibrium state may be produced also by other factors, e.g. radiation. The great majority of reactions involving stabilised radicals and other active species in solids occur under a relaxation régime, which, in the Reviewers' opinion, is responsible for the appearance of several unusual features, in particular stepwise recombination.

Formulae for reaction kinetics in frozen systems can be obtained from a combined examination of the equation of state of the system, the equation of material balance describing the distribution of components in individual phases, and kinetic equations defining specific reaction rates in each phase.

Examining the origin of equations for describing reactions occurring under a kinetic régime[44,60-64], we note that experiment shows that the system is then almost in thermodynamic equilibrium, and the unknown equation of state for the frozen system can be replaced by two principles soundly based on experiment. Freezing may be supposed to involve formation of a two-phase system, in which the reaction velocity is $v = v_L + v_S$, where v_L and v_S are the rates in the liquid microphase and in the solid phase respectively. With complete transfer of solutes to the liquid microphase we can ignore v_S, while the great molecular mobility of the reactants allows us to use for v_L the kinetic formula for the rate of a reaction in an ordinary liquid phase, taking into account the changes in temperature and in physicochemical properties accompanying freezing.

The Reviewers and their coworkers have obtained kinetic equations for reactions taking place under a kinetic régime[28,44,61,65]. For the rate of reaction in the liquid microphase of a frozen solution we can write

$$v_L = k^0 \cdot \exp(-E/RT) \cdot \prod_j c_{jL}^{n_j} \tag{1}$$

where E is the activation energy of the reaction determined in the liquid phase, k^0 the pre-exponential factor, T the temperature of the experiment, c_{jL} the concentration of the jth reactant in the liquid microphase, in contrast to its concentration c_j in the unfrozen solution, and n_j the order of the reaction with respect to this reactant. We suppose that a specimen of volume V is frozen, in which the total concentration of all solutes (reactants, catalyst, additives, etc.) is $\sum_i c_i$. We suppose also that the frozen solution at temperature T contains a liquid microphase of volume V_L with a total concentration of solutes of $\sum_i c_{iL}$. Provided that the solutes become entirely concentrated in the liquid microphase on freezing, the material-balance equation is

$$V \cdot \sum_i c_i = V_L \cdot \sum_i c_{iL}. \tag{2}$$

Since the experimental reaction velocity v_{exp} is determined for the whole unfrozen specimen of volume V, the material-balance equation with respect to rates becomes

$$v_{\text{exp}} V = v_L V_L. \tag{3}$$

We introduce the concept of a concentrating factor β_i, the ratio of the concentration of the ith component in the liquid microphase of the frozen solution to its concentration in the unfrozen solution. When such concentrating is complete, β_i is the ratio of the volumes of the unfrozen solution and of the liquid microphase. From (2) and (3) we have

$$\beta_i = \sum_i c_{iL} \Big/ \sum_i c_i = V/V_L = v_L/v_{\text{exp}} \tag{4}$$

or

$$\sum_i c_{iL} = \beta_i \cdot \sum_i c_i \quad \text{and} \quad v_{\text{exp}} = v_L/\beta_i. \tag{5}$$

If the equation of state of the system is not known, experimental results show that $\sum_i c_{iL}$ can be determined by means of the relation

$$T_0 - T = \Delta \cdot \sum_i c_{iL}, \tag{6}$$

where T_0 is the melting point of the solvent and Δ its cryoscopic constant. Combining (5) and (6), we obtain

$$\beta_i = \frac{T_0 - T}{\Delta \cdot \sum_i c_i} \quad \text{and} \quad v_{\text{exp}} = v_L \frac{\Delta \cdot \sum_i c_i}{T_0 - T}. \tag{7}$$

From (1) and (7) we find that the experimental reaction velocity in the frozen solution is given by

$$v_{\exp} = k^{0} \cdot \exp(-E/RT) \cdot \left[\frac{T_0 - T}{\Delta \cdot \sum_i c_i}\right]^{\left(\sum_j n_j - 1\right)} \cdot \prod_j c_j^{n_j}. \tag{8}$$

The formula for the rate of a reaction in a frozen solution can be written as the product of the reactant concentrations and a factor that behaves formally as a rate constant:

$$v_{\exp} = k_{\exp} \cdot \prod_j c_j^{n_j}, \tag{9}$$

where

$$k_{\exp} = k^{0} \cdot \exp(-E/RT) \cdot \left[(T_0 - T)/\Delta \cdot \sum_i c_i\right]^{\left(\sum_j n_j - 1\right)}, \tag{10}$$

i.e. $k_{\exp}$ is the product of the usual reaction rate constant at temperature T and the concentrating factor β_i raised to a power depending on the total reaction order $\sum_j n_j$. The concentrating factor depends on the properties of the solvent (its melting point and cryoscopic constant), the experimental temperature, and the total concentration of all the solutes $\sum_i c_i$. The concentrating factor and temperature T will be larger the greater is the difference $T_0 - T$ and the smaller are Δ and $\sum_i c_i$. The inverse proportion relating β_i with Δ and $\sum_i c_i$ has a clear physical explanation. The equilibrium state between the liquid solution and the frozen solvent at temperature T corresponds to a definite concentration of solutes, which is inversely proportional to the cryoscopic constant of the solvent. Thus the lower had been the concentration of solutes in the liquid solution $\sum_i c_i$ the more strongly should they be concentrated for the freezing point of the solvent to be depressed by $T_0 - T$.

The reactants, reaction products, catalysts, and other additives contribute to $\sum_i c_i$. In the simplest case the concentration of an inert additive in the reaction mixture c_a far exceeds the sum of the concentrations of the remaining components (other than the solvent):

$$c_a \gg \sum_i c_i. \tag{11}$$

We can then write

$$\sum_i c_i \approx c_a, \quad \sum_i c_{iL} \approx c_{aL} \tag{12}$$

$$\beta_i = \beta_a = \frac{T_0 - T}{\Delta \cdot c_a}, \tag{13}$$

i.e. the ratio of the volumes of unfrozen solution and liquid microphase, and hence the degree to which the reactants become concentrated, depend on the concentration of the inert additive.

Table 4 lists formulae for the rate constants $k_{\exp}$ of various types of reactions occurring in frozen solutions in the presence and in the absence of an additive. The experimental rate constants determined in frozen solutions containing an additive are seen to be independent of the reactant concentrations and to differ from the constants for the same reaction in the liquid phase by the $(\sum_j n_j - 1)$th power of the factor $\beta = (T_0 - T)/\Delta c_a$. In the absence of an additive, however, values of $k_{\exp}$ for reactions involving either a decrease of an increase in the number of moles depend on the instantaneous concentration of the reactants and are a function of the extent of reaction. The explanation is that, with reactions involving a change in the number of moles, the volume of the liquid microphase will change during the reaction in order to satisfy the condition of phase equilibrium. This requirement is equivalent to the condition

$$\sum_i c_{iL} = \text{const} \tag{14}$$

in the given solvent at temperature T.

Table 4. Values of factor γ in the formula

$$k_{\exp} = k^{0} \cdot \exp(-E/RT) \cdot \frac{T_0 \cdot T}{\Delta} \cdot \gamma$$

for the experimental rate constants of various types of reactions*.

Type of reaction	Factor
$A+B \longrightarrow C$	$([A]+[B]_0)^{-1}$
$A+B \longrightarrow C+D$	$([A]_0+[B]_0)^{-1}$
$A+B \longrightarrow C+D+E$	$(2[A]_0+[B]_0-[A])^{-1}$
$A+B+K \longrightarrow C+K$	$\dfrac{T_0-T}{\Delta \cdot ([A]+[B]_0+[K])^2}$
$A+B+K \longrightarrow C+D+K$	$\dfrac{T_0-T}{\Delta \cdot ([A]_0+[B]_0+[K])^2}$
$A+B+K \longrightarrow C+D+E+K$	$\dfrac{T_0-T}{\Delta \cdot (2[A]_0+[B]_0+[K]-[A])^2}$

* With $\sum_i c_i \simeq c_a$ we have $k_{\exp} = k^{0} \cdot \exp(-E/RT) \cdot \left(\frac{T_0-T}{\Delta \cdot c_a}\right)^n$, where $n = 2$ for bimolecular reactions in the presence of a catalyst (K), and $n = 1$ for uncatalysed reactions.

In order to obtain analytical expressions for the time variation of the concentrations of reactants or reaction products, the corresponding differential kinetic equations must be integrated. Considering as example the reaction A + B → C + D + E occurring in a frozen solution in the presence of an additive of concentration c_a, which does not appear in the stoichiometric equation, we write for the experimental rate constant

$$v_{\exp} = \frac{d[C]}{dt} = k_{\exp}[A] \cdot [B], \tag{15}$$

where (Table 4)

$$k_{\exp} = k_0 \cdot \exp(-E/RT) \cdot \frac{T_0 - T}{\Delta \cdot c_a}. \tag{16}$$

The instantaneous concentrations [A], [B], and [C] during the reaction are related to the initial concentrations $[A]_0$ and $[B]_0$ by the formulae

$$[A] = [A]_0 - [C] \text{ and } [B] = [B]_0 - [C]. \tag{17}$$

Substituting (17) in (15), we obtain

$$\frac{d[C]}{dt} = k_{\exp}([A]_0 - [C])([B]_0 - [C]). \tag{18}$$

The variables in this differential equation are separated:

$$\frac{\mathrm{d}[\mathrm{C}]}{([\mathrm{A}]_0-[\mathrm{C}])([\mathrm{B}]_0-[\mathrm{C}])}=k_{\exp}\cdot \mathrm{d}t. \tag{19}$$

Rearrangement of the left-hand side yields

$$\frac{1}{[\mathrm{A}]_0-[\mathrm{B}]_0}\cdot\left(\frac{\mathrm{d}[\mathrm{C}]}{[\mathrm{B}]_0-[\mathrm{C}]}-\frac{\mathrm{d}[\mathrm{C}]}{[\mathrm{A}]_0-[\mathrm{C}]}\right)=k_{\exp}\cdot \mathrm{d}t \tag{20}$$

integration of which, with the initial condition $[\mathrm{C}]=0$ at $t=0$, gives

$$[\mathrm{C}]=\frac{[\mathrm{A}]_0[\mathrm{B}]_0\{1-\exp[k_{\exp}\cdot t([\mathrm{A}]_0-[\mathrm{B}]_0)]\}}{[\mathrm{B}]_0-[\mathrm{A}]_0\cdot\exp[k_{\exp}\cdot t([\mathrm{A}]_0-[\mathrm{B}]_0)]}, \tag{21}$$

It is evident that Eqn. (21), describing the rate curve representing accumulation of the reaction product C, is identical in form with the equation for the liquid phase, but with the usual rate constant $k=k_0\exp(-E/RT)$ replaced by $k_{\exp}$ (Eqn. 16).

For the same reaction taking place in a frozen solution containing no additive the rate is given by Eqn. (15) but with $k_{\exp}$ dependent on the instantaneous concentration of one of the starting materials (Table 4):

$$k_{\exp}=k_0\cdot\exp(-E/RT)\cdot\frac{T_0-T}{\Delta\cdot(2[\mathrm{A}]_0+[\mathrm{B}]_0-[\mathrm{A}])}. \tag{22}$$

Since formulae (17) still hold, we can write for the reaction velocity the differential equation

$$\frac{\mathrm{d}[\mathrm{C}]}{\mathrm{d}t}=k_0\cdot\exp(-E/RT)\cdot\frac{T_0-T}{\Delta}\cdot\frac{([\mathrm{A}]_0-[\mathrm{C}])([\mathrm{B}]_0-[\mathrm{C}])}{[\mathrm{A}]_0+[\mathrm{B}]_0+[\mathrm{C}]}, \tag{23}$$

or

$$\frac{\mathrm{d}[\mathrm{C}]}{\mathrm{d}t}=k\frac{([\mathrm{A}]_0-[\mathrm{C}])([\mathrm{B}]_0-[\mathrm{C}])}{[\mathrm{A}]_0+[\mathrm{B}]_0+[\mathrm{C}]}, \tag{24}$$

where

$$k=k_0\cdot\exp(-E/RT)\cdot\frac{T_0-T}{\Delta}.$$

After separation of variables Eqn. (24) becomes

$$\mathrm{d}[\mathrm{C}]\frac{[\mathrm{A}]_0+[\mathrm{B}]_0+[\mathrm{C}]}{([\mathrm{A}]_0-[\mathrm{C}])([\mathrm{B}]_0-[\mathrm{C}])}=k\cdot\mathrm{d}t. \tag{25}$$

Integration of this equation, after the requisite rearrangements and with the initial condition $[\mathrm{C}]=0$ at $t=0$ will give

$$\frac{1}{[\mathrm{A}]_0-[\mathrm{B}]_0}\cdot\left[(2[\mathrm{A}]_0+[\mathrm{B}]_0)\cdot\ln\left(1-\frac{[\mathrm{C}]}{[\mathrm{A}]_0}\right)-[\mathrm{A}]_0\cdot\ln\left(1-\frac{[\mathrm{C}]}{[\mathrm{B}]_0}\right)-2[\mathrm{C}]\right]=kt. \tag{26}$$

Analytical expressions can similarly be obtained for the time dependence of the concentration [C] of the product of other types of bimolecular reactions in frozen solutions. Table 5 shows that it is only when the solution contains an additive or the number of moles remains unchanged that the rate curves of reactions in frozen solutions are described by the same equations as in the liquid phase but with different constants. The experimental rate constants are then proportional to the concentrating factor, and therefore depend either on the sum of the initial concentrations of the starting materials or on the concentration of the additive.

In the absence of an additive an explicit equation for the rate of accumulation of a product can in general ($[\mathrm{A}]_0\neq[\mathrm{B}]_0$) be obtained only for reactions in which the number of moles is maintained. For reactions involving a change in the number of moles formal kinetic equations cannot be used to describe the rate curves in frozen systems. In particular, processing experimental data on the basis of formal equations may lead to errors in determining the order of a reaction.

The model also provides a qualitative explanation and a quantitative description of the observed bell-shaped temperature dependence of reaction velocity (Fig. 1). The physical meaning of such variation is that freezing the solutions and cooling them below the freezing point tends to slow down the reaction in conformity with the Arrhenius law and to accelerate it because of the increase in concentration of the reactants and the change in physicochemical conditions in the liquid microphase: competition between these three effects is responsible for the appearance of a maximum.

Table 5. Analytical formulae for the time dependence of the concentration of a product C of various types of bimolecular reactions (Table 4) occurring in frozen solutions in the absence of an additive*.

Reaction	Formula for [C], where $k_{\exp}=k_0\cdot\exp(-E/RT)\cdot\frac{T_0-T}{\Delta}\cdot\gamma$	γ
$\mathrm{A}+\mathrm{B}\rightarrow\mathrm{C}$	$\frac{1}{[\mathrm{A}]_0-[\mathrm{B}]_0}\left[[\mathrm{B}]_0\cdot\ln\left(1-\frac{[\mathrm{C}]}{[\mathrm{A}]_0}\right)-[\mathrm{A}]_0\cdot\ln\left(1-\frac{[\mathrm{C}]}{[\mathrm{B}]_0}\right)\right]=k_{\exp}t$	1
$\mathrm{A}+\mathrm{B}\rightarrow\mathrm{C}+\mathrm{D}$	$[\mathrm{C}]=\frac{[\mathrm{A}]_0[\mathrm{B}]_0\{1-\exp[k_{\exp}\cdot t([\mathrm{A}]_0-[\mathrm{B}]_0)]\}}{[\mathrm{B}]_0-[\mathrm{A}]_0\cdot\exp[k_{\exp}t([\mathrm{A}]_0-[\mathrm{B}]_0)]}$	$([\mathrm{A}]_0+[\mathrm{B}]_0)^{-1}$
$\mathrm{A}+\mathrm{B}\rightarrow\mathrm{C}+\mathrm{D}+\mathrm{E}$	$\frac{1}{[\mathrm{A}]_0-[\mathrm{B}]_0}\left[(2[\mathrm{A}]_0+[\mathrm{B}]_0)\cdot\ln\left(1-\frac{[\mathrm{C}]}{[\mathrm{A}_0]}\right)-(2[\mathrm{B}]_0+[\mathrm{A}])\cdot\ln\left(1-\frac{[\mathrm{C}]}{[\mathrm{B}]_0}\right)\right]=k_{\exp}t$	1

---

*In the presence of an additive ($\sum_i c_i\simeq c_a$) the concentration [C] is given for all reactions by the formula for the reaction $\mathrm{A}+\mathrm{B}\rightarrow\mathrm{C}+\mathrm{D}$, with $\gamma=1/c_a$.

In order to find the extrema in the general temperature dependence of reaction velocity in a frozen solution we differentiate Eqn. (8) with respect to temperature:

$$\frac{\partial v_{\exp}}{\partial T}=k^0\cdot\exp(-E/RT)\cdot\left(\prod_j c_j^{n_j}\right)\cdot\left(\frac{1}{\Delta\cdot\sum_i c_i}\right)^{\left(\sum_j n_j-1\right)}\cdot(T_0-T)^{\left(\sum_j n_j-1\right)}\cdot\left[\frac{E}{RT^2}-\frac{\sum_j n_j-1}{T_0-T}\right] \tag{27}$$

and equate this $\partial v_{\exp}/\partial T$ to zero. Formula (27) shows that this is possible only if

$$(T_0-T)^{\left(\sum_j n_j-1\right)}\cdot\left[\frac{E}{RT^2}-\frac{\sum_j n_j-1}{T_0-T}\right]=0. \tag{28}$$

This can occur in several cases:

$$\text{(a)}\quad (T_0-T)\left(\sum_j n_j-1\right)=0,$$

i.e. the extremal point T^* corresponds to the melting point of the solvent, a case which is of no special interest and therefore will not be examined;

$$\text{(b)}\quad \frac{E}{RT^2}-\frac{\sum_j n_j-1}{T_0-T}=0 \tag{29}$$

in which there are several possibilities. When the aggregate order of the reaction is unity (i.e. $\sum_j n_j = 1$), it follows from (29) that the presence of an extremum requires that $E/RT^2 = 0$. If $E \neq 0$, this condition is not realised at any temperature: i.e. the temperature dependence of $v_{\exp}$ for first-order reactions is devoid of extrema. With $\sum_j n_j = 1$ we have

$$\frac{\partial v_{\exp}}{\partial T} \approx \frac{E}{RT^2} \cdot \exp(-E/RT) > 0. \qquad (30)$$

Hence $v_{\exp}$ decreases as the temperature falls, and no acceleration of the reaction should be observed when solutions are frozen. Nor is condition (29) realised at any temperature if $\sum_j n_j < 1$. This means that the temperature dependence of $v_{\exp}$ does not pass through extrema, and the reaction velocity decreases with fall in temperature.

The total reaction order must exceed unity, i.e. $\sum_j n_j - 1 > 0$, for extrema to be present. The extremal point is then found by solving Eqn. (29) for temperature:

$$T^* = \left\{ \frac{E^2}{4R^2\left[\left(\sum_j n_j\right) - 1\right]^2} + \frac{E \cdot T_0}{R\left[\left(\sum_j n_j\right) - 1\right]} \right\}^{1/2} - \frac{E}{2\left[\left(\sum_j n_j\right) - 1\right]} \cdot \qquad (31)$$

This formula shows that the temperature T^* depends on the aggregate order of the reaction, and falls as the order increases. It depends also on the freezing point of the solvent and the activation energy in the liquid phase. Thus if several parallel reactions, having different orders or differing markedly in activation energy, take place in a system, each will occur at a maximum rate at a particular temperature of the frozen solution. This implies that, by conducting the process in the frozen solution at a chosen temperature, we are able to accelerate selectively one or more reactions occurring in parallel in the system.

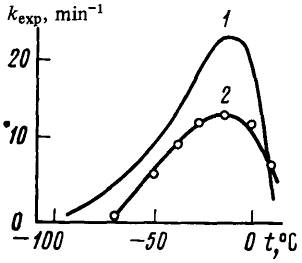

Figure 7. Temperature dependence of rate constant for the oxidation of hydrazobenzene by 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl in frozen dioxan: 1) calculated curve; 2) experimental curve.

The occurrence in frozen solutions of the maximum reaction velocity predicted by the model indicates that these reactions have a negative temperature coefficient, i.e. an effective activation energy less than zero, over the temperature range $T_0 - T^*$. A formula can be obtained for the effective activation energy of a reaction in a frozen solution by differentiating with respect to the reciprocal of the temperature the logarithm of the experimental rate constant (Eqn. 10):

$$E_{\text{eff}} = -R\frac{d \ln k_{\exp}}{d(1/T)} = E - \left[\left(\sum_j n_j\right) - 1\right]\frac{RT^2}{T_0 - T}. \qquad (32)$$

This expression (32) indicates that, when the solution freezes, the activation energy of the reaction changes sign, and remains negative down to the temperature T^*, when it vanishes; after this E_{eff} again becomes positive.

VI. SOME APPLICATIONS OF THE MODEL

Experimental results are well reproduced by the equations obtained[42-44,60-66]. As example Fig. 7 compares the experimental temperature dependence with the calculated relation for the rate constant in the oxidation of hydrazobenzene by 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl. Good qualitative agreement is evident, and at several temperatures nearly identical calculated and experimental values.

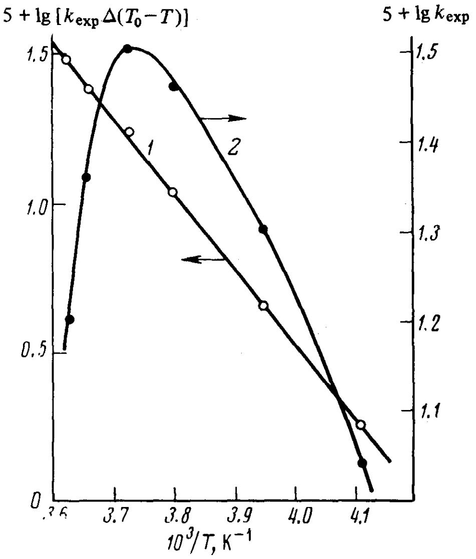

Figure 8. Influence of the reciprocal of the temperature in the Menshutkin reaction in frozen benzene on: 1) $\lg[k_{\exp}\Delta(T_0 - T)]$; 2) $\lg k_{\exp}$.

Results plotted in conformity with the Arrhenius equation do not lie on a straight line (Fig. 8). Linearisation can be effected by the use of coordinates allowing for transition of the system into the frozen state. Table 6 shows good agreement between the values thus obtained for the activation energies of reactions in frozen solutions and the corresponding activation energies in the liquid phase. Good agreement is evident also between calculated and experimental temperatures for maximum reaction velocity.

Let us consider briefly the possibilities of the structural–kinetic model for describing the kinetics of reactions occurring under a relaxation régime[67]. Stepwise recombination in the destruction of radicals stabilised in solids is especially interesting from this point of view. It is observed in systems of the most diverse chemical nature, including polymers[68–79]. The recombination of peroxy-radicals obtained by the photolysis of frozen aqueous hydrogen peroxide was one of the first examples of the stepwise recombination of radicals and the special role of phase transitions in effecting chemical reactions at low temperatures[9,71]. Fundamental kinetic laws were formulated[73] for the stepwise recombination of radicals.

Table 6. Calculated and experimental temperatures of maximum reaction velocity $t_{\mathrm{max}}^{\mathrm{calc}*}$ and $t_{\mathrm{max}}^{\mathrm{exp}}$, with activation energies in the liquid phase and in frozen solutions E and E_{fr} (R = 4-hydroxy-2,2,6,6-tetramethylpiperidinooxyl).

Solvent	E, kcal mole^{-1}	E_{fr}, kcal mole^{-1}	$t_{\mathrm{max}}^{\mathrm{calc}}$, °C	$t_{\mathrm{max}}^{\mathrm{exp}}$, °C
		$CH_3I + (C_2H_5)_3N$		
Benzene	9.4±1.0	11.4	−9±2	−5
Nitrobenzene	9.7±1.0	11.8	−8±2	−5
Dioxan	6.8±1.0	9.6	−9±2	−6
Water	20.3±1.0	23.2	−8±2	−8
		$R + C_{12}H_{12}N_2$		
Dioxan	6±1.0	6.5	−14±2	−20
		$R + C_6H_8O_6$		
Water	12±2	17	−10.5±3	−10

*Deviations calculated on the basis of the error adopted for E in ±1.0 kcal mole^{-1}.

The temperature dependence of the fraction of stabilised radicals (the "annealing" curve) is not in general linear. It probably represents the temperature dependence of the molecular mobility necessary for the destruction of radicals. The curve for radicals in adipic acid is almost linear under normal pressure, but at high pressures it becomes a more complicated function of temperature[74]. The thermal stability of radicals increases with increase in pressure, which is consistent with a decrease in molecular mobility with rise in pressure. It depends on the method of preparing the specimen and the mode of generation of the radicals (e.g. the type of radiation).

Various ideas and hypotheses have been put forward on the mechanism of the destruction of radicals in solids[68,70,73,75–78]. A polychromatic kinetic model of radical reactions in solids has been proposed[69] for the quantitative explanation of recombination. It has recently been suggested[79,80] that the free volume plays a part in the kinetics of radical destruction. Existing models do not explain all the observed regularities, and many concepts based on them are formally kinetic in character.

The concepts underlying the structural–kinetic model[44] also provide a qualitative description of the main kinetic features of the reactions of active species in solids[67]. They lead to a kinetic equation for the stepwise recombination of radicals, including the initial rapid destruction[67]. Such an approach will explain many aspects of solid-phase polymerisation and reactions in polymer systems. The laws governing photochemical reactions in solids can be explained by the same ideas. Solid-phase processes are characterised by a disproportionately large effect of small additions. Yields of products in photochemical and radiation-chemical reactions in multicomponent systems are usually non-additive and have abnormal values, while the rates of the processes are high. Tunnelling and the transfer of excitation and the free valency are often postulated to explain these features.

The concepts underlying the structural–kinetic model show, in the Reviewers' opinion, the absolute necessity of taking into account the fact[67] that, in regions surrounding already formed stabilised radicals, the medium possesses significantly different properties from those of the original matrix before exposure (this possibility had been pointed out by Semenov[2]). The yield of radicals and other species in this new structure will differ from their yield in regions of the solid not yet damaged by radiation. Thus differences in the mechanism and the efficiency of processes occurring in these regions of the solid must be taken into account. In particular, it must be expected that the yield of radicals will increase (because of the diminished cage effect) in radiation-damaged regions, i.e. where stabilised radicals are already present. Such an approach provides an explanation of the enhanced probability of formation of radicals near already existing radicals, and hence the increase in their rate of destruction with increase in dosage. The suggested mechanism may explain the high energy yield of the destruction of radicals, the low apparent activation energies, and the close similarity of radical-destruction rate constants in different substances[68]. The same mechanism should lead to a change in the type of dependence of the rate of accumulation of active particles on the dose. The formation of considerable quantities of radical-recombination products becomes understandable.

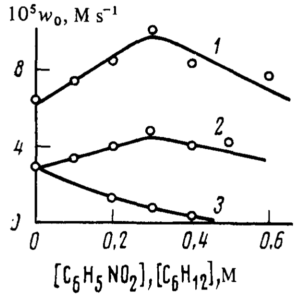

Figure 9. Effect of additives on rate w_0 of reaction of triethylamine with iodomethane in frozen solutions in: 1) dioxan at −8°C with additions of nitrobenzene (initial reactant concentration 0.11 M); 2) benzene at −5°C with additions of nitrobenzene (initial reactant concentrations 0.15 M); 3) as (2) but with added cyclohexane.

The existence in frozen solid matrices of regions of phase heterogeneity with a high mobility of interacting species would permit a physically clear interpretation of many kinetic features of chemical reactions in frozen solutions. These concepts have permitted a comparison of experimental and calculated values, as well as the prediction and detection of several new phenomena.

The rates of chemical reactions in frozen solutions are controlled by adding to the reaction mixture substances that are not involved in the process described by the stoichiometric equation. According to the model described in Section V, additions of inert substances should increase the volume of the liquid microphase and diminish the reactant concentrations. Non-polar additives behave in this way. Fig. 9 shows that polar additives have a dual effect: with low concentrations of the polar nitrobenzene reaction rates in the frozen solution are higher than in the solution without additive, because of the increase in polarity; with increase in the nitrobenzene concentration the dilution of the reactants in the liquid microphase increases because of the change in volume of this phase. The combined action of these two opposite effects leads to the appearance of maxima in the dependence of the initial reaction velocity on the additive concentration. The influence of the dielectric constant on reactions in frozen solutions has been discussed in detail[61,62].

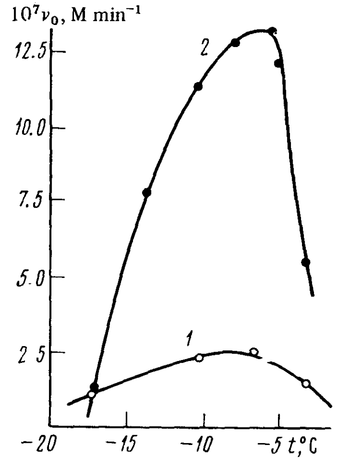

Figure 10. Temperature dependence of rate of oxidation of 4-hydroxy-2,3-dimethyl-1-naphthyl dihydrogen phosphate (2.5×10^{-5} M) by hydrogen peroxide (3.5×10^{-5} M) at pH 7.0 (0.1 M phosphate buffer) in ice in the presence of peroxidase (1.5×10^{-9} M): 1) individual oxidation; 2) in the presence of *p*-hydroxyphenyl dimethyl phosphate (1.4×10^{-5} M) as activator.

To describe the effect of additives we can formulate the general rule that the reaction is retarded in the frozen solution if the rate of the process in the liquid additive as solvent is lower than its rate in the solvent used in the experiment; an additive may either lower or raise the rate in a frozen solution if the rate in the liquid additive as solvent is greater than in the solvent to be frozen. Thus the rate of a process in a frozen solution can be regulated by additions of substances that are not involved in the stoichiometric equation and do not influence the kinetics of the reaction in the liquid phase. It is important to stress that the quantities of additives do not exceed 5% by volume, and are comparable with the concentrations of the reactants.

The structural–kinetic model suggests special effects produced by freezing for reactions having a complicated mechanism and involving a large number of species. Such processes include many biochemical and especially enzymic reactions. The spatially close approach of the reactants should lead to marked acceleration of such reactions, but diffusion hindrance would lead to sharp retardation.

The above suggestions have found some confirmation in the investigation of the two-substrate oxidation of quinol phosphates by hydrogen peroxide in the presence of peroxidase in frozen solutions[81]. Substrate–substrate activation is observed for this reaction in the liquid phase[82]: when two different compounds are oxidised together, the presence of one substrate activates the oxidation of the other. Only one of the substrates is oxidised, while the activator is not consumed until considerable degrees of conversion have been reached. Activation is a result of the concerted oxidation of substrates differing in reactivity at the stages of formation and interaction of radicals.

Fig. 10 illustrates the temperature dependence of the rate of two-substrate oxidation in ice. The presence of the activator is seen to increase the rate of oxidation of 4-hydroxy-1-naphthyl phosphate. The phenomenon of substrate–substrate activation in ice confirms the main assumptions of the structural–kinetic model, and shows that both freezing and the introduction of an additive—the other substrate—enable the rate of the process to be controlled and the efficiency of the enzyme to be enhanced.

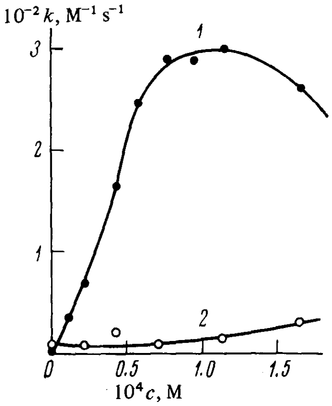

Figure 11. Dependence of rate constant of reaction of glycylphenylalanine (3.3×10^{-4} M) with fluoro-2,4-dinitrobenzene (3.3×10^{-4} M) on concentration of hexadecyltrimethylammonium bromide *c* at pH 7.25 (0.1 M phosphate buffer) in: 1) ice at −10°C; liquid phase at 20°C.

The concepts of the phase heterogeneity and the special properties of frozen solutions have enabled additional structure formation in ice to be predicted and detected. The example of nucleophilic substitution between glycylphenylalanine and fluoro-2,4-dinitrobenzene in ice has revealed a phenomenon resembling micellar catalysis in the liquid phase[83]. Comparison of the results plotted in Fig. 11 show that hexadecyltrimethylammonium bromide becomes active in ice at concentrations that do not influence the reaction in the liquid phase. It is interesting that in the latter the main reaction is accompanied by hydrolysis of fluoro-2,4-dinitrobenzene, whereas transition of the system to the frozen state changes the direction of reaction: freezing accelerates selectively the condensation and suppresses the hydrolysis.

The above examples lead to the important conclusion that the freezing of a system is an effective new method for controlling the rate and the mechanism of a chemical reaction.

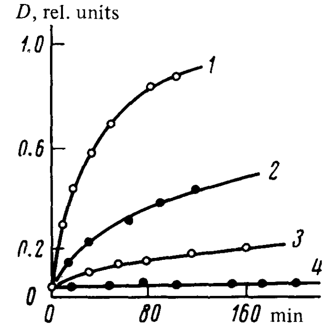

Figure 12. Rate curves for the accumulation of azobenzene in the oxidation of hydrazobenzene (initially 1.1 × 10^{-4} M) in the presence of 0.01 M ethanol in dioxan solution by: 1) iminoxyl radical in frozen solution at −5°C; 2) iminoxyl radical in liquid solution at 20°C; 3) air in liquid solution at 20°C; 4) air in frozen solution at −5°C.

The structural–kinetic model of reactions in multicomponent systems has led to the prediction and the detection of kinetic selection[28], the essence of which is that, among several parallel reactions in a liquid phase, only one is accelerated preferentially when the system passes into the frozen state. We consider as example two parallel bimolecular reactions

$$A+B \xrightarrow{k_1} E+F \tag{I}$$

$$C+D \xrightarrow{k_2} K+H \quad . \tag{II}$$

If D is present in excess, reaction (II) can be regarded as unimolecular and written

$$C \xrightarrow{k_3} K+H, \tag{III}$$

where $k_3 = k_2[D]$. From Eqn. (8) the rates of reactions (I) and (III) in the frozen solution are

$$v_1 = k_{1\,\mathrm{exp}}[A][B] = \frac{T_0-T}{\Delta\cdot([A]_0+[B]_0)}\cdot k_{01}\cdot\exp(-E_1/RT) \tag{33}$$

$$v_3 = k_{3\,\mathrm{exp}}[C] = k_{02}\cdot\exp(-E_2/RT)\cdot[D][C] \quad . \tag{34}$$

The ratio of the rates at temperature T is

$$\frac{v_1}{v_3} = \frac{T_0-T}{\Delta\cdot([A]_0+[B]_0)}\cdot\frac{k_{01}\cdot\exp(-E_1/RT)\cdot[A][B]}{k_{02}\cdot\exp(-E_2/RT)\cdot[C][D]} \quad , \tag{35}$$

The corresponding ratio in the supercooled liquid phase at the same temperature is

$$\frac{v_{1L}}{v_{3L}} = \frac{k_{01}\cdot\exp(-E_1/RT)}{k_{02}\cdot\exp(-E_2/RT)}\cdot\frac{[A][B]}{[C][D]}. \tag{36}$$

Comparison of (35) and (36) shows that the rate ratio varies differently in liquid and frozen solutions. Transition of the system from one phase to the other leads to a difference in rates defined by the relation

$$\frac{v_1/v_3}{v_{1L}/v_{3L}} \simeq \frac{T_0-T}{\Delta\cdot([A]_0+[B]_0)}. \tag{37}$$

Fig. 12 illustrates the effect of freezing on the oxidation of hydrazobenzene by atmospheric oxygen and by the 4-hydroxy-2,2,6,6-tetramethylpiperidino-oxyl radical in dioxan. Calculation for 253 K gives the value 3.6 × 10^4, so that the rate of oxidation by dissolved oxygen has decreased by a factor exceeding 35 000. Yet the rate of oxidation by the radical has accelerated in frozen solutions relative to the liquid phase. A similar pattern is observed in the oxidation of ascorbic acid[28].

One factor affecting the activation of chemical reactions on transition to the frozen state is the concentrating of the reactants. Such effects should be most strongly developed, of course, in reactions involving molecular complexes. Data on the halogenation of alkenes indicates that the phenomenon of a negative temperature coefficient is intensified when the system passes into the solid phase[66]. The combined activation of chemical processes by low temperatures and complex formation is clearly evident in the example of halogenations. Low-temperature reactions in the absence of a solvent (Table 1) have usually been investigated at temperatures at which the reactants exist in the solid phase. The preparation of such specimens may involve the formation of structural and phase discontinuities. Such a possibility is indicated by n.m.r. investigations on chlorine–alkene systems[84]. Thus at low temperatures some common features are exhibited by reactions in binary systems in the absence of a solvent and in multicomponent systems containing a solvent.

---oOo---

Research on frozen multicomponent systems has shown that the structural and phase inhomogeneity of the specimens has a decisive influence on the kinetics of chemical reactions occurring in such systems. Experimental results indicate that transition of a system from one phase to another is accompanied by a considerable change in physicochemical properties. Even in cases in which structural inclusions can be regarded as a liquid phase, its density, viscosity, dielectric constant, and other physicochemical characteristics cannot be obtained by extrapolating values for the truly liquid systems. These parameters are determined by the properties of the frozen specimen as a single whole.

The situation is further complicated by the absence of a strict definition for most physicochemical parameters at low temperatures and in the solid phase. Hitherto we have known really very little about the true phase condition of multicomponent systems at low temperatures, especially when subject to various radiations and with change in temperature. In the Reviewers' opinion the most fertile approach to the solution of many problems of low-temperature chemistry is to consider not only the specific chemistry of the process but also the effect of the actual phase condition of the whole system.

Only macrokinetic rules based on the structural–kinetic model have yet been obtained for frozen multicomponent systems. Further investigations are necessary to establish the dependence of the rate constant on the structure and the phase condition of the system, and to determine the quantitative influence of various factors, such as the movement of inclusions, methods of obtaining them, and the role of thermodynamic and kinetic factors in effecting chemical changes in frozen solid matrices. Solution of these problems is of great theoretical and practical interest. Research on chemical and biochemical reactions at low temperatures will enlarge our views on the mechanism of chemical change under extreme conditions, permit new approaches to the control of chemical synthesis, and enable optimum conditions to be predicted for the preservation of medical and biochemical preparations, as well as foodstuffs.

Problems of Combustion in Chemical Technology and in Metallurgy

A.G.Merzhanov

Combustion processes leading to the formation of valuable products of chemical technology and metallurgy—acetylene, carbon black, starting materials for acid manufacture, metal oxides, ferro-alloys, refractory compounds, etc.—are surveyed with emphasis on the possibilities and the advantages of combustion as a technical chemical procedure. Prospects for the widespread utilisation of combustion processes in chemical technology and metallurgy are examined on the basis of specific examples. Certain aspects of the development of combustion theory in connection with technical problems are discussed. A list of 78 references is included.

CONTENTS

I. INTRODUCTION

The term *combustion* is usually applied to a strongly exothermic chemical reaction occurring at temperatures resulting from the evolution of the heat of reaction. Two fundamentally different combustion régimes can be established: in the layered (wave) process reaction occurs in a narrow zone separating the reactants from the heated reaction products and moving spontaneously through the material at a definite speed in the form of a combustion wave; in the homogeneous process the reaction occurs in a combustion chamber to which reactants are continuously supplied and from which reaction products are continuously removed, while reactants and products are mixed. A characteristic feature in both cases is the high temperature arising during the reaction from the liberation of the chemical energy of the initial system, unconnected with an external supply of energy. Other forms of combustion include, for instance, the diffusion combustion of gases, in which the reactants are not mixed but are fed from different sides to a flame front whose position is stabilised in space.

The theoretical foundations were laid during the 1930 to 1940s by the fundamental investigations of Semenov and his school[1-3]. He examined the laws of the evolution and removal of heat in the reacting material[4], and calculated for the first time the critical conditions for thermal explosion. Subsequently Frank-Kamenetskii[5,6] and Todes[7-10] made important advances in the theory of the thermal explosion of gases. The theory of flame propagation was established by Zel'dovich and Frank-Kamenetskii[11]. Zel'dovich worked out the theories of combustion limits[12] and the combustion of unmixed gases[13], and also discussed the thermal conditions of exothermic reactions in a flow-type reaction vessel[14,15]. Several theoretical investigations of thermal explosion, ignition, and the propagation of a combustion wave in a condensed system have been undertaken by the Reviewer[16-20].

Two broad uses of combustion can be distinguished. Firstly the generation of power utilises the heat of reaction and very often, but not always, the energy of the expanding gaseous products. In the second use a product of combustion is itself of interest, as the desired result of a technical process.

The generation of power has been hugely developed and has exerted a strong influence on the theory of combustion. Almost all problems in the theory arose from the utilisation of chemical energy. Combustion theoreticians on their part have made an important contribution to energetics. The joint efforts of scientists and designers have developed such fields as engine manufacture, heat and power engineering, and rocket technology.

The second use has been developed mainly by technical chemists and metallurgists in isolation from combustion theory, and has reduced to working out the technology of individual products. Unfortunately, the extent and the level of investigations have been inadequate, and do not correspond to the great importance of this problem for the national economy.

This Review is an attempt to systematise the main combustion processes employed to obtain useful substances (gaseous and condensed products of chemical industry, metals and alloys, refractory inorganic compounds, etc.), to formulate specific features of combustion as a process of chemical technology, and to discuss certain problems associated with its development. Other aspects of combustion are also of interest to chemical technology and metallurgy, among them security from fire and explosion in chemical industries (the theoretical foundations of safety techniques), the production of technical furnaces burning natural fuels, and the organisation of thermal processes in flames. Here, however, we shall discuss only problems on synthesis, which are the most urgent and the least investigated.

II. MAIN TYPES OF TECHNICAL COMBUSTION PROCESSES

We shall discuss briefly the most widely used technical combustion processes.

1. Combustion of Hydrocarbons

The combustion of hydrocarbons is used in chemical industry to obtain various products (process gas, ethylene and acetylene, carbon black, etc.). Many variants of the process are used, distinguished by the starting material (usually natural gas and air), the concentration ratio of combustible and oxidant, the design of burners or combustion chambers, and methods of removing the required products.

Process gas is manufactured by the combustion of a hydrocarbon according to the equation

$$C_nH_{2n+2} + \frac{n}{2} O_2 = n\,CO + (n+1)\,H_2.$$

The products are in thermodynamic equilibrium, and are used for the synthesis of ammonia and methanol[21].

Acetylene and carbon black are obtained by combustion that is kept incomplete[22-26]. Excess of a hydrocarbon is pyrolysed in the flame formed by burning the major part of the hydrocarbon:

$$C_nH_{2n+2} \to C_2H_4 \to C_2H_2 \to C.$$

This process has been termed *oxidative pyrolysis*. Sometimes different hydrocarbons are used for combustion and pyrolysis, the latter being introduced directly into the flow of combustion products. Acetylene is an intermediate product of pyrolysis. It is therefore obtained by quenching (water is usually sprayed into the reacting mixture). The duration of the pyrolysis stage (which should be optimum) and the intensity of quenching (which should be great) determine the yield of acetylene — the chief index of the efficiency of a particular technical scheme.

Carbon black is the final product of pyrolysis, which is made as complete as possible in manufacture. A specific design feature of the plant is the presence of collectors for the condensed phase (soot collectors). Important characteristics of carbon black are its degree of dispersion and its impurity content, which depend on the conditions of pyrolysis and the starting material.

Because of variation in these parameters many brands of carbon black are available for particular purposes.

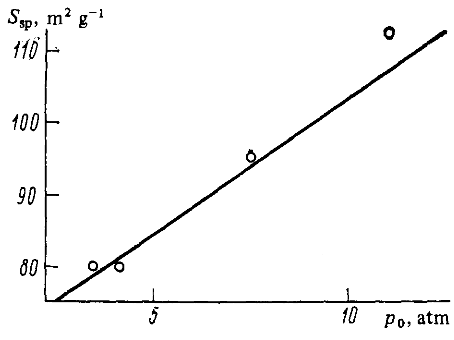

Figure 1. Dependence of specific surface of carbon black on initial pressure of acetylene[28].

In the above method the combustion itself does not lead to the formation of acetylene and carbon black, but has the ancillary role of providing a high temperature. Carbon black is produced not only by oxidative pyrolysis but also by other processes, e.g. the burning and detonation of acetylene (acetylene black)[27,28]. Fig. 1 illustrates the effect of the conditions on the characteristics of the product, showing the dependence of the specific surface of the carbon black on the initial pressure of acetylene[28].

A new method for the production of ethylene and acetylene is the so called immersion combustion of hydrocarbons[29,30]. Oxygen preheated to ~ 600°C is blown into a liquid hydrocarbon (e.g. kerosene), which vaporises and burns in the bubbles thus formed. After the oxygen has been used up, the hydrocarbon vapour is pyrolysed to ethylene and acetylene. Contact with the liquid phase results in effective quenching. The exhaust gases contain a substantial quantity of the required products.

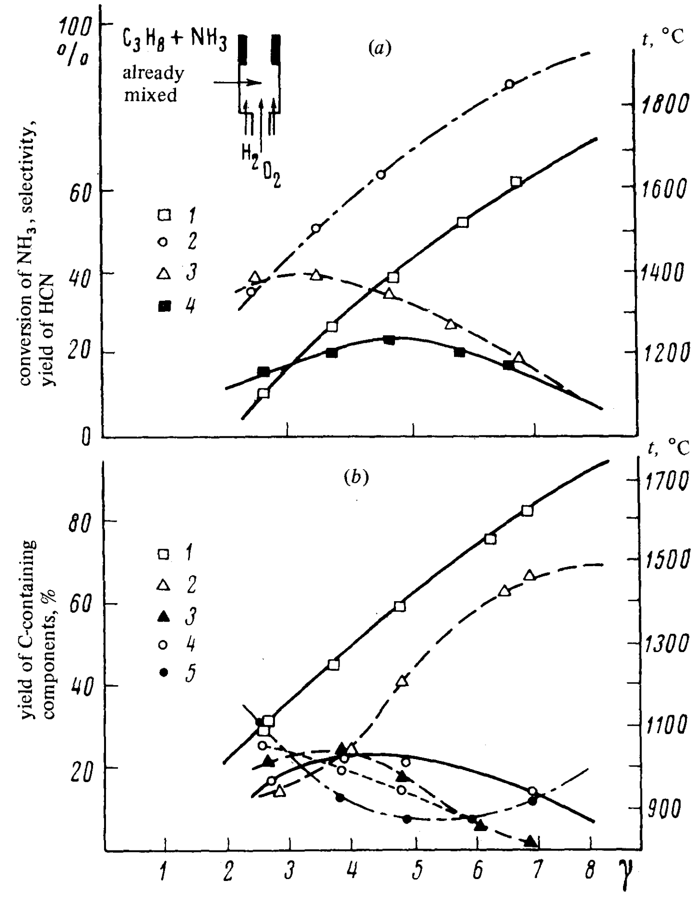

Figure 2. Dependence of combustion temperature and yield of carbon-containing products on ratio γ of space velocities of H_2–O_2 and C_3H_8–NH_3 mixtures[33]: (*a*) *1*) temperature; *2*) conversion; *3*) selectivity; *4*) yield of HCN (based on N); (*b*) *1*) temperature; and yields based on carbon of: *2*) CO; *3*) C_2H_4 + C_2H_2; *4*) CH_4; *5*) CO_2.

The combustion of hydrocarbons is used also for the production of hydrogen cyanide (manufacture of hydrocyanic acid). For this purpose ammonia is introduced either into the initial mixture or into the flow of combustion products[31-33]. The process can be represented empirically as

$$C_nH_{2n+2} + O_2 + NH_3 \to HCN + \ldots\ .$$

The yield of hydrogen cyanide (based on nitrogen) is high. The processes differ according to the raw material (e.g. with $n = 1$[31] or 3[33]) and the conditions of mixing of the reactants. The chief results obtained[33] for the synthesis of hydrogen cyanide are illustrated in Fig. 2.

2. Gas-flame Synthesis of Gaseous Products from the Elements

The reaction can be written

$$\underset{\substack{\text{fuel}\\ \text{element}}}{X_{L,G}} + \underset{\text{oxidant}}{Y_G} = \underset{\substack{\text{required}\\ \text{product}}}{Z_G}$$

where X and Y are the reactants and Z the reaction product. Combustion is easily conducted in burners or combustion chambers to a very high degree of completion: there are no fundamental difficulties in controlling the combustion. Further developments on these lines involve mainly intensification of the process and utilisation of the heat of combustion. In this respect a furnace technique, based on the solution of heat-engineering problems, has proved very effective[34].

The gas-flame synthesis of gaseous compounds from the elements has found widespread application in acid manufacture for the production of (*a*) hydrogen chloride (manufacture of hydrochloric acid)

$$H_2 + Cl_2 = 2HCl;$$

(*b*) sulphur trioxide (sulphuric acid)

$$S + O_2 = SO_2;$$

(*c*) phosphorus pentoxide (phosphoric acid)

$$2P + 2.5O_2 = P_2O_5.$$

3. Roasting of Sulphide Raw Material

This process[35–37] is interesting in giving simultaneously two required products having completely different purposes:

$$\underset{\text{fuel}}{MS_m} + \underset{\text{oxidant}}{\left(m + \frac{n}{2}\right)O_2} = \underset{\text{product I}}{MO_n} + \underset{\text{product II}}{m\,SO_2},$$

Metal oxides are used in metallurgy for the production of metals, and sulphur dioxide serves for the manufacture of sulphuric acid. Sulphide minerals are widely distributed in Nature (M = Fe, Mo, Cu, Ni, Zn, etc.).

Roasting is usually conducted in combustion reactors having a fluidised bed with an air blast. Particles of concentrate are continuously introduced, and the cinders (particles of oxide) are removed. Water is sometimes sprayed in to control the temperature. The variations in design of fluidised-bed vessels for the roasting of sulphide raw material have been discussed in detail[37]. The main difficulty is to achieve completeness of reaction. The process is characterised by comparatively low temperatures: for example, pyrites (FeS_2) is roasted at 800–900 and molybdenite at 600°C. Higher temperatures involve the formation of nodules, fusion, impaired access of air to the inner layers of particles, and lowered efficiency. It is interesting that the adiabatic temperatures for the combustion of sulphides are far higher than the roasting temperatures. For example, the combustion of molybdenum sulphide develops temperatures of ~ 1500°C in air, but above 3000°C in oxygen. Such a large difference between the maximum possible and the actual temperatures suggests that use of a fluidised bed is not the best method of organising combustion in roasting and that there are many opportunities for intensifying the process. Strictly speaking, the existing process of roasting bears little resemblance to combustion. Although it is close to homogeneous combustion, the considerable artifical lowering of temperature causes marked degeneration of the combustion. It is not by chance that the term "combustion" is not used in relation to this technique in the technical literature, and the combustion vessels are termed *furnaces*.

However, successful attempts have been made to organise the combustion of sulphides in a different manner. Thus the combustion of pyrites in a cyclone chamber with tangential feed gave a temperature of 1400°C, at which the oxide was molten, which made separation of the products more convenient[38]. The possibilities of using cyclone furnaces for the roasting of sulphides have been examined[39].

At the present time the two products are not manufactured together. In chemical industry the process is directed to the production of sulphur dioxide, while the metal oxides constitute low-quality by-products; the opposite situation occurs in metallurgy. This is also an indication of inadequate organisation of the process.

4. Blast-furnace Process

The blast-furnace process is one of the oldest and most important in metallurgy. It is based on the incomplete combustion of carbon, and can be represented schematically as

$$C + \begin{matrix} C + O_2 \rightarrow CO + Q; \\ \underset{\substack{\text{reducible}\\ \text{cpd.}}}{MO_m} \quad + Q \end{matrix} \rightarrow \underset{\text{product}}{M + \ldots .}$$

Carbon acts as both fuel and reducing agent. The burning of part of the carbon evolves heat, which raises the temperature of the mixture of the metal oxide with the rest of the carbon to values at which reduction to the metal takes place. At moderate temperatures carbon monoxide, formed by the combustion of carbon, also takes part in the reduction. The reduced metal is the desired product of the blast-furnace process.

The scheme of the process resembles oxidative pyrolysis: incomplete combustion also takes place here, and combustion has an ancillary role as a source of heat. However, the chemistry of the main reaction, leading to formation of the product, is essentially different.

The blast-furnace process is most widely used for the production of cast iron from iron ores:

$$\underset{\text{ore}}{\text{Iron}} + \underset{\substack{\text{fuel}\\ \text{(coke)}}}{\text{Carbon}} + \underset{\substack{\text{(limestone,}\\ \text{dolomite)}}}{\text{Fluxes}} + \text{Air} = \underset{\text{iron}}{\text{Cast}} + \text{Slags} + \underset{\text{gas}}{\text{Blast-furnace}}$$

A blast furnace (combustion chamber) consists of a hearth, in which the fuel burns and the charge melts, together with a shaft containing the melting material being fed to the hearth. The temperature in the hearth during the production of cast iron is 1300–1900°C.

Other metallurgical products, e.g. ferromanganese from manganese ores, are obtained by the blast-furnace method.

5. "Ex-furnace" Thermite Process

The main purpose of the thermite process[40–42] is to obtain metals from their oxides (or other compounds) by redox reactions in the condensed phase with the use of chemical elements as reductants. The chemical equation of the process is

$$\underset{\text{reducible cpd.}}{MX_m} + \underset{\text{reducing element}}{\frac{m}{n}M'} = \underset{\text{product}}{M} + \underset{\text{by-product (slag)}}{\frac{m}{n}M'X_n},$$

where M = Fe, Mn, V, Co, etc.; M′ = Ca, Al, Si, Mg, etc.; and X = O, Cl, etc.

Thermite processes have been known for a long time; the first experiments were made by Beketov during the nineteenth century.

If much heat is evolved in the thermite reduction, the process may take place under conditions of combustion. This case is referred to in metallurgical literature as an "ex-furnace"† thermite process. The example best known in the theory of combustion is the iron-aluminothermic process[43–45]

$$Fe_2O_3+2Al=2Fe+Al_2O_3.$$

An important practical task of the thermite process — the smelting of metals or alloys ‡ — can be achieved only if the metallic and slag phases in the combustion products separate out. For this it is necessary and sufficient that the temperature of combustion should be higher than the melting point of the products §, while the time of phase separation at the combustion temperature should be less than the thermal relaxation (cooling) time of the system.

The efficiency of extraction depends on the completeness of the redox reactions and the phase separation. Fig. 3 shows as example the dependence of the yield of metal on the particle sizes of iron oxide and of aluminium in the smelting of a ferroaluminium master alloy (80% Fe + 18% Al + 2% Si). The charge comprised 10 kg of iron oxide (98% Fe_2O_3) and 4.9 kg of aluminium powder (97% Al) with 0.8 kg of lime (90% CaO).[41] Study of ways for controlling thermite processes in order to ensure completeness in the main task of research in this field. One of the most effective methods is to introduce addivites for various purposes (slag-forming, preheating, etc.). The temperature of the thermite process is high, usually 2000–3000°C. The main charge and an ignition charge (primer) are placed in very simple open vessels with refractory walls and a hole for removal of the metal.

The thermite process has been most widely employed in ferrous metallurgy for the production of ferro-alloys and master alloys[41–46], most often with aluminium as reducing element.

Combined processes are also known, in which combustion is accomplished with an additional source of heat (preheating additives, raising the initial temperature of the charge by heating in a furnace). This extends considerably the range of systems in which combustion can be accomplished. The blast-furnace process can also be regarded as involving thermite reduction, with carbon as reducing element. However, the distinctive additional source of heat (the combustion of carbon in air) is responsible for a different, more complicated organisation of production.

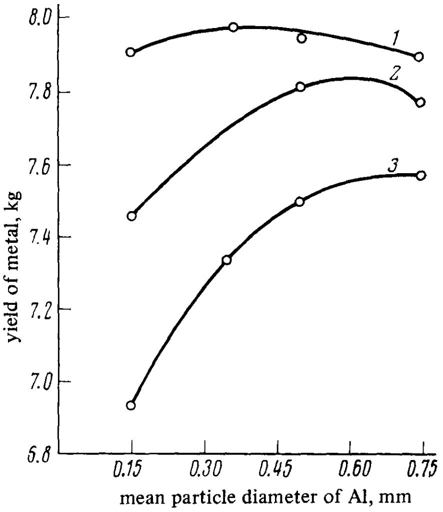

Figure 3. Effect of mean particle diameter of aluminium on yield of metal for different mean particle diameters of iron oxide (mm): *1*) 0.36; *2*) 0.55; *3*) 0.76.[41]

Thermite processes are used also to obtain non-ferrous metals[42]. However, the exploitation of combustion is less efficient than in the production of ferro-alloys and master alloys.

6. Self-propagating High-temperature Synthesis of Refractory Inorganic Compounds

This is the "youngest" technical combustion process[47–50]. Work in this field began in 1967, after discovery of the propagation of a combustion front in powdered mixtures of high-melting chemical elements, resulting in the formation of refractory compounds. Later other elements (of low melting point, liquid, and gaseous) were used for the synthesis. The general chemical scheme of the process, which has been termed *self-propagating high-temperature synthesis*, can be written.

$$\underset{\text{fuel elements}}{\sum_{i=1}^{m} a_i X_i} + \underset{\text{oxidising elements}}{\sum_{j=1}^{n} b_j Y_j} = \underset{\text{product}}{Z},$$

where X = Ti, Zr, Hf, V, Nb, Ta, Mo, W, etc.; Y = B, C, N, Si, S, Se, Al, etc.; and Z represents borides, carbides, nitrides, silicides, etc.

---

† The term "ex-furnace" is unfortunate, firstly, because it is terminologically inexact. The word "ex-furnace" implies that a furnace exists but that the process is for some reason conducted outside it, somewhere at its side. The sense would have been conveyed more accurately by "non-furnace" or "furnaceless". Secondly—perhaps the most important—the term indicates not the essential nature of the process but a technical consequence (absence of a furnace). In this sense it is more correct to speak of self-propagating thermite processes.

‡ Alloys are obtained by reducing two (or more) compounds together.

§ Very often the combustion temperature is higher also than the melting points of the reactants, and the reduction accompanying combustion occurs entirely in the liquid phase.

The elements X are in the form of powdered metals, the Y elements are used in powdered, liquid, or gaseous states, and the product Z is refractory and usually solid at the combustion temperature. The first group of elements (metals) act as fuels, and the latter group (non-metals) as oxidising agents. Chemical reaction between the elements takes place in the condensed phase, even if one of the reactants is a gas. In most of the processes the reaction is accompanied by the evolution of a large quantity of heat, which is responsible for the possibility of combustion. Thus this process involves a strongly exothermic reaction between chemical elements in a condensed phase taking place under combustion conditions.

The usual forms of the process with $m = 1$ and $n = 1$ have now been supplemented by other variants ($m \neq 1$ and $n \neq 1$), leading to the production of more complicated compounds:

(*a*) $m = 1$, $n = 2$ (carbonitrides MC_xN_y, where M = Ti, Zr, Nb, Ta);[51]

(*b*) $m = 2$, $n = 1$ ($Nb_xZr_{1-x}N$,[51] $Mo_xNb_{1-x}S_2$, $Ti_xCr_{1-x}B_2$, $Ti_xW_{1-x}C$);[52,53]

(*c*) $m = 2$, $n = 2$ (mixed carbonitride $Nb_xZr_{1-x}C_yN_z$).[51]

This process entails some of the highest combustion temperatures (~2500–4000°C).

Three types of processes can occur depending on the state of aggregation of the elements— (1) combustion of mixtures of X and Y powders in a vacuum of an inert gas (e.g. production of carbides, borides, and silicides), (2) combustion of powdered X in the gaseous oxidant Y (e.g. production of nitrides by burning metals in gaseous nitrogen), and (3) combustion of powdered X in a liquid oxidant Y (e.g. production of nitrides by burning metals in liquid nitrogen). The powders may first have been compressed or may be used in a loose state.

Special reaction vessels are used, different for each of the above three modifications of the process. The most common at present are gas-free synthesis vessels for processes of type (1).[54] A characteristic feature of the self-propagating high-temperature processes is the absence of by-products. Together with the possibility of complete conversion of the reactants (theoretical yields), this enables high-quality refractory products to be obtained, satisfying the most rigorous modern requirements with respect to materials behaviour.

An example is the production of titanium carbide, which is effectively used in the compositions of solid alloys, high-temperature materials, and abrasive pastes. Investigation of the mechanism of the combustion of mixtures of powdered titanium and carbon blacks[55] has helped to establish the main factors controlling the rate and the completeness of synthesis, among them the particle size of the titanium, the density of the pellets and the proportions of reactants in the charge, and the removal of heat from the combustion products. The experimental linear burning velocity varied[55] over the range 0.5–5 cm s^{-1} depending on the parameters of the initial mixture. The calculated adiabatic temperature was 3200 K, and the experimental temperature ~ 3000 K.[56]

Research on the mechanism of combustion of the titanium–carbon sytem has led to the development of the efficient technical production of titanium carbide[53] by a batch process in vessels of capacity 4–10 litres. This technology permitted the experimental production of high-quality titanium carbide powders. The product obtained from PTS (or PTM) titanium powder and Pm-15TS carbon black under optimum conditions contained (% by weight) 19.6–19.8 combined carbon, 0.1 uncombined carbon, 0.1 oxygen, and traces of nitrogen.

Various combined processes are now being developed, one of them involving the self-propagating high-temperature synthesis and thermite processes. A possible scheme is

$$\underset{\substack{\text{reducible}\\\text{product}}}{MX_m} + \underset{\substack{\text{element}\\\text{(reductant}\\\text{and oxidant)}}}{Y} \rightarrow \underset{\text{product}}{MY_n} + \underset{\text{by-product}}{YX_k},$$

An example is the reaction[57]

$$WO_3 + 3B = WB + B_2O_3.$$

The essence of this combined process is that the metal—one of the reactants in the self-propagating process—is formed by a prior thermite reaction. The combined process is cheaper than the self-propagating process alone, but gives products of poorer quality.

The self-propagating high-temperature method has at present found its widest application for the production of powdered refractory compounds, although other applications may be of interest (the manufacture of solid articles, the deposition of coatings, and the synthesis of single crystals). The general scheme of utilisation of these processes and products is shown diagrammatically in Fig. 4.

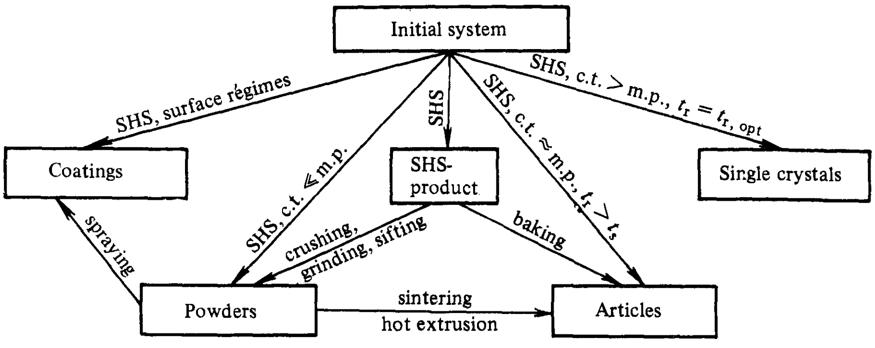

Figure 4. Diagram of uses of self-propagating high-temperature synthesis (SHS) processes and products: c.t. = combustion temperature; m.p. = melting point of product; t_r = thermal relaxation (cooling) time of product; $t_{r,\,opt}$ = optimum value of t_r; and t_s = duration of sintering.

Principal indices of technical combustion processes.

Process	Raw material	Product	State of aggregation of product under normal conditions	Principal applications	Combustion		State of aggregation of reactants in combustion zone	Chemical nature of combustion
					régime	temp., °C		
Combustion of C_xH_y	natural gas	unsat. C_xH_y, process gas, carbon black	gas, solid	organic synthesis	layer, homogeneous	1300–1700	gas	oxidation, pyrolysis
Gas-flame synthesis	S, P	oxides	gas	acid production	layer, homogeneous	1000–2500	gas	synthesis from elements
Oxidising roast	sulphides	oxides	gas, solid	acid production, metallurgy	homogeneous	600–900	gas, solid	oxidation
Blast-furnace process	iron ore	cast iron	solid	metallurgy	homogeneous	1600–1900	solid, liquid	redox
Thermite	oxide, Al	ferro-alloys, master alloys	solid	metallurgy	layer	2000–3000	liquid	redox
SHS	powdered metals and non-metals	refractory compounds	solid	inorganic materials	layer	2500–4000	gas, liquid solid	synthesis from elements

The most common technical combustion processes have been outlined above. They differ in many characteristics—the raw material used, the state of aggregation and purpose of the products, the chemistry of the reaction, the conditions and temperature of combustion, etc. Their main unifying feature is that the products of combustion contain a useful substance, which provides the reason for carrying out the process. The Table compares the main features of the processes that have been described.

III. COMBUSTION AS A TECHNICAL CHEMICAL PROCEDURE

1. Technical Features of Combustion

We shall now examine the chief specific features of combustion that permit its use in chemical technology, drawing where possible a comparison with the most widely used furnace and rapidly developing plasma processes. Almost all the peculiarities of combustion are due to its strongly exothermic character. This is responsible for the high temperatures of burning and the absence of external supplies of energy. The high temperatures in turn produce high reaction velocities and complete conversion of starting materials into end-products ¶.

When the reaction goes to completion, condensed products are of high quality and gaseous products are obtained in high yields †. The extremely high reaction velocities lead to high outputs. Since an external supply of energy is unnecessary, the equipment is simple and reliable. These factors are responsible for the favourable economics of the process. In chemical technology combustion is thus a highly efficient method for obtaining high-quality products cheaply.

Combustion is intermediate between furnace and plasma processes with respect to physical parameters (temperature ‡ and rate), but surpasses them considerably in certain technical parameters, primarily the consumption of electrical energy and the equipment. An almost negligible quantity of energy is required to initiate combustion, and the process itself takes place entirely on the basis of the intrinsic energetic possibilities of the system. Furnace and especially plasma processes require an immense consumption of electrical energy to produce the high temperatures involved. Simple equipment — combustion vessels, burners — is used for combustion, it is reliable in operation, with an almost unlimited life. High-temperature furnaces and especially plasmatrons are less reliable, with a short life, since the heating elements often deteriorate because of the high energy intensity. Thus the development of plasmachemistry is held back at the present time largely by the absence of improved plasmatrons.

¶ At high temperatures the reversibility of combustion may become evident (e.g. in dissociation of the product), with consequent thermodynamic incompleteness of conversion. On cooling, however, the thermodynamic equilibrium of the combustion products is usually displaced towards formation of the required product, and by controlling (if necessary diminishing) the rate of cooling we can eliminate the incompleteness of reaction due to thermodynamic factors. The equilibrium can be influenced also by varying the pressure and the temperature of combustion.

† When the required product is an intermediate the situation is more complicated.

‡ For various systems the temperature of combustion usually lies in the range 1000–4000° C; the temperature of furnace processes does not exceed 2500°C, and the mass-average temperature of the jet in plasmachemical processes reaches 10 000°C.

Combustion has wide possibilities when technical processes are conducted in large plant units. The fundamental difficulties associated with the change in scale from laboratory apparatus to industrial plant do not usually exist for combustion processes: very often combustion takes place more easily and more completely in large than in small volumes.

The possibility of accomplishing combustion at high and ultrahigh pressures is of great importance. In many cases fundamentally new constructions are not required, and modern high-pressure apparatus can be used. The combination of high pressures with high temperatures in furnace processes involves great difficulties, and high-pressure plasmatrons do not exist at all.

The erroneous opinion is held among technologists that technical processes based on combustion are difficult to control. An understanding of the factors governing the rate and the completeness of the chemical reactions involved will enable effective methods of control to be established. Particular combustion régimes can be deliberately maintained by regulating the temperature by the introduction of an additional source of energy or dilution of the initial reactants with the products, by varying the pressure and the concentrations in the reaction zone, by establishing a definite disperse composition when condensed phases are involved, and by other methods.

From a survey of the above considerations it may be concluded that combustion is one of the most ideal processes of chemical technology. It is therefore desirable to obtain products where possible under conditions of combustion.

2. Conditions for the Accomplishment of Processes of Chemical Technology under a Combustion Régime

In considering the possibility of conducting technical processes under combustion conditions we must pose two questions: (i) when can combustion be accomplished at all; and (ii) when can combustion be used for technical purposes.

The first question is answered by combustion theory[12]. The precise quantitative solution depends on many factors—the kinetic character of the combustion (simple or stepwise reactions, slight or marked kinetic inhibition by reaction products), the state of aggregation of the reactants, the combustion régime (homogeneous or layered steady state or oscillatory), etc. Fundamentally, however, the solution is common to all cases. We shall therefore examine for simplicity the propagation of a combustion wave during a first-order reaction in the gas phase.

In theory there exist necessary and sufficient conditions for a combustion wave to be propagated. The necessary conditions are

$$\beta = \frac{R(CT_0 + Q)}{CE} \ll 1;$$

$$\gamma = \frac{R(CT_0 + Q)^2}{CEQ} \ll 1,$$

where Q is the heat of reaction, E the activation energy, C the heat capacity at constant pressure § (molar or specific depending on the units in which Q has been expressed), T_0 the initial temperature of the reactants, and R the gas constant. These conditions evidently include the reaction parameters of combustion Q, E, and C, together with T_0 characterising the initial state of the system.

The sufficient condition is determined from the relation between the evolution of heat in the combustion wave and the loss of heat to the surrounding medium. In order that a combustion wave shall be propagated, it is sufficient that the heat losses should be less than a critical value: $\eta < \eta_{cr}$. The quantity η can be determined from the formula

$$\eta = \frac{T_{adb} - T_c}{T_{adb} - T_0},$$

where T_c is the temperature of combustion in the presence of heat losses. For the present example

$$T_{adb} - \frac{RT_{adb}^2}{E} \leqslant T_c \leqslant T_{adb}$$

so that

$$\eta_{cr} = \gamma.$$

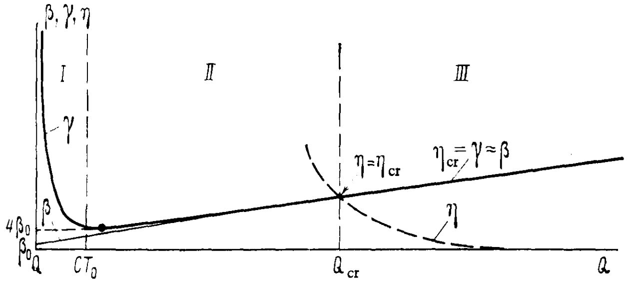

Figure 5. Necessary and sufficient conditions for propagation of combustion waves.

For clarity the necessary and sufficient conditions can be shown graphically. Fig. 5 illustrates the dependence of β, γ, and η on Q for constant T_0 and E with $\beta_0 = RT_0/E \ll 1$ ¶. The heat of reaction is chosen as variable on this graph, since it is the most important characteristic of the combustion. In most cases, when the composition of the products is known or can readily be assumed, the heat of reaction can be determined from thermochemical considerations. Three characteristic ranges (I)–(III) can be distinguished in Fig. 5, characterised by small, medium, and large heats of reaction.

(I) A combustion wave cannot be propagated, since the necessary conditions cannot be observed because of the large value of γ. Rates of reaction at T_{adb} and T_0 are comparable, and the pattern of propagation of a reaction zone through the substance, which is characteristic of combustion, is impossible.

---

§ In the theory of combustion we use the mean heat capacity determined by means of the formula

$$C = \frac{1}{T_{adb} - T_0} \int_{T_0}^{T_{adb}} C_p(T)\,dT,$$

where T_{adb} is the adiabatic (thermodynamically calculable) temperature of combustion.

¶ Strictly speaking, such a relation with a constant activation energy can be obtained only by diluting the initial reactants with inert products, but qualitatively it represents a more general rule. Special effects, not considered in the theory, arise when the heat of reaction is very large.

(II) The necessary conditions are observed, but the sufficient condition is not satisfied. A combustion wave cannot be propagated, since heat losses from the reaction zone are large. If combustion is initiated by special means, it is unable to develop, and dies out.

(III) Both necessary and sufficient conditions are observed, and the process has all the characteristic features of combustion. Usually $Q \gg CT_0$ and $\beta \simeq \gamma$.

A similar situation occurs in other, more complicated cases. There is no definite boundary between ranges (I) and (II). The critical heat of reaction Q_{cr}, separating ranges (II) and (III), is quite specific, and is determined in the theory of combustion limits[12] from the critical condition for propagation of a combustion wave. It depends both on the kinetic factors characterising the rate of evolution of heat in the combustion wave and on the geometric and thermophysical factors characterising the conditions of combustion. The latter include the geometrical scale of the burning system (the diameter of the specimen, tube, or jet) and the effective heat-transfer coefficient from the reaction zone to the surrounding medium. Even under the same conditions the critical heat of reaction may vary greatly on passing from one system to another. Whether or not a given system will burn cannot be predicted merely on the basis of information on the heat of reaction. The various classifications of the ability of exothermic systems to burn, based on values of this parameter and detached from the kinetic characteristics of the system and the thermophysical circumstances, are therefore untenable. Furthermore, determination of the critical conditions of combustion in any specific case is unreal—despite the theoretical possibilities—both because methods of calculation have been inadequately developed and because the data necessary for the calculation are lacking.

In such a situation a preliminary analysis can most reasonably be made by calculating thermodynamically the adiabatic temperature of combustion. Although the result will not give an unambiguous answer to the question, it is always useful, since some experience of working with a given class of systems enables a correct appraisal to be made of the possibility of combustion in a particular system. For example, experimental studies of the self-propagating high-temperature synthesis of four classes of refractory compounds—carbides, borides, nitrides and silicides — show that combustion does not occur when $T_{adb} < 1500$ K, systems always burn when $T_{adb} > 2500$ K, and additional investigations are required for intermediate values.

The answer to the second question — when combustion can be used for technical purposes—depends on the technical demands made. Here the main indicators are the yield and the possibility of isolating the product, its quality (for condensed substances), and the cost of the starting material. Detailed discussion of these criteria is innecessary, so that we shall merely examine a few examples.

It has already been noted that metal and slag phases should separate in the thermite production of ferro-alloys and master alloys. If such separation does not take place, the combustion cannot be used for the preparation, because of the difficulty of isolating the product. Phase separation is clearly possible when the combustion temperature is higher than the melting points of all the combustion products. For it to be complete, however, the operating conditions must ensure long thermal relaxation times, so that the system does not cool before complete phase separation can occur. The theory of the thermite process[41] has established criteria indicating the possibility of metal extraction in any specific case, and has suggested methods for controlling the process (preheating or slag-forming additives, the combination of combustion and furnace methods, etc.).

Complete conversion is very important to self-propagating high-temperature processes, in order to avoid contamination of the product with unchanged reactants, as isolation (i.e. purification) of the product is almost impossible. For the same reason single-phase products should be obtained.

The production of acetylene and ethylene by incomplete combustion of a hydrocarbon is possible only if adequate quantities of intermediate products of the pyrolysis of hydrocarbons are formed and if effective quenching is ensured.

It must be remarked, however, that the conditions of technical combustion depend on how the process is organised, and with correct organisation are very often feasible. It is therefore more important to satisfy conditions under which combustion can in general be accomplished (in systems whose use is economically justified).

IV. SOME PROMISING LINES OF ADVANCE IN THE USE OF COMBUSTION PROCESSES IN CHEMISTRY AND TECHNOLOGY

Analysis of the possibilities for applying combustion to chemical production suggests that only a small proportion of useful processes have yet been exploited. For this reason the development of research on combustion towards technical objectives offers great promise.

Firstly, we may note that the application of combustion processes to the chemistry and technology of inorganic materials is a novel and little investigated problem. Great prospects are opened up, whose full scope is at present difficult to envisage. The variety of factors characterising the composition and structure of powdered inorganic compounds and materials based on them leads to difficulties in establishing the scientific foundations of control for ensuring that quite definite products are obtained. The use of combustion methods for these purposes presents a difficult and fascinating scientific problem, whose solution is closely connected with the need to develop the theory of combustion.

Among promising tasks is firstly expansion of the range of inorganic compounds formed by interaction of the elements under conditions of combustion (it is the easiest). Here we may have in mind the synthesis of semiconducting compounds (sulphides, selenides, tellurides, phosphides, etc.), refractory compounds based on rare-earth metals, refractory one-phase composite compounds (mainly multicomponent solid solutions), and new modifications of binary compounds under conditions of combustion at high and ultrahigh pressures, etc.

It is of interest to apply self-propagating high-temperature processes to compounds of metals (e.g. chlorides and oxides), firstly because the use of a cheaper material than powdered metals will lower the cost of refractory compounds and secondly because the volatile components (chlorides) will permit combustion in the gas phase yielding the products as with homogeneous gas-phase deposition) in the form of powders of high specific surface, which is important for certain applications. It is tempting to try to transfer gas-phase precipitation to combustion conditions (by analogy with the transfer of certain furnace processes in the self-propagating high-temperature method). However, systems with chlorides or oxides as components are in most cases insufficiently exothermic, so that the main problem is to compound (select) high exothermic combinations. Here a thermodynamic approach may prove very effective. A thermodynamic analysis of the combustion of several systems involving chlorides has been made[58]. As an example[40], the reaction

$$BCl_3 + NH_3 = BN + 3HCl$$

is weakly exothermic and leads to an adiabatic temperature rise of only 500–600 deg. Nevertheless, the introduction of a gaseous mixture of hydrogen and chlorine into the initial mixture may raise the adiabatic temperature considerably and make possible the establishment of a combustion régime. The consequent decrease in the yield of the nitride from the boron is not very great. Analogous methods can be used in other cases.

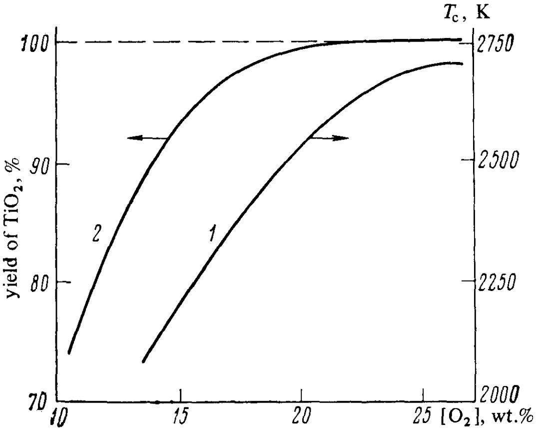

Figure 6. Thermodynamic calculation for $TiCl_4 + O_2 + H_2$ system with H : Cl $\simeq$ 2 and p = 1 atm: *1*) combustion temperature; *2*) yield of TiO_2.

An important practical task is to obtain titanium dioxide pigment from the tetrachloride:

$$TiCl_4 + O_2 = TiO_2 + 2Cl_2 \ .$$

This reaction is at present accomplished in the jet of an oxygen plasma, which is one of the greatest achievements of plasmachemistry[59]. It is therefore especially interesting to examine the possibilities of combustion for solving this problem. The temperature of adiabatic reaction between titanium tetrachloride and oxygen is ~ 1200 K,[60] which may be too low for combustion. However, the introduction of hydrogen into the initial mixture (giving titanium dioxide together with hydrogen chloride) will establish quite good thermodynamic conditions for combustion to occur (Fig. 6). The main difficulty in the experimental investigation will evidently be to control the degree of dispersion and the phase constitution of the dioxide with the aim of satisfying technical requirements.

Zel'dovich has put forward the interesting idea that cyanogen and its decomposition products might be used as reductants. Mixtures of cyanogen and oxygen develop very high temperatures on combustion, so that the excess of cyanogen could efficiently be used for gas-phase reduction (and probably for nitriding).

An important practical problem is to make solid articles from refractory compounds or composite materials by combustion. Its solution will lead to the introduction of combustion methods into powder metallurgy, which will undoubtedly aid progress. At present combustion methods yield refractory compounds in the form of powders, from which articles are produced by the usual sintering processes of powder metallurgy. However, sintering often takes place during combustion. It would be useful to study the completeness of sintering as a function of the combustion conditions and to learn how to control the process. Articles may then be obtained directly from the initial components under a combustion régime in a single technical stage. Compositions occupy a special position in the problem, and attempts have been reported[61] to obtain solid mixtures by combustion.

Several other types of use of combustion processes in the chemistry and technology of inorganic materials are of interest — the employment of surface combustion for the application of coatings for various purposes, the growing of single crystals by cooling liquid or condensing gaseous combustion products, etc.

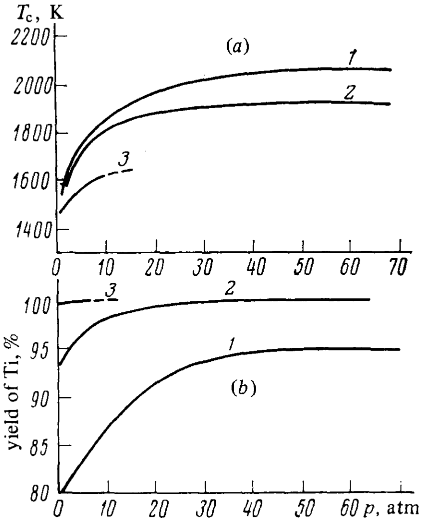

Figure 7. Pressure dependence of: *a*) combustion temperature; *b*) yield of titanium for $TiCl_4$ + Mg system containing different proportions (%) of magnesium: *1*) 20 (stoichiometric); *2*) 22; *3*) 24.

There are also several important but little developed uses of combustion in metallurgy and chemical technology. The production of non-ferrous metal powders, e.g. titanium, offers great possibilities. One of the most familiar methods for obtaining titanium is based on the thermite reaction[62]

$$TiCl_4 + 2Mg = Ti + 2MgCl_2.$$

In industry it is accomplished by molten magnesium with a spray of titanium tetrachloride by a furnance method (to give so called titanium sponge). However, this reaction is sufficiently exothermic to be of interest from the viewpoint of combustion. The results of special thermodynamic calculations[58] illustrated in Fig. 7, together with some preliminary experiments, show that magnesium is able to reduce the tetrachloride to titanium under a combustion régime, and this process should be of industrial importance. The main task is evidently to examine the quality of the titanium obtained in this way. It can readily be shown that several other metals may be produced by analogous processes. An interesting problem is to obtain metal powders of different degrees of dispersion, as well as powdered alloys.

The oxidation of sulphides offers great opportunities for the application of combustion methods. As already remarked, existing processes for roasting sulphide ores in a fluidised bed are inefficient, since the energy reserves of the system itself are by no means fully utilised (the working temperatures in the technical process are far lower than the combustion temperatures actually obtainable). It appears useful to examine the possibilities of combustion in a stream of a highly dispersed sulphide and oxygen (or air greatly enriched with oxygen). Very high temperatures will develop, and lead to a qualitatively different mechanism of oxidation. It can be regarded[39] as involving two stages, in the first of which sulphur burns to form its oxides. Combustion takes place in the vapour phase. The thermal flux from the combustion front heats a particle to a high temperature and causes thermal dissociation of the sulphide. Thus the first stage involves the burning of sulphur vapour, and the metal plays no part in the reaction. This mechanism recalls the burning of a hydrocarbon drop as described by Varshavskii[63]. In the second stage the residue, consisting of the metal (or a lower sulphide) burns away, by either vapour-phase or heterogeneous combustion depending on the relation between the combustion temperature and boiling point of the metal (see theory of combustion of metal particles[64]). By this mechanism oxidation processes should go to completion.

The use of combustion methods to obtain chemical reagents shows promise. The self-propagating high-temperature method, for example, is able to yield chemically pure specimens of many inorganic compounds. Borovinskaya et al.[65] have recently produced salts of certain inorganic acids by combustion processes:

$$NH_3 + H_2 + Cl_2 \rightarrow NH_4Cl;$$

$$V_2O_5 + Mg \rightarrow MgVO_4:$$

$$CaO + C + O_2 \rightarrow CaCO_3.$$

Simple and mixed gases have been obtained[66] by the combustion of pyrotechnic compositions, which may be of practical value under specific conditions.

The above is a by no means complete list of promising lines of research on combustion processes in chemical technology.

V. TECHNICAL PROCESSES AND COMBUSTION THEORY

We shall now consider the relation between problems of chemical technology and combustion theory. We have already noted in the Introduction the extremely small contribution made by chemical technology to the general theory of combustion, whose development was stimulated mainly by energetic problems. Indeed, the development of such processes as the blast-furnace production of cast iron, the roasting of sulphide ores, and the manufacture of acetylene did not present to the science of combustion a single major problem of general theoretical importance.

An exception is the work by Tesner and his colleagues[24] on the formation of soot in flames, in connection with the problem of obtaining carbon black. The importance of this work extends beyond the specific problem, since the burning of gases accompanied by the formation of condensed products is very widespread and is met in various applied processes. An understanding of the mechanism of formation of a condensed phase in the circumstances will permit not only control of the state of dispersion of condensed combustion products (which is of direct practical importance) but also development of the theory of the combustion of gases to take into account the influence of the kinetics and the thermodynamics of condensation processes on the rate of burning (establishment of a theory of so called "condensation" combustion).

However, it would be erroneous to assume that known technical combustion processes do not contain interesting theoretical problems: such problems exist, and are by no means few. We shall discuss some of them.

The immersion preparation of acetylene and ethylene involves the combustion of a gas bubble. This type of combustion of heterogeneous systems (in contrast to that of drops of fuel suspended in a gaseous oxidant) remains almost uninvestigated. The limited volume of oxidant, the intense heat transfer from the combustion zone to the liquid phase, the continuously increasing volume of the hot hearth, the stepwise chemical reaction, and other features may be responsible for several interesting effects of theoretical importance.

It is no less important to extend the theory[67] of the stepwise combustion of gases to exothermic oxidation accompanied by endothermic pyrolysis as in the incomplete combustion of hydrocarbons. Such a theory should reveal the factors primarily responsible for the structure of the combustion zone, in order to indicate ways of establishing high concentrations of intermediate products and of obtaining them in high yield by the optimum application of quenching media (when an intermediate is the required product) or of ensuring completeness of combustion (when a final product is required). Attempts have been made to give a detailed mathematical description of the process taking into account all possible reactions. However, it would be more useful to formalise the description[67] and consider only the most important stages.

The above account indicates that the problem of stepwise combustion arises also in the roasting of sulphides. Here, however, it extends to the diffusion combustion of heterogeneous systems. The stepwise burning of particles and their aggregates is an almost undeveloped branch of combustion theory.

Interesting theoretical problems of combustion are connected also with the thermite extraction of ferro-alloys and master alloys. One of these is to develop a theory of liquid-phase gas-free combustion allowing for diffusion processes. Interest in this arises from the use under industrial conditions of coarse granules of reactants and the fact that the limiting kinetic régimes of theory are not realised in liquid-phase combustion. A diffusion-kinetic theory of liquid-phase processes of gas-free combustion should indicate ways of diminishing the incompleteness of thermite reactions caused by diffusion hindrances. Another problem[46] is the possibility of explosion in the combustion of highly exothermic compositions (such as molybdenum trioxide with aluminium) in large quantities owing to gas formation resulting from partial vaporisation of the reactants.

The development of self-propagating high-temperature processes was from the very beginning closely connected with combustion theory. The peculiar forms of conversion of the reactants has led to the development of new trends in combustion theory, and the large range of new substances to the discovery of hitherto unknown phenomena. The mechanism of gas-free[20,55,68-71] and filtration[72-74] combustion has been investigated, the phenomena of spin[75,76] and oscillatory[20,68,75-77] combustion have been observed, régimes of surface and layer-by-layer combustion[72-74], the propagation of a combustion front, and burning down[55,70-72] have been studied, and methods have been worked out for calculating the rate of propagation of a combustion wave with broad zones of chemical reaction[71,78].

Although the survey in this section is incomplete, it indicates that not only energetics but also technology has given rise to many interesting problems in combustion theory.

* * *

Combustion can occupy an important position in modern chemistry, with its tendency to intensify processes and accomplish new reactions by establishing so called "extreme" conditions. The purpose of this Review was to direct attention to this. Highly intensive technical chemical processes have already been organised on the basis of combustion, and there are clear prospects for the further development of this trend. Problems in chemical technology may be expected to give a new impetus to the development of combustion theory.

The Development of Methods for the Description of Adsorption Isotherms within the Framework of the Fundamental Postulates of Langmuir's Theory

V.E.Ostrovskii

The review deals with the problem of the form of isotherms for adsorption on homogeneous and inhomogeneous surfaces with and without dissociation when the adsorbate molecule occupies a single elementary site on the surface or several such sites, for polymolecular adsorption, and for adsorption in the micropores.
The bibliography includes 74 references.

CONTENTS

I. INTRODUCTION OF FUNDAMENTAL POSTULATES

The equilibrium in adsorption can be characterised by specifying the adsorption isotherm:

$$v = \mathrm{f}(p), \tag{1}$$

where v is the amount of adsorbed gas (or vapour) and p the equilibrium pressure, and the form of the function

$$Q = \mathrm{f}_1(v), \tag{2}$$

where Q is the differential heat of adsorption.

Depending on the characteristics of the surface, the nature of the adsorbent, temperature, and pressure, the functions expressed by Eqns.(1) and (2) may be varied.

In the present review, adsorption is considered mainly within the framework of the adsorption theory the foundations of which were laid by Langmuir. However, initially we shall consider briefly the pre-Langmuir concepts concerning the nature of the phenomena at the interface between the solid and the gas or vapour. The first theoretical ideas about the adsorption of gases and vapours were put forward by Arrhenius in 1911 [1] and were somewhat later treated mathematically by Eucken[2]. Arrhenius began with the van der Waals hypothesis that there is no sharp phase transition between the liquid and its vapour and that there is a transitional layer the properties of which vary continuously from those of the liquid to those of the vapour on moving away from the surface of the liquid. Since the adsorbability sequence for various gases and vapours agrees with the condensability sequence, Arrhenius assumed that the adsorption forces are of the same type as molecular forces and hence are functionally related to the force constant in the van der Waals equation.

Developing this view, Eucken believed the transitional layer to be a miniature atmosphere whose molecules are retained near the surface under the influence of a potential ϵ, which is a function of the distance between the adsorbed molecule and the surface[2]:

$$\varepsilon = c/\mathrm{f}(r)\ , \tag{3}$$

where c is a constant which depends on the nature of the adsorbent and the adsorbate. In contrast to Eucken, Bakker [3] assumed that the molecules in the transitional layer attract one another with a force that decreases exponentially with increase of the distance between them.

Polanyi went further than other investigators in his development of Arrhenius's ideas, his first studies on this problem having been published in 1916.[4] He believed that the force field near the adsorbent should have the same properties as the gravitational field, i.e. it cannot be shielded, does not influence the interaction of the adsorbed molecules, and is independent of temperature, but, in contrast to the gravitational field, is specific. The degree of adsorption was calculated from the distribution of the potential, i.e. it was necessary to know the form of the relation $\epsilon = f(\varphi)$, which defines the volume of the space over the adsorbent surface in which the potential is greater then ϵ. In Polanyi's theory, this relation defines an infinite family of isotherms and permits the calculation of the degree of adsorption at any specified temperature. The nature of the $f(\varphi)$ curve, expressing the distribution of the potential, was determined from a single adsorption isotherm recorded below the critical temperature of the adsorbate. The required distribution was obtained as a result of the simultaneous solution of the equations

$$\varepsilon = RT\ln(p_0/p) \tag{4}$$

and

$$\varphi = v/d, \tag{5}$$

where p_0 is the vapour pressure at a temperature T and d the density of the adsorbed substance in the liquid state at the temperature T. Polanyi assumed that the forces of cohesion between the molecules are due to the fact that the latter are polarised in a specific manner.

Later London showed[5] that, when two particles are sufficiently close to one another, their electrons move in such a way that the states in which the electrons of both species are displaced in the same direction relative to their nuclei are statistically preferable. This phenomenon is a result of the interaction of the instantaneous dipole moments, and is responsible for the presence of the cohesion forces.

The postulates constituting the basis of Polanyi's theory have been frequently criticised (see, for example, McBain[6]), and, although numerous experimental data are consistent with this theory, towards the beginning of the 1930's it was already widely believed that not only the adsorption of gases but also the adsorption of vapours (in the initial stage) must be described in terms of Langmuir's ideas and not those of Polanyi (see, for example, Dubinin[7]). On this basis of the physical concepts of Polanyi's theory, Zhukhovitskii[8] formulated in 1938 a theory of adsorption from real solutions and compared its conclusions with experimental data. Quantitative tests showed that the formulae of the potential theory conflict with experiment; for example, in order to explain the position of the adsorption maximum as a function of the concentration of carbon tetrachloride in benzene, it was necessary to assume an average adsorption potential of 85 000 cal, which is quite unrealistic for van der Waals forces. The predictions of the theory were not fulfilled even qualitatively. Thus the component for which the theory predicted negative adsorption underwent position adsorption from solutions which were dilute with respect to it. Zhukhovitskii's results[8] throw doubt on the physical picture of adsorption constituting the basis of Polanyi's theory.

The foundations of the modern adsorption theory were laid in 1916 by Langmuir[9], who assumed that, on each unit area of the crystal surface, there should be a definite number of sites capable of adsorbing gaseous molecules. More molecules can be adsorbed only as a result of the formation of additional molecular layers. The forces acting between two layers of adsorbed gas molecules must be much smaller than those acting between the surface layer of the crystal and the first layer of adsorbed molecules. The rate of evaporation from the second layer is usually much higher than from the first layer, so that the number of molecules in the second layer must be negligibly small. When a gas molecule collides with a section of the surface already coated by a layer of adsorbed molecules, it usually re-evaporates so rapidly that the phenomenon is indistinguishable from reflection. According to Langmuir, in the adsorption of vapours at pressures approaching the saturation vapour pressure there should be a tendency for the thickness of the adsorbed films to become greater than one monolayer.

Langmuir began with the postulate that the forces acting between the atoms of the crystal and those of the adsorbed substance are of the same type as the forces acting between the adjacent atoms of the crystal; the manifestation of these forces is a result of the chemical unsaturation of the surface atoms in the crystal. (A similar idea had been expressed somewhat earlier by Haber[10].) The residence time of the adsorbed molecules on the surface depends on the strength of the surface forces.

Langmuir considered quantitatively the following six cases of adsorption.

(1) The surface consists of elementary areas of the same kind (henceforth we shall refer to such a surface as homogeneous) and the gas is adsorbed in the form of molecules each of which occupies a single elementary site.

(2) The surface consists of more than one kind of elementary site and adsorption takes place as in case 1.

(3) Adsorption on an amorphous surface (henceforth such surfaces will be referred to as inhomogeneous).

(4) Adsorption on a homogeneous surface, but on each elementary site more than one adsorbed molecule may be retained.

(5) Adsorption with dissociation on a homogeneous surface.

(6) Deformation of adsorbed films on a homogeneous surface having a thickness greater than the value corresponding to one molecule.

The process leading to the formation of adsorbed films with a thickness greater than the value corresponding to one molecule is referred to as polymolecular adsorption, in contrast to monomolecular adsorption (cases 1–5), in which the thickness of the adsorbed layer does not exceed the value corresponding to one molecule.

The Langmuir isotherms are considered below and the progress in adsorption theory for the cases enumerated above is analysed. To facilitate the exposition, the different cases of adsorption have been grouped in a manner different from that used in Langmuir's study[11].

II. ADSORPTION ISOTHERMS ON A HOMOGENEOUS SURFACE IN THE ABSENCE OF INTERACTION BETWEEN THE ADSORBED MOLECULES

1. Each Adsorbate Molecule Occupies One Elementary Site on the Adsorbent Surface

In 1916[9] and then in 1918[11] Langmuir published a kinetic derivation of the equation of the isotherm for this simplest case. Suppose that θ_0 is the fraction of the free adsorbent surface, i.e. the ratio L/N, where N is a number of adsorbed molecules per cm^2 of the surface under the conditions of maximum adsorption (i.e. in this case the number of elementary sites per cm^2) and L the number of adsorbed molecules per cm^2 of the surface, θ_1 the fraction of the occupied surface ($\theta_1 = 1 - \theta_0$), and Z_0 the number of collisions of the adsorbate molecules with 1 cm^2 of the adsorbent surface per second, and, according to the kinetic theory of gases, we have

$$Z_0 = \frac{N_0 p}{\sqrt{2\pi MRT}} \tag{6}$$

(N_0 is the Avogadro number and M the molecule weight of the gas); if the pressure is expressed in mmHg, then

$$Z_0 = 3.52 \times 10^{22}\, p/\sqrt{MT}. \tag{7}$$

Suppose that α is the probability of adhesion, i.e. the ratio of the number of molecules adsorbing to the number of molecules colliding with the surface per unit time (on a completely free surface) and β is the rate of desorption of the adsorbed molecules from the fully coated surface.

We then have at equilibrium

$$(1-\theta_1)\,\alpha Z_0 = \beta\theta_1, \tag{8}$$

whence

$$\theta_1 = \alpha Z_0/(\beta + \alpha Z_0). \tag{9}$$

If $\alpha/\beta = \sigma_1$, the Eqn.(9) transforms into

$$\theta_1 = \sigma_1 Z_0/(1 + \sigma_1 Z_0). \tag{10}$$

This is the required adsorption isotherm. Introducing the notation $ap = \sigma_1 Z_0$, where a is a constant, we have

$$\theta_1 = ap/(1 + ap). \tag{11}$$

Eqn. (11) can be formulated in the form of the equation of a rectangular hyperbola:

$$\theta_1 = a\left(\frac{1}{p} + a\right)^{-1}. \qquad (12)$$

For this reason, Eqn. (11) is sometimes referred to as the hyperbolic adsorption isotherm. For values of p so small that $ap \ll 1$, we have

$$\theta_1 = ap, \qquad (13)$$

i.e. Henry's equation holds. If p is so large that $ap \gg 1$, then

$$\theta_1 \rightarrow 1. \qquad (14)$$

Under these conditions, Eqn. (11) can be written in the form

$$ap(1-\theta_1) = 1, \qquad (15)$$

i.e.

$$1-\theta_1 = \theta_0 = 1/ap. \qquad (16)$$

Thus, when the degree of surface coverage tends to unity, the fraction of the free surface is inversely proportional to the pressure.

The problem of whether or not experimental data are described by isotherm (11) is usually elucidated with the aid of one of the following methods.

One can use the equation

$$\frac{p}{\theta_1} = \frac{1}{a} + p, \qquad (17)$$

obtained by rearranging Eqn. (11). Eqn. (17) describes a linear plot of p/θ_1 against p and makes it possible to determine a from experimental data.

The second method involves the use of the equation of a linear plot of p/v against p:

$$\frac{p}{v} = \frac{p_{1/2}}{v_\infty} + \frac{p}{v_\infty} \qquad (18)$$

where v_∞ is the maximum degree of adsorption corresponding to the formation of a monolayer and $p_{1/2}$ the pressure at which $v = \frac{1}{2}v_\infty$. Eqn. (18) can be obtained from the expression

$$v = v_\infty p/(p_{1/2} + p), \qquad (19)$$

which in its turn can be obtained from Eqn. (11) if account is taken of the fact that $\theta_1 = v/v_\infty$ and $1/a = p_{1/2}$ [the latter is a consequence of Eqn. (11)]. This method makes it possible to determine $p_{1/2}$ and hence also a and v_∞, provided that Eqn. (18) holds.

The following procedure is sometimes used to compare experimental data with isotherm (11).[12] After some rearrangement, logarithms are taken in Eqn. (8), which yields

$$\ln(\theta_1/p) = \ln a + \ln(1-\theta_1). \qquad (20)$$

For not unduly high values of θ, we have

$$\ln(1-\theta_1) \simeq -\theta_1, \qquad (21)$$

since the series expansion

$$\ln(1-\theta_1) = -\left[\theta_1 + \frac{1}{2}\theta_1^2 + \frac{1}{3}\theta_1^3 + \ldots\right] \qquad (22)$$

is valid. For this reason Eqn. (20) can be replaced approximately by the equation

$$\ln(\theta_1/p) = \ln a - \theta_1, \qquad (23)$$

which describes a linear plot of $\ln(\theta_1/p)$ against θ_1. If isotherm (11) describes the experimental data, the slope of the straight line should be -1; the value of a can then be determined from the intercept on the ordinate axis.

Temkin[13] obtained Eqn. (11) by a statistical method. He used for this purpose the partition function for the adsorbed layer (Z_a):

$$Z_a = (f_a)^N \cdot \frac{L!}{N!\,(L-N)!}\ , \qquad (24)$$

where f_a is the partition function of the molecule adsorbed in a specific manner, N the number of molecules in the adsorbed layer, L the number of surface sites, and $(f_a)^N$ the partition function of the adsorbed layer in which the molecules can be accommodated in only one way. Substitution of Z_a in the expression for the Helmholtz free energy and differentiation with respect to L yield the equation of the chemical potential of the adsorbed state. After setting the chemical potential of the adsorbed state equal to the chemical potential of the gas, i.e. assuming equilibrium, Temkin obtained Eqn. (11). This shows that Eqn. (11) is valid for the given case of adsorption regardless of the mechanism by which adsorption equilibrium is attained. Temkin established a relation between the constant a in Eqn. (11) and the heat of adsorption†. We shall restrict the treatment by quoting only the approximate equation, analogous to the approximate Nernst formula[16] for interphase equilibria, since the exact equation contains the heat capacity of the adsorbed layer, which is as yet unknown for the vast majority of adsorbent–adsorbate systems. The approximate equation is

$$\lg\frac{1}{a} = -\frac{Q}{4.57T} + 1.75\lg T + i', \qquad (25)$$

where i' is the so called conventional chemical constant, which can be assumed to be approximately equal to 3 for molecules and 1.5 for atoms, and Q is the heat of adsorption.

2. The Adsorption Isotherm for Polyatomic Molecules Dissociating on the Surface into Mobile Atoms (Mobile Films)

Suppose that the adsorption of each atom requires a single elementary site. The necessary condition for the adsorption of a diatomic molecule colliding with the surface is then the presence of two adjacent free elementary sites. The probability that any of the elementary sites on the surface is free equals $1-\theta_1$. When the adsorbed atoms can migrate on the surface (mobile films), the probability that any two adjacent sites on the surface are free is equal to the product of the probabilities that each is free, i.e. equals $(1-\theta_1)^2$. The necessary condition for the desorption of diatomic molecules from the surface is the presence of adsorbed atoms on two adjacent elementary sites on the surface. The probability of such an event is θ_1^2. Then the condition for the equality of the rates of adsorption and desorption at equilibrium is

$$\alpha(1-\theta_1)^2 Z_0 = \beta\theta_1^2. \qquad (26)$$

---

† In non-Soviet literature, priority in the statistical derivation of isotherm (11) is frequently given to Fowler (see, for example, Trapnell[14]), who published his study two years later than Temkin[13].

This equation was obtained by Langmuir[11]. After substitutions, we obtain

$$ap(1-\theta_1)^2=\theta_1^2. \tag{27}$$

The positive solution of Eqn. (27) is

$$\theta_1=\sqrt{ap}/(1+\sqrt{ap}). \tag{28}$$

For low coverage, when $\theta_1 \ll 1$, Eqn. (28) becomes

$$\theta_1=\sqrt{ap}, \tag{29}$$

i.e. the degree of adsorption is proportional to the square root of the pressure. For an almost completely covered surface, where $(1-\theta_1) \ll 1$, we have

$$(1-\theta_1)=\sqrt{1/ap}. \tag{30}$$

If the molecule dissociates on the surface into three species, each of which occupies a single elementary site, then, when $\theta_1 \ll 1$, we have

$$\theta_1=\sqrt[3]{ap}, \tag{31}$$

and, when $(1-\theta_1) \ll 1$, we have

$$(1-\theta_1)=\sqrt[3]{1/ap}. \tag{32}$$

In order to test whether or not the experimental data are described by Eqn. (28), it is convenient to put the latter in the form

$$\frac{\sqrt{p}}{v}=\frac{1}{\sqrt{a}\cdot v_\infty}+\frac{\sqrt{p}}{v_\infty}. \tag{33}$$

Eqn. (33) describes a linear plot of $\sqrt{p}/v$ against $\sqrt{p}$, its slope yielding the volume of the monolayer v_∞ and the intercept on the ordinate axis yielding the value of a.

A second method for comparing the experimental data with Eqn. (28), which is applicable at pressures such that $\sqrt{ap} \ll 1$, is as follows. One can use the equation

$$\ln(\theta_1/\sqrt{p})=\ln\sqrt{a}-\sqrt{a}\sqrt{p}, \tag{34}$$

which is obtained by rearranging Eqn. (28) and taking logarithms, provided that one subsequently replaces $\ln(1+\sqrt{ap})$ by the first term of the series expansion

$$\ln(1+\sqrt{ap})=\sqrt{ap}-\frac{1}{2}ap+\frac{1}{3}ap\sqrt{ap}-\frac{1}{4}a^2p^2+\ldots \tag{35}$$

Eqn. (34) describes the straight line

$$\ln(\theta_1/\sqrt{p})-\sqrt{p}.$$

Temkin[13] derived Eqn. (28) by a thermodynamic method and showed that, in order to describe the relation between the coefficient a and the heat of adsorption, one can employ the approximate Eqn. (25).

3. The Adsorption Isotherm of a Gas Each Molecule of which Occupies More than one Elementary Site on the Surface (Mobile Films)

If the molecules are adsorbed without dissociation, then the activation energy for their migration on the surface must be lower than the activation energy for desorption, since migration does not require the complete dissociation of the bonds between the adsorbed molecules and the adsorbent. Therefore, when the gas adsorbed without dissociation is desorbed at an appreciable rate at any temperature, the adsorbed film cannot be stationary.

The exact adsorption isotherm for this case is unknown in a general form, although various workers undertook the solution of this problem, which is frequently encountered in practice. An approximate solution in the most general form has been given by Ostrovskii and Temkin[17,18]. The calculation is performed by a kinetic method, i.e. by equating the expressions for the rates of adsorption and desorption. The resulting equation is solved for p (or θ_1). The equation for the rate of adsorption will be formulated as follows:

$$r_+=\alpha p\, f(\theta_1), \tag{36}$$

where $f(\theta_1)$ is a function of the degree of surface coverage, which has to be determined. We shall consider, as an example, the adsorption of molecules (for example those of benzene) such that each requires seven elementary sites ($n = 7$) distributed on the surface as shown in the Figure; each adsorbent atom has six nearest neighbours; $z = 18$ is the number of surface sites which can be occupied on rotation of the adsorbed molecule about the fixed site which it occupies (0), which is not included in the number z; such a surface corresponds to the (111) face of a cubic crystal. We shall consider on the adsorbent surface a group of atoms (each of which is the centre of an elementary site), consisting of the central atom 0 and its 18 neighbours 1, 2, 3, ..., 18 (see Figure). If the central atom is occupied, the implication is that one of the septets of atoms 0, 6, 7, 8, 9, 2, 1 or 0, 1, 9, 10, 11, 3, 2 or 0, 2, 11, 12, 13, 4, 3, etc. is occupied, while the other sites can be occupied or free. If the central atom is free, then any of the atoms 1–18 can be either occupied or free. One must take into account the fact that the adsorption of each molecule reduces the probability of adsorption on the neighbouring sites; for example, the centre of the molecule adsorbed next to that shown in the Figure can no longer be located at points, 5, 4, 3, etc.

$f(\theta_1)$ was calculated in terms of Bethe's approximation[19]. It was assumed that the probability of any given distribution can be formulated thus:

$$g\xi^{An_0+Bn_1}\xi_1^{n_0}\xi_2^{n_1}, \tag{37}$$

where ξ_1 is the probability that the central atom is occupied, ξ_2 the probability that any one of the 18 atoms closest to the central atom is occupied, $n_0 = 0$ if the central atom is free, $n_0 = 1$ if the central atom is occupied, n_1 is the number of occupied atoms nearest to the central atom (with the exception of those contained in the same septet as the central atom if the latter is occupied), ξ is introduced to take into account the fact that ξ_1 and ξ_2 are not independent, A and B are constants, and g is the statistical weight of the given distribution.

The relative probability of any given distribution is

$$g\varepsilon_1^{n_0}\varepsilon_2^{n_1}, \tag{38}$$

where

$$\varepsilon_1=\xi^A\xi_1 \text{ and } \varepsilon_2=\xi^B\xi_2. \tag{39}$$

The values of g corresponding to various combinations of n_0 and n_1 were calculated[17]. Next the average number of species at the sites closest to the central site were determined for cases where the central atom is occupied and free and $\epsilon_2 = f(\theta_1)$ was calculated. The probability expressed in terms of ϵ_2, that there are on the surface seven free sites distributed in such a way that the given molecule can be adsorbed on them, was determined. Having expressed ϵ_2 in terms of θ_1, the required equation of the rate of adsorption was obtained. For the adsorption of a molecule resembling that of benzene on the (111) face of a cubic crystal, one obtains

$$r_+=\alpha'\ \alpha_0'\ p(1-\theta_1)^7\left(\frac{3}{3-\theta_1}\right)^6. \tag{40}$$

Apart from Eqn.(40), Ostrovskii and Temkin[17] also derived the corresponding equations for the adsorption of a molecule on four sites, as shown in Figs.*b* ($n = 4$, $z = 8$) and *c* ($n = 4$, $z = 6$). Generalisation by induction of the three equations obtained leads to the expression

$$r_+ = \alpha'(n, z)\,\alpha_0'\,p(1-\theta_1)^n\left[\frac{z}{z-(n-1)\theta_1}\right]^{n-1}. \tag{41}$$

For $n = 2$ [when $n = 2$, $\alpha'(n,z) = 1$ and $\alpha = \alpha_0'$], Eqn.(41) yields

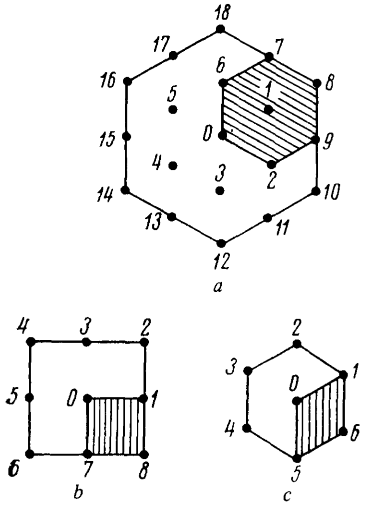
$$r_+ = \alpha_0'\,p(1-\theta_1)^2\frac{z}{z-\theta_1}, \tag{42}$$

which agrees with the equation obtained earlier by Roberts and Miller using the same approximation[20]. Ostrovskii and Temkin[17] quote numerical values of $\alpha'(n,z)$ for certain typical combinations of n and z. In the case under consideration, the equation for the rate of desorption (r_-) is

$$r = \beta\theta_1. \tag{43}$$

Eqns.(41) and (43) lead to an adsorption isotherm of the following type[18,21]:

$$p = \frac{1}{a}\cdot\frac{\theta_1}{(1-\theta_1)^n}\cdot\left[1-\frac{1}{z}(n-1)\theta_1\right]^{n-1}. \tag{44}$$



A model of adsorption on the (111) face of a face-centred cubic crystal (*a* and *c*) and on the (100) face of a cubic crystal (*b*).

When $n = 1$, Eqn.(44) leads to Eqn.(11). When $n = 2$ and $z = 2$, i.e. for the adsorption of a molecule on two sites in the case of a linear arrangement of sites, Eqn.(44) yields

$$p = \frac{1}{a}\frac{\theta_1}{(1-\theta_1)^2}\cdot\frac{2-\theta_1}{2}. \tag{45}$$

As a result of an exact solution by the thermodynamic method, Temkin[22] obtained the adsorption isotherm for molecules resembling carbon monoxide on two centres for a linear arrangement of sites:

$$p = \frac{1}{a}\frac{\theta_1(2-\theta_1)}{2(1-\theta_1)^2}. \tag{46}$$

In comparing isotherms (46) and (45), one must bear in mind that, for molecules such as carbon monoxide, the factor 2 appears in the partition function owing to the asymmetry of the molecule. In the adsorption of symmetrical molecules, for which Eqn.(44) was derived, this factor should not appear. This implies that isotherms (45) and (46) agree numerically. Thus Bethe's approximation leads to the exact result for the one dimensional case.

If $1/a$ is defined as the proportionality coefficient between p and θ_1 in the range where $\theta_1 \ll 1$, isotherm (44) predicts a more rapid increase of p with θ_1 then isotherm (11). For example, in the case considered above with $n = 7$, $z = 18$, and $\theta_1 = 0.5$, we obtain, according to Eqn.(11), $p = 1/a$ and, according to Eqn.(43), $p = 10.7/a$. In order to show whether or not the experimental data for the relation between p and θ_1 are described by Eqn.(44), one determines $1/a$, as described above, from data obtained in the region where $\theta_1 \ll 1$. Theoretical $\theta_1 - p$ curves calculated by Eqn.(44) are then plotted for the postulated value of n and for values of z corresponding to the presence of four or six nearest neighbours at each surface adsorbent atom (the most frequently encountered cases for crystalline materials). The points corresponding to the experimental results are then drawn on the same plot and their positions are compared with the positions of the theoretical curves.

III. ADSORPTION ISOTHERMS ON INHOMOGENEOUS SURFACES IN THE ABSENCE OF INTERACTION BETWEEN THE ADSORBED MOLECULES

The problem of the form of adsorption isotherms on inhomogeneous surfaces was formulated for the first time by Langmuir[11], who called such surfaces "amorphous", assuming that, as a rule, on the surfaces of [crystalline] solids there are elementary sites of only one or a few different types, while on amorphous materials such as glass all the areas can have different adsorption capacities. In such cases the surface may be regarded as divided into infinitesimally small regions $d\rho$, each of which is characterised by a specific value of a. If the law governing the distribution of sites with respect to adsorption capacity is known, i.e. if the form of the function $a(\rho)$ is known, the overall adsorption can be obtained by integration with respect to all the values of ρ:

$$\frac{L}{N} = \int_0^1 \frac{pa(\rho)\,d\rho}{1+pa(\rho)}. \tag{47}$$

Later Taylor[23,24] developed the idea that the surface of crystalline materials must be inhomogeneous with respect to catalytic activity and adsorption capacity. According to Taylor, the atoms located on the surface of the crystal faces are the most "saturated" (the saturation of valence forces is considered); the atoms located on the crystal edges are less saturated and those at the crystal vertices are saturated to a still smaller extent. If this is the case, there may be differences also between the atoms located on different crystal faces, near lattice defects, etc. As a result, the activation energy for adsorption and the rates of adsorption and desorption will differ at different surface sites.

1. The Adsorption Isotherm on a Surface Characterised by a Linear Distribution of Elementary Sites with Respect to Adsorption Capacity

The adsorption isotherm for this case was obtained by Temkin[25]. Following Temkin, we shall assume that the different areas on the surface are characterised by different adsorption capacities, i.e. different values of a in Eqn.(11). The interaction forces between the adsorbed species will be neglected, so that the relative distribution of the adsorbed molecules may be disregarded. We shall imagine that all the elementary areas on the surface are numbered in order of decreasing values of a (1, 2, 3, ..., N, ..., L). We shall denote by s the fraction of the surface traversed on moving along it from area to area in the direction of increasing ordinal number of the latter, i.e. the relative number of the site (N/L). According to the earlier hypothesis concerning the multiplicity of the values of a, the latter is a monotonic function of s. At the same time, in order to examine the dependence of a on s, Temkin considered the variation of the heat of adsorption (per molecule) ϵ with s on the basis that a and ϵ are linked by the equation

$$a=\frac{F_a}{F_g kT}\cdot e^{\varepsilon/kT}, \tag{48}$$

where F_a and F_g are the partition functions of the adsorbate molecule in the adsorbed and gaseous states. Suppose that the relation between ϵ and s is given by the equation

$$\varepsilon=\varepsilon^0-cs, \tag{49}$$

where c is a constant and $\epsilon^0=\epsilon$ when $s=0$. According to Eqn.(48),

$$a=a_0e^{-f_1s}, \tag{50}$$

where $a_0=a$ for $s=0$ and

$$f_1=c/kT. \tag{51}$$

Following Temkin, we shall refer to surfaces for which Eqn.(49) is satisfied as linearly inhomogeneous surfaces.

For adsorption without dissociation, we have

$$\theta_1=\int_0^1\frac{ap\,\mathrm{d}s}{1+ap}. \tag{52}$$

After substituting Eqn.(50) in (52), we obtain

$$\theta_1=\int_0^1\frac{a_0e^{-f_1s}p\,\mathrm{d}s}{1+a_0e^{-f_1s}p}, \tag{53}$$

and after integration we have

$$\theta_1=\frac{1}{f_1}\ln\frac{1+a_0p}{1+a_1p}, \tag{54}$$

where $a_1=a_0e^{-f_1}$, i.e. $a_1=a$ when $s=1$, so that

$$f_1=\ln(a_0/a_1). \tag{55}$$

If the surface is strongly inhomogeneous, i.e. if $a_0\gg a_1$, it is possible to distinguish a range of pressures in which the following inequalities hold:

$$a_0o\gg 1,\quad a_1p\ll 1, \tag{56}$$

i.e. the most strongly adsorbing areas are almost all occupied, while the least strongly adsorbing areas are almost all free. Temkin refers to this region as the region of moderate surface coverages. If inequality (56) holds, then we have the approximate relation

$$\theta_1=\frac{1}{f_1}\ln a_0p. \tag{57}$$

In the literature, Eqn.(57) is usually referred to as the Temkin isotherm. An isotherm of this type was put forward for the first time by Frumkin and Shlygin[26] as an empirical formula for the description of the behaviour of the platinum electrode in acid solutions in the region of the so called hydrogen arrest.

At low surface coverages, where $a_0p\ll 1$, the Temkin isotherm transforms into the equation

$$\theta_1=(a_0-a_1)\,p/f_1, \tag{58}$$

if following the series expansion

$$\ln(1+x)=x-x^2/2-x^3/3-\ldots \tag{59}$$

only the first term is retained. Eqn.(58) is analogous to Henry's law. If $a_0\gg a_1$, then

$$\theta_1=a_0o/f_1. \tag{60}$$

This equation leads to an interesting conclusion. The heat of adsorption calculated from the proportionality coefficient between the adsorption and pressure in the Henry region on a uniformly inhomogeneous surface should differ by only RT from the heat of adsorption on the most active sites (since f_1 is inversely proportional to T). This conclusion may be of interest, particularly for gas chromatography, where the method for the determination of the heats of adsorption from Henry's constant is widely used.

For the adsorption of diatomic molecules with dissociation into atoms on a uniformly inhomogeneous surface, the isotherm is

$$\theta_1=\frac{1}{f_1}\ln\left(\frac{1+\sqrt{a_0p}}{1+\sqrt{a_1p}}\right)^2, \tag{61}$$

which gives rise at moderate coverages to the following approximate equation equivalent to Eqn.(57):

$$\theta_1=\frac{1}{f_1}\ln a_0o, \tag{62}$$

At low coverages, Eqn.(61) leads to the expression

$$\theta_1=\frac{2}{f_1}\sqrt{a_0o} \tag{63}$$

[cf. Eqn.(29) for a homogeneous surface]. In order to test whether or not the experimental data at moderate coverages are described by Eqn.(57) or (62), it is sufficient to demonstrate the linearity of the plot of θ_1 against $\ln p$. The slope of the resulting straight line is equal to the ratio kT/c and a_0 can be determined from the intercept on the ordinate axis.

2. The Adsorption Isotherm on a Surface Characterised by Exponential Inhomogeneity

Exponentially inhomogeneous surfaces are those with an exponential distribution of the elementary areas with respect to adsorption capacity. We shall define the distribution function in the form

$$\mathrm{d}L=CL\,e^{-\frac{\varepsilon-\varepsilon_1}{k\Theta}}\mathrm{d}\varepsilon, \tag{64}$$

where ϵ_1 is the minimum heat of adsorption on the least strongly adsorbing sites, Θ a constant having the dimensions of temperature, and the constant C can be found from the normalisation condition

$$\int \mathrm{d}L = L, \tag{65}$$

which yields

$$C = \gamma/kT, \tag{66}$$

where

$$\gamma = T/\Theta. \tag{67}$$

The equation of the adsorption isotherm will be formulated as follows:

$$\frac{L}{N} = \int_{\varepsilon_1}^{\varepsilon_0} C\mathrm{e}^{-\frac{\varepsilon-\varepsilon_1}{k\Theta}} \frac{a_1 p \exp[(\varepsilon-\varepsilon_1)/kT]}{1 + pa_1 \exp[(\varepsilon-\varepsilon_1)/kT]} \mathrm{d}\varepsilon. \tag{68}$$

The problem of the form of the isotherm for the case under consideration was examined for the first time by Zel'dovich[27], who showed that, in the range of moderate coverages [which corresponds to the integration of Eqn.(68) in the range from $\epsilon_0 = \infty$ to $\epsilon_1 = 0$], an isotherm of the following form is obtained:

$$\theta_1 = \frac{\pi\gamma a_1^\gamma}{\sin \pi\gamma} \cdot p^\gamma. \tag{69}$$

Temkin and Levich[28], who, unlike Zel'dovich, carried out the integration with respect to surface coverages and not energies, later obtained the same equation for the region of moderate coverages. The constant γ is proportional to T and $0 < \gamma < 1$. When it is assumed that $\Theta = \infty$ (i.e. $\gamma = 0$) in Eqn.(64), then at moderate coverages, i.e. with $(1/a_0) \ll p \ll (1/a_1)$, Eqn.(69) leads approximately to the logarithmic Temkin isotherm [Eqn.(62)]. If $\gamma = 1$, then the following equation holds approximately at moderate coverages[28]:

$$\theta_1 = a_1 p \ln(1/a_1 p). \tag{70}$$

A general solution of Eqn.(68), from which it is possible to obtain Eqn.(69) as a special case, was published recently[29].

An equation of type (69) is usually referred to as the Freundlich isotherm. Freundlich[30] was the first to use the expression

$$v = cp^{1/n} \tag{71}$$

for the description of numerous data on adsorption equilibria over a wide range of pressures and temperatures. If the Freundlich isotherm is valid, then at moderate surface coverages the plot of θ_1 against $\lg p$ is a straight line whose slope is equal to γ.

Apart from the derivation of the equation for monomolecular adsorption on the basis of a specified law governing the distribution of sites with respect to adsorption capacity, Temkin and Levich[28] solved in a general form the converse problem of the determination of the type of distribution of sites with respect to their adsorption capacity when the form of the adsorption isotherm is known. The solution was applied to the logarithmic isotherm, the Freundlich isotherm, and certain other isotherms. In particular, it was shown by this method that the Schmidt–Il'in isotherm[31,32] cannot be obtained for any distribution of sites on an inhomogeneous surface with respect to adsorption capacity. In other words, this isotherm cannot be represented as the limiting sum of isotherms (11).

IV. ADSORPTION ISOTHERMS ON A HOMOGENEOUS SURFACE WITH INTERACTION BETWEEN THE ADSORBED SPECIES

The decrease of the heat of adsorption with increasing surface coverage of the adsorbent can be caused either by the inhomogeneity of the surface or by the operation of repulsion forces between the adsorbed species. Repulsion forces consist of the repulsion forces between the filled electron shells of the adsorbed species, which diminish rapidly with distance, and the forces which decrease comparatively slowly with distance. The latter can be of different types. The possibility of effects associated with the mutual influence of the adsorbed species was pointed out for the first time by Langmuir[33]. Somewhat later the results of measurements of the heats of adsorption of hydrogen on tungsten were explained[34] with the aid of the hypothesis of repulsion forces.

Langmuir[33] assumed that the interaction forces between the adsorbed molecules in a two-dimensional monolayer film are the same type as the forces responsible for the deviation of the equation of state for real gases from the equation for an ideal gas. In the derivation of the equation of state for the adsorbed layer, the virial equation for a two-dimensional gas is used:

$$FS_0 = RT - \frac{1}{2}\Sigma rf, \tag{72}$$

where F is the two dimensional pressure, S_0 the surface area containing 1 gram-atom of the adsorbate, and f the interaction force, which is a function of the distance r; the summation is carried out with respect to all the pairs of adsorbed atoms on the surface. Langmuir obtained the equation of the adsorption isotherm in the form

$$\theta_1 = \frac{\alpha p\, \mathrm{e}^{m/T}}{A_{1.5} T^{3/2}}, \tag{73}$$

where $A_{1.5} = 7.98 \times 10^6$ atm $K^{-3/2}$ is a constant and m is a constant related to the heat of adsorption Q by the equation $Q = n(m + lT)$, where n and l are constants and $m = f(\theta_1)$. Later the problem of the role of the interaction of the adsorbed species due to the operation of dipolar forces was examined by Temkin[25], who obtained an equation for the isotherm representing in an explicit form the relation between the pressure and the degree of coverage. Like Langmuir, Temkin began with the virial theorem for a two-dimensional gas, but, unlike Langmuir, restricted the treatment to surface coverages for which it is possible to neglect the cases of the simultaneous interaction of three and more gas molecules. The interaction law was used in the following form:

$$\varepsilon(r) = \mu^2/r^3, \tag{74}$$

where μ is the dipole moment of the adsorbed molecule. Temkin derived the equation of the adsorption isotherm from the equation of state for the adsorbed layer with the aid of the Gibbs equation:

$$L = \frac{1}{kT} \frac{\partial F}{\partial \ln p}. \tag{75}$$

This leads to the Williams isotherm, proposed[35] as the empirical formula

$$\ln(p/L) = BL + C, \tag{76}$$

where B and C are constants. If the interaction forces are fairly large, then, as shown by Temkin[25], Eqn.(76) differs little from that of the logarithmic isotherm for not unduly low values of L (in the region of moderate coverages). Under these conditions, Eqn. (76) is close to

$$\theta_1 = \frac{1}{A} \ln a_0 p. \tag{77}$$

The constant a_0 has the same significance as a_0 in the logarithmic isotherm [Eqn. (57)]. We have $A = BN$, where

$$B = 2\pi \int_0^\infty (1 - e^{-\varepsilon(r)/kT})\, r\, d\, r.$$

Thus the physical significance of the constant A differs from that of the constant f_1 in Eqn. (57) and is characterised by a different temperature dependence.

The authors [25,33] assume that the interaction is determined by forces of the same type as that in molecules of real gases. The physical picture underlying these equations can explain only a decrease of the heat of adsorption per mole of gas of the order of RT. In practice an appreciably greater reduction of the heat of adsorption is frequently observed as the surface becomes saturated.

Kobozev and Gol'dfel'd [36] examined the interactions associated with the effect involving the fixation of the adsorbed atoms on the surface. They assumed that, in the adsorption at any centre, there is a change in the adsorption potential not only of the given centre, in consequence of the saturation of the adsorption forces, but also a decrease of the adsorption potential extending over a number of neighbouring adsorption centres (since the atoms of the solid are close-packed). On moving away from the occupied centre, the attenuation of the adsorption potential decreases in accordance with a law of the type

$$\varphi_r = \varphi_0 - \varphi_0 \cdot f(r) = \varphi_0 [1 - f(r)], \tag{78}$$

where φ_r is the potential of the adsorption centre at a distance r from the occupied centre with $[\partial f(r)/\partial r] < 0$. A characteristic feature of this approach is the assumption that the repulsion of the molecules in the adsorbed layer is due to the polarisation of the adsorbent itself and not to the interaction of the adsorbent molecules. According to the authors, interactions of this type can extend over extremely long distances, are intense, and should occur for both polarised and electrically symmetrical adsorbed species. The adsorption isotherm is derived using the equation of state of a two-dimensional gas in the form

$$\left(F - \frac{\Delta}{A_2^2}\right)(A_2 - A_1) = RT, \tag{79}$$

where A_2 is the area of the entire surface, A_1 twice the area of the adsorbed molecules themselves, and $\Delta = f_1[\varphi_0, f(r)]$. The equation of the adsorption isotherm is

$$p/\theta_1 = p + C \cdot \exp[\varphi_0(1 - \psi(\theta))/RT]\ ‡, \tag{80}$$

where $\varphi_0[1 - \psi(\theta)]$ is the adsorption energy and C a constant.

A graphical method for the calculation of the values of $C \exp\{\varphi_0[1 - \psi(\theta)]/RT\}$ from the experimental $p/\theta - p$ adsorption isotherms has been described [36]. It makes it possible to compare the theory with experimental results.

Vol'kenshtein [37] examined the problem of the form of the adsorption isotherm for different laws governing the interaction between the adsorbed species. He assumed that the interaction is independent of the relative orientation of the molecules and that the interaction forces are not capable of being saturated. The equations for the rates of adsorption (r_+) and desorption (r_-) are

$$r_+ = Z_0 a (1 - \theta_1) \cdot \exp[-E(\theta_1)/RT], \tag{81}$$

$$r_- = \beta\theta_1 \exp[-(\Delta Q(\theta_1) + E(\theta_1))/RT], \tag{82}$$

where E is the activation energy for adsorption.

Under conditions of equilibrium, Eqns. (81) and (82) lead to the expression

$$\Delta Q(\theta_1) + RT \ln[(1 - \theta_1)/\theta_1] = RT \ln(1/\sigma_1 p). \tag{83}$$

Assuming that the adsorbed atoms on the surface are located at the sites of a square lattice, Vol'kenshtein found that

$$\theta_1 = (r_0/r)^2 \tag{84}$$

(r_0 is the minimum possible distance between two adsorbed molecules and r the shortest distance between two adsorbed molecules). Assuming that

$$\Delta Q(\theta_1) = -\Delta\Phi(r)\big|_{r = r_0/\sqrt{\theta_1}}, \tag{85}$$

he obtained the equation

$$RT \ln[(1 - \theta_1)/\theta_1] - \Delta\Phi(r_0/\sqrt{\theta_1}) = RT \ln(1/p\sigma_1). \tag{86}$$

The solution of this equation for θ_1 with the specified $\Delta\Phi(r)$ interaction law yields the equation of the adsorption isotherm. In the region of very low and very high coverages, it is possible to neglect the second term in Eqn. (86). One then obtains the Langmuir isotherm [Eqn. (11)]. In the region of moderate coverages, the form of the adsorption isotherm depends on the interaction law. However, Vol'kenshtein does not consider the problem of the convergence of the sums expressing the interaction energy between the adsorbed molecules and their neighbours on the surface, which throws doubt on the validity of his conclusions§.

There has been a fairly large number of studies whose authors describe the repulsion of molecules from one another by statistical procedures such as the Bethe–Peierls [38,39] and Bragg–Williams [40] methods and the method of correlation functions [41]. In terms of the Bragg–Williams approximation, when the interaction between the molecules is taken into account by introducing an average molecular field, the adsorption isotherm is [40]

$$\theta/(1 - \theta) = ap \cdot \exp(z_1 J\theta_1/kT), \tag{87}$$

where z_1 is the number of adsorption centres on the surface closest to the given centre and J is the overlap integral (a constant).

Fedyanin [41] took into account the correlation between the adsorbed molecules, which was neglected in the Bragg–Williams approximation, and obtained the adsorption isotherm

$$\theta/(1 - \theta) = ap/[1 + ap\varphi(1/kT, z_1, J)], \tag{88}$$

where

$$\varphi(1/kT, z_1, J) = -z_1, [1 - \exp(J/kT)/1 + ap\exp(J/kT)]. \tag{89}$$

A novel idea concerning the nature of the long-range forces, leading to the repulsion of the adsorbed species, has been put forward by Breger and Zhukhovitskii [42]. Treating the electrons of the adsorbent as a Sommerfeld electron gas, they postulated that the electrons are

---

‡ In the formulation of Eqn. (80) for the isotherm, there is a misprint in the paper of Kobozev and Gol'dfel'd [36] [Eqn. (10a)].

§ Pointed out by M. I. Temkin.

combined with the adsorbed species and are not involved in the motion of the remaining electrons forming the electron gas of the adsorbent. Thus adsorption results in the formation of nodes, the number of which increases as adsorption proceeds. The presence of the nodes increases the overall energy of the adsorbent electrons, which is manifested as the repulsion between the adsorbed species. The authors showed that such repulsion is inversely proportional to the distance and that, even with $r = 20$ Å, the repulsion energy is still 0.08 eV.

The electronic nature of the long-range forces in adsorption was assumed also in other investigations. Boudart[43] explained the decrease of the heat of adsorption with surface coverage on metals by the increase in the potential energy of the electrons due to the appearance of an additional potential jump in adsorption. He regarded the surface layer as a planar condenser with the charge uniformly distributed over the plates. Since for a given capacitance the energy of the condenser is proportional to the square of the charge, Boudart obtained a linear relation between the heat of adsorption and surface coverages. However, the "smearing" of the charge over the surface has been inadequately justified in physical terms.

In contrast to Boudart, Temkin[44] explained the decrease of the heat of adsorption with coverage by an increase of the kinetic energy of the electrons. He treated the layer of adsorbed atoms on the metal surface as a surface alloy, assuming that the electrons of the adsorbate atoms on the surface are combined with the free electrons of the surface metal atoms, forming a two-dimensional electron gas. The charge density at the surface increases, since the excess positive charge of the adsorbed atoms must be compensated. In the adsorption of an atom, there is a gain of some energy, part of which is evolved in the form of heat of adsorption and another part is used in increasing the kinetic energy of the electron gas. The treatment in such terms was carried out within the framework of the simplest Sommerfeld model on the assumption of a non-interacting electron gas. In contrast to the adsorption models postulating interaction between the chemisorbed species, which decreases with distance in accordance with some law, in the electron gas model the energy of the adsorbed layer depends only on the total number of adsorbed species but not on their relative positions. If the effective charge of the adsorbed species η is independent of θ_1, the adsorption energy is

$$\varepsilon = \varepsilon^0 - \eta^2 \frac{h^2N}{4\pi m^*}\theta_1, \tag{90}$$

where ϵ^0 is the value of ϵ corresponding to $\theta_1 = 0$, η is expressed in units of the elementary electric charge, h is the Planck constant, and m^* is the effective mass of the electron. The equation of the isotherm corresponding to Eqn.(90) is[45,46]

$$\ln ap = \frac{\eta^2h^2N}{4\pi m^*kT}\theta_1 + \ln\frac{\theta_1}{1-\theta_1}. \tag{91}$$

If the treatment is restricted to the first term of the expansion in Taylor's series of the second term on the right-hand side of Eqn.(91),

$$\ln\frac{\theta_1}{1-\theta_1} = 4\left(\theta_1-\frac{1}{2}\right)+\frac{16}{3}\left(\theta_1-\frac{1}{2}\right)^3+\dots+\frac{4^n}{2n-1}\left(\theta_1-\frac{1}{2}\right)^{2n-1}+\dots\P, \tag{92}$$

then Eqn.(91) is converted into Eqn.(57), with

$$f_1 = \eta^2\frac{h^2N}{4\pi m^*kT} \text{ and } a_0 = a\,e^2. \tag{93}$$

Fedyanin[47] estimated the contribution of the interaction of electrons to the overall kinetic energy of the electron gas. The theory of the mutual influence of adsorbed species was also investigated by Osherov[48], who considered the delocalisation of the wave functions of the electrons in the adsorbent crystal during adsorption.

V. POLYMOLECULAR ADSORPTION ISOTHERMS ON A HOMOGENEOUS SURFACE

If the pressure of the adsorbate vapour is close to the vapour pressure at the experimental temperature, the average thickness of the layer adsorbed on the surface of the adsorbent may exceed that of one molecule. As stated above, the adsorption isotherm for this case was obtained for the first time by Langmuir[11]. We shall now reproduce briefly Langmuir's derivation. Suppose that θ_0 is the fraction of the free surface and θ_{01}, θ_{02}, ... θ_{0n}, etc. are the fractions of the surface occupied by 1, 2, ..., n layers of adsorbed molecules. Then

$$\theta_0+\theta_{01}+\theta_{02}+\dots+\theta_{0n}=1. \tag{94}$$

The average degree of surface coverage by adsorbed molecules is

$$v/v_m = \theta_{01}+2\theta_{02}+3\theta_{03}+\dots+n\theta_{0n}, \tag{95}$$

where v_m is the degree of adsorption corresponding to the coverage of each site on the surface by one molecule. The rate of desorption of molecules from the nth layer is

$$\underset{\leftarrow}{r_n} = \beta_n'\theta_{0n}, \tag{96}$$

where β_n' is the rate of desorption of molecules from the nth layer when $\theta_{0n} = 1$. The rate of adsorption in the nth layer is

$$\underset{\rightarrow}{r_n} = \alpha_n'p\theta_{(n-1)}, \tag{97}$$

where α_n' is the rate of adsorption of molecules in the nth layer at the given pressure for $\theta_{n-1} = 1$. Having formulated the equilibrium conditions for each layer and using Eqns.(94) and (95), Langmuir obtained

$$\frac{v}{v_m} = \frac{a_1p+2a_1a_2p^2+3a_1a_2a_3p^3+\dots}{1+a_1p+a_1a_2p^2+a_1a_2a_3p^3+\dots}, \tag{98}$$

where $a_n = \alpha_n'/\beta_n'$. After dividing the numerator and denominator on the right-hand side of Eqn.(98) by the numerator, we obtain

$$\frac{v}{v_m} = \frac{a_1p}{1+Ap+Bp^2+Cp^3+\dots}, \tag{99}$$

where

$$\begin{gathered} A = a_1 - 2a_2, \\ B = a_2(4a_2 - 3a_3 - a_1), \\ C = 2a_2(6a_2a_3 - 2a_3a_4 + a_1a_2 - a_1a_3 - 4a_2^2). \end{gathered} \tag{100}$$

Eqn.(99) represents the adsorption isotherm for the case under consideration formulated in a general form. As a special case, Langmuir analysed the situation where $a_1 \neq a_2$, but $a_2 = a_3 = a_4 = \dots, a_n$. This corresponds to approximately identical adsorption capacities in all the layers except the first. After appropriate rearrangements, Eqn.(99) is converted into

$$\frac{v}{v_m} = \frac{a_1p}{(1-a_2p)(1-a_2p+a_1p)}. \tag{101}$$

¶ In Temkin's paper[46], there is a misprint in the formulation of the general term of the expansion.

Later Brunauer, Emmett, and Teller[49] assumed that the adsorption in all the layers other than the first takes place with a heat change equal to the heat of condensation E_Z. We then have in Eqn.(101)

$$a_1 = a_1^0 \exp(E_1/RT) \tag{102}$$

and

$$a_2 = a_2^0 \exp(E_L/RT). \tag{103}$$

After the notation

$$c = \frac{a_1^0}{a_2^0} \exp[(E_1 - E_L)/RT] \tag{104}$$

and

$$u = pa_2 \tag{105}$$

has been introduced, Eqn.(101) is converted into

$$v/v_m = cu/[(1-u)(1-u+cu)]. \tag{106}$$

It is seen from Eqn.(106) that $v \to \infty$ when $u \to 1$. Therefore and also on the grounds that $v/v_m \to \infty$ when $u \to 1$, Brunauer, Emmett, and Teller assumed that

$$u = p/p_0, \tag{107}$$

where p_0 is the vapour pressure over the liquid adsorbate.

It follows from Eqns.(103), (105), and (107) that

$$p_0 = 1/a_2^0 \exp(E_L/RT). \tag{108}$$

After substituting Eqns.(107) and (108) and algebraic rearrangements the following equation is obtained for the isotherm:

$$\frac{p}{v(p_0-p)} = \frac{1}{v_m c} + \frac{c-1}{v_m c} \cdot \frac{p}{p_0}, \tag{109}$$

which is the equation of a linear plot of $p/v(p_0-p)$ against p/p_0. This equation is usually called the BET equation. It makes it possible to calculate the values of v_m and c when experimental data are available for the relation between v and p. If it is assumed that the area occupied by the adsorbed molecule of the given gas is constant and independent of the nature of the surface, then it is possible to determine the surface areas of adsorbents with the aid of Eqn.(109). This possibility is widely used in practice. The physical picture of adsorption constituting the basis of the derivation of the BET equation has been frequently discussed in the literature. It follows from Eqn.(104) that the coefficient c may be determined from the heat of adsorption in the first layer, provided that the ratio a_1^0/a_2^0 is known. In their publication[49], Brunauer et al. assumed that $a_1^0/a_2^0 = 1$. Then

$$c = \exp[(E_1 - E_L)/RT]. \tag{110}$$

However it has been shown, for example by Harkins and Boyd[50] and Beebe et al.[51], that c can be calculated from heats of wetting $E_1 - E_L$ or from calorimetric measurements of E_1, which are much higher than the values obtained from the BET isotherm when it is assumed that c is defined by Eqn.(110).

This may be due to three causes[52]. Firstly, a_1^0/a_2^0 may differ from unity. Secondly, the heat of adsorption in the second and succeeding layers may differ from the heat of condensation of the adsorbate, approaching it only gradually with increase of the number of adsorbed layers. Thirdly, in view of the inhomogeneity of the adsorbent surface, the BET equation is valid only in the region $\theta \gtrsim 0.5$, where the surface inhomogeneity does not have an appreciable effect. For this reason, the values of E_1 are calculated from the BET isotherm using data obtained for $\theta > 0.5$. As a result, one may expect that average values of E_1 will be obtained only for those molecules of the first layer which are adsorbed at sites with lower adsorption energies and not for the entire first layer. On the other hand, in the determination of the heats of wetting one obtains data averaged over the entire adsorbent surface. Statistical calculations have shown[53-55] that there are in fact no adequate grounds for believing that $a_1^0/a_2^0 = 1$ in the general case.

The second of these possible causes of disagreement between the values of c obtained in calculations from adsorption isotherms and from measurements of $E_1 - E_L$ was examined in detail by Clampitt and German[56]. These investigators based their treatment on the finding that, with increase in the thickness of the adsorbed film starting from two monolayers, the heat of adsorption of molecules from the gas phase to the film varies smoothly up to the heat of condensation. Using a method analogous to that described by Brunauer et al.[49], they derived an equation for polymolecular adsorption formally agreeing with the BET equation. The difference between these equations is that Clampitt and German[56] obtained

$$c = (a_1^0/a_2^0)\exp[(E_1 - 2E_L + E_S)/RT], \tag{111}$$

where

$$E_S = E_L - 1.35[RT + \gamma_0 (M/d)^{2/3}] \tag{112}$$

(γ_0 is the surface tension of the film and d the adsorbate density in the liquid state). In the next paragraph we shall return to the third cause of the disagreement between the values of c.

The problem of the validity of Eqn.(107), which is one of the principal components of the BET theory, has been frequently discussed in the literature. It has been stated (for example in Refs. 57–59), that there is no sufficient evidence for adopting this equation. It is more correct to assume that

$$u = p/g, \tag{113}$$

where $g \neq p_0$. The use of Eqn.(107) may be justified only because it can be derived from the simple equation of the BET isotherm, which can be readily used to determine the specific surfaces of solids.

When adsorption does not take place on a smooth surface but within the adsorbent pores whose diameter cannot be regarded as very large compared with the dimensions of the molecules, then there is a possibility of adsorbing a finite number of layers of adsorbate molecules on such a surface. An equation has been obtained for the polymolecular adsorption isotherm in pores bounded by two parallel planes[49], which, in contrast to the simple BET equation [Eqn.(109)], contains three parameters:

$$\frac{v}{v_m} = \frac{cu}{1-u} \cdot \frac{1-(n+1)u^n + nu^{n+1}}{1+(c-1)u - cu^{n+1}}, \tag{114}$$

where n is the number of adsorbed layers. When $n = 1$, this equation is converted into the equation of the Langmuir isotherm [Eqn.(11)] and, for $n \to \infty$, it is converted into the BET equation [Eqn.(109)].

The case where adsorption saturation is reached at pressures lower than p_0 has been investigated[60]. The authors suggested that this effect is associated with capillary condensation. By taking into account capillary condensation, equations were obtained for adsorption isotherms in which there is a fourth parameter, whose value depends on the heat of condensation of the adsorbent vapour, in addition to the parameters in Eqn.(114). These equations are extremely complex and have hardly any practical value.

VI. POLYMOLECULAR ADSORPTION ISOTHERMS ON INHOMOGENEOUS SURFACES

This equation of the BET isotherm [Eqn.(109)] can be used only in the range $0.05 < p/p_0 < 0.3$. One of the main causes of the failure of the BET isotherm for $p/p_0 < 0.05$ is surface inhomogeneity and, under the conditions where $p/p_0 > 0.3$, the interaction between the adsorbed molecules becomes significant. None of these effects can be taken into account by the BET theory. We shall consider the problem of the form of polymolecular adsorption isotherms on inhomogeneous surfaces. The first attempts to describe polymolecular adsorption processes on such surfaces were made by McMillan[61] and Walker and Zettlemoyer[62]. In these studies the surface was treated as a mixture of a finite number of adsorption centres with different adsorption energies. Then

$$v = \frac{u}{1-u}\left[\frac{v_{mA}c_A}{1+(c_A-1)u} + \frac{v_{mB}c_B}{1+(c_B-1)u} + \ldots + \frac{v_{mi}c_i}{1+(c_i-1)u}\right], \quad (115)$$

where c_A, c_B, ..., c_i and v_{mA}, v_{mB}, ..., v_{mi} are constants analogous to the constants c and v_m in Eqn.(109), which, however, refer to adsorption centres of types A, B, ..., i respectively. Eqn.(115) can be used to describe adsorption on an adsorbent consisting of a mechanical mixture of substances, each of which has a homogeneous surface.

The case where i is very large is more general. In order to obtained the adsorption isotherms on such a surface, simple summation must be replaced by integration. The integration requires that one specifies the law governing the distribution of sites on the surface with respect to heats of adsorption or standard Gibbs free energies of adsorption $\Delta G^0_{a_1}$. It is known from monomolecular adsorption data that the distribution of surface sites with respect to adsorption capacity can be usually described with the aid of a linear or exponential distribution law. The problem has been examined of finding the form of the polymolecular isotherms for any distribution of surface sites with respect to standard Gibbs free energies, when the monomolecular adsorption isotherm for the corresponding site distribution law is known[63].

The equation of the polymolecular adsorption isotherm can be put in the form

$$v = \frac{v_m c p}{(p_0-p)[1+(c-1)p/p_0]}, \quad (116)$$

and comparison of Eqns.(102), (103), (104), and (108) shows that

$$c = a_1 p_0. \quad (117)$$

Having substituted Eqn.(117) in (116), we obtain

$$v(1-u) = v_m \frac{a_1 p/(1-u)}{1+[a_1 p/(1-u)]}. \quad (118)$$

Comparison of Eqn.(118) with the equation of the Langmuir isotherm for monomolecular adsorption

$$v = v_m \frac{a_1 p}{1+a_1 p} \quad (119)$$

shows that the equation of the monomolecular adsorption isotherm can be converted into the equation of the polymolecular adsorption isotherm by replacing

$$\left.\begin{matrix} v \text{ by } v(1-u) \\ p \text{ by } p/(1-u) \end{matrix}\right\}. \quad (120)$$

and

The reverse conversion can be achieved by assuming that $p_0 = \infty$ in the equation of the polymolecular adsorption isotherm. If the surface is uniformly inhomogeneous, the monomolecular adsorption isotherm is described by an equation of type (62). Having replaced θ_1 by v/v_m and having substituted the variables in Eqn.(62) in accordance with Eqn.(110), we obtain the polymolecular adsorption isotherm on a uniformly inhomogeneous surface:

$$v = \frac{v_m}{f_1(1-u)} \ln \frac{1+a_0 p/(1-u)}{1+a_1 p/(1-u)}. \quad (121)$$

For a strongly inhomogeneous surface, where $a_0 \gg a_1$, in the region of moderate coverages Eqn.(121) becomes

$$v = \frac{v_m}{f_1(1-u)} \ln \frac{a_0 p}{(1-u)}. \quad (122)$$

In the case of an exponentially inhomogeneous surface, the adsorption isotherm has the following form in the region of moderate monolayer coverages under the conditions of polymolecular adsorption:

$$v = c\frac{p^\gamma}{(1-u)^{(1+\gamma)}}, \quad (123)$$

where

$$c = \frac{\gamma\pi v_m a_1^\gamma}{\sin \pi\gamma}. \quad (124)$$

Eqn.(123) can be obtained from the equation of the Freundlich isotherm, which describes monomolecular adsorption on an exponentially inhomogeneous surface at moderate coverages when the variables are substituted in accordance with formula (120).

In polymolecular adsorption, transition to the region of high surface coverages occurs already when $p/p_0 \simeq 0.05$. For this reason, in the case of polymolecular adsorption it is of interest to consider the adsorption not only in the region of moderate coverages but also in the region of high coverages. The equation of the adsorption isotherm for moderate and high surface coverages has therefore been obtained[64] by integrating the degrees of adsorption at sites with different adsorption capacities up to a minimal heat of adsorption in the first layer. When adsorption in layers above the first was considered[64], the same assumptions were made as in the derivation of the BET isotherm. The equation of the isotherm is

$$\frac{v}{v_m} = \frac{\pi\gamma \exp[E_L\gamma(h-1)/RT]}{\sin \pi\gamma} \cdot \frac{u^\gamma}{(1-u)^{(\gamma+1)}} - \frac{\gamma u \cdot \exp[E_L\gamma(h-1)/RT]}{(1-\gamma)(1-u)^2} \times$$
$$\times\left[1 - \frac{1-\gamma}{2-\gamma}\cdot\frac{u}{(1-u)} + \frac{1-\gamma}{3-\gamma}\left(\frac{u}{1-u}\right)^2 - \frac{1-\gamma}{4-\gamma}\left(\frac{u}{1-u}\right)^3 + \ldots\right], \quad (125)$$

where h is the ratio of the minimum heat of adsorption in the first layer to the heat of condensation E_L. For fairly small values of u, Eqn.(125) is converted into

$$\frac{v}{v_m} = \frac{\pi\gamma \exp[E_L\gamma(h-1)/RT]}{\sin \pi\gamma} \cdot \frac{u^\gamma}{(1-u)^{(1+\gamma)}}. \quad (126)$$

By taking logarithms in Eqn.(126), it is possible to obtain an expression which permits the determination of γ and h from a plot of $\lg[v(1-u)]$ against $\lg[u/(1-u)]$ using adsorption measurements in the region of fairly small values of u. The observed values of γ and h can then be used to describe the adsorption at high surface coverages using for this purpose Eqn. (125).[65] This makes it possible to determine whether or not the theory described above describes the experimental results.

By substituting Eqn. (107) in Eqn. (125) and assuming that $p_0 = \infty$, it is possible to obtain the equation of the monomolecular adsorption isotherm for moderate and high coverages corresponding to an exponential distribution of surface sites with respect to adsorption capacity.

VII. ISOTHERM FOR ADSORPTION IN MICROPORES

Adsorption by microporous adsorbents (i.e. adsorbents containing pores whose radius exceeds only slightly the size of the adsorbate molecules) at temperatures so low that dispersion forces are of decisive importance in the adsorption interaction constitute a special case. Langmuir did not consider it. We shall examine it in order to illustrate the view frequently encountered in the literature that the physical picture of polymolecular adsorption is not always adequate for the description of the adsorption of vapours when the amount adsorbed is greater than the volume of the adsorbate monolayer on the adsorbent surface. The theory of adsorption in micropores has been developed mainly by Dubinin and his coworkers[66,67]. It is assumed that micropores are filled at once and not layer by layer. The theory of the bulk saturation of micropores uses the temperature invariance of the characteristic adsorption equation noted by Polanyi. The characteristic adsorption equation is

$$\theta_1 = \exp[-(A'/E)^2]. \tag{127}$$

It is usually called the Dubinin–Radushkevich equation. Here θ_1 is the degree of bulk saturation of the adsorption space, E the characteristic adsorption energy (a parameter of the distribution function), and A' the differential molar work of adsorption, which is defined in the theory of bulk saturation of micropores as the decrease in the Gibbs free energy:

$$A' = RT\ln(p_0/p) \quad , \tag{128}$$

where p is the vapour pressure of the given substance in the standard state at a temperature T. The equation of the adsorption isotherm for the case under consideration can be formulated as follows[67]:

$$\theta_1 = \exp[-(A'/\beta E_0)^2], \tag{129}$$

where $\beta = E/E_0$ (E_0 is the characteristic adsorption energy for a standard vapour, benzene being usually employed as the standard. For adsorption in very small pores, where the adsorption interactions are strongest, the more general equation

$$\theta_1 = \exp[-(A'/E)^n], \tag{130}$$

where n is an integer, has been suggested[68] for the distribution function of θ_1 with respect to A'. Eqn. (127) can be regarded as a special case of Eqn. (130).

The theory of the bulk saturation of micropores is widely used to describe adsorption on activated charcoals, zeolites, microporous silica gels, etc.

VIII. CONCLUSION

The foundation of the modern theory of adsorption were laid by Langmuir in 1916–1918. The Soviet scientists Frumkin, Dubinin, Roginskii, Zel'dovich, Temkin, and others have contributed much to the development of the theory. The Langmuir, Freundlich, and Temkin isotherms are most widely used in studies on adsorption and the kinetics of heterogeneous catalytic processes and electrode processes (see for example, Refs. 14 and 69–71). The Dubinin–Radushkevich isotherm together with the Brunauer–Emmett–Teller isotherm, which is generally employed to determine the specific surfaces of solids, are extensively applied in the description of physical adsorption.

The above discussion permits the conclusion that the formal description of adsorption isotherms within the framework of Langmuir's fundamental postulates can now be regarded as largely completed. In certain cases the solutions may be refined. However, with present experimental techniques and the accuracy currently achieved in the results, refinements in the solutions cannot be of any practical value.

Apparently the most serious of the currently unsolved problems in the field under consideration is that of the quantitative elucidation of the physical causes of the inhomogeneity of catalysts and adsorbents. In this sense calorimetric studies and also studies of isotope exchange on catalyst surfaces are most promising. Methods for the investigation of surface inhomogeneity with the aid of measurements of the rates of isotope exchange have been developed and have been used successfully by Boreskov and the catalytic school of which he is the Head (see, for example, Refs. 72–74).

The problem of which physical (or physicochemical) parameters determine the nature of the distribution of surface sites with respect to adsorption capacity and of the quantitative expression of the relation between these parameters and the adsorption capacity is of special interest (in particular, it is not clear why experimental data frequently yield an exponent in the equation of the Freundlich isotherm close to 0.5). In other words, although adsorption isotherms can in fact successfully describe experimental data, the hypotheses concerning the distribution of surface sites with respect to adsorption capacity used in their derivation have no adequate physical justification at the present time.

In the adsorption of vapours on porous bodies, the observed surface inhomogeneity may be due to the presence of narrow pores. The heats of adsorption of vapours do not differ very greatly from the heats of their condensation, exceeding the latter usually by a factor of only 2–3 even in the region of low surface coverages. Thus the adsorption of vapours can be as a rule explained by the action of van der Waals forces. Since such forces are additive, the heats of adsorption of vapours in pores whose size is comparable to the size of the adsorbate molecules should be greater than on a smooth surface. In this case the distribution of surface sites with respect to heats of adsorption can be related functionally to the distribution of adsorbate pores with respect to radii. In the chemisorption of permanent gases, for example in the adsorption of oxygen or hydrogen at the usual temperatures of catalytic experiments, the heat of adsorption frequently exceeds the heat of condensation even by an order of magnitude. In such cases the decrease of the heats of adsorption with surface coverage can amount to tens of kcal mole^{-1}. This effect cannot be accounted for by the operation of van der

Waals forces. One of the possible causes may be the presence of impurities. However, the adsorption can be frequently described by the Freundlich isotherm, but it is not clear why the presence of impurities should lead so often to an exponential distribution of sites with respect to adsorption capacity.

We shall consider briefly the possibility of reaching conclusions concerning the nature of surface site distribution with respect to adsorption capacity or about the adsorption mechanism (for example, how many elementary areas on the surface are required for the adsorption of each molecule) solely on the basis of the form of the adsorption isotherm. In practice, adsorption isotherms are as a rule investigated over a fairly narrow pressure range (electrochemical studies in which the change of potential may correspond to a pressure change by a factor of 10^5 constitute an exception). In this case the possibility of describing the results with the aid of, for example, a power or logarithmic isotherm does not by itself demonstrate the validity of the corresponding distribution of surface sites with respect to adsorption capacity. In order to deduce the nature of the inhomogeneity, it is necessary to consider the isotherms together with the results obtained by other methods, for example the calorimetric method, the method of surface isotope exchange, the ESR method, studies of the kinetics of adsorption and desorption, etc.

The Long-range Interaction between Colloid and other Particles and the Formation of Periodic Colloid Structures

I.F.Efremov and O.G.Us'yarov

The general relations governing the formation of gel-like systems in electrolyte solutions have been formulated for particles of different size and shape. Comparison of the results of numerous experimental studies with data derived by theoretical analysis confirms the decisive role of long-range forces in the formation of periodic colloid structures and the extensive occurrence of these structures in nature and in technology. Peptisation, thixotropic processes, and syneresis as well as the phenomenon of reversibility in the formation of periodic colloid structures are examined and methods for estimating the interaction forces between dispersed particles are discussed on the basis of the rheological properties of periodic colloid structures.
The bibliography includes 343 references.

CONTENTS

I. INTRODUCTION

By virtue of their unusual physicomechanical properties and characteristic capacity for thixotropic transformations, peptisation, and syneresis, periodic colloid structures (PCS), i.e. tactoids, heterogeneous gels, and gel-like systems, have for a long time attracted the continuous attention of investigators[1-9]. Examination of experimental and theoretical data established that the properties of disperse structures are to a large extent determined by the relative positions and orientation of the dispersed particles and also by the thickness of the liquid layers separating them[5-20]. Thus, over long quasiequilibrium distances (compared with atomic dimensions) between the particles, disperse structures consist of thixotropic and usually relatively unstable periodic colloid structures. However, when the particles stick together with retention of very thin liquid layers between them or when the adhesion process is accompanied by the appearance of direct contacts, fairly stable systems are formed, which have virtually no thixotropic properties and exhibit only a weak syneresis and a weak capacity for peptisation. Such relations have been observed, for example, for precipitates formed when metallic sols coagulate[21-23], for certain electrophoretic coatings[24], etc.

According to Rebinder's classification, thixotropic periodic colloid structures are reversible coagulation structures, while direct adhesion of particles and their further growth lead to the formation of irreversible condensation-crystallisation structures[14,25-27]. At the same time one must emphasise that the concept of periodic colloid structures is broader than that of coagulation structures and that not all periodic colloid structures (for example, equilibrium dispersions of swollen latex particles, micellar structures, etc.) can be classified as coagulations—thermodynamically non-equilibrium systems. The abundance of periodic colloid structures in nature and industry and their important role in various natural and industrial processes have been confirmed by the results of optical, X-ray diffraction, and electron microscope studies on a wide variety of disperse structures, including the results of direct observations on stabilised latex dispersions (Figs. 1 and 2).

The study of structure formation processes is associated with the development of concepts concerning surface forces of different types and acting over fairly long distances. The present advances in the theory of surface phenomena and also studies on coagulation (flocculation), gel formation, and the properties of gel-like systems have demonstrated the wide occurrence of long-range aggregation processes in which the characteristics of the particles and the relations governing their interactions are clearly manifested. In consequence of the predominance of attraction forces over long distances and the presence of a barrier preventing direct contact, in the mechanism of these processes the colloid particles are arranged in fixed relative positions with retention of liquid layers between them. On the other hand, in certain types of periodic colloid structures the fixation of particles is determined by the predominance of repulsion forces, as a result of which constrained conditions arise in the system.

The concept of the decisive influence of long-range interaction on the formation of thixotropic structures was put forward for the first time by Freundlich[28]. Subsequently many further experimental and theoretical studies led to its thorough confirmation, amplification and extension to a wide variety of classes of colloid structures[5-7]. This review discusses the principal results of such studies, which are being particularly vigorously prosecuted at the present time.

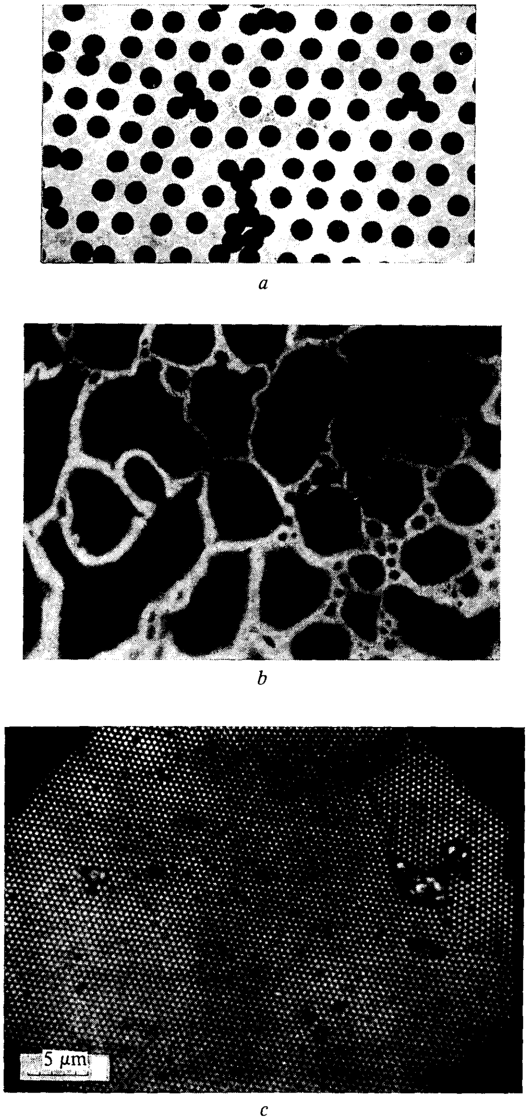

Figure 1. Electron photomicrographs of periodic colloidal structures: *a*) polystyrene latex with a particle radius of 950 Å; *b*) particles of epoxy-resin; *c*) particles of a styrene–butadiene copolymer with a radius of 1400 Å–lattice defects and dislocations are visible[11].

II. LONG-RANGE SURFACE FORCES

It is known that attractive forces (van der Waals–London forces, forces due to permanent electric and magnetic dipoles, and forces due to dipoles induced by the polarisation of ionic double layers) and ionic–electrostatic repulsion forces can act between particles. The fact that these are long-range forces is responsible for the probability of further aggregation, i.e. the fixation of particles at a secondary potential minimum (Fig. 3).

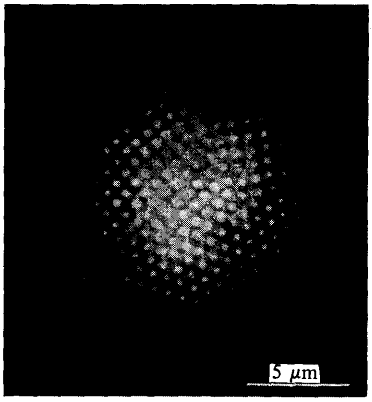

Figure 2. A photomicrograph of a polystyrene latex with a particle radius of 1700 Å for a solid phase concentration of 8 vol.%—the regions corresponding to the coexistence of the hexagonal and cubic lattices are clearly manifested[11].

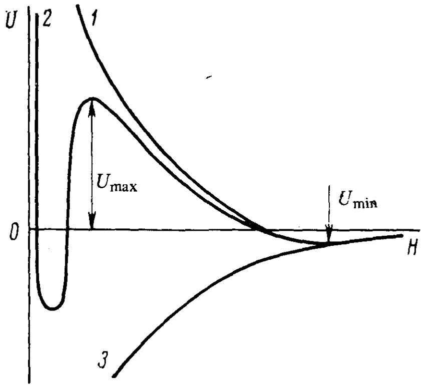

Figure 3. Various types of relations between the interaction energy of the dispersed particles and the distance between their surfaces.

Apart from molecular and dipole attraction forces as well as ionic–electrostatic repulsion forces, forces of a different type can also be manifested in the formation of periodic colloid structures.

Forces Due to the Viscoelastic Resistance of Anomalous Liquid Layers

Such forces offer resistance both to the mutual approach of the surfaces and to their separation from one another and, like ionic layers, influence the occurrence of a secondary minimum on the interaction energy curve for the particles[5,29–32]. The unusual relation between the disjoining pressure and the thickness of the film wetting the surface of quartz was recently explained in terms of the structural component and the three-layer model of a polar liquid film (presence of a layer with enhanced enthalpy or the so called partially fused layer)[33,34].

Forces Resisting the Rupture of Adsorption Layers Containing Surfactant or Polymer Molecules

The interaction between surfaces stabilised by adsorption layers (steric and entropy factors) has already been discussed[35-43].

One must also take into account the following factors: the thermal (Brownian) motion of particles[44-49]; gravitational[50,51], and centrifugal[52,53] forces which frequently appear to be equivalent to attraction forces and promote structure formation; mechanical compressive forces[29,54-55] and hydrodynamic[56-58] and capillary forces[59-62], which frequently have a marked influence on the properties of disperse and capillary-porous systems, as well as inertial, mirror image, and other forces[58].

Intermolecular van der Waals–London Forces

Despite the significant defects of the London–Hamaker microscopic theory[63], its equations are still widely used. The attraction energy between two identical spherical particles with a radius a and a distance R between their centres is given by the following expression when no account is taken of electromagnetic retardation:

$$U_m = -\frac{A}{6}\left(\frac{2a^2}{R^2-4a^2} + \frac{2a^2}{R^2} + \ln\frac{R^2-4a^2}{R^2}\right), \tag{1}$$

where A is the Hamaker constant; for low values of $H = R - 2a \ll a$ (H is the shortest distance between the interacting surfaces), we have

$$U_m = -\frac{A}{12}\left(\frac{a}{H} - 2\ln\frac{a}{H}\right), \tag{2}$$

or in a still simpler form

$$U_m = -Aa/12H. \tag{2$'$}$$

The corresponding formulae where account is taken of electromagnetic retardation were obtained by Schenkel and Kitchener[64] and for two spheres with radii a_1 and a_2 by Wiese and Healey[65]. Similarly, for $H \ll a_1$, a_2, we have[66]

$$U_m = -Aa_1a_2/6H(a_1 + a_2). \tag{3}$$

For two identical plates with a thickness b and a separation H, the expression is[20,67]

$$U_m = -\frac{A}{12\pi}\left[\frac{1}{H^2} + \frac{1}{(H+2b)^2} - \frac{2}{(H+b)^2}\right]f(H), \tag{4}$$

where $f(H)$ is a function taking into account the electromagnetic retardation; its value for different H can be determined from tables and the graph quoted in Kruyt's book[67] and in the monograph of Sonntag and Strenge[36].

When $H \ll b$, we have

$$U_m = -\frac{A}{12\pi H^2}. \tag{5}$$

All these formulae are valid on the assumption that the interacting bodies are *in vacuo*. Allowance for the influence of liquid layers usually reduces to finding the effective Hamaker constant; the following simple relation is then frequently used[58,63]:

$$A = (\sqrt{A_{11}} - \sqrt{A_{22}})^2, \tag{6}$$

where A_{11} and A_{22} are constants for the particles and the medium *in vacuo*. However, Eqn. (6) is not rigorous[68] and, when the values of A_{11} and A_{22} are similar, the calculation leads to considerable errors.

The principal defects of the microscopic theory are as follows: (1) the applicability of the law of interaction of gas particles to condensed bodies is postulated; (2) the complete additivity of the electronic interactions is assumed; (3) the summation of such interactions over short distances between bodies is replaced by integration with respect to volume. The macroscopic theory of the intermolecular interaction of condensed bodies[69], based on the analysis of electromagnetic field fluctuations, is free from these defects. Dzyaloshinskii, Lifshits, and Pitaevskii[70,71] took into account the influence of the dispersion medium.

According to the macroscopic theory, the solutions of the problem of the interaction of bodies via a liquid layer assume a simple form for distances H which are both large and small compared with $\lambda_0/2\pi$ (λ_0 is the fundamental length in the absorption spectrum or the London wavelength). The following expression has been obtained for the force of the interaction between two plane-parallel particles *1* and *2* via a liquid layer *3* for large values of $H \gg \lambda_0/2\pi$ (for dielectrics, $\lambda_0/2\pi \simeq$ 20–30 nm):

$$P_m = \frac{3\hbar c}{16\pi^2 H^4\sqrt{\varepsilon_{30}}}\int_1^\infty\left[\frac{s_{10}-p)(s_{20}-p)}{(s_{10}+p)(s_{20}+p)} + \frac{(s_{10}-\alpha p)(s_{20}-\beta p)}{(s_{10}+\alpha p)(s_{20}+\beta p)}\right]\frac{dp}{p^2}, \tag{7}$$

where $s_{10} = (p^2 - 1 + \alpha)^{1/2}$, $s_{20} = (p^2 - 1 + \beta)^{1/2}$, $\alpha = \epsilon_{10}/\epsilon_{30}$, $\beta = \epsilon_{20}/\epsilon_{30}$ (ϵ_{10}, ϵ_{20}, and ϵ_{30} are the static dielectric constants of the plates and the liquid layer), $\hbar = h/2\pi$ is the Planck constant, c the velocity of light, and p the parameter with respect to which the integration is carried out.

Calculations based on Eqn. (7) can be carried out by a graphical procedure. The accuracy of the calculations is in many instances determined primarily by the appropriate choice of the static dielectric constants.

For two identical plates, $\epsilon_{10} = \epsilon_{20}$ and Eqn. (7) simplifies to

$$P_m = \frac{\hbar c\pi^2}{240H^4\sqrt{\varepsilon_{30}}}\left[\frac{\varepsilon_{10}-\varepsilon_{30}}{\varepsilon_{10}+\varepsilon_{30}}\varphi\left(\frac{\varepsilon_{10}}{\varepsilon_{30}}\right)\right]. \tag{8}$$

The function $\varphi(\epsilon_{10}/\epsilon_{30})$ has been calculated by Lifshits[69] and the calculation for $\epsilon_{10} \neq \epsilon_{20}$ has been carried out by Devereux and de Bruyn[72]. For two metallic plates in a medium with a dielectric constant ϵ_{30}, the function $\varphi(\infty) = 1$, since $\epsilon_{10} = \epsilon_{20} = \infty$. Then

$$P_m = \frac{\hbar c\pi^2}{240H^4\sqrt{\varepsilon_{30}}}. \tag{9}$$

The same equation was obtained by Casimir[73,74] on the basis of the microscopic theory with $\epsilon_{30} = 1$.

Integration of Eqn. (8) leads to an expression for the attraction energy between two plates at a distance of 1 cm:

$$U_m = -\frac{\hbar c\pi^2}{720H^3}\left(\frac{\varepsilon_{30}-1}{\varepsilon_{30}+1}\right)\varphi(\varepsilon_{30}), \tag{10}$$

or

$$U_m = -\frac{K}{H^3}, \tag{11}$$

where K is the constant of the molecular attraction forces over long distances.

Using Deryagin's transformation[75], the formula for the attraction energy between two spheres can be obtained from Eqn. (11):

$$U_m = -\frac{\pi K a}{2H^2}. \tag{12}$$

For two plates with $H \ll \lambda_0/2\pi$, we have

$$P_m = \frac{\hbar}{16\pi^2 H^3} \int_0^\infty \int_0^\infty x^2 \left[\frac{(\varepsilon_1 + \varepsilon_3)(\varepsilon_2 + \varepsilon_3)}{(\varepsilon_1 - \varepsilon_3)(\varepsilon_2 - \varepsilon_3)} \exp x - 1 \right] \mathrm{d}\,x\,\mathrm{d}\,\xi. \qquad (13)$$

Neglecting unity compared with the term containing $\exp x$ and integrating with respect to x, we obtain

$$P_m = \frac{\hbar}{8\pi^2 H^3} \int_0^\infty \frac{(\varepsilon_1 - \varepsilon_3)(\varepsilon_2 - \varepsilon_3)}{(\varepsilon_1 + \varepsilon_3)(\varepsilon_2 + \varepsilon_3)} \,\mathrm{d}\,\xi, \qquad (14)$$

where ϵ_1, ϵ_2, and ϵ_3 are the dielectric constants as a function of the imaginary frequency $i\xi$. It follows from the above equation that the sign of the molecular interaction force is determined by the values of ϵ_1, ϵ_2, and ϵ_3. One must assume that, when the interacting surfaces approach one another, the sign of the quantity P_m may be reversed as a result of the different changes in the complex dielectric constant in them layers.

The microscopic and macroscopic theories of molecular forces yield [virtually] identical relations for the attraction forces *in vacuo* as a function of distance, differing only in the values of the constants. The experimental characteristics agree best with calculations based on the macroscopic theory[76–81].

The long-range nature of the molecular forces in condensed systems has been confirmed by the direct measurements of Abrikosova and Deryagin[76–81] as well as other investigators[82]. Many important studies have been made recently on the further development of the macroscopic theory, the improvement of the microscopic theory, and the development of methods for the calculation of the intermolecular attraction constants. This is because direct calculations of the forces of interaction via liquid layers are very complicated and have been carried out on the basis of Lifshits's theory for the simplest case of plates infinite in extent and separated by a planar gap the size of which must correspond to the limiting conditions ($H \gg \lambda_0/2\pi$ or $H \ll \lambda_0/2\pi$).

Van Kampen and coworkers[83–85] proposed a simpler method for the calculation of molecular forces equivalent in its approach to the Lifshits method; they considered the interaction between harmonic oscillators located at the interface. Using this method, Mitchell and Ninham[86] obtained the following expression for the attraction energies between two identical spheres in a liquid medium (for $H \ll a$):

$$U_m = -\frac{1}{12}\left(A_1 \frac{a}{H} - 2A_2 \ln \frac{a}{H}\right), \qquad (15)$$

where A_1 and A_2 are constants.

For $A_1 = A_2$, this equation is transformed into Hamaker's equation [Eqn. (2)] [when the particles and the dispersion medium have similar spectroscopic characteristics (for example in the case of quartz and mica particles in water)]. For semiconductor and particularly metal dispersions in liquid dielectrics, A_1 and A_2 must differ significantly, so that Eqns. (1) and (2) cannot be used. Muller and Churaev[87] calculated the values of U_m for particles of metal hydrosols on the basis of the macroscopic theory using the spectroscopic characteristics of water and the metals. Churaev[88–90] calculated the molecular components of the disjoining pressure in terms of Lifshits's theory for thick and thin wetting films of non-polar liquids. On the basis of a number of simplifying assumptions, he obtained recently an equation for the dependence of the molecular forces on distance for the entire range of film thicknesses and he also calculated the dispersion interaction forces in the transitional region[91]. A satisfactory agreement was achieved between the results of the calculations and experimental data.

The good agreement between the calculations based on Lifshits's theory and experimental molecular force constants has been pointed out in a number of interesting studies[69–81, 92–98]. On the basis of the analysis of the equations of the macroscopic theory, Churaev[99] showed that Hamaker's constants for the interaction via a liquid layer cannot be obtained by the summation of the constants for the interaction *in vacuo*. The results of the calculations of the attraction forces between identical bodies via a liquid layer exhibit appreciable discrepancies for both theories.

Taking into account double and triple correlations, Renne and Nijboer[100] derived approximate formulae for the atom–wall and two plane-parallel plate models. The studies of Rusanov and coworkers[101–104] and other investigators[105–107] were devoted to the solution of the problem of the molecular interaction between colloid particles in a liquid dispersion medium. The problem of the interaction of coaxial cylindrical and concentric spherical surfaces has been solved[108] on the basis of Lifshits's theory. A number of studies[109–111] were devoted to problems of the shielding of van der Waals forces in electrolyte solutions. The influence of the molecular condenser (Stern layer) on the overall interaction forces between colloid particles and on the stability of sols has been examined by Martynov and Muller[112, 113].

The Interaction Forces between Colloid Particles with Permanent Electric Dipole Moments

Studies on colloid solutions in the field of rectangular pulses (π-field) and in a rotating electric field (B-field) have shown that in many cases the colloid particle is a permanent electric dipole[114–119] due to the spontaneous unipolar orientation of the polar molecules (ions) adsorbed on the surface of the particle[114, 115]. Measurement of the relaxation times for the orientation of the particles in the π-field and the determination of the angle by which the dichroic axis of the particle deviates from the direction of the B-field make it possible to calculate the dipole moment μ_p. The values of μ_p for various colloid particles amount to hundreds of thousands and millions of debyes[115].

The data compiled in Table 1 [120] demonstrate the surface nature of the dipole, the results being confirmed by the results of electron-optical studies on other suspensions and sols, for example the sols of various modifications of HgS. At the same time, these data do not of course constitute proof of the impossibility of the bulk-phase nature of the rigid dipole, which may arise as a result of the spontaneous orientation of the polar groups of the material of the disperse phase.

Identical particles of ferromagnetic materials behave similarly to the dispersed particles of dielectrics with permanent dipole moments[121–123].

The Interaction Forces between Induced Electric Dipoles

The deformation of the ionic double layer (DL) occurring under the influence of a particular factor produces an electric field with a radius of action of the order of the size of the dispersed particles, leading to their long-range interaction. The polarisation of the DL plays an important role in the electrophoretic precipitation of suspensions, determining the quality of the coating, in the electrical treatment of cement pastes, electromelioration, vibrocondensation of dispersed materials, etc.

An approximate formula has been derived for the induced dipole moment[124,125]:

$$\mu_i = \frac{6a}{\sqrt{\pi}}\left[\left(\frac{\zeta\varepsilon_{\text{д}0}}{2} + \frac{zeb_i}{3r_e}\right)\frac{\zeta\varepsilon_{\text{д}0}r_e}{\Theta\varkappa^2}\right]E, \tag{16}$$

where ζ is the electrokinetic potential, z and r_e are the valence and the effective radius of the counterions, e is the electronic charge, b_i a coefficient taking into account the anomalous mobility of the counterions, E the external electric field strength, and Θ the product of the Boltzmann constant and the absolute temperature. Eqn. (16) was obtained from the expression for the energy of the polarisation interaction derived using the insufficiently reliable Stauff formula[126], which does not take into account the tangential fluxes of the diffuse-layer ions.

Table 1. The molecular dipole moments (μ_p^0) of the liquid medium and specific (per cm^2) dipole moments (μ_p^s) of diamond (in CGSE units).

Dispersion medium	$10^{18}\mu_p^0$	$10^{14}\mu_p^s$	Dispersion medium	$10^{18}\mu_p^0$	$10^{14}\mu_p^s$

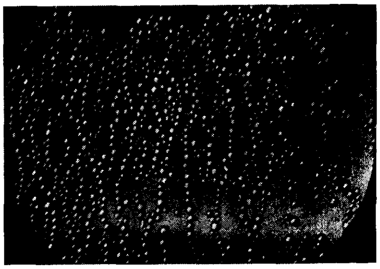

Figure 4. A photomicrograph of the aggregates formed in the latex under the influence of an external electric field.

The interaction of the induced dipoles usually leads to the appearance of chain aggregates (Fig. 4), which was first noted by Muth[127] and was subsequently studied in detail by many investigators[128-132]. Dukhin and coworkers[133-139] as well as other investigators[140-145] have made a major contribution to the development of concepts concerning the DL polarisation.

The following correct formula for the dipole–dipole interaction between two spherical particles has been proposed[139]:

$$V_{ip} = -4\varepsilon_{30}E^2B^2\frac{a^9}{(2+H/a)^3}, \tag{17}$$

where $B = \frac{1}{2} - 3[\cosh(u_1/2) - 1]/[4\cosh(u_1/2) + \kappa a]$ and u_1 is the dimensionless potential of the Stern layer. In addition, the overall interaction energy of these particles in an external electric field was calculated. The energy of the overlapping of the ionic double layer was determined from the equation derived without restriction to the value of the u_1 potential[146].

The Ionic-Electrostatic Repulsion Forces Between Surfaces

These arise when diffuse ionic layers having identical charges overlap[147-158]. In some studies[148-152], the system of interacting ionic double layers is treated with some degree of approximation as corresponding to equilibrium and the corresponding forces are referred to as the equilibrium electrical surface forces. They are governed by the change in the energy density of the electrostatic field[152] and also by the variation of the chemical potentials of the ions and the solvent in the gap between the surfaces which have approached one another[5].

In recent studies undertaken to develop further the DL theory, account has been taken of the influence of the intrinsic volume of the ion and of pair correlations on the DL structure[159], of the DL polarisation on electrophoresis and diffusiophoresis[160], and of adsorbed ions on the DL structure and polarisability[161]; problems concerning the discrete nature of the DL, [162] the determination of the surface potential of the spherical particles[163], and the comparison of the constant surface potential and constant surface charge conditions in the Deryagin–Landau–Verway–Overbeek (DLVO) theory of the stability and coagulation of colloids[164] have also been examined. In addition the results of studies on the interaction of DL-charged surfaces have been published: in a solution of a mixture of electrolytes[165,166]; for planar particles in concentrated dispersions[167]; for spherical particles in concentrated dispersions containing a dispersion medium with a low dielectric constant[168]; for planar and spherical particles in an aqueous medium[169]; at constant surface potentials[170] and surface charges[65,171,172] and also at a constant potential of one surface and a constant charge of another[173,174]; for surfaces with energetic and geometrical inhomogeneities[175-177]. Calculations have been made on the DL interaction over long distances[165,166,178] and an equation has been proposed which can be used for weakly charged surfaces[178]:

$$U_i = \frac{\varepsilon_{30}\psi_0^2 a(R-a)}{R}\ln\left\{1 + \frac{a}{R-a}\exp[-\varkappa(R-2a)]\right\}, \tag{18}$$

where R is the distance between the centres of the particles, ψ_0 the surface potential, and κ the Debye parameter.

A formula has also been obtained for the calculation of the energy U_i in the interaction of two similar spheres over long distances (for $\kappa a \gg 1$) without limitation as regards ψ_0. [146]

An interesting attempt has been made in a number of studies to examine from a single standpoint the energy of the interaction (the van der Waals attraction and the electrostatic repulsion energies) of charged surfaces.

Here a joint study was made of the low-frequency electromagnetic fluctuations and of the statistical charge distribution between two plates[179,180] and account was taken of the influence of the dielectric constant of the medium on the energy of the ions located near the interface[181]. The image method has been used[182] to calculate the interaction energy of two dielectrics *1* and *2* of different types separated by a layer of a dielectric *3*.

The dependence of the dimensionless potential u_1 of the Stern layer on the electrolyte concentration and the specific adsorption of the ion was studied recently[183]. It was concluded that the relation

$$n_c z^6 = \text{const}, \tag{19}$$

(where n_c and z are the critical concentrations and the valence of the counterions), established by Deryagin and Landau for dimensionless potentials $u_1 \geqslant 10$, should hold for arbitrary identical surface charges.

For different surface charges, the overlapping of ionic layers causes the mutual approach of the particles. For the same sign of the surface charges, but somewhat different potentials, the ionic-electrostatic forces P_i determine the repulsion of the particles over comparatively long distances and their attraction over short distances. The height of the maximum on the $P_i = f(H)$ curve depends on the lowest potential[184-186]. The interaction of the DL of inhomogeneous plates with different but constant charge densities has been studied[187], while another investigation[188] has dealt with the interaction of two plates immersed in ideal and non-ideal electrolyte solutions.

We may note that, as for molecular forces, the theoretical relations governing the action of surface ionic-electrostatic forces have been subjected to extensive experimental tests, the results of which basically confirmed their validity[29,36,37,147,189-196].

III. THE FIXATION OF PARTICLES AT A SECONDARY POTENTIAL MINIMUM AND THE FORMATION OF LOCAL PERIODIC COLLOID STRUCTURES

Under certain conditions, there is a fairly deep distant minimum on the curve for the interaction energy of colloid particles, $U(H) = U_m(H) + U_i(H)$, which determines the possibility of the mutual fixation of the particles with retention of the liquid layer between them. The probability of further aggregation and the lifetime of the aggregate formed depend on the depth of the minimum $U_{\min}$ and on the height of the potential barrier $U_{\max}$, which reduces the frequency I of the effective collisions[66,197-199], as a result of which the particles are fixed at the primary minimum (short-range aggregation):

$$I = \frac{16\pi DaN}{2\int\limits_2^\infty \exp(U/\Theta)\,\mathrm{d}\,s/s^2} \simeq \frac{16\pi DaN}{\frac{1}{2\varkappa a}\exp(U_{\max}/\Theta)}, \tag{20}$$

where N is the numerical concentration (the number of particles per unit volume) and D the diffusion coefficient.

The fixation of particles at a secondary minimum has been observed by numerous investigators[5-7] and confirmed by the results of many studies undertaken recently and designed to investigate the influence on the further aggregation of electrolytes[112,113,200-211] of the size, shape, and concentration of the colloid particles[5,65,212-217], and of the external force fields—electrical[124-128,139,218-223], magnetic[121,224-226], gravitational[50,51], centrifugal[52,53] hydrodynamic[56-58,227], etc.

A long-range interaction frequently occurs in processes involving the adhesion of the dispersed particles to a solid surface in the liquid medium. This has been confirmed by numerous experimental data[228-243]. Thus, when particles are deposited in air and also on a support in a liquid, the force required to strip them off, which is equal in absolute magnitude to the force of adhesion, is as a rule much greater in the former case[244-246]. Evidently the fixation of the particles at long distances corresponds to lower adhesion forces, while on deposition in air and the subsequent maintenance of the test specimens in the dispersion medium there are either no liquid layers between the particles and the macrosurface or their thickness is very low.

The theory of the collective interaction of particles has not as yet been duly developed. Therefore, in considering the problems associated with the formation and properties of periodic colloid structures, one usually begins with the relations governing the variation of the pair potential as a function of distance.

The Influence of Electrolytes on Long-Range Aggregation Processes

According to the DLVO theory, an increase of electrolyte concentration in the dispersion medium causes a contraction of the diffuse component of the DL and a decrease of the repulsion barrier. At the same time there is an increase in the depth of the secondary minimum $U_{\min}$ and a corresponding increase of the probability of long-range aggregation of particles, which is proportional to $\exp(U_{\min}/\Theta)$.

Table 2. The exponents ν in the equation nz^ν = const. for long-range aggregation processes.

*Sol stabilised by poly(vinyl alcohol).

It has been known for a comparatively long time on the basis of experimental findings that gel-formation occurs at lower electrolyte concentrations than coagulation and the valence of the ions has a significant influence on the amount of electrolyte necessary for gel formation[247]. This relation has been demonstrated theoretically in studies[201,202] dealing with the interaction of two infinitely large plates and two spherical particles immersed in a symmetrical electrolyte.

It has been shown that, for a constant depth of the secondary force minimum, the following relation holds for the concentration and valence of counterions over a wide range of variation of the potential u_1:

$$nz^{2.5} = \text{const}, \tag{21}$$

and, when the effect of electromagnetic retardation for molecular forces is taken into account, we have

$$nz^{3.5} = \text{const}. \tag{22}$$

Both the limiting equations (21) and (22) and the intermediate equations with power exponents in the range 2.5–3.5 apparently hold in long-range aggregation processes.

The rate of gel formation and the stability of the gel usually depend on many factors (polydispersity, the presence of impurities, etc.), which are frequently difficult to take into account and this makes it difficult to obtain reliable results. For this reason, the relations between the valence and concentration of ions, derived from the results of many investigators and illustrated in Table 2, are approximate and depend on the methods used for the experimental determination of the PCS characteristics.

The concentrations of electrolytes required for coagulation and gel formation are compared in Table 3. Similar data were obtained by Kratochvil et al.[263] in a study of sols of microcrystalline cellulose and by Aleksandrova and Mochalova[264], as well as other investigators[265-268].

Table 3. The concentrations of electrolytes in the coagulation of an Fe_2O_3 sol and its conversion into a gel[28].

Content of disperse phase, g litre^{-1}	4,92	52,6
Electrolyte	Coagulation threshold, mmole litre^{-1}	gel-formation threshold, mmole litre^{-1}
NaCl	325.0	45.0
KCl	350.0	45.1
KBr	500.0	62.0
Na_2SO_4	3.25	12.0
$Na_2(COO)_2$	2.75	9.5
ν	7.1	2.3

Thus the results of the experimental investigation of the gel-formation processes in sols are consistent with the conclusions reached from the theoretical examination of the dependence of the depth of the secondary minimum on the concentration and valence of the ions. Calculation of the values of ν in the relation nz^{ν} = const. can evidently yield information about the type of aggregation: ν = 6–7 for short-range coagulation and ν = 2.5–3.5 for long-range aggregation.

It has been shown[268] that, when the dispersed particles are fixed at long distances from the macrosurface, Eqn. (21) also holds; together with Eqn. (22), it must be regarded as a general criterion of the influence of electrolytes on long-range aggregation processes.

At the same time it follows from the analysis of Table 3 that the aggregation of particles is greatly influenced both by the concentration of the electrolyte in the system and by the concentration of the disperse phase. Thus it has been established[249] that, for an Fe_2O_3 concentration of 13.05 g litre^{-1} and a specific KCl consumption equal to 1.532×10^{-3} mole g^{-1}, the sol becomes turbid, the process being accompanied by local gel formation. Subsequently, with increase of the specific consumption of KCl, the individual gel-like regions are combined, giving rise to a thixotropic structure throughout the entire volume of the sol, which then breaks down owing to the short-range coagulation of the particles.

The Influence of the Size and Shape of the particles on their Mutual Fixation at Long Distances

Processes involving the formation of gel-like systems depend on the size and shape of the particles[5,65,212-217], which can be explained by taking into account quantitatively the forces operating in the system.

The interaction of homogeneous plates of different thicknesses for the same values of the parameters characterising their molecular attraction and ionic-electrostatic repulsion energies has been studied[20] and it has been shown that the rate of aggregation of large particles with one another and with small particles should be greater than the rate of the short-range coagulation of small particles. This conclusion has been confirmed by an experimental study of the kinetics of the formation of aggregates in suspensions[269]. At the same time the probability of the long-range aggregation of thick plates is higher than that of thin plates, since in the latter case the depth of the secondary energy minimum is smaller. Such relations have been noted in studies of gel formation in a number of disperse systems[270-274]. It has been established that a liquid is formed in gel formation primarily between large planar particles, while small particles remain predominantly in a free state and during syneresis are separated together with the syneretic liquid.

The method developed[20,45,46] for plotting curves characterising the interaction energy of three plates as a function of their relative positions made it possible to examine the influence of the concentration of the disperse phase on the short- and long-range aggregation processes[5]. It has been shown, that for fairly long distances between the surfaces, both thin and thick plates resist direct aggregation. This corresponds to a low bulk-phase (or weight) concentration of small planar particles and a high concentration of large particles. With increase of the content of the disperse phase, the distances between the surfaces and hence the resistance to aggregation diminish more sharply for thin plates, which is the reason for their coagulation at concentrations in the range where coarsely disperse systems can still be stable.

Consideration of potential curves for the interaction of three particles made it possible to explain qualitatively a number of the characteristic features of coagulation and gel formation in highly and weakly disperse colloid solutions. For example the rapid decrease of the depth of the minimum with increase of the content of thin plates is responsible for the difficulty of obtaining concentrated gels from highly disperse sols and, even if such gels are formed, rapid syneresis is their characteristic feature, as for gels containing coarsely dispersed particles. The interaction of plates of different types and dimensions is analogous although more complex.

In contrast to plates, the height of the ionic-electrostatic barrier and hence the resistance to aggregation of spherical particles increase with increase of their size (Fig. 5). In particular, this factor has been used by Oden[275] to fractionate sulphur sols. At the same time a fairly deep secondary energy minimum has been observed for large spherical particles and for large particles of other shapes. For this reason, long-range aggregation processes should be particularly common in coarsely disperse systems[67]. This is confirmed by the existence of many concentrated periodic colloid structures, for example pastes, capable of peptisation and thixotropic transformations. Cement solutions (in the initial period of solidification)[276,277], silica[278-280] and Prussian Blue[274] gels, gel-like sulphur deposits[256], etc.

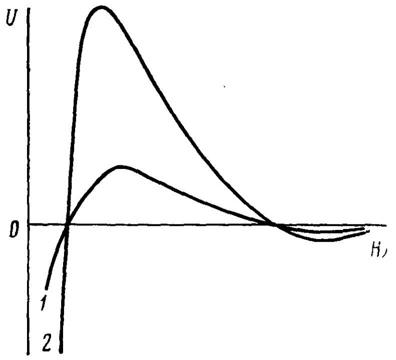

Figure 5. Dependence of the interaction energy of small (curve *1*) and large (curve *2*) spherical particles on the distance between their surfaces.

Furusawa and coworkers[212] investigated the aggregation of spherical polystyrene particles in different narrow fractions and established that, in the electrolytic coagulation of the most coarsely disperse system, the aggregation of particles occurs as a result of their fixation at a secondary minimum, because the stability of the system is restored after the removal of the electrolyte. Wiese and Healey[65] constructed a diagram (Fig. 6) where regions corresponding to the stable state of the system (region I) and to the unstable state leading to coagulation at the primary (region II) and secondary (region III) minima were defined as a function of the concentration of ions and the ratio of the radii of the particles. In the calculations, the dimensions of the particles, the surface charge, and other parameters were varied.

In connection with the wide occurrence of polydisperse systems, the question of interaction of particles of different size assumes particular importance. It has been shown[215] that fixation of small particles at long distances from relatively large particles can lead to the stabilisation of suspensions and emulsions for optimum electrolyte concentrations and a_1/a_2 ratios. Many experimental data confirming this conclusion are available. But it has been observed that small particles in rubber latexes execute "irregular" motions around large globules, behaving, as it were, as satellites of the latter[281,282]. Bethold and Snyder[278] patented a method for increasing the size of silica particles and for obtaining a stable sol containing 30 vol.% of the disperse phase by mixing suspensions with different degrees of dispersion.

Examination of the interaction of ellipsoids of rotation[215] showed that, in the presence of a repulsion barrier and a deep secondary minimum, the fixation of particles takes place preferentially for a parallel orientation of the symmetry axes (Fig. 7*a*). Since the size of the barrier is to a first approximation proportional to the radius of curvature[75], the probability of aggregation of greatly extended ellipsoids via their vertices is high for a particular ratio of the attraction and repulsion forces and there is a possibility of aggregation over both short and long distances (Fig. 7*b*). The fixation of anisodiametric particles when anisotropic forces (for example, dipolar forces) operate between them should occur with a relative shift of the particles, i.e. for angles in the range $0 \leq \gamma < \pi/2$, where γ is the angle between the direction of the principal symmetry axis of the ellipsoids and the line joining their centres (Fig. 7*c*).

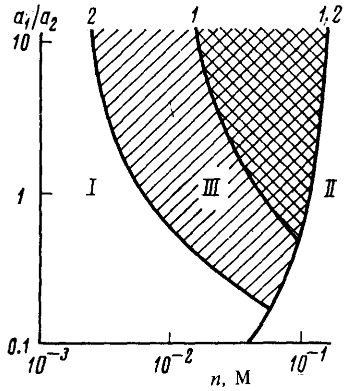

Figure 6. Stability diagrams of disperse systems consisting of particles of different sizes (a_2 = 0.1 μm) with (curve *1*) and without (curve *2*) allowance for the electromagnetic retardation effect: I) the region of the existence of stable systems; II) the region of short-range coagulation; III) the region of long-range coagulation.

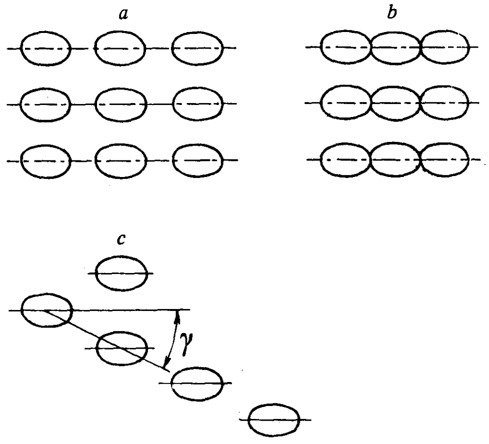

Figure 7. A scheme characterising the distribution of ellipsoidal particles and the formation of periodic colloid structures.

The structures arising as a result of the interaction of non-spherical (or spherical but non-polarised) particles usually possess anisotropic properties. Here one should mention in the first place a wide variety of periodic tactoid structures consisting of particles in the form of plates and rods[67]. Chain aggregates or dendritic structures arise as a result of dipole–dipole interaction from spherical monodisperse systems of particles placed in an electric field (Fig. 4). Similar behaviour has been observed for many tactoids also in the absence of an external field (Fig. 8).

Figure 8. A scheme characterising the distribution of particles in tactoids.

Tactoids are the simplest (model) periodic colloid structures of the local type, the formation of which is determined by the fixation of the particles at a secondary minimum and is accompanied by the loss of potential energy ($\Delta U < 0$).[5-7,13,22,23] They are closely related, on the one hand, to liquid crystals and liquid-crystal phases in solutions of soaps, lipoids, and polymers† and, on the other hand, to gels, pastes, and gel-like systems. The similarity of the structures of local type, i.e. structures which usually do not arise throughout the volume of the dispersion‡, has been noted for a long time by many investigators[15-17,283,284].

IV. THE INTERACTION OF PARTICLES UNDER "CONSTRAINED" CONDITIONS AND THE FORMATION OF PERIODIC COLLOID STRUCTURES WITH A LIMITED VOLUME OF THE MEDIUM

In stable colloid systems "constrained" conditions arise as a result of the increase of the concentration of the disperse phase. The increase of the number of particles involved in free Brownian motion prior to this leads to their mutual approach and to the overlapping of the ionic atmosphere or solvation shells and hence to the appearance of repulsion forces. In this case the average distance between the interacting surfaces becomes smaller than the coordinate H_0 corresponding to the secondary minimum on the pair potential curve (Fig. 9). A further increase of the concentration of the particles decreases the stability of the system in consequence of the decrease of the depth of the potential wells located in the region of positive values of the energy[45,46,285].

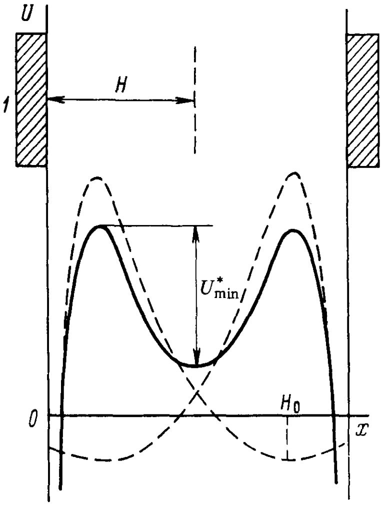

Figure 9. Dependence of the energy of interaction of particles *1* and *2* with a third particle on distance under restricted volume conditions. The dashed curves characterise the pair interaction potential.

For periodic colloid structures in a limited volume of the medium, an increase of potential energy is a characteristic feature ($\Delta U > 0$); they are formed throughout the volume of the system. The latter factor is responsible for the large-scale order in the distribution of the colloid particles, which can be readily observed from the bright iridescent colour of the dispersion[4,10,11,286]. In this case the periodic colloid structures play the role of a diffraction grating; the appearance of iridescence shows that the distances between the particles (and the dimensions of the particles themselves) are comparable to the wavelength of the transmitted light.

Numerous periodic colloid structures of the second type have been ovserved in latexes[4-8,10,11,210,286-291]. Many investigators have observed surprisingly regular lattices of latex particles (Figs. 1 and 2). In the stage preceding the formation of such quasicrystalline two-dimensional periodic colloid structures, the dispersion consisted of stable particles between which repulsion forces with a fairly large radius of action operated. "Constrained" conditions arose in such cases usually as a result of the evaporation of the liquid medium. In the Schiller layers, in deposits consisting of particles resistant to mutual aggregation, and also in creamy compositions, the restriction of the volume and "constrained" conditions are usually caused by gravitational or centrifugal forces.

---

†A comparative study of colloid particles and associated complexes of dissolved polyelectrolyte macromolecules has led to the conclusion that the interaction of these particles [as well as the interaction of the swelling latex particles (micelles) in surfactant solutions] is determined by general relations, which may be determined on the basis of unique physical principles.

‡ Under certain conditions and for a sufficiently high concentration of the disperse phase, a complete immobilisation of the system is possible.

Thus repulsion forces are responsible for the appearance of periodic colloid structures of the second type and attraction forces give rise to local periodic colloid structures.

The Influence of Electrolytes on the Interaction of Particles under "Constrained Conditions"

It has been shown[210,287] that, depending on a number of parameters, aqueous dispersions of polyacrylonitrile can exist both in the form of mobile suspensions and in the gel-like state. At a low electrolyte concentration and in the presence of a fairly high content of the disperse phase, periodic colloid structures are formed in which the particles are separated by quasiequilibrium liquid layers as a result of strong ionic-electrostatic interactions. Such systems possess viscoelastic and viscoplastic properties. With increase of the concentration of electrolytes, the radius of action of the ionic-electrostatic repulsion forces diminishes, which either gives rise to structures made up of locally ordered regions or causes a conversion of the gel into a mobile fluid state characterised by the absence of shear strength. In the former case the regularity of the structure is maintained in consequence of the fixation of the particles at distances corresponding to the coordinate of the second minimum. One should note that the "liquefying" action of small amounts of salts has been observed previously by Fryling[288] and also by Brodnyan and Lloyd Kelley[289,290] in studies of the rheological behaviour of a number of latexes.

Table 4. The exponents ν for polyacrylonitrile dispersions in the presence of different concentrations of electrolytes (τ_0 is the limiting shear stress).

τ_0, dyn cm^{-2}	10^2[NaCl], M	10^4[MgCl$_2$], M	ν	τ_0, dyn cm^{-2}	10^2[NaCl], M	10^4[MgCl$_2$], M	ν
10	0.2	4.10	2.6	75	1.00	8.40	3.6
20	0.3	4.90	2.8	100	1.50	10.0	3.8
25	0.4	5.40	2.9	200	5.30	19.0	4.8
50	0.6	7.50	3.0	τ_{max}	16.0	26.0	6.0

The transition from long-range to short-range aggregation (coagulation) with increase of the concentration of electrolyte in the dispersion medium takes place gradually and frequently these stages of the structure formation process cannot be very clearly distinguished§. For example, the exponent ν in the equation nz^{ν} = const. for polyacrylonitrile dispersions in the concentration ranges 2.50×10^{-3}–1.00×10^{-2} M NaCl and 4.10×10^{-4}–8.40×10^{-4} M MgCl$_2$ amounts to 2.5–3.5, which demonstrates, according to Serebrovskaya and coworkers[201,202], the aggregation of particles with retention of the liquid layer separating them (Table 4).

The significant intensification of short-range aggregation at electrolyte concentrations close to the critical concentration n_c (5.30×10^{-2} M for NaCl and 1.90×10^{-3} M for MgCl$_2$) is responsible for the breakdown of the gel. The exponent $\nu = 6.0$ corresponds to this transition from the gel-like structure to a coagel, analogous to syneresis and accompanied by the evolution (displacement) of the syneretic liquid, which is consistent with the theory of the stability of lyophobic colloids[148-152], which has been used to prove the Schultze–Hardy rule in the form of Eqn. (19).

V. THE REVERSIBILITY OF PROCESSES INVOLVING THE FORMATION OF PERIODIC COLLOID STRUCTURES. PEPTISATION, THIXOTROPY, AND SYNERESIS

The mobility of the bonds between the elements of the quasicrystalline lattice, which is due to the comparatively small depth of the potential minimum, determines the most important properties of periodic colloid structures—the reversibility of the processes involving their formation and the possibility of peptisation and of thixotropic transformations.

A quantitative theory of these processes has not yet been devised. In discussing them, one must take into account the depths of the primary and secondary minima and also the changes in the conditions governing the mobile equilibrium (quasiequilibrium) between the particles fixed at the minima and existing in a free state in the bulk of the system. Indeed, experiment has shown that sol-gel transformations, induced by various physicochemical factors, can be regarded with some approximation as corresponding to equilibrium, as is assumed for crystallisation and dissolution processes. Naturally, this approach is justified only when coagulation and subsequent recrystallisation in the periodic colloid structures are very slow and do not have an appreciable influence on the aggregation equilibrium.

The existence of a mobile aggregation equilibrium in the aggregation of many colloid solutions has been observed by a number of investigators[5,22,23,52,53,209,242,253-255,292-299]. Thus, using an optical microscope, Okamoto and Hachisu[23] observed the Brownian movement of gold sol particles (forming aggregates) in the dispersion medium over a certain range of electrolyte concentrations. Using the method of the low-angle scattering of X-rays, Kratky et al.[299] measured the degree of aggregation of molecules in solutions of an azo-dye (Chlorantine Light Violet 2RLL) and established that the aggregation equilibrium depends on the concentration of the ions in solution, temperature, and the content of the dye. Similar relations were noted also in a study[297] of the coagulation of gold sols in a flow ultramicroscope.

In discussing the problem of the aggregation equilibrium in colloid solutions, Frens and Overbeek[294,295] concluded that the relation between the number of primary particles, the number of aggregates, and their size is determined by the minimum in the free energy of the system; for ion-stabilised dispersions, this minimum is related to the DL parameters. Thus there is a possibility in the DLVO theory of taking into account not only the processes involving the formation of aggregates but also their decomposition processes, determined by the finite depths of the primary and secondary minima.

Similar but more detailed ideas were developed in a series of studies by Martynov and Muller[300-303] for long-range aggregation or, in the authors' terminology,

---

§ The transition from long-range to short-range aggregation may be observed from the disappearance of iridescence[286,291].

"barrierless coagulation"¶. It was shown that, under certain conditions, coagulation (aggregation) can occur only in consequence of a remote potential well[302]. Since the depth of this well is as a rule small, there is a comparatively high probability of the decomposition of the aggregate formed. One should note that the coagulation mechanism proposed by the authors[300–303] remains valid, subject to certain assumptions, also for systems a characteristic feature of which is the presence of a repulsion barrier between the particles: the relations established should hold also for a near potential well at electrolyte concentrations exceeding the critical value.

Analysis of the kinetics of slow coagulation[302], presupposing allowance for the decomposition processes of the aggregates formed, is of significant interest, since it has been found that the shape of the curves relating the total number of particles to time makes it possible to determine the decomposition coefficient and the depth of the potential well in which the fixation of the particles takes place. Furthermore, the height of the barrier can be found from the coefficient of the retardation of aggregation, and hence the fundamental parameters of the interaction between the particles may be calculated.

The decomposition of the aggregates and their formation take place spontaneously as quasiequilibrium processes; in contrast to this, peptisation and thixotropic transformations take place as a result of physicochemical and mechanical influences on the system.

Local Periodic Colloid Structures ($\Delta U < 0$)

Such structures, arising as a result of long-range aggregation, usually undergo peptisation comparatively readily; for example they consist of tactoids[18,19,22,23,241,253–255,283,304,305], freshly prepared gels and gel-like deposits[5,15–17,64,206–209,242,253–255,292–297], and flocculated emulsions[203,285,306–308]. Many disperse structures are peptised on simple contact with the dispersion medium containing stabilising ions or surfactant molecules, which occurs fairly frequently in the swelling of various argillaceous minerals[309–312] as well as pastes obtained from latexes, dyes, pigments[5], and colloid silver deposits[313].

However, one should bear in mind that peptisation is not usually quite complete (i.e. some of the precipitate remains)†. Thus the aggregation equilibrium in an AgI sol, observed on varying the concentration of the solid phase, changes with time: the aggregates are gradually stabilised and decompose to a lesser extent following dilution[313]. It is important to note that peptisation proceeds most completely when the electrolyte concentration in the intermicellar liquid in the initial state does not exceed the critical concentration causing the disappearance of the repulsion barrier[22,23,52,53].

Periodic Colloid Structures with a Limited Volume of the Medium ($\Delta U > 0$)

Such structures are characterised by their capacity for almost complete peptisation, since, following the decrease of the content of the disperse phase (the numerical concentration), the system tends to pass to a lower energy level, which is accompanied by a simultaneous increase of entropy‡. This process has been studied experimentally[10,52,53,210,291].

Anomalous Liquid Layers

Anomalous liquid layers preventing direct contact between the particles play an important role in peptisation processes, like the adsorption of ions from solution at the interface, which alters significantly the ion-electrostatic interaction of the particles. The influence of these factors on peptisation can be followed in relation to the intracrystalline swelling of various argillaceous minerals in electrolyte solutions. Norrish[309] showed by the method of low-angle X-ray scattering that the interplanar spacings H_B in swollen montmorillonite are to a large extent determined by the position of the exchangeable cation in the lyotropic series and its concentration in solution. For H^+ and Li^+ ions, H_B varies linearly to a first approximation as a function of $1/\sqrt{n}$; Na-montmorillonite exhibits the same relation at electrolyte concentrations $n < 0.3$ M, while at a concentration of approximately 0.3 M the interplanar spacings can be simultaneously $H_B = 19$ and 40 Å.

The interplanar spacings in specimens of an argillaceous mineral placed in KCl, NH_4Cl, and CsCl solutions do not as a rule exceed 15 Å whatever the concentration of the electrolyte. However, it has been observed[309,317] that the capacity of K-montmorillonite specimens for swelling depends on the method of their preparation. K-Montmorillonite which had been kept in a concentrated KCl solution and then placed in a dilute KCl solution does not swell, in contrast to the Li- and Na-montmorillonites in LiCl and NaCl solutions. At the same time, when a clay specimen which had been subjected to preliminary treatment in a dilute NaCl solution is placed in a dilute KCl solution, the high values $H_B \simeq 100$ Å persist after the exchange of Na^+ ions for K^+ ions and the lattice does not undergo appreciable changes.

The experimentally observed intracrystalline swelling of various cationic forms of montmorillonite has been explained[318] on the basis of the theory of the interaction of dispersed particles and the values of H_B have been calculated as a function of the concentration of the electrolyte in the disperse medium and have been found to agree fairly well with the experimental data, qualitatively and quantitatively. It proved necessary to take into account the specific adsorption of the ions in the dense component of the DL as well as the limit of the plastic strength of water near the interface[319–321].

The shear strength of the liquid layers should lead to the appearance of hysteresis loops in swelling–contraction processes[320–323]. For example, when the concentration

---

¶ We believe that the term "barrierless coagulation" cannot be regarded as successful, since it corresponds merely to the model adopted by the authors in which infinitely large barriers and hence the absence of coagulation at the primary minimum are postulated.

† The periodic colloid structures corresponding to thermodynamic equilibrium as well as those in which the particles are separated by very high repulsion barriers, which brings the system closer to equilibrium, are apparently exceptions.

‡ The conditions governing the formation and existence of spontaneously dispersable systems with low interfacial energies have been discussed[314–316].

of the electrolyte is varied, the volume of the sedimentation deposit of Oglanlinsk Na-bentonite varies as in intracrystalline swelling[322], but the branches of the curve corresponding to the decrease and increase of the concentration of ions in the dispersion medium do not coincide. This type of variation must be explained by the fact that, on swelling, the shear strength of the liquid prevents the mutual separation of the elementary packets of montmorillonite and on contraction it prevents their mutual approach.

The problem of the capacity for peptisation of local periodic colloid structures is closely related to the phenomenon of thixotropy, i.e. to the ability of the structure to be restored after its disturbance under the influence of mechanical stress (stirring, vibration, etc.). Such a transition is usually accompanied by a change of effective viscosity by several orders of magnitude. At the same time it is known that, together with ideal thixotropy, there are many instances of an incomplete restoration of the strength characteristics of periodic colloid structures: in each succeeding thixotropic transformation, the volume occupied by the gel diminishes to an increasing extent until the disperse phase separates in the form of a dense deposit. Under these conditions, the strength of the gel frequently increases and the restoration period shortens. However, in many systems there is a characteristic decrease of strength and a gradual liquefaction of the gel, leading to complete irreversibility. Many gels (as a rule dilute gels) have no thixotropic properties: their strength is not restored even after the first disruption of the structure. Thus there are intermediate types between ideal thixotropic systems and systems without thixotropic properties[5].

Various processes resulting in a decrease of the strength of colloid structures, i.e. in liquefaction, are frequently classified as thixotropic. However, liquefaction can also occur as a result of slow coagulation, which disrupts the gel lattice and causes a sharp decrease in strength. The latter evidently has no bearing on thixotropy and is more likely to be a syneretic process. In particular, this is frequently observed in periodic colloid structures with a limited volume of the medium: coagulation (fixation at the primary minimum) leads to an increase of the distances between the particles or their aggregates, which is responsible for the disruption of the lattice of the gel and hence for the decrease in its strength.

The processes occurring in syneresis may be examined on the basis of the theory of slow coagulation, where, however, one must take into account the cooperative effect, i.e. the influence of a single particle attached to the aggregate on the interaction of all the particles. This constitutes a very difficult task. The current theory of slow coagulation[197-199] is based on the concept of pair interaction between particles, which has been justified with adequate approximation for dilute systems. In gels, each particle is surrounded by neighbours and the energy of their collective interaction must be expressed by the exponent in Eqn. (20). The overall height of the barrier $U^*_{\max}$ for the pair interaction is defined, according to Wiese and Healy[65], as the arithmetical sum of the absolute height of the repulsion barrier $U_{\max}$ and the depth of the secondary minimum $U_{\min}$.

Phenomena analogous to thixotropic recovery processes frequently occur in disperse systems under the influence of external force fields: electrical, magnetic, ultrasonic, etc. In dilute dispersions, these fields are responsible for the formation of structures, for example chain aggregates, which may decompose after the removal of the field, i.e. may be spontaneously peptised[121,124,125,128,324].

VI. ESTIMATION OF THE INTERACTION FORCES BETWEEN DISPERSED PARTICLES ON THE BASIS OF THE RHEOLOGICAL PROPERTIES OF PERIODIC COLLOID STRUCTURES

When specific deformation processes in colloidal dispersions, pastes, and deposits are considered, it is important to know the relation between the stresses operating in the system and its flow rate. Problems of this kind constitute the subject of rheology—the science of the fluidity of matter[325]. However, rheology, which is a component of physochemical mechanics[25,26], is restricted to phenomenological methods for the description of the deformation process without elucidating the relation between the strength of disperse systems and the surface forces of the interaction between particles. Furthermore, the latter problem, the solution of which is apparently still in its initial stage, is of great practical importance, primarily for the development of new methods whereby various materials with specified properties could be obtained[326].

Periodic colloid structures usually have a high yield point and they can therefore be regarded as plastic solids or, according to Rebinder's classification[14,327], as solid systems, in contrast to liquid systems (dilute sols, emulsions, etc.) for which the yield point is zero. The calculation of the strength of such systems is as a rule based on model concepts and certain assumptions concerning the parameters of the interaction of the particles. The models employed evidently constitute only a first approximation and do not fully reflect the real structure of the disperse material. This applies mainly to systems characterised by low equilibrium (quasiequilibrium) distances between individual particles and hence a significant non-uniformity of the distribution of particles in the bulk phase of disperse porous bodies. For periodic colloid structures of the local type and particularly for such structures formed under the conditions of a restricted volume, the introduction of model concepts is fully justified, although the methods of calculation in the case of short-range and long-range aggregation are not fundamentally different.

In most studies dealing with the strength of gels and gel-like systems, a uniform distribution of the particles of the disperse phase is postulated. For example, in a study of glyceryl tristearite suspensions in hydrocarbons, Nederveen[328] determined the average distance between the particles, assuming that van der Waals–London forces as well as Born repulsion forces operate between them, and calculated the moduli of elasticity of the dispersions from the formula proposed by van den Tempe[329]. The appreciable discrepancies between the experimental and calculated data were accounted for by the imperfection of the model.

Volarovich and Gutkin[330] showed that the limiting stresses due to the existence of periodic colloid structures, occurring in simple shear deformation, may be found from the expression

$$\tau_0 = \frac{4}{\pi} N U_0, \qquad (23)$$

where U_0 is the energy of the pair interaction of the particles. On the assumption that the fixation of the particles in the lattice takes place owing to long-range dipolar forces, the authors[331] calculated the values of τ_0, which were in the order of hundreds of dyn cm^{-2} and were close to the values of τ_0 observed experimentally for a number of suspensions[332].

A similar model was also used in another study[8], where the relation between the limiting shear stresses in periodic colloid structures was considered as a function of the concentration of the solid phase and of the electrolyte in the dispersion medium. Molecular and ionic-electrostatic interaction forces between the particles were taken into account, while the energy of the interaction of rigid electrical dipoles, which should probably be shielded by the counterdipoles in electrolyte solutions, were disregarded. The results of the calculations, which are in good qualitative and quantitative agreement with experimental data, explained many of the known facts, namely the decrease of the strength of periodic colloid structures of the second type with increase of the concentration of ions in the system[210], the parabolic relation between τ_0 and the numerical concentration of the particles[287], etc.

A chain model of disperse structures has been proposed by Rebinder et al.[326] It is designed mainly for the calculation of the strength of disperse materials such as catalysts, the porosity of which may vary within wide limits, although it can be used successfully also for estimating the mechanical properties of local periodic colloid structures. In constructing the model, the occurrence of chain aggregates consisting of spherical particles of identical size in contact was postulated. The chains are distributed along three mutually perpendicular directions and intersect, forming nodal points. In order to characterise the system, it is sufficient to know the diameter of the particles $2a$ and their number N_0 in the aggregate; its strength Q_m depends on the strength q_1 of a single contact and

$$Q_m \simeq 10^{10} q_1 \frac{1}{d^2} \beta, \tag{24}$$

where d is the average pore diameter in angstroms, Q_m is expressed in kgf cm^{-2}, and $\beta = 4/\pi - 2/N_0 + 1/N_0^2$.

An experimental test of Eqn. (24), showed that the equation predicts fairly accurately the force of cohesion of the particles q_1, provided that Q_m is known[333]. At the same time, it has been stated[333] that the difference between the values of q_1, found from the results of microscopic and macroscopic measurements, may be attributed to some uncertainty in the estimation of q_1 from the measured strength of individual contacts, which varies within the limits of six orders of magnitude.

A somewhat modified model of disperse structures, consisting of a series of repetitions of the same unit cell (which is not necessarily closed), was proposed by Yakhnin and Taubman[334]. The basic element of the cell is a conventional edge containing N_0 particles having the same diameter $2a$. Then

$$Q_m = kq_1/a^2 N_0^2, \tag{25}$$

where k is a dimensionless coefficient, which depends on the shape of the cell and the fraction of the effective (structural) units in the chain. It is important to note that the concepts developed by the authors[334] have been extended to the case of the particles of the disperse phase modified by surface-active substances, which alter the forces of interaction between the particles. Subsequently the distribution of the particles with respect to cohesive forces was taken into account within the framework of the model of Yakhnin and Taubman[335].

Considering the dissipation of energy of the flow of a plastic material, Michaels and Bolger[336] showed that the limiting shear stresses may be calculated from the equation

$$\tau_0 = \frac{3\varphi}{2\pi^2 a^3} U_0, \tag{26}$$

where φ is the bulk-phase concentration of the solid. The derivation of Eqn. (26) is not associated with model concepts, is general, and does not involve any assumptions concerning the nature of the linkages between the particles. Using this approach, Hunter and coworkers[337-339] subsequently investigated the problem of the influence of electrical double layers, temperature, and steric stabilisation of suspensions on the energy of cohesion of the particles in the aggregate U_0.

Information about the interaction of the particles can be obtained from compression measurements[340, 341] and also from data obtained by studying the elastic properties of dispersions[342]. For example, Ottewill and coworkers[340] found the interaction forces between the particles as a function of the distance H between their surfaces by determining the dependence of the elastic deformation of moisture-saturated Na-montmorillonite specimens and powders containing monodisperse polystyrene particles on the external load. The electron-microscope photographs of the latex quoted by the authors[340] permit the conclusion that the distribution of particles in the systems investigated is fairly rigorously ordered, and the systems can probably be classified as periodic colloid structures with a limited volume of the medium, since the range of variation of H for all loads amounted to several tens and hundreds of angstroms.

The application of external electrical and magnetic fields and the associated electrorheological[124-132] and magnetorheological[226, 343] aggregation effects proved to be extremely promising for the estimation of the degree of interaction between dispersed particles. In contrast to spontaneously coagulated suspensions and sols, the aggregates arising under the influence of the fields are extended, which significantly facilitates the interpretation of experimental data. In consequence of the rapid development of a number of fields in chemical engineering, where electrical and magnetic treatment of disperse systems is being used on an increasing scale, such studies assume particular urgency.

The theoretical and experimental data concerning the long-range interaction of colloid particles confirm the validity of ideas about periodic colloid structures of the first and second types. In order to devise a rigorous theory of the processes involved in the formation of such systems, which is very important for the successful development of the science of surface phenomena and for the improvement of various technological processes, it is necessary to solve many complex problems, which arise primarily in consequence of the insufficiently complete investigation of the interaction forces between particles. Thus there are no methods for the calculation of the forces acting between surfaces having anomalous liquid layers or between surfaces separated by a layer or solution with a high concentration of ions; the theory of the interaction of surfaces stabilised by surfactants and polymers has been inadequately developed, and so on. Particular mention should be made of the necessity for the solution of the problem of the collective interaction of particles, which can occur in general under the influence of attraction and repulsion forces of different types.

Latexes containing virtually monodispersed spherical particles have been used recently with increasing frequency as model systems for the investigation of structure formation processes. The results for the study of such dispersions have been widely discussed in the present review. However, this does not mean that latexes occupy a dominant position among other periodic colloid structures, which are common in nature and industry, although their importance is many respects incontrovertible. There is no doubt that certain sedimentary rocks, soils, cement pastes, ceramic and paper compositions, clay dispersions, gelled emulsions and foams, creams, etc. are of primary importance. Unfortunately their extensive investigation is complicated by the fact that they are usually polydisperse, the shape of the particles is irregular, many components, including various impurities, are present, and frequently also both chemical and physicochemical processes take place. It therefore appears to be necessary to investigate systematically and thoroughly real polydisperse systems for variable values of different parameters, which will help in the solution of theoretical and practical problems. The research must be directed primarily towards the study of the influence of electrolytes, temperature, and other factors on long-range aggregation, peptisation, thixotropic transformations, and syneresis, as well as the rheological properties of periodic colloid structures.

The determination of the relations governing the behaviour of particles in dispersions is possible on the basis of the theory of molecular and ionic solutions, the development and improvement of which constitutes a very complex and topical problem at the present time.

Nucleophilic Substitution of Hydrogen in Aromatic Systems

O.N.Chupakhin and I.Ya.Postovskii

The literature data on the substitution of hydrogen under the influence of nucleophilic agents in aromatic and heteroaromatic systems and in quinones are reviewed. The absence of anionic stabilisation of the hydrogen substituted with its pair of binding electrons is responsible for the specific nature of the reactions under consideration, which is different from that of the nucleophilic substitution of other species and from that of the electrophilic substitution of hydrogen, necessitating the use of an oxidant in most instances.
The bibliography includes 227 references.

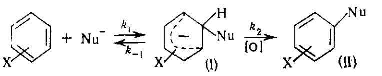
CONTENTS

I. INTRODUCTION

In one form or another the problems of the nucleophilic substitution of hydrogen have been reflected in the literature on nucleophilic aromatic substitution of anionically stabilised groups [1,2] and hydride shifts [3-5], in reviews dealing with aromatic and heteroatomic cations [6-9]. There exists a monograph [10] as well as a series of review articles on the nucleophilic aromatic [11-17] and heteroaromatic [18-21] substitution of anionic bearing groups. Concepts concerning the structures of the intermediate σ complexes [15-17], the involvement of π complexes [21], and the role of one-electron steps in such reactions [22-27] have been developed with the aid of chemical and physical methods. Extensive data have been accumulated, including quantitative measurements of kinetic and thermodynamic parameters, correlations between the rate constants and the influence of the activating or eliminated group, and solvation, catalytic, and isotopic effects. However, these results can by no means always be used to interpret the nucleophilic substitution of aromatically combined hydrogen, because such reactions are different from the electrophilic substitution of hydrogen as well as from the nucleophilic substitution of anionically stabilised species†.

The hydride ion is not involved in the formation of hydrogen bonds, is not solvated, and shows no tendency whatever towards any anionic stabilisation. Anionic or anionoid σ complexes, containing hydrogen at the germinal site, are as a rule more stable than the corresponding structures with a group capable of being stabilised in the form of an anion. For this reason it has come to be accepted [28] that the removal of the hydride ion involves considerable difficulties and requires several conditions. This is probably the case when the hydride ion is removed as such without using an oxidant. A dehydrogenating oxidising agent may be deliberately introduced into the reaction mixture or, for a favourable ratio of the oxidation-reduction potentials of the σ complexes and the starting materials, the substrate itself can serve as the oxidant. In the present review it is shown that the use of an oxidant can lead to low activation energies and to the possibility of carrying out the process under mild conditions.

S_NH reactions probably proceed via a two-stage mechanism in the vast majority of cases with formation of an intermediate. The mechanism shows that, depending on the ratio of the rate constants, the interaction can proceed in different ways:



.

The constant k_2 depends on the ratio of the oxidation-reduction potentials of the intermediate (I) and the oxidant. When $k_1 \gg k_{-1}$ and k_2 is large, the process is completed with formation of the product (II). When $k_1 \gg k_{-1}$ and k_2 is small, the reaction may stop at the stage of the product (I); when $k_1 \ll k_{-1}$ and k_2 is large, the σ complex (I) is present at a vanishingly low quasistationary concentration and the process can develop only in the presence of an appropriately selected oxidant. In the absence of an oxidant or when its oxidising capacity is inadequate, other processes may be observed—the substitution of other groups when these are present or the dimerisation of the substrate.

The fact that in many instances σ complexes can be isolated in a pure state in S_NH reactions is in all probability responsible for the lack of terminological consistency in the description of such reactions: they are sometimes regarded as addition reactions even in those instances where the intermediate has not been isolated and has not been detected by other methods [29,30]. According to Ingold, the term "bimolecular nucleophilic substitution" can be applied to all such reactions, despite the existence of intermediate addition products [28].

In the present review an attempt has been made to treat from general standpoints the S_NH reactions in various aromatic systems, both activated and not activated by nitro- and aza-groups, and in quinones. Such parallels can be usefully drawn in the treatment of nucleophilic substitution of hydrogen and related phenomena. Particular attention has been devoted to the elucidation of the role of the oxidant in these processes and also to the discussion of the quantitative data characterising the reactions of the S_NH type in the series of aromatic compounds.

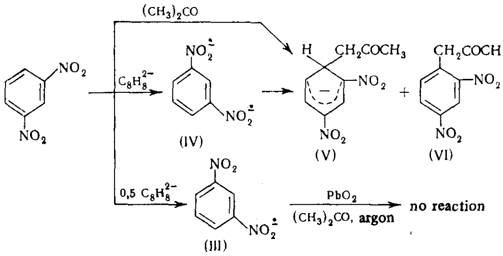
---

†We suggest that nucleophilic substitution of hydrogen be designated by the symbol S_NH, emphasising the specific nature of such reactions.

II. S_NH REACTIONS OF NITRO-COMPOUNDS

The reactions of aromatic compounds activated by a nitro-group with different nucleophiles have all the features of the interaction between an electron donor and acceptor (oxidant and reductant) and depend on the number and positions of the nitro-groups in the substrate, the nature of the nucleophile, and the involvement of the oxidant. The interaction can result in the respective formation of donor–acceptor complexes, anionic σ complexes (Meisenheimer complexes), or products of the nucleophilic substitution of hydrogen. An increasing amount of data is being published, showing that the products obtained as a result of complete electron transfer can play a significant role also in S_NH reactions[23].

As an example, one may quote a study of the reaction of *m*-dinitrobenzene with the carbanion formed from acetone in an alkaline medium (Yanovskii's reaction). Gol'teuzen et al.[31] resorted to the simulation of electron transfer processes using the cyclooctatetraene dianion $C_8H_8^{2-}$ instead of the acetone carbanion:



By adding specific amounts of this dianion, it was possible to control separately the formation of both the radical-anion (III) and the biradical-dianion (IV) from dinitrobenzene. It was established that the radical-anion (III) is not involved in the reaction with the acetone anion, while the dianion (IV) yields the product of Yanovskii's reaction—the σ complex (V), together with the product (VI) of the nucleophilic substitution of hydrogen. This provides a sound basis for the assumption that the biradical-dianion (IV) is located on the reaction coordinate in the formation of the σ complex (V). Other examples indicating that the involvement of electron transfer products in reactions of the S_NH type is quite likely are also known[27,32].

Whether or not the reaction stops at the Meisenheimer addition stage depends to a considerable degree on how effectively the negative charge is delocalised over the electron-accepting groups. The differences between the delocalisation energies on passing from aromatic nitro-compounds to anionic σ complexes (−8 kcal mole^{-1} for nitrobenzene, 1 kcal mole^{-1} for 2,4-dinitrobenzene, and 10 kcal mole^{-1} for 1,3,5-trinitrobenzene) show how strong is the influence of the successive introduction of nitro-groups in the *meta*-positions[33].

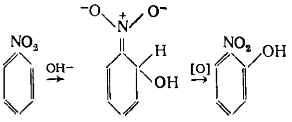
Numerous stable Meisenheimer complexes containing a hydrogen atom at the geminal site have been described[15]. Their oxidation makes it possible to obtain substituted aromatic polynitro-compounds, although in the literature there are only isolated reports on this problem[34-36]. Studies indicating a systematic approach to the investigation of the oxidation of hydride-active hydrogen in anionic σ complexes were only published as late as 1973–1974.[37,38] It has been shown[37] that both two-electron (the tropylium cation, lead tetraacetate, hypohalogenites, and halogens) and one-electron [Fenton's reagent, silver nitrate, and iron(III) chloride] oxidants can be used for the oxidation reaction and that the rate of oxidation depends on the standard potential of the oxidant. The first quantitative data appear to have been obtained[38] (Table 1) for the oxidation potentials of the anionic σ complexes at a rotating platinum electrode. They demonstrate the necessity for the use of a strong oxidant in order to obtain substituted polynitro-compounds.

Table 1. The polarographic oxidation potentials of the σ complexes of nitro-compounds with acetone in 0.1 *N* $(C_4H_9)_4NClO_4$ as the supporting electrolyte (relative to the saturated calomel electrode).

Initial nitro-compound	$E_{1/2}$, V	*E*, mV	No.of electrons	Reversibility
1,3-Dinitrobenzene	0.330	85	2	Irreversible
2,4-Dinitroanisole	0.325	75	2	»
1,3,5-Trinitrobenzene	0.825	80	2	»

The use of optimal conditions ensures a fairly smooth course of the S_NH reactions of nitro-compounds, which makes them important on a preparative scale and in some cases on an industrial scale. Examples of such reactions are considered below.

The treatment of nitrobenzene with dry powdered alkali has been known for a long time as a method for the synthesis of *o*-nitrophenol:[39,40]

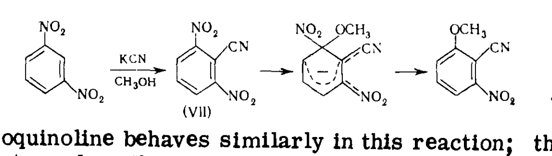


Presumably the residue eliminated here is a free hydride ion, which is accepted by the oxidant. The oxidant may be potassium nitrate or hexacyanoferrate(III). In the absence of an oxidant, nitrobenzene itself plays the role of the hydride ion acceptor, being reduced to azoxybenzene:

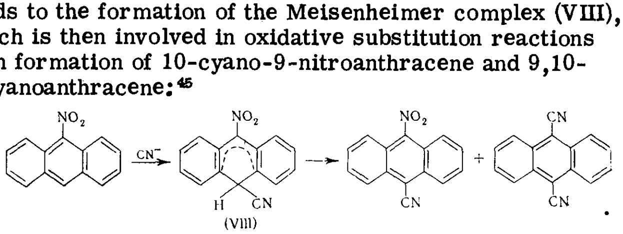
$$C_6H_5NO_2 \xrightarrow{H^-} C_6H_5{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}C_6H_5$$

Trinitrobenzene readily exchanges one of its hydrogens for a hydroxy-group, forming picric acid when it is acted upon by an alkaline solution of potassium hexacyanoferrate(III).[41]

The cyanide ion is able to substitute hydrogen in the 2-position of *m*-dinitrobenzene[42]; the nitro-compound present in excess serves as the H^- acceptor. It is of interest that the reaction does not then stop. The dinitrobenzonitrile(VII) formed is so electrophilic that it captures an alkoxide anion, the steady-state concentration of which is undoubtedly very low. Under these conditions, one of the acceptors (the nitro-group) leaves the system:

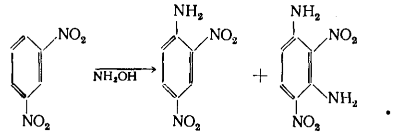


6-Nitroquinoline behaves similarly in this reaction; the heteroatom plays the role of a second nitro-group.[43] Picric acid forms a disubstitution product with KCN, the capture of hydride residues proceeding via an intramolecular mechanism and being completed by the formation of a hydroxylamine derivative[44]. The reaction of 9-nitroanthracene with the cyanide ion in dimethylformamide leads to the formation of the Meisenheimer complex (VIII), which is then involved in oxidative substitution reactions with formation of 10-cyano-9-nitroanthracene and 9,10-dicyanoanthracene:[45]

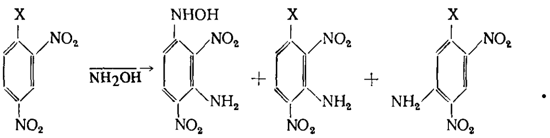


(VIII)

The reaction of dinitrobenzene with hydroxylamine in an alcoholic alkaline solution, discovered by Meisenheimer and Patzig[46], is an interesting example of the direct substitution of hydrogen by a nucleophile:

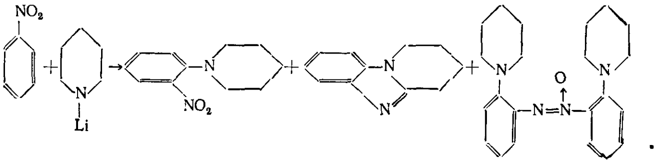


The reaction proceeds under mild conditions and with an almost quantitative yield, which makes it preparatively important. It was established that the introduction of a methyl group lowers the reactivity of dinitrobenzene, while the introduction of a nitro-group increases it. Subsequently Gitis et al.[47] established the mechanism of this reaction; they also made a more detailed study of the influence of the ring substituent on the reactivity of *m*-dinitrobenzene and identified three types of substitution products[48]:



On reaction with hydroxylamine, 2-nitronaphthalene forms 2-nitro-1-naphthylamine, while trinitrobenzene gives rise to picramide.[46]

Alkyl and aryl derivatives of lithium and Grignard reagents reduce nitro-compounds. In contrast to this, organic amides give rise to the substitution of the hydride ion. Thus lithium piperidide reacts with nitrobenzene to form a low yield of the *ortho*-substitution product (IX) together with its ring-closure product [1,2-tetramethylenebenzimidazole (X)] and reduction product [2,2′-dipiperidinoazoxybenzene (XI)]:[49]

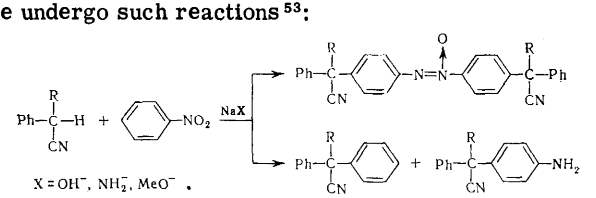


(IX) (X) (XI)

The sodium salts of amines form as a rule *para*-substitution products: on reaction with nitrobenzene, sodium piperidide yields 9-(*p*-nitrophenyl)piperidine[50], while the potassium salt of carbazole forms 9-(*p*-nitrophenyl)carbazole[51]. Sodium diphenylamide is involved in a similar reaction[52].

Contrary to expectation, on being mixed with sodamide in liquid ammonia, nitrobenzene is not involved in a Chichibabin substitution reaction, but forms a complex mixture of unidentified products[50].

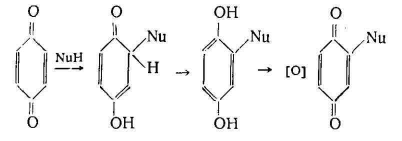
The carbanions formed from CH acids in the presence of bases give rise to Meisenheimer complexes on reaction with polynitro-compounds[15]. These are usually fairly stable products, but can be converted into substitution products by choosing an appropriate oxidant[37,38]. Comparatively recently, it proved possible to make nitrobenzene undergo such reactions[53]:



III. S_NH REACTIONS OF QUINONES

Quinones are not aromatic compounds; they can be classified as unsaturated cyclic $\alpha\beta$-diketones. However, although ketones do not in fact belong to the class of aromatic compounds, they are very close to them genetically and readily regenerate a benzenoid structure. Comparison of similar S_NH reactions of quinones and aromatic (and heteroaromatic) compounds permits a better understanding of the general nature of such processes. The reactions of quinones with nucleophiles are of interest as models of oxidation-reduction processes occurring in organisms with participation of *p*-benzoquinone and 1,4-naphthoquinone derivatives—ubiquinones and tocopherylquinones[54,55].

Quinones are involved in these processes as fairly active electrophiles—their interaction with uncharged nucleophiles involves the simultaneous nucleophilic substitution of hydrogen in the quinone and the electrophilic substitution of hydrogen in the nucleophile:

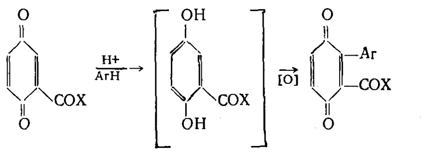


(XII)

There is an initial 1,4-addition of the nucleophile to the quinone, completed by the formation of adducts having the structure of hydroquinones (XII). In order to convert them into substitution products, it is sometimes necessary to use an oxidant, although in certain instances intermediates of type (XII) have not been detected, the final substituted quinone being formed[29].

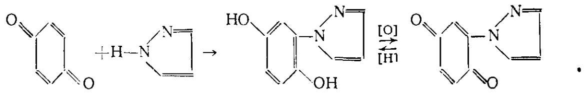
Reactions in which quinones form neither addition products nor hydrogen substitution products in the absence of an oxidant,[57] are discussed below.

It has been shown that benzoquinone and its carbonyl derivatives react under conditions of acid catalysis with nucleophiles such as dimethylaniline, phenols, or their ethers, and even alkylbenzenes.[58] With few exceptions, the reactions proceed at room temperature and are completed by the formation of arylbenzoquinones. Ag_2O is used for the oxidation of the adduct:



X=Me, OR .

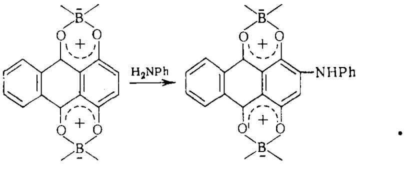
The interaction of quinones with heteroaromatic compounds having an excess of π electrons (pyrrole, furan, etc.) also leads to the formation of products of the substitution of hydrogen in quinones under oxidative conditions[59-61]. Pyrrole forms mono- and di-addition products involving the 2- and 5-positions or the 3-position, when the first two are occupied. Pyrazole reacts at the nitrogen atom and, as in the preceding case, the addition products are readily and reversibly oxidised[61]:



The interaction of benzo- and naptho-quinones with thiophen[62], furan[63,64], enol ethers[61], and CH acids[65] has also been investigated.

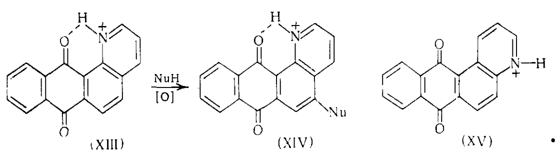
When reactions with diene-like nucleophiles (for example indole) are considered, one must bear in mind the possibility that quinones are involved not only in S_NH reactions but also in Diels–Alder addition reactions[29], which has not always been taken into account[66,67].

Direct nucleophilic attack on the quinone fragment is impossible in 9,10-anthraquinone, its activating effects being merely transmitted to the adjacent benzene ring. For this reason, anthraquinones are relatively inactive in the S_NH reactions characteristic of benzo- and naphthoquinones. For example, anthraquinone-2-sulphonic acid gives rise to alizarin only on being fused with alkali[68]. Anthraquinones containing in the *peri*-position with respect to the carbonyl group a substituent capable of combining with a proton and forming a chelate ring acquire greatly enhanced electrophilic properties and readily react with nucleophiles. Electronic interactions in chelate rings influence the distribution of electron density in the ring with the substituent, which is reflected in the localisation of the $C_{(2)}-C_{(3)}$ bond[69]. The influence of chelate formation on the reactivity is also manifested by the fact that 1-hydroxyanthraquinone is much more reactive in hydride-ion substitution reactions than 2-hydroxyanthraquinone. The involvement of boric acid as a catalyst in the arylamination of quinizarin[56] consists in the formation of a chelate ring, which increases sharply the reactivity of the substrate:



Direct amination with ammonia[70] and secondary amines[57] of 1- and 2-hydroxyanthraquinones and the substitution of hydrogen in the alkyl- and aryl-amine residues in quinizarin[71,72], 1-amino-4-hydroxyanthraquinone, and 1,4-diaminoanthraquinone[73] also belong to reactions of the type under consideration.

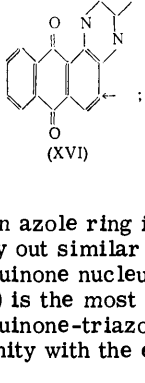
In a series of studies by Gorelik and coworkers, the influence of the heteroaromatic ring of the azine or azole type annelated to anthraquinone on the reactivity of the system with respect to a nucleophile was elucidated. The very important problem in the chemistry of anthraquinone discussed above, namely the increase of its electrophilic properties as a result of the involvement of the carbonyl group in chelate formation, is being solved by the synthesis of structures in which a favourable position of the protonated heterocyclic nitrogen permits the formation of a chelate ring with an intramolecular hydrogen bond. Under these conditions, two factors have a synergistic effect: the formation of the ammonium (azinium) cation and the enhancement of the electron-accepting properties of the carbonyl group. For example, the cation (XIII) reacts smoothly with thiophenoxides, sulphinic acids[74], and alkylamines[75], forming the substitution products (XIV):



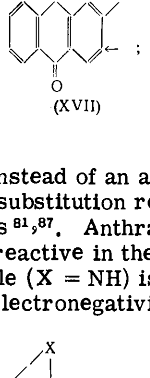
(XIII) (XIV) (XV)

The quinone (XV) does not enter into these reactions[74], which demonstrates the validity of the conclusion[69] that chelate formation plays an important role in the transfer of the positive charge in the chain and that there is conjugation in structures of type (XIII).

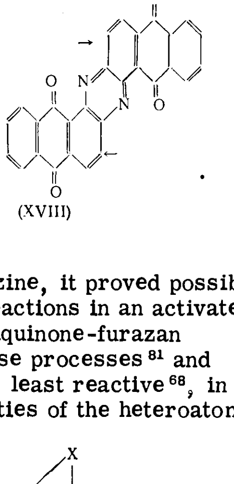
The activation of the anthraquinone nucleus by the annelation of an azine has been demonstrated for naphtho[2,3-*a*]phenazine-8,13-dione (XVI)[76-78], naphtho-[2,3]quinoxaline-7,12-diones (XVII)[79], and anthraquinone-azine (XVIII)[80][‡]:



(XVI)

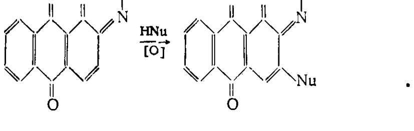


(XVII)



(XVIII)

Using an azole ring instead of an azine, it proved possible to carry out similar substitution reactions in an activated anthraquinone nucleus[81,87]. Anthraquinone-furazan (X = O) is the most reactive in these processes[81] and anthraquinone-triazole (X = NH) is least reactive[68], in conformity with the electronegativities of the heteroatoms:



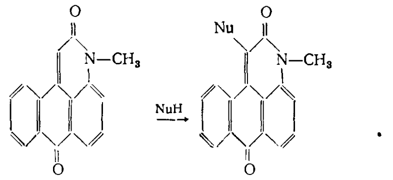
Although in the majority of cases S_NH reactions take place in the anthraquinone nucleus, nevertheless nucleophilic attack involving also the annelated fragment has been described[78], in agreement with the results of quantum-chemical calculations[88].

The substitution of hydrogen atoms in anthrapyridone has been observed on treatment with amines[89], cyanide ions, and hydroxide ions[90]. The distribution of π-electron density and other reactivity indices of anthrapyridone are different[91] from those of the anthraquinones discussed

---

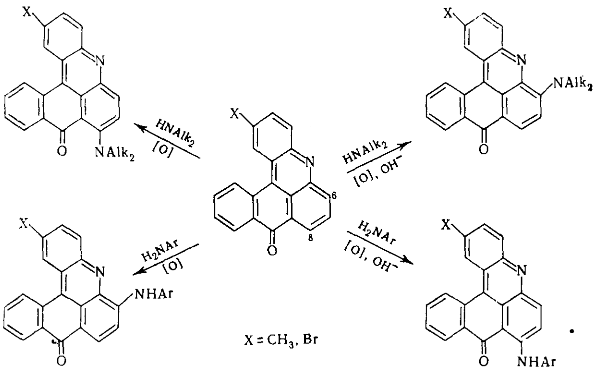
[‡] The arrows indicate the direction of nucleophilic attack.

above, since substitution takes place in the pyridine fragment. It is of interest that *N*-unsubstituted anthrapyridone does not react with amines, although this finding has not so far been explained:



The so-called ceramidonine—9*H*-naphtho[3,2,1-*kl*]-acridin-9-one–is an analogue of anthrapyridone. In contrast to anthrapyridone, in this case hydrogen is substituted in the anthraquinone part of the molecule[92,93]. The reaction is carried out in solution in pyridine under oxidising conditions, $KClO_3$ or $FeCl_3$ being used as oxidants.

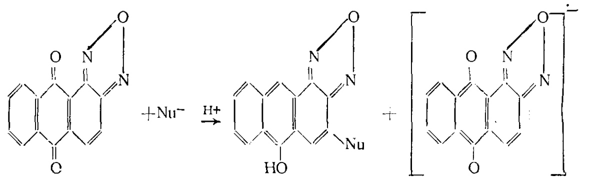
The direction of nucleophilic attack depends significantly on the nature of the amine and the presence of a base[92]. In the absence of bases, alkylamines substitute hydrogen in the 8-position and arylamines in the 6-position. The introduction of an alkali metal or tetraethylammonium hydroxide into the reaction mixture alters the orientation of the nucleophile and under these conditions an aromatic amine is directed to the 8-position and an aliphatic amine to the 6-position. A rare instance of the substitution of hydrogen rather than the halogen has been noted in the reaction of cyclohexylamine with 5-chloroanthraquinone-thiadiazole, in which the chlorine is activated with respect to nucleophilic substitution, according to current views, by both anthraquinone and thiadiazole components[94]:



A change in the direction of nucleophilic attack has also been observed in the amination of 1-hydroxyanthraquinone[72] by secondary alkyl amines. In aqueous solutions of dimethylamine and piperidine, the alkylamine residue substitutes hydrogen exclusively in the 2-position, while in pyridine solution substitution in the 2- and 4-positions takes place with formation of a mixture of products. In the absence of a solvent, 1-hydroxyanthraquinone gives rise to 1-hydroxy-2,4-dipiperidinoanthraquinone. The different modes of reaction have been explained by the characteristics of the solvation of both the initial amine and of the transition state arising when the 2- and 4-positions are attacked.

The role of the oxidant in the reactions of anthraquinone derivatives discussed above is exceptionally important. It determines the mode of reaction and the yield of products. In the oxidation of the unstable intermediate formed reversibly[95], the reaction is directed towards the nucleophilic substitution of hydrogen. In the absence of atmospheric oxygen or another oxidant, there is a possibility of several types of interaction of quinones with nucleophiles: (a) the reaction proceeds via the abstraction of a hydride ion from the intermediate by the initial quinone[82]; (b) the substitution reaction does not occur, the dimerisation of the substrate with formation of the corresponding bianthraquinonyl being observed[72,95]; (c) when the molecule contains a group capable of anionic stabilisation, it is substituted (for example, a hydroxy-group)[57].

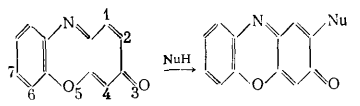
The interaction of anthraquinones with nucleophiles can occur during the initial period as a donor–acceptor process and instances of complete charge transfer have been noted. Thus radical-anions have been detected in the reactions of hydroxide ions with quinones[96] and of anthraquinones with sulphite ions[97,98], in the direct amination of quinizarin[57], and also in the nucleophilic substitution of hydrogen by CN^-, OH^-, and $OAlk^-$ ions in anthraquinone-furazan[84]:



(XIX) (XX)

Most of the initial quinone (XIX) is converted into the stable radical-anion (XX). It is believed that the formation of charge-transfer complex does not constitute an intermediate stage but proceeds as a parallel reaction[86]. On the other hand, it has been suggested that the radical-anions may precede the formation of σ complexes[97,98].

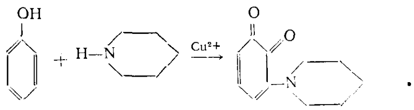
A series of studies have been made on the S_NH reactions of phenoxazinone derivatives[99–107]. In the fractions investigated, phenoxazinone, which contains the quinone imine fragment in its structure, exhibits much similarity with quinones:



Like quinones, phenoxazinones are capable of having their hydrogen substituted under oxidising conditions by residues of nucleophiles such as thiophenols[100], alkylamines[101], arylamines[102], arenesulphinic acids[103], and mercapto-compounds[104]. Hydrogen is apparently substituted always via a stage involving the formation of an intermediate addition product, which can be isolated when the experiment is carried out in the absence of air[105].

A systematic study has been made of the influence of the annelation of benzene rings on the electrophilic properties of phenoxazinone[106,107]. Analysis of the electronic structures of 2-phenoxazinone and its derivatives by the LCAO-MO method in the Hückel approximation showed[106] that benzophenoxazinones in which benzene is not annelated to the quinone imine component, contain, apart from the 7-position, a second electrophilic centre—the *peri*-position with respect to the heterocyclic nitrogen in the quinonoid ring. The calculated data were confirmed experimentally; a mixture of three compounds was found in the reactions of 3-phenoxazinone with thiophenols: 7-substituted, 1-substituted, and 1,7-disubstituted 3-phenoxazinone derivatives[107]. The method of oxidative amination of phenols discovered in 1955 by Brackman and

Havinga[108] has considerable synthetic possibilities. The above workers established that amino-*o*-quinones can be obtained by oxidising phenol and 2-naphthol with oxygen in the presence of the copper complex of morpholin.



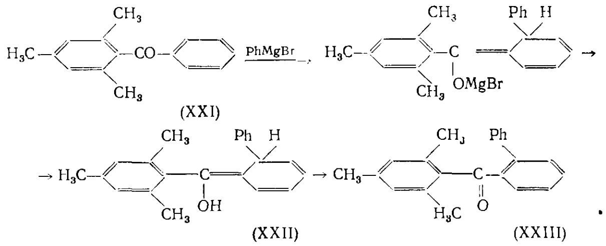
Phenol is initially oxidised to *o*-quinone, which then undergoes the S_NH reaction. Still earlier it was shown that catechol is involved in the oxidative amination reaction[109]. Sodium iodate in alcohol can also be used as the oxidant in this reaction[110].

Subsequently this method was successfully extended to phenols containing annelated azine[111–115] and azole[116,117] rings. In the oxidation of heterocyclic phenols in the presence of the copper(II) complex of a secondary amine, the corresponding *o*-quinones are usually formed with the amine residue in the quinonoid component[118], although in certain cases the heterocyclic fragment of the molecule is aminated[114,117]. Annelation of the quinone ring leads to a redistribution of electron density in the heterocyclic part of the molecule and alters significantly the nature of its reactivity. Isoquinoline quinones, for example, are aminated in the 3-position, although nucleophilic agents usually attack the $C_{(1)}$ atom of isoquinoline.[18]

IV. OTHER INSTANCES OF S_NH REACTIONS

As far as we are aware there are no examples in the literature of the activation of the nucleophilic substitution of hydrogen by SO_2R, CN, and $\overset{+}{N}R_3$ groups. The explanation is probably the tendency of the groups themselves to be split off in the form of anions on treatment with nucleophilic agents.

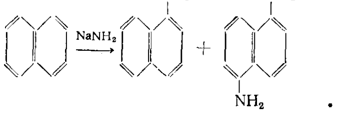
However, there are examples of S_NH reactions in systems activated by the carbonyl or carboxy-group. Thus phenylmagnesium bromide attacks the *o*-position relative to the carbonyl group in the reaction with benzoylmesitylene (XXI), forming 2′-phenylbenzoymesitylene (XXIII). The dihydro-compound (XXII) can be sometimes isolated in small amounts as a side product[119]:



(XXI) (XXII) (XXIII)

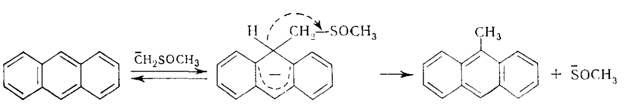
p-Hydroxybenzoic acid mixed with salicyclic acid can be obtained by fusing potassium benzoate with potassium hydroxide[120].

In 1901, Sachs[121] discovered the reaction which is a unique instance of an S_NH process in a non-activated aromatic system: fusion of naphthalene with sodamide leads to the substitution of hydrogen with formation of a mixture of 1-naphthylamine and 1,5-naphthylenediamine:



It is even more surprising that naphthols and naphthylamines, which occur in an anionic form in the presence of bases and should be highly deactivated with respect to nucleophilic attack, undergo similar reactions. However, 1- and 2-naphthols form 5-amino-derivatives, while 1- and 2-naphthylamines give rise to 1,5- and 2,5-naphthylenediamines respectively in yields of 20–50%.

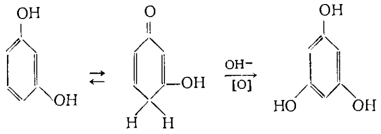
The nucleophilic alkylation of anthracene and phenanthrene by dimethyl sulphoxide and methyl phenyl sulphone[122–124], the carbanions of which are formed under the influence of sodium hydride in hexamethylphosphoramide, was reported in 1966. According to the authors[124], the formation of the final methyl derivatives takes place as a result of a hydride shift and the removal of the sulphinate residue from the anionic σ complex (XXIV):



(XXIV)

It is striking that systems with reduced aromaticity undergo this reaction, while benzene, naphthalene, and thionaphthene do not.

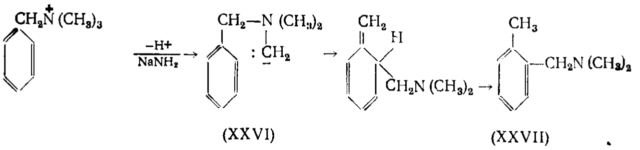
The nucleophilic substitution of hydrogen in the system activated more with respect to electrophilic attack than with respect to nucleophilic attack is represented by the reactions of phenols with alkalis, which lead to the formation of polyphenols with evolution of hydrogen. For example, when resorcinol is fused with alkali, phloroglucinol is formed[120]. This is explained by the fact that a tautomeric form of resorcinol (XXV) enters into the reaction and the latter reduces intrinsically to the substitution of hydrogen in a quinonoid system[50]. The reaction occurs only in the presence of an oxidant[125,126].



(XXV)

Certain intramolecular octet rearrangements and anomalous reactions can probably be classified as S_NH processes. Such intramolecular substitution of the hydride ion occurs, for example, in the Sommelet–Hauser rearrangement[127–129].

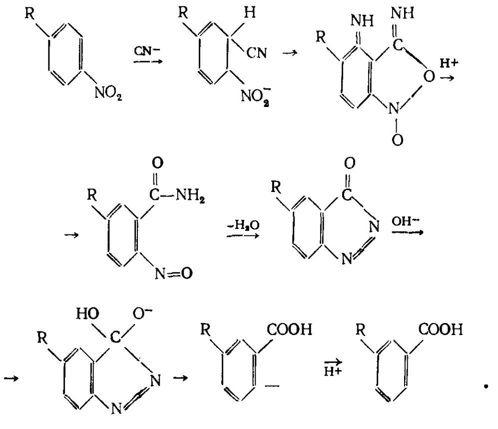
When quaternary benzylammonium salts are treated with strong bases, a proton is abstracted with formation of the ylid (XXVI). The free electron pair then attacks the aromatic ring, which has been activated by the ammonium group whose influence is transmitted via the methylene bridge:



(XXVI) (XXVII)

If the product (XXVII) is remethylated and again subjected to the rearrangement, it is possible to introduce another methyl group into the ring and continue in this way until the hexasubstituted benzene derivative is obtained[129].

The interaction of halogenonitrobenzens with KCN in ethanol at 150°C (the Richter reaction)[130,131] also constitutes essentially an S_NH reaction. Formally, this involves the substitution of the nitro-group, but the COOH group is not found at the site previously occupied by the nitro-group. The mechanism of this reaction has been the subject of a prolonged discussion; the mechanisms proposed by Rosenblum[132] are supported at the present time. It has been incontrovertibly demonstrated that the first stage involves the formation of an anionic σ-complex followed by the removal of hydride-active hydrogen from the latter:



V. S_NH REACTIONS OF AZA-ACTIVATED SYSTEMS

The substitution of a hydrogen atom with its binding electrons in the aromatic cyclopropenylium and tropylium carbonium ions and also in oxa-, thia-, and selena-activated heteroaromatic compounds is described in reviews published in 1974–1975.[6,133]

Aza-activation plays an exceptionally important role in the above processes. In the simplest azine (pyridine), the aza-group exhibits a polarising activity as powerful as that of the exocyclic nitro-group in nitrobenzene. The enhanced reactivity of azine compounds is observed in the *o*-(α-) and *p*-(γ-)positions, where the entropy of activation for electrostatic attraction is greatly enhanced. The nitro-group is known to have a stronger activating influence than the aza-group in the nucleophilic substitution of anionically stabilised species in aromatic systems ($k_{NO_2}/k_{aza} > 1$).[18] However, the intrinsic nucleophilic properties of the aza-group are responsible for its tendency to undergo specific proton solvation, which leads to an increase of reactivity and the reversal of the reactivity sequence: $k_{NO_2}/k_{aza} < 1$.

Only rare instances of S_NH reactions in aromatic aza-systems where neither the reactant nor the substrate is charged are so far known. In the vast majority of cases, the substitution of hydrogen may be achieved by the additional activation by the charge of either the attacking reactant (nucleophile) or the substrate (azine). The papers published up to 1960–1965 were devoted to reactions involving the anionic form of the attacking reactant (H_2N^-, CN^-, and OH^-) and also to organometallic compounds in which the carbon–metal bond is to a large extent polar. These studies have been described in a number of reviews and monographs[2,18,19,134,135]. Whereas only isolated studies using the cationic activation of the azine by its conversion into the *N*-acylammonium form have been made up to that time[136-140], in the last ten–fifteen years systematic investigations have been made and considerable advances have been achieved in the field of the nucleophilic reactions of acylammonium cations[7,9] and also cations arising on formation of azine *N*-oxides[8,141].

This section deals with problems of the activation of aromatic aza-compounds by quaternisation and protonation and also the involvement of nucleophilic substitution of systems not activated by a charge, which have not so far been dealt with in the reviews already published.

1. Quaternary and Protonated Salts

Quaternary and protonated azine salts are on the whole less electrophilic than the corresponding *N*acyl salts[7] or *N*-oxide ethers[8]. Their reduced reactivity is undoubtedly a consequence of the fact that the alkyl group and the proton exhibit electron-donating properties, in contrast to the electron-accepting properties of the acyl or ether residues. Aryl residues occupy an intermediate position between these two types. The use of quaternary and protonated salts is preparatively simpler and in addition makes it possible to introduce them into compounds containing OH, NH_2, and NHR groups, which cannot be done with acyl salts, owing to the transacylation which occurs under these conditions.

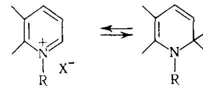
It has been frequently postulated that the mechanism of the S_NH reactions of azines involves "addition–elimination"[1,7-10], but kinetic data[142,143] confirming the validity of these hypotheses have been obtained only in recent years.

The formation of intermediate addition products on substitution of hydrogen in azinium cations can be observed experimentally, as in the corresponding processes with participation of nitro-activated systems and quinones. The profile of the potential energy surface of the delocalisation of the negative charge following the introduction of additional aza-groups or benzo-annelation constitutes a favourable factor, stabilising σ complexes, lowers the energy of their formation and thereby increases the reactivity of the initial azinium cations. For this reason, the manifestation of the higher reactivity of aza- and benzo-azines compared with the simplest azine (pyridine) is to be expected in S_NH reactions and in the substitution of the groups eliminated.

Quaternary salts constitute a very convenient object for study, since the addition product formed is uncharged and is therefore more stable than the classical Meisenheimer anionic complexes. This makes it possible to investigate in detail the structures of such compounds, including X-ray diffraction analysis, which is particularly important for the understanding of the stereochemistry of the transition state[12].

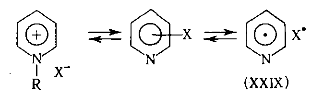
Reactions leading to the substitution of hydrogen under the influence of anionic and anionoid reagents are known in the series of quaternary and protonated salts of azines. Reactions with negatively charged species have been studied in greatest detail. A tendency towards interaction with nucleophilic agents is manifested by the azinium cations within the quaternary salts themselves. A classical example of such an interaction between the cation and anion, accompanied by charge transfer, is provided by alkylpyridinium iodide and its analogues[144-146].

The enhancement of the nucleophilic properties of the counterion in the series $ClO_4^- < C_6H_5SO_3^- < NO_3^- < CH_3COO^- < OCH_3^- < Cl^- < Br^- < N_3^- < OH^- < SCN^- < I^- < CN^- < S_2O_3^-$ [147,148] leads to an equilibrium between anions such as CN^-, SH^-, and OH^- and covalent structures, which is strongly displaced to the right[149-151]. The stability of covalent compounds of type (XXVIII) also increases in the sequence pyridine < quinoline < acridine.



(XXVIII) .

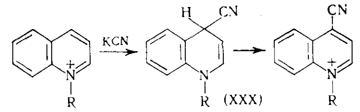
Complexes with partial charge transfer and biradical species, usually arising in an excited state, occupy an intermediate position between the purely ionic salts ($X = ClO_4$ or NO_2) and covalent structures—the so called "cryptosalts"[149] (X = CN or OH).



(XXIX) .

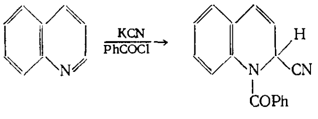
Charge-transfer complexes similar to compound (XXIX) can in all probability play in important role in the mechanism of S_NH reactions.

Alkylpyridinium salts and their analogues readily react with potassium cyanide in an aqueous medium[152-154], forming initially the dihydro-compounds (XXX), which may be oxidised by iodine to the corresponding nitriles[152], for example:



(XXX) .

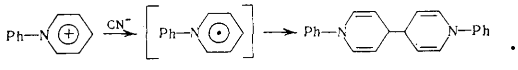
Dihydroquinoline (XXX) is an analogue of Reissert's compounds[155], which arises in the reaction of an acylquinolinium salt with the cyanide ion:



(XXXI) .

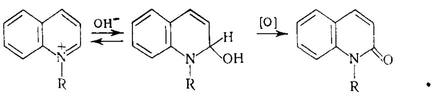
The causes of the formation of the 4-addition [compound (XX)] and 2-addition [compound (XXXI)] products when alkyl- and acyl-quinolinium cations are attacked respectively have not been elucidated[156]. The reactions of the cyanide ion with alkylacridinium[157] and phenanthridinium[158] salts occur similarly. The micellar catalysis by surfactants of the reaction of cyanide with a quaternary salt of nicotinamide[159] has been investigated and it has been established that the rate constants increase in the presence of low concentrations of the detergent and following the addition of zwitterionic compounds.

Certain data concerning the mechanism of the reaction of the cyanide ion with azinium cations have now been obtained. In particular, it has been established that the product of addition in the 2-position is formed initially and then rearranges to the corresponding 4-derivatives[160], which resembles the formation of Servis complexes in the series of aromatic nitro-compounds[15]. When phenylpyridinium chloride was allowed to react with the cyanide ion in an inert atmosphere in an aqueous acetone solution, *N*-phenylpyridyl radicals were detected[161] and the reaction led to the isolation of a dimeric product without nitrile groups:



This led the authors to the hypothesis that the interaction of quaternary pyridinium salts with CN^- proceeds via a one-electron mechanism: in the absence of air, it is completed by the recombination of the intermediate radicals. The presence of oxygen is responsible for another course of the reaction: an addition product is formed, which can then be subsequently oxidised with elimination of the nitrile residue[157].

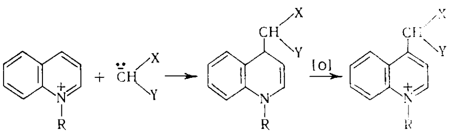
Pozharskii et al. recently demonstrated the substitution by the amide ion of the hydrogen in methylacridinium iodide, which is so far the only example of the involvement of a quaternary salt in the Chichibabin reaction[162]. The final product of the familiar interaction of azinium cations with the hydroxide ion may be regarded as a result of the substitution of hydrogen when the reaction is carried out in the presence of an oxidant, for example potassium hexacyanoferrate(III):



In the absence of an oxidant, there is also a possibility of the formation of oxo-compounds mixed with an equal amount of the dihydro-compound as a result of the disproportionation of pseudobases[163]. Such disproportionation of pyridine and quinoline proceeds via the open-chain form of the pseudobase (derivatives of glutaconaldehyde[164]).

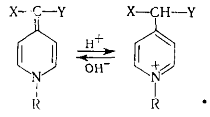
The reactions of carbanions of the type $\bar{C}H_2$–COX include the interaction of pyridinium and benzopyridinium salts with methyl ketones, β-dicarbonyl compounds, cyanoacetic ester, etc. in the presence of strong bases[165-170].

The reactions of CH-active compounds with azinium cations are of interest as models of the addition of acetone and hydroxyketones to diphosphopyridine dinucleotide[171], discovered in 1954. Pyridinium and quinolinium cations usually form 4-substituted products[165,167,169,170], while isoquinolinium[165,172] and acridinium[166,173,174] cations form 1- and 9-substituted products respectively:



Here X = H, $COOCH_3$ or CN and Y = NO_2, CN, $COOCH_3$, or COC_6H_5.

Adducts, which are probably intermediate in the formation of substituted products although this has not been demonstrated kinetically, can be frequently isolated from the reaction mass. The stability of the addition products increases with decrease of the aromaticity of the initial azines: pyridine < quinoline < acridine. Dihydro-compounds are readily oxidised in air[173] and can be dehydrogenated by other oxidants: lead tetra-acetate in benzene, permanganate in acetone, chloranil, etc.[174,175]. In the presence of alkalis, the oxidation of adducts leads to the formation of coloured "dihydrocompounds" (XXXII) of the quinonoid type, which are rearomatised on treatment with acids[165]:



(XXXII)

The methyl groups in the α- and γ-positions relative to the aza-group in heteroaromatic compounds are known to exhibit some CH acidity. It has been shown that these compounds are able to react with the acridinium in the absence of base catalysis[176-179]. However, one cannot rule out the possibility that the catalytic effect is shown by the reactants themselves, which are bases. Methylated heterocycles, both in the form of bases and quaternary or protonated salts, can be made to react with the acridinium cation. In its turn, the substrate can be used also in the form of the protonated salt and, in the presence of active nucleophiles (quinaldine and lepidine), hydrogen can be substituted in the acridine base too. The condensation takes place under oxidising conditions; suitable oxidants are sulphur (melt) and atmospheric oxygen bubbled through a solution in a polar solvent.

Table 2. The rate constants for the methylation of heterocycles by acridine hydrochloride (in DMF, 120°C, bubbling with air).

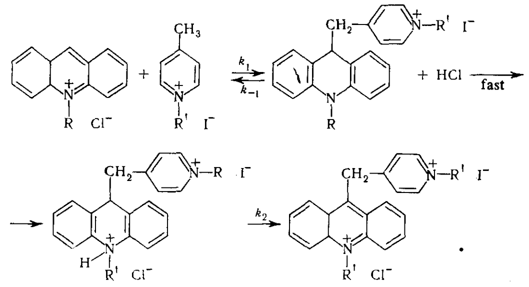
Heterocycle	10^3k, litre mole^{-1} s^{-1}
4-Picoline methiodide	0.50±0.01
4-Picoline ethiodide	0.51±0.01
4-Picoline N-2-propiodide	0.47±0.01
2-Picoline methiodide	0.132±0.007
4-Methylquinoline methiodide	0.50±0.002
2-Methylquinoline methiodide	0.248±0.016
2-Methylbenzothiazole methiodide	0.183±0.003
2-Methylbenzimidazole methiodide	0.031±0.002
Acridine + 4-picoline methiodide	0.062±0.003

This reaction is unusual because it proceeds only in the presence of an oxidant and the addition products characteristic of acridine in an inert atmosphere cannot be detected even in the ultraviolet spectra of the reaction mixtures[142].

The study of the kinetics of the reaction of acridine hydrochloride with the quaternary salts of methylated heterocycles under the conditions of a zero-order reaction with respect to oxygen showed that it is of second order overall and of first order with respect to each reactant. The rate constants are listed in Table 2. The reactions proceed with low activation energies (9–13 kcal mole^{-1}).

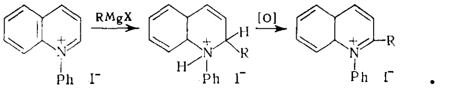
The reactivities of the heterocycles in this reaction (4-methylquinoline > 4-picoline > 2-methylquinoline > 2-methylbenzothiazole > 2-picoline > 1,2-dimethylbenzimidazole) are consistent with the acidities of the protons of the methyl groups based on deuterium-exchange data[180]. Protonation of acridine increases the rate of reaction and the electron-donating properties of the alkyl chain hardly influence the rate.

In many instances the kinetic curves are S-shaped owing to an induction period, which decreases with increase of temperature and the concentrations of the reactants. This shows that the reaction proceeds via an intermediate compound, which is present at a vanishingly low quasistationary concentration.



The example discussed demonstrates the decisive role of the oxidant in both S_NH reactions, where the σ complex is formed at a quasistationary concentration and the substitution of hydrogen can be achieved only in the presence of an oxidant.

As already mentioned, the carbon–metal bond in organometallic compounds, including Grignard reagents, is highly polarised and approaches a linkage of the ionic type. The reactions of alkyl- and aryl-azinium cations with organometallic compounds constitute an example intermediate between their reactions with anions and uncharged species. Quaternary pyridinium salts and their benzo-derivatives combine with Grignard reagents to form dihydro-compounds[181-185], which are mainly unstable and are readily oxidised to the corresponding substitution products[182]:



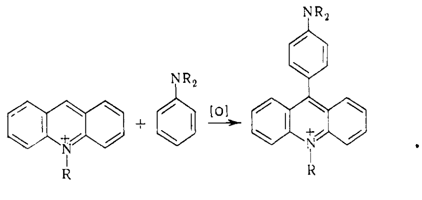
The analogous interaction of benzylpyridinium chloride with cyclopentadienyl-lithium is completed by the substitution of the hydride ion[186].

Among the uncharged nucleophiles used to substitute hydrogen in heteroaromatic cations, mention should be made of alkyl- and aryl-amines and their derivatives, heterocycles with an excess of π electrons, and phenols[187-198]. These are undoubtedly much weaker nucleophiles than anionic reagents. Whereas in the series of acyl salts[7] and *N*-oxide ethers[8], the S_NH reactions of anionoid reagents can be achieved even with pyridine, among the quaternary salts those of quinoline and isoquinoline are inactive[199], although their protonated salts can be made to react in this way[200,201]. The cations whose activity has been increased by benzoannelation (acridine[187]) or by an additional aza-group (diazanaphthalenes[198,202,203]) react smoothly with uncharged nucleophiles, forming adducts or hydrogen substitution products depending on the nature of the substrate.

The quaternary salts derived from acridines, both unsubstituted and containing substituents in the 9-position[204], instantly combine with alkylamines, forming the corresponding acridans. Acridans, containing hydrogen at the geminal site, may be oxidised by an acridinium salt as a result of an intermolecular hydride transfer[205].

The hydride ion is abstracted and substituted in the *N*-alkylacridinium cation following attack by arylamines under oxidising conditions (melt with sulphur, bubbling of air through a solution in dimethylformamide or dimethyl sulphoxide). It has been shown that in the melt with sulphur the reaction does not proceed via a stage involving the preliminary thionation of acridine, sulphur behaving merely as an oxidant[189]. The yields of aminoarylacridinium salts are 80–90%. The side products are acridinone or thioacridinone depending on the experimental conditions.

Arylamines containing various substituents in the ring and in the aminogroup, including arylhydrazones of aldehydes and ketones and carboxylic acid arylhydrazides, may be used in these reactions[206]:



Halogens exhibiting an appreciable *–I* effect lower the reactivity of arylamines; groups with a *–M* effect fully deactivate the nucleophile when they are introduced both in the ring and in the amino-group (Table 3). The basicity of aromatic amines may serve as an indirect criterion of their nucleophilic properties. Amines with a high basicity ($pK_a > 4$) readily react with the acridinium cation; amines with $pK_a = 3.5–2.5$ react but under more severe conditions; compounds with $pK_a < 2.5$ are not reactive.

Table 3. The reactions of arylamines with acridine hydrochloride.

Initial arylamine	pK_a	Reaction conditions		Yield, %

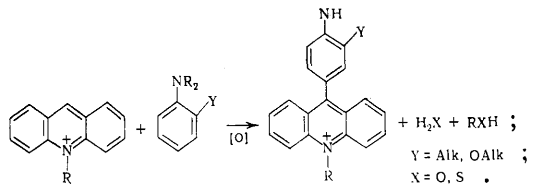
*The reaction does not occur; 9-aminoarylacridine was not detected chromatographically in the reaction mixture.

A number of anomalies have been noted in the interaction of arylamines with acridinium salts. Thus phenylhydrazine causes dimerisation of the acridine residues with formation of *NN*-dialkyl-9,9′-biacridanyls[207]. Sterically hindered arylamines behave in an unusual manner. *ortho*-Substituted dialkylanilines undergo dealkylation and monoalkyl derivatives are formed instead of the expected *NN*-dialkylaminoacridinium salts.

The alkyl group split off does not pass to the ring but is eliminated and converted into an alkanethiol when the reaction is carried out in a melt with sulphur or into an alcohol when the oxidant is oxygen[204,208]. The reactions of *NN*-dialkylanilines containing bulky residues give rise to complexes containing three iodine atoms and not to the usual 9-aminoarylacridinium iodides[209]. Such unexpected formation of tri-iodides is probably associated with electron transfer from the electron-donating reactant to the electron-accepting reactant, although one cannot rule out the possibility also of other oxidation-reduction processes, which may lead to the formation of free iodine.



Some data have been obtained for the mechanism of the reactions with arylamines. The primary interaction of the acridinium cation with a dialkylaniline results in the formation of a 1 : 1 charge transfer complex[210], which may be located on the reaction coordinate[199].

The study of the rates of the process demonstrate the absence of base catalysis, the kinetic isotope effect in the reaction with 2,4,6-trideuteroaniline being reduced approximately by a factor of three: $k_H/k_D = 2.28$ (Table 4).[143] Together with the NMR studies on the reaction mixtures, these data show that, as in the reaction with reactive methyl-substituted heterocycles, the oxidative substitution of hydrogen by arylamines proceeds via a stage involving the formation of an intermediate, which probably has the structure (**XXXIII**)§.

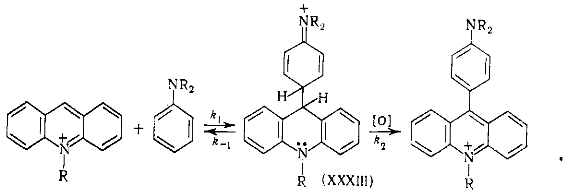


Table 4. The rate constants of the reactions of acridine methiodide with arylamines in DMF on bubbling with air.

Arylamine	Reaction temp., °C	10^2k, litre $mole^{-1}$ h^{-1}	Arylamine	Reaction temp., °C	10^2k, litre $mole^{-1}$ h^{-1}
Aniline	100	0.081	*NN*-Dimethylaniline	100	0.047
Aniline	110	0.124	*NN*-Dimethylaniline	120	0.118
Aniline	120	0.216	*NN*-Dimethylaniline	130	0.180
Aniline	130	0.293	*N*-Methylaniline	120	0.170
2,4,6-Tri-deutero-aniline	120	0.095	*o*-Toluidine	120	0.198

The activation energies are also low in this case. The appearance of a kinetic isotope effect can be explained by the high value of k_{-1}. The steric hindrance arising on

---

§The formation of the analogous σ complex of trinitrobenzene with phenol, in which the two species are connected via a C–C junction, has been demonstrated recently by NMR.[211]

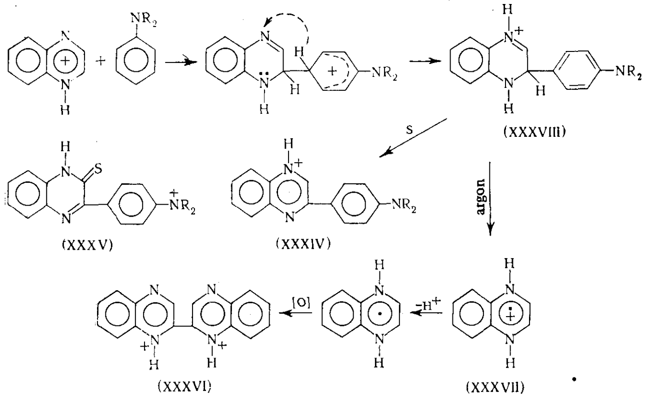
formation of the state (XXXIII) in *ortho*-substituted dialkylanilines can explain their cleavage in these reactions. The dynamics of the interaction of the alkylacridinium cation with five-membered heterocycles, such as indole, with phenols[196] is probably similar to that already discussed.

It was noted above that the introduction of an additional aza-group into the azine molecule activates it with respect to participation in $\mathrm{S_N}$H reactions. Indeed, using quaternary quinoxalinium salts, it is possible to carry out the oxidative subtitution of hydrogen by residues of nucleophilic heterocycles such as pyrrole and indoles[202]. The corresponding 3-methylquinazolinium salts give rise to anomalously stable σ complexes, which are not dehydrogenated by oxidants such as chloranil, iron(III), and sulphur[198]. This manifests the tendency of the 3-alkylquinazolinium cation towards its preferential existence in the form of dihydro-compounds, for example, covalent hydrates[212]. The 1-methylquinazolinium cation does not exhibit a tendency towards interactions of this type[203].

The interaction of protonated salts of azines with uncharged nucleophiles does not differ in principle from the reactions of the quaternary salts. However, one should bear in mind that in this instance there is a possibility of proton transfer from the substrate to the basic reactant, for example an arylamine, and the reactions then proceed with participation of equilibrium concentrations of the reactants. When the reactant is appreciably basic, this can probably constitute an obstacle to such reactions. The principles of additional activation are in this case the same as for quaternary salts and for this reason here too the most reactive compounds are acridine salts—hydrochlorides, sulphates, nitrates, phosphates[191], and salts with organic acids. The yields of the amino-arylation products are nearly quantitative when the oxidant is sulphur or air in dimethylformamide solution, while the yield of the reaction in nitrobenzene, which probably behaves as an acceptor of hydride ions, is about 46%[205]; the yields of acridinylindoles are 64–68%[213] and those of acridinylphosphonates are 70%.[214] In the series of quinoline derivatives nucleophilic hydrogen substitution reactions proceed less satisfactorily; aminoaryl derivatives are formed in yields of about 50%[200] and the yields of quinolinylindoles are 5%.[215] Derivatives of pyridine have not been obtained from its hydrochloride in these reactions.

In the reactions of both protonated and quaternary salts, the successful occurrence of the $\mathrm{S_N}$H processes depends on the correct choice of oxidant. Quinoxaline hydrochloride reacts with dimethylaniline in a melt with sulphur; together with the normal hydrogen substitution product (XXXIV) (14%), this involves the formation of the thiono-derivative (XXXV) (60%). Under argon in dimethylformamide solution, the same reactants give rise to 2,2'-diquinoxaline (XXXVI) only. When the reaction is carried out in air, no products are detected. The appearance in the reaction mass of the radical-cation (XXXVII), detected by ESR, can be explained by the homolytic decomposition of the σ complex (XXXVIII). The inhibition of the reaction by oxygen is most probably associated with chain termination via the formation of a peroxide from the radical-cation (XXXVII).[216]

The different mode of reaction in the presence and absence of oxygen in the present instance and in the cases considered previously[95,157] suggests that many of the reactions, which are usually carried out in air, may lead to other results when they are performed in an inert atmosphere.

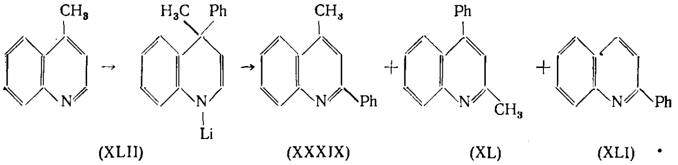


2. Azines which Are Not Activated by a Charge

The vast majority of examples of the substitution of hydrogen in aromatic aza-compounds which are not additionally activated by a charge refer to the interaction of these systems with nucleophiles having a negative charge or with very powerful uncharged nucleophiles such as organometallic compounds. These include in the first place the well known substitution of hydrogen in aza-activated compounds by the amide anion (the Chichibabin reaction) and on fusion with alkalis. These reactions have been considered in detail in a number of reviews and books[134,135]. We shall merely mention that, until recently, the Chichibabin reaction was regarded[217] as a process characteristic of six-membered nitrogenous heterocycles. Simonov and Pozharskii established that many imidazoles containing annelated benzene rings are capable of being aminated by sodamide[135]. This shows that studies on other $\mathrm{S_N}$H reactions in the series of azoles and related systems would be useful.

There is a considerable similarity between the Chichibabin amination and the reactions of aromatic aza-compounds with organometallic reagents. Examples of reactions of azines with organometallic nucleophiles have been discussed in a number of reviews[18,218]. Studies were published in 1967–1971 where the reaction mechanisms were investigated by infrared spectroscopy and NMR[219–222] and the addition products of organolithium compounds, whose formation had been previously postulated, were identified.

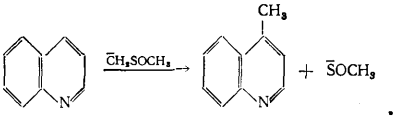
Interesting results were obtained in a study of the reactions of lepidine with phenyl-lithium[219]:



(XLII) (XXXIX) (XL) (XLI)

In this case 2-methyl-4-phenylquinoline (XL) (yield 0.5%) and 2-phenylquinoline (XLI) (yield 3%) are formed together with the main product—2-phenyl-lepidine (XXXIX) (yield 96.5%). A mechanism has been proposed according to which the addition product 1-lithio-4-methyl-4-phenylquinoline (XLII) is formed initially and then rearranges to compound (XXXIX) as a result of the nucleophilic substitution of hydrogen in the 2-position. The nucleophilic substitution of the 4-methyl group leads to compound (XL). Finally the displaced hydride ion may substitute the methyl group in the 4-position with formation of compound (XLI).

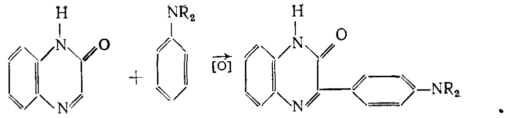
The interaction of free azines with carbanions has been described. Certain instances of such interaction were discussed above[175,176]. Almost all the reactions involve the reactive acridine, which has been shown to form addition products with aliphatic and aromatic methyl ketones in the presence of sodium methoxide[166,174]. The reactions of methyl sulphones[123] and methyl sulphoxides[122,124] with quinoline, isoquinoline, acridine, phenanthridine, and benzoxazole in the presence of sodium hydride are of interest as methods for the preparation of the corresponding methylated azines:



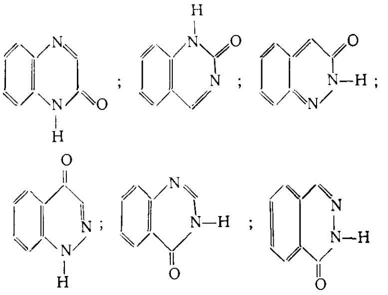
As already mentioned, even the non-activated anthracene and phenanthrene systems are involved in this reaction[122]; however, pyridine, which is more aromatic, proved to be unreactive.

The instances of the nucleophilic substitution of hydrogen where neither the attacking reactant or the substrate are activated by a charge are the rarest reactions in the heteroaromatic series. Whereas the substitution of hydrogen by uncharged nucleophiles (amines, phenols, systems with an excess of π electrons) are usual in the series of quinones, among heteroaromatic compounds these reactions appear to be the privilege of the less aromatic systems with low π-binding energies.

Thus acridine[187] and phenazine activated by the nitrogroup[223] are capable of undergoing direct substitution of hydrogen by arylamines in the presence of an oxidant. The involvement of certain diazanaphthalenones in reactions with arylamines and heterocycles having an excess of π electrons[224,225] has been recently demonstrated, for example:



According to Katritzky[226], diazanaphthalenones satisfy all the criteria of aromaticity, like other azinones, and therefore the instances under consideration can be quite justifiably classified as aromatic nucleophilic substitution reactions. Of the six isomeric diazanaphthalenones



only the first three (quinoxalinone, 2-quinazolinone, and 3-cinnolinone) are capable of undergoing reactions involving the substitution of their hydrogen on treatment with uncharged anionoid agents. Quantum-chemical analysis of the structures of these isomers and the study of the chemical shifts of the substituted protons indicate the absence of any correlation between the chemical shifts and the charge densities, on the one hand, and the reactivities of these compounds, on the other. However, calculations have shown that their reactivities vary in opposition to the energies of radical localisation and are determined by the degree of departure of the system from aromaticity[227].

Examination of literature data shows that these are as yet insufficient to give a complete idea about the criteria of the reactivity and the mechanisms of S_N^H reactions, nevertheless the considerable preparative scope of these reactions, which makes it possible to obtain compounds belonging to a wide variety of classes, should stimulate further theoretical and synthetic studies in this field.

Thermal Rearrangements of Vinylcyclopropanes

E.M.Mil'vitskaya, A.V.Tarakanova, and A.F.Plate

Various types of reactions of compounds containing vinylcyclopropane groups are considered, particular attention being devoted to data from which the mechanisms of the rearrangements can be inferred.
The bibliography includes 100 references.

CONTENTS

I. INTRODUCTION

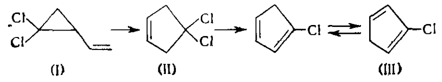
Vinylcyclopropanes are of interest for the investigation of the mutual influence of the cyclopropane ring and an unsaturated group. This influence is illustrated particularly by the relative lability of such systems, which undergo intramolecular rearrangements under various influences (for example, high temperature).

Numerous examples of thermal rearrangements of vinylcyclopropanes are now known. They have been described mainly in the last decade. The types of reactions undergone by the compounds under consideration depend significantly on their structure. In many cases, the isomerisation proceeds with formation of cyclopentenes. When the relative positions of the hydrogen atom in the 1-alkyl substituent and the vinyl group are favourable (*cis*-1-alkyl-2-vinylcyclopropane systems), electrocyclic reactions, including a 1,5-hydrogen shift and yielding dienes, take place. The reactions of divinylcyclopropanes constitute a characteristic example of the Cope rearrangement.

In the present review a systematic account is given of examples of rearrangements of vinylcyclopropanes in accordance with the types of their reactions. Particular attention is devoted to the discussion of studies whose authors attempted to elucidate the mechanisms of the reactions.

II. ISOMERISATION OF VINYLCYCLOPROPANES TO CYCLOPENTENES

The first example of this rearrangement was described in 1959 by Neureiter[1]. In a study of the thermolysis of 1,1-dichloro-2-vinylcyclopropane (I) at 475–500°C, he established that this yields a mixture the main components of which are 4,4-dichlorocyclopentene (II) and 2-chlorocyclopentadiene (III). The latter was obtained via stages involving dehydrochlorination of (II) followed by isomerisation:



(I) (II) (III) .

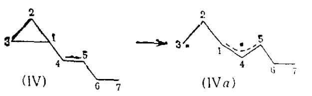
Later it was established that at a lower temperature (200–275°C) the only reaction product is the dichloride (II).[2,3]

Two pathways to the formation of a five-membered ring in this reaction are possible: the biradical pathway (via an intermediate stage involving the opening of the trimethylene ring) and the synchronous pathway (in which there is a simultaneous rupture of the three-membered ring and the formation of a new bond). The latter pathway (a 1,3-suprafacial shift with inversion at the migrating atom or an antarafacial shift with retention of configuration) is allowed on symmetry grounds.

In a number of studies (among which those of Frey must be mentioned), the kinetics of the thermolysis of various substituted monocyclic and bicyclic vinylcyclopropanes were investigated in order to elucidate the mechanism of the rearrangement (Table 1). The results are compared with the kinetic parameters of the thermal rearrangements of the corresponding alkylcyclopropanes in the discussion of the mechanisms of the rearrangements of vinylcyclopropanes. Both biradical[2,3,6,9,10,23,24] and synchronous[4,5,8,12,25] mechanisms for the formation of cyclopentenes have been proposed.

The lower activation energies for the reactions of vinylcyclopropanes compared with the values of E_a for the geometrical and structural isomerisation of alkylcyclopropanes (Table 2) and the low entropies of activation supported the synchronous mechanism[31].

However, the kinetic data obtained could be interpreted also on the hypothesis of the intermediate formation of a biradical. In this case the observed entropy of activation can be attributed to a certain rigidity of the intermediate allyl system. This rigidity is due to the increase of the potential barrier to rotation about the $C_{(1)}-C_{(4)}$ bond from 3.5 to 16.1 kcal on passing from the hydrocarbon (IV) to the corresponding allylically stabilised biradical (IVa):[15]



(IV) (IVa) .

On the other hand, the differences between the activation energies for the reactions of monocyclic vinyl- and alkyl-cyclopropane can be attributed to the involvement of the π electrons of the double bonds in the stabilisation of the biradical. Indeed, the difference between the activation energies for the reactions of 1-methyl-1-vinylcyclopropane (Table 1) and 1,1-dimethylcyclopropane (Table 2), amounting to 13.2 kcal mole^{-1}, is close to the resonance energy of the allyl radical (12.6 ± 0.8 kcal mole^{-1}), which Benson and coworkers determined experimentally[24].

Table 1.* Thermal isomerisation of vinylcyclopropanes to cyclopentenes**.

		132—160	9.69	26.3	20
	 —"—	— 108—138	13.7 13.4	33.5 34.3±1.4	21 22
	 —"—	— 108—138	13.9 17.1	33.9 39.6±1.4	21 22

Thus the kinetic data do not allow an unambiguous choice between the synchronous and biradical mechanisms of the thermal isomerisation of vinylcyclopropanes. In recent years, there has been an increase in the number of facts supporting the biradical reaction pathway.

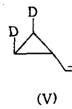
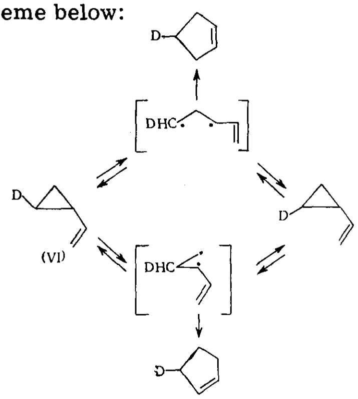
Willcott and Cargle investigated the thermal transformations of 1-(*trans*-2-deuterovinyl)-*trans*, *trans*-2,3-dideuterocyclopropane (V), and *trans*-2-deuterovinylcyclopropane (VI):



(V)

Here structural isomerisation is accompanied by a degenerate *cis*–*trans* isomerisation [32,33]. It was established that (1) the rearrangement takes place with inversion of configuration at two carbon atoms and (2) the geometrical isomerisation is at least five times faster than the formation of cyclopentenes. The results led to the conclusion that kinetically independent intermediate compounds are formed in the reaction investigated in accordance with the scheme below:

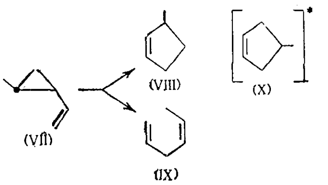


---

*Tables 1, 3, and 4 list only those examples of the reactions for which the kinetic parameters have been determined.

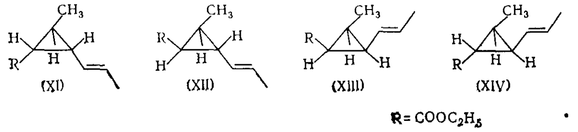
**Quantitative parameters of the simultaneous isomerisation to other olefins are quoted for some of the hydrocarbons.

The study of the thermal isomerisation of *trans*-1-methyl-2-vinylcyclopropane (VII), the reactions of which at 270–330°C proceed with the same activation parameters via two pathways, led to a similar conclusion[6,7]:

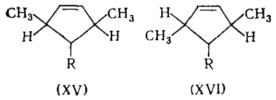


Methylcyclopentene is the "usual" product[†] of the rearrangement of vinylcyclopropanes. The diene (IX) can be formed only from *cis*-1-methyl-2-vinylcyclopropane (this will be discussed in greater detail below). Thus, the isomerisation to cyclopentene is accompanied by *trans*–*cis* isomerisation in this case too.

Data obtained in the study of the thermal transformations of the esters (XI)–(XIV) also constitute evidence against the synchronous mechanism[34]:

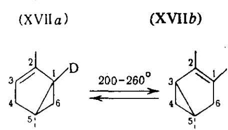


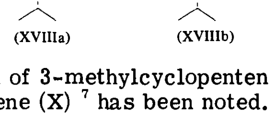
It was found that the above compounds readily undergo isomeric interconversions, the two isomeric cyclopentenes (XV) and (XVI) being also obtained, together with dienes, in various proportions (depending on the structure of the initial vinylcyclopropane).



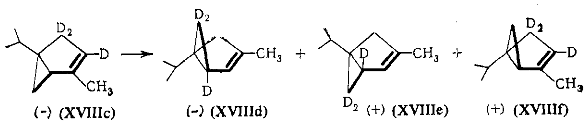
The composition of the reaction product would have been different if one of the possible symmetry-allowed 1,3-sigmatropic shifts occurred. However, according to Mazzocchi and Tamburin[34], the available data are insufficient to rule out the possibility that the reaction proceeds via a combined (concerted and non-concerted) pathway.

A similar rearrangement has been observed also in a series of bicyclic condensed compounds containing a three-membered ring and a double bond in the larger ring. An example of such rearrangements is provided by the degenerate isomerisation of bicyclo[3,1,0]hex-2-ene (XVII)[35] and Δ^3-thujene (XVIII).[17,18,35,36] (At higher temperatures, the three-membered ring is opened—see below.)



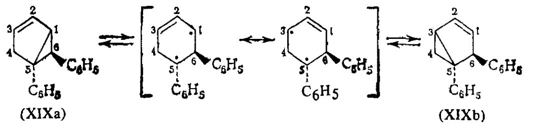


In a detailed study of the reactions of optically active deuterated Δ^3-thujene (XVIIIc) at 240°C, Doering[17] concluded that the reaction proceeds with intermediate formation of biradicals, since the reaction products (XVIII, *d*–*f*) are inconsistent with the predicted formation of the single compound (XVIII*f*) (via a concerted mechanism in accordance with the Woodward–Hoffmann rules):

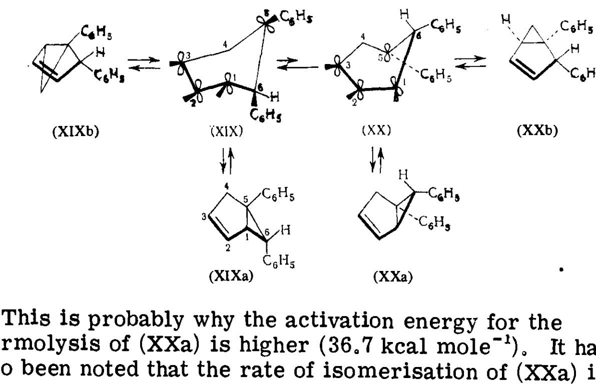


In order to elucidate the pathway whereby vinylcyclopropanes rearrange to cyclopentenes, two methods were used in the above investigations: (1) comparison of the activation parameters for the reaction with those for the simultaneous geometrical isomerisation, for which the mechanism may be regarded as established; (2) comparison of the observed composition of the reaction products and the composition postulated on the basis of the synchronous mechanism. To prove the proposed mechanism, one frequently investigates the stereospecificity of the reaction. Stereospecificity is an invariable consequence of the concerted mechanism. However, stereospecificity alone cannot serve as an adequate evidence for the synchronous mechanism[17].

For example, the stereospecificity of the reversible thermal isomerisation of *trans*-5,6-diphenylbicyclo[3,1,0]hex-2-ene (XIXa) and *trans*-4,5-diphenylbicyclo[3,1,0]hex-2-ene (XIXb)[19,37] can be a result of either the synchronous reaction or a process which may proceed via an intermediate biradical stage in which the rate of closure of the new ring is higher than that of the inversion of the configuration at C$_{(5)}$:



The calculated minimum activation energy for the conversion of (XIXa) into (XIXb) via the biradical (31.5 kcal mole^{-1}) proved to be very close to the experimental value Ea = 32.4 kcal mole^{-1}.[19] The stereospecificity of this reaction is apparently determined by the high energy barrier separating the radicals (XIX) and (XX). In the transformation (XIX) → (XX), there is an appreciable enhancement of the steric interaction between the two phenyl groups, which leads to the breakdown of the coplanarity of the phenyl group and the radical centre at C$_{(5)}$ and hence to decreased conjugation:



This is probably why the activation energy for the thermolysis of (XXa) is higher (36.7 kcal mole^{-1}). It has also been noted that the rate of isomerisation of (XXa) is

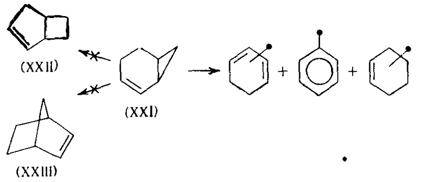
---

[†] The formation of 3-methylcyclopentene (VIII)[6] and of 4-methylcyclopentene (X)[7] has been noted. Somewhat different activation parameters were obtained in these reactions (see Table 1).

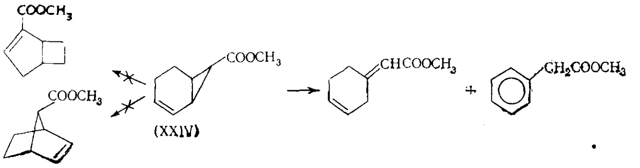
appreciably lower than the rate of reaction of (XIXa). Thus Swenton and Wexler's experimental data[19] confirm the biradical reaction mechanism which they proposed.

The lower activation energies and reaction temperatures for bicyclo[3,1,0]hex-2-ene systems are striking (Table 1). The observed lower activation energy compared with E_a for the rearrangement of monocyclic vinylcyclopropanes has been attributed to the contribution of the strain energy of the five-membered ring (+6.8 kcal mole^{-1})[17,38] and, in the presence of substituents, to the additional stabilisation of the biradical state due to the involvement of the substituents[19,20].

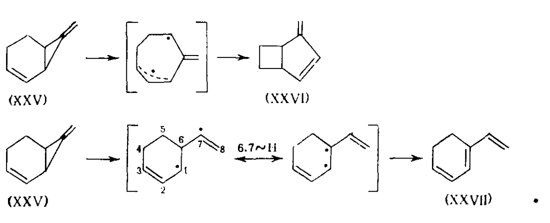
It is noteworthy that the thermal transformations of condensed compounds in the bicyclo[4,1,0]hept-2-ene series {in contrast to bicyclo[3,1,0]hexenes} do not proceed via the mechanism of the rearrangement of vinylcyclopropanes discussed above. Thus a complex mixture of hydrocarbons, the main components of which are methylcyclohexadienes, is formed from bicyclo[4,1,0]hept-2-ene (XXI) at 300–500°C:[39]



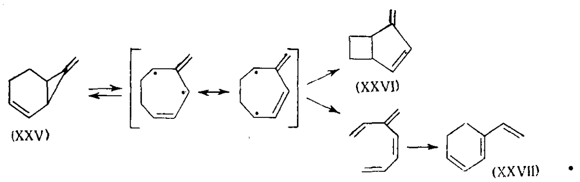
Bicyclo[3,2,0]hex-2-ene (XXII) and bicyclo[2,2,1]-heptene (XXIII), the formation of which would have been expected if there were a rearrangement to the corresponding cyclopentene system, were not detected over the entire experimental temperature range. This applies also to the transformations of the ester (XXIV):[3]



7-Methylenebicyclo[4,1,0]hept-2-ene (XXV), which contains both vinyl and methylenecyclopropane fragments, constitutes an exception in the above series of compounds[21,22]. The methylenecyclopropane fragment is in fact responsible for the specific features of the behaviour of this hydrocarbon. 7-Methylenebicyclo[4,1,0]hept-2-ene isomerises under comparatively mild conditions (at a temperature as low as 110°C) in two independent ways with formation of 4-methylenebicyclo[3,2,0]hept-2-ene (XXVI) and 1-vinylcyclohexa-1,3-diene (XXVII) in proportions of 4 : 1. The ratio of the reaction products changes with increase of temperature above 300°C in favour of the hydrocarbon (XXVII).[22] The activation parameters for the two types of reaction differ appreciably from one another according to one of the investigations (Table 1), which may be due to the fact that the reactions proceed via different transition states, formed in accordance with the mechanism indicated below:



An alternative reaction mechanism corresponds to the identical activation parameters for reactions of both types obtained by Billups et al.[21]:



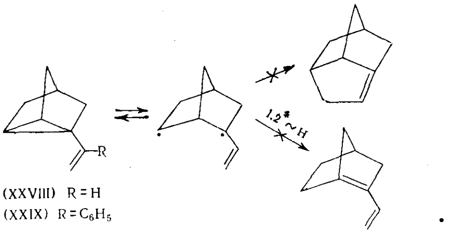
In conclusion of this section, examples of the "anomalous" behaviour of certain vinylcyclopropanes at an elevated temperature will be quoted.

(1) Cases are known where compounds containing the vinylcyclopropane systems do not isomerise to cyclopentenes. These include the following:

(a) the compounds of the bicyclo[4,1,0]hept-2-ene series already mentioned;

(b) 1-alkyl-2-vinyl- and 1,2-divinyl-cyclopropanes, the rearrangements of which take place in a different way (see below);

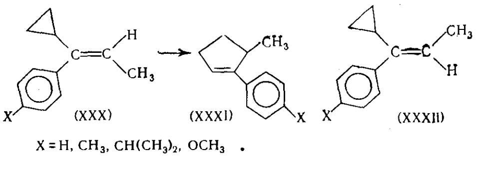
(c) the hydrocarbons (XXVIII) and (XXIX) do not change up to 475°C, i.e. under conditions such that even cyclopropanes isomerise. This is probably due to the fact that the rearrangements would necessarily lead to the formation of strained compounds with a double bond at the bridgehead.



(2) The presence at the $C_{(4)}$ atom of the vinyl group and in the cyclopropane ring of substituents, such as the alkyl group (Table 1), the phenyl[2,41–43], cyclopropyl[2,14,35,44], vinyl[15,25,35,45], and ester[34,46,47] groups and chlorine atoms in the cyclopropane ring[1–3] does not affect the mode of rearrangement of monocyclic vinylcyclopropanes.

At the same time the introduction of substituents at the $C_{(5)}$ atom involved in a double bond has a significant influence on the behaviour of vinylcyclopropanes.

Thus the *trans*-isomer (XXX) is converted almost quantitatively into the substituted cyclopentene (XXXI) in the temperature range 360–390°C. On the other hand, a complex mixture of products, in which the content of the expected cyclopentene does not exceed 20%, is formed from the *cis*-isomer (XXXII); the process is accompanied by intense polymerisation (up to 60%)[41]:



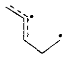
X = H, CH$_3$, CH(CH$_3$)$_2$, OCH$_3$.

---

‡ The symbol ~H denotes a hydrogen shift.

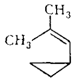
This finding has been explained by the fact that the steric interaction of the cyclopropane ring and the alkyl substituent in the *cis*-isomer prevents the formation of a *cis*-allyl biradical of type (XXXIIIa), which precedes cyclopentene. A *trans*-allyl biradical of type (XXXIIIb) should be formed from compound (XXXII).[48,49]

(XXXIIIa)

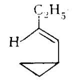


(XXXIIIb) .

That the transformation of hydrocarbon (XXXIV) has the highest known activation energy of all the thermal isomerisations of vinylcyclopropanes (Table 1) is a consequence of the steric influence of the *cis*-methyl group.



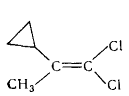
(XXXIV)



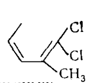
(XXXV) .

On the other hand, the activation energy for the transformation of hydrocarbon (XXXV), containing the *trans*-ethyl group, does not differ from the value of E_a for the unsubstituted vinylcyclopropane (Table 1).

The transformation of 1,1-dichloro-2-cyclopropylprop-1-ene (XXXVI) takes place at 450°C with formation of a complex mixture, the main component of which is the dichloro-derivative (XXXVII):[3]

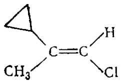


(XXXVI)

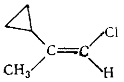


(XXXVII) .

Thus the introduction of two electron-accepting substituents hinders the involvement of the π electrons of the double bond in the opening of the cyclopropane ring. In this case, the usual thermal decomposition of the three-membered ring takes place, namely a reaction which has a higher activation energy than that for the rearrangement of vinylcyclopropanes. The study of the thermal transformations of the isomeric monochloro-derivatives (XXXVIII) and (XXXIX) showed that the electronic influence of the chlorine atom prodominates over the steric influence[3]:

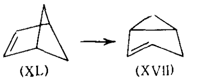


(XXXVIII)



(XXXIX) .

(3) The rearrangement of vinylcyclopropanes is an exothermic reaction (by approximately 25 kcal mole^{-1}) and the reverse reaction is not, as a rule, observed[17]. Systems characterised by a higher strain energy are an exception[50-54]. For example, bicyclo[2,1,1]hex-2-ene (XI) is converted into bicyclo[3,1,0]hex-2-ene (XVII),[50,51] while the reverse process does not take place:



(XL) (XVII) .

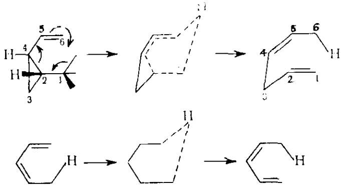
This reaction probably proceeds via a synchronous mechanism, like the 1,3-suprafacial shift with inversion of configuration at the migrating atom, which is confirmed by the stereospecificity[52,54] and the kinetic parameters of the reactions[51,54].

III. ISOMERISATION OF VINYLCYCLOPROPANES INVOLVING A 1,5-HYDROGEN SHIFT

When the steric configuration of 1-alkyl-2-vinylcyclopropanes is favourable, suitable conditions are created for the occurrence of the electrocyclic reaction, involving a 1,5-hydrogen shift and the opening of the cyclopropane ring and leading to isomeric dienes. The simplest case of a rearrangement of this type is the quantitative conversion of *cis*-1-methyl-2-vinylcyclopropane (XLI) above 160°C into *cis*-hexa-1,4-diene (XLII):[6,7,55]

(XLI) (XLII) .

The structural requirements and the geometry of the transition state for the 1,5-hydrogen shift in *cis*-1-alkyl-2-vinylcyclopropanes and *cis*-1,3-dienes are illustrated below:

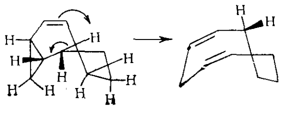


This rearrangement proceeds via a suprafacial mechanism in accordance with the Woodward–Hoffmann rules for the conservation of orbital symmetry[56].

Table 3 presents the activation parameters for the reactions of vinylcyclopropanes occurring with a 1,5-hydrogen shift (data for certain 1,3-dienes are presented for comparison).

It is striking that the activation energy for the above transformation is much lower than the values of E_a for the rearrangement of vinylcyclopropanes into cyclopentenes. The factors A are also lower and correspond in magnitude to the values of A for the Cope rearrangement (Section IV). The low value of A suggests a rigid transition complex in which the free rotations of the methyl and vinyl groups have been lost.

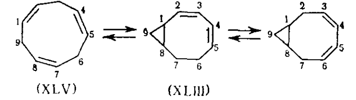
The 1,5-hydrogen shift takes place readily in bicyclo-[n,1,0]olefins (n = 5, 6, or 7), which have a saddle-shaped conformation.



The migrating hydrogen atom is in the *trans*-position relative to the cyclopropane methylene group and this is why a *cis*-diolefin is formed. The thermal opening of the cyclopropane ring in bicyclo[n,1,0]olefins (n = 5, 6, or 7) proved to be a convenient method for the synthesis of *cis*,*cis*-1,4-diene systems.

Thus at 130–200°C bicyclo[5,1,0]oct-2-ene[35,61], bicyclo[6,1,0]non-2-ene[35,60], bicyclo[6,1,0]nona-2,5-diene[62], bicyclo[6,1,0]nona-2,4-diene[60,62,63], and bicyclo[7,1,0]dec-2-ene[17] isomerise smoothly to the corresponding monocyclic compounds.

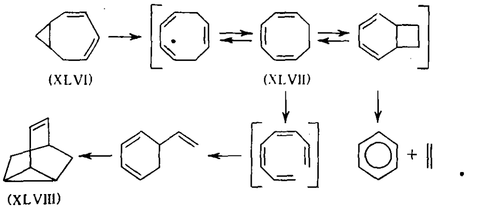
In system (XLIII), the $C_{(7)}-C_{(3)}$ hydrogen shift (a homodienyl shift), competes with the $C_{(6)}-C_{(2)}$ hydrogen shift (a dienyl shift)[60,62,63]:



(XLV) (XLIII) .

Above 160°C the equilibrium is displaced towards the cyclononatriene (XLV). For example, at 170°C we have the ratios (XLV) : (XLIII) : (XLIV) = 93 : 6 : 1.[62]

A mixture of hydrocarbons (XLVII) and (XLVIII) and benzene was obtained from bicyclo[5,1,0]octa-2,4-diene (XLVI) at 225°C in accordance with the following reaction mechanism[47]:

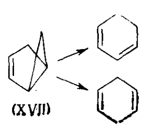


(XLVI) (XLVII) (XLVIII)

The corresponding heteroanalogue (XLIX) undergoes a similar isomerisation[64]:

(XLIX)

The non-planar conformation necessary for the 1,5-hydrogen shift is not achieved in bicyclo[n,1,0]olefins (n = 3 or 4). Thus bicyclo[3,1,0]hex-2-ene (XVII) isomerises to a mixture of cyclohexa-1,3-diene and cyclohexa-1,4-diene above 300°C:[7,65–67]



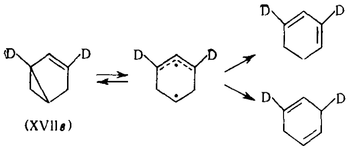
(XVII)

lg$A$ = 14.28 s^{-1}; E_a = 50.2 kcal mole^{-1};

lg$A$ = 14.095 s^{-1}; E_a = 50.2 kcal mole^{-1}.

The activation energies quoted are much higher than the values of Ea for reactions proceeding via a 1,5-hydrogen shift (Table 3). Furthermore, this mechanism does not explain the preferential formation of a conjugated diene on isomerisation (cyclohexa-1,3-diene and cyclohexa-1,4-diene do not undergo thermal isomeric interconversions[68]).

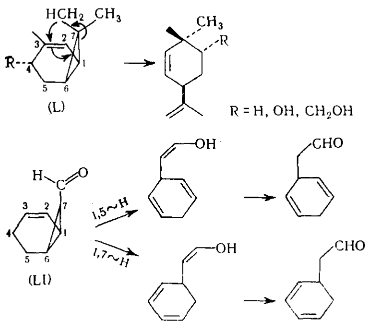
Data obtained in 1973 in studies on the thermolysis of deuterated bicyclo[3,1,0]hex-2-ene (XVIIc) support the biradical mechanism of reactions via a 1,2-hydrogen shift[67]:



(XVIIc)

Evidently, enormous distortions are needed in system (XXI) with n = 4 in order that a transition state be formed for which an electrocyclic reaction involving a 1,5-hydrogen shift is possible. The thermal transformations of bicycloheptene (XXI) take place only via the radical mechanism[39] (see Section II).

Certain substituted derivatives of bicyclo[4,1,0]hept-2-ene [(L) and (LI)][59,69–72] and bicyclo[3,1,0]hex-2-ene[73] are partly isomerised via a six-unit electrocyclic transition state involving a 1,5-hydrogen shift (which is confirmed by the stereospecificity of the reactions and the kinetic parameters):



(L)

R = H, OH, CH₂OH

(LI)

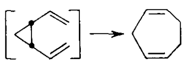
However, these reactions bear only a formal analogy to the isomerisation considered in this Section, since in the case of hydrocarbon (L) the hydrogen atom of the $C_{(7)}-CH_3$ side chain migrates and in the case of aldehyde (LI) the hydrogen atom attached to the carbon atom in the 4- or 5-position relative to the carbonyl group migrates.

IV. ISOMERISATION OF DIVINYLCYCLOPROPANES (THE COPE REARRANGEMENT)

1. *cis*-Divinylcyclopropanes

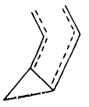
The isomerisation of *cis*-divinylcyclopropanes, which may be regarded as a special case of the Cope rearrangement of 1,5-dienes, is an interesting example of the [3,3] sigmatropic rearrangement.

The *cis*-isomer of divinylcyclopropane (LII) is so labile that it rearranges to cyclohepta-1,4-diene already under the conditions of its formation[42,49,74,75]:



(LII)

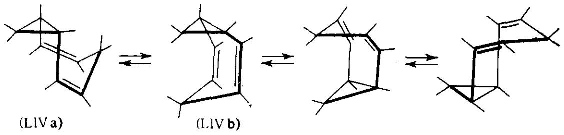
Examination of the geometry of divinylcyclopropane leads to the conclusion that the only possible transition state in the rearrangement investigated is the quasi-boat structure (LIII) in which the vinyl groups overhang the plane of the three-membered ring:



(LIII)

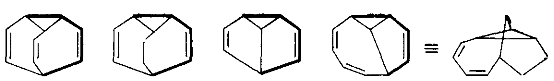
Any other orientations of the vinyl groups would have led to the *trans*,*trans*- or *cis*,*trans*-heptadienes which are not observed. Since only slight changes in the position of the vinyl groups are necessary in the *cis*-isomer in order to attain such a transition state, the rearrangement takes place readily. The reversible degenerate rearrangements of a series of bicyclic and tricyclic unsaturated hydrocarbons belong to the same type of reactions.

The *cis*- and *trans*-isomers of bicyclo[5,1,0]hepta-2,5-dienes (LIVb) and (LIVa) isomerise at room temperature via the stage involving the formation of the thermodynamically less favourable *cis*-form[35,49]:



(LIVa) (LIVb)

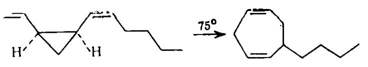
The allyl groups in bullvalene are rigidly fixed in the cisoid conformation. Rapid reversible isomerisation leads to the approximate equivalence of all the carbon atoms of bullvalene[35,49,76-79]:



(LV) (LVI) (LVII) (LVIII)

Bullvalene analogues, namely dihydrobullvalene (LVI),[79] semibullvalene (LVII),[80,81] and isobullvalene (LVIII),[82,83] isomerise similarly. Table 4 lists the kinetic parameters of the isomerisation of *cis*-divinylcyclopropanes (data for certain 1,5-dienes and *cis*-divinylcyclobutane are included for comparison). The Cope rearrangement is characterised by comparatively low activation energies and low negative activation entropies.

More stable (stable at room temperature) *cis*-1,2-divinylcyclopropanes are also known: *cis*-1-(*cis*-hex-1-enyl-)2-vinylcyclopropane (LIX)[89] and the bicyclic hydrocarbons (LX),[62,87,90,91] (LXI)[88] (Table 4), (LXII), and (LXIII):

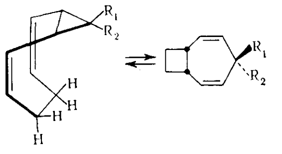


(LIX)

Table 4. Thermal isomerisation of 1,5-dienes and *cis*-divinylcycloalkanes.

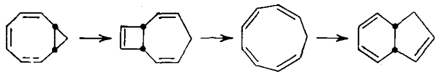
Initial hydrocarbon	Isomerisation product	Temperature, °C	lg$A$ (s^{-1})	E_a, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	Ref.
		—	11,1	35.5	—	84
		220—300 220—300	10.5±0.1 10.5±0.1	34.2 35.7	— —	85 86,
		65,4—108,5	10.7	22.4	—11.7	86
 (LII)		5—20	—	—	—5.3	75
 (LV)		10—83 25—123	12.0 12.9	11.8±1,0 12.8±0.1	—5.0 —2.3	77 78
 (LVIII)		11—30	—	—	—10	83
 (LX)		35—48	13.2	25,0±0.5	—	87
 (LXI)		—	11.7	22,9	—7.2	88

The latter isomerise only at 150–180°C. The rearrangement is difficult owing to the steric hindrance by the methyl groups in the *cis*-conformations[89]:



(LXII) R_1=H; R_2=CH_3;
(LXIII) R_1=R_2=CH_3.

Bicyclo[6,1,0]nonatriene (LXIV) is converted at 90°C into hydrocarbon (LXVI). However, it has been established that the reaction proceeds in succession via a number of stages, each of which takes place with conservation of orbital symmetry[92]. The first stage is the Cope rearrangement to bicyclo[5,2,0]nona-2,5,8-triene (LXV):

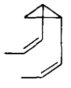


(LXIV) (LXV) (LXVI) .

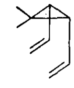
Thus the analogy between the transformations of hydrocarbon (LXIV) and the vinylcyclopropane rearrangement to cyclopentenes, discussed in certain reviews[17,93], is purely formal.

In contrast to unsubstituted divinylcyclopropane, substituted *cis*-divinylcyclopropane systems do not change even under fairly severe conditions.

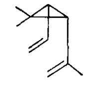
Hydrocarbons (LXVII)–(LXXI), which are stable at room temperature, undergo geometrical isomerisation on heating to 170–180°C, yielding a mixture of *trans*- and *cis*-olefins instead of the expected Cope rearrangement[94–97]:



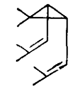
(LXVII)



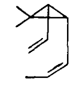
(LXVIII)



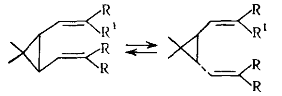
(LXIX)



(LXX)



(LXXI)



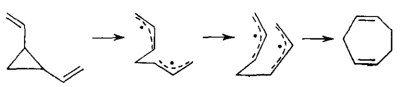
.

The activation energy observed for the transformation of hydrocarbon (LXX) [E_a = 33 kcal mole^{-1}; lg$A$ (s^{-1}) = 12.4; ΔS = −3.8 e.u.][97] is one of the lowest for the homolytic dissociation of the C–C bonds in cyclopropane (Table 2), which can be accounted for by the involvement of two allyl groups in the stabilisation of the transition state.

The difference in the behaviour of substituted and unsubstituted *cis*-divinylcyclopropanes is due to the steric interactions of the substituents in the transition state.

2. *trans*-Divinylcyclopropanes

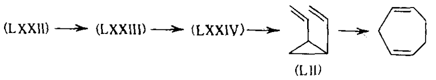
Since the discovery of the rearrangement of *trans*-1,2-divinylcyclopropane (LXXII)[42] and the determination of its Arrhenius parameters [lg$A$ = 12.09 (s^{-1}) and E_a = 32.10 kcal mole^{-1}],[98] studies on this subject have not been continued. Since the rearrangement hydrocarbon (LXXII) led to the same product as the Cope rearrangement of *cis*-divinylcyclopropane (LII), it has been suggested that the central linkage dissociates owing to the rigid geometry of the cyclopropane ring with formation of the *trans*-allyl biradical (LXXIII), the two allyl components of which then assume the *cis*-positions as in (LXXIV):[35,49]



(LXXII) (LXXIII) (LXXIV) .

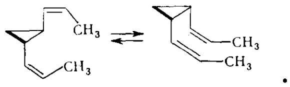
However it remained obscure whether the isomerisation proceeds only via intermediate biradicals or whether biradical (LXXIV) cyclises to *cis*-divinylcyclopropane (LII) with its subsequent rearrangement via a quasi-boat six-unit transition state.

Products containing *trans*-1,2-dialkenylcyclopropane fragments have been isolated in recent years from the oil of *Distyopteris* and the seaweed *Ectocarpus siliculosees*; this aroused more interest in the study of the mechanism of the transformations of *trans*-divinylcyclopropanes. It has been established that at 150–205°C the racemisation of (−)-*trans*-1,2-divinylcyclopropane (LXXII) is accompanied by the geometrical isomerisation to the corresponding *cis*-isomer (LII), which is in its turn rapidly and quantitatively converted into cyclohepta-1,4-diene; here the opening of the cyclopropane ring in the *trans*-isomer is a biradical and not an electrocyclic process[99]:



(LII) .

At 180°C, the *trans*-isomer (LXXV) underwent only geometrical isomerisation with formation of an equilibrium mixture of the *trans*- and *cis*-isomers; the resistance of the latter to the Cope rearrangement was discussed previously[94]:



(LXXV) (LXXII) .

The study of the stereochemical specificity of the thermolysis of other isomeric *trans*-1,2-dialkenylcyclopropanes yielded additional evidence ruling out the possibility of the direct formation of cycloheptadienes from the intermediate *cis*-allyl biradicals of type (LXXIV).[94,100]

---o0o---

Thus data obtained in kinetic studies on the thermal transformations of vinylcyclopropanes with formation of cyclopentenes can be interpreted both on the basis of ideas involving the synchronous mechanism and on the hypothesis of the intermediate formation of a biradical. However, the results obtained in recent years in studies on the stereochemical specificity of the thermolysis and of the transformations of deutero-derivatives of vinylcyclopropanes are more consistent with the biradical mechanism of the vinylcyclopropane rearrangement.

When the specific configuration of the vinylcyclopropane systems is favourable (*cis*-1-alkyl-2-vinylcyclopropanes and *cis*-divinylcyclopropanes), suitable conditions are created for the occurrence of concerted sigmatropic reactions proceeding via a six-membered cyclic transition state.

The Solvation of Inorganic Substances and Complex Formation in Non-aqueous Solutions

A.M.Golub

Various views on the nature of the dissolution process are examined and the latter is explained as a consequence of the solvation of the solute. Methods for the determination of solvation numbers and solvating capacities of solvents are analysed and an attempt is made to explain solvation and the influence of the nature of the solvent on complex formation reactions taking into account modern ideas about chemical bonding. The fundamental characteristics of complex formation and inorganic synthesis in non-aqueous and mixed solutions are described.
The bibliography includes 358 references.

CONTENTS

I. INTRODUCTION

The study of the nature of solutions and of the influence of solvents on the reactivity of substances, particularly inorganic substances, has attracted the attention of chemists for a long time. This problem has become particularly urgent, since the majority of chemical engineering processes are carried out in solution and in view of the likely use of lanthanide complexes in non-aqueous solutions[1-3] as lasers. It is very remarkable that the quantum yield for $NdCl_3$ dissolved in a mixture of $SeOCl_2$ with $SnCl_4$ or $SbCl_5$ is ten times higher than for aqueous solutions of neodymium salts[4].

It is well known that the solvent has a significant influence on the state and properties of the solute; however, there is as yet no well-constructed theory on the basis of which one could predict the suitability of a particular solvent for given reactions or for the dissolution of various substances. Nor are there any fairly well-established views concerning solvation phenomena in solutions[5].

According to Mishchenko and Poltoratskii[6], "the nature of ionic solvation forces remains unexplained". On the other hand, there have been numerous studies on the structure of solutions and on complex-formation reactions in non-aqueous systems[7]. It is therefore necessary to analyse the data which have accumulated in order to discover the relation between solvation and complex formation, on the one hand, and to what extent the use of non-aqueous solutions promotes the development of inorganic synthesis, on the other.

II. THE SOLVENT POWER OF SOLVENTS AND THE PROPERTIES OF ELECTROLYTE SOLUTIONS

The old rule "like dissolves in like" is far from being universal, although attempts are sometimes made to revive it even now. Thus, after studying the dependence of the solubility of substances on the properties of the solvent, Semenchenko and then Shakhparonov[8-11] concluded that the relative polarities of the substances involved play a significant role. According to these investigations[8-11], solubility should be highest in those cases where the generalised moments, i.e. the ratios of the dipole moments and the molecular volumes, of the solute and the solvent are similar. Hildebrand and Scott maintain that substances having the same density of interaction energy are miscible[12]. According to Pearson, the so called hard acids or bases dissolve in hard solvents (which themselves behave as hard bases and acids respectively) and soft acids or bases are soluble in soft solvents[13]. However, Pearson's soft acids ($GaCl_3$, I_2, etc.) dissolve readily in alcohols, amines, and hydrazine, which are hard bases. The above rule is to some extent justified in relation to the miscibilities of organic compounds. The Lavoisier rule, developed by Shreder[14], is applicable to many solid non-electrolytes: other conditions being equal, the solubility of solids increases with decrease of their melting point. The rule is usually expressed by the Schroeder–Le Chatelier equation:

$$\lg s = -\frac{\Delta H_m}{RT} + \frac{\Delta H_m}{RT_m}, \tag{1}$$

where s is the solubility, ΔH_m the heat of fusion, T the experimental temperature, and T_m the melting point.

In the case of electrolytes, the solvent power of solvents is usually estimated taking into account their dielectric constants[15,16]. After considering the solubilities of salts in water and some other solvent, Izmailov and coworkers[15,16] established the following relation:

$$\lg \frac{s_{H_2O}}{s_{Solv}} = L\left(\frac{1}{\varepsilon_{Solv}} - \frac{1}{\varepsilon_{H_2O}}\right) + P\left(\frac{1}{\varepsilon_{H_2O}} - \frac{1}{\varepsilon_{Solv}}\right), \tag{2}$$

where L and P are constants and ϵ is the dielectric constant. When a number of assumptions are made, Eqn. (2) can be transformed into

$$\lg s_{Solv} = F + w\varepsilon, \tag{3}$$

where F and w are constants.

The above view was originated by Born[17], who explained dissolution and solvation as a consequence of the ion–dipole interaction[18-24]. According to Born[17], when an ion is transferred from a vacuum into a medium with a dielectric constant ϵ, the solvation energy, equal to the difference between the field energies *in vacuo* and in the given medium, is evolved,

$$E = \frac{z^2e^2}{2r} - \frac{z^2e^2}{2\varepsilon r} = \frac{z^2e^2}{2r}\left(1 - \frac{1}{\varepsilon}\right). \tag{4}$$

Consequently, the solubility of salts should decrease with decrease of the dielectric constants of the corresponding liquids[25,26].

The limitations of the electrostatic concept become evident already in relation to propane-1,2-diyl carbonate, which has a high dielectric constant (ϵ = 69) but dissolves many compounds much less effectively than dimethylformamide (ϵ = 36.1) or dimethyl sulphoxide (ϵ = 48.9). In highly polar nitromethane (dipole moment 3.54 D) the solubility of alkali metal halides is low; transition metal halides are also sparingly soluble in this solvent[27]. On the other hand, acetonitrile, which has almost the same dipole moment (3.2 D) and dielectric constant (38.8), readily dissolves compounds of different classes and even silver nitrate[28], which is sparingly soluble in water.

One cannot explain from this standpoint the low solubilities in water of salts of the type $Cs_2[PtCl_6]$, $[Co(NH_3)_6]$.$[P(Mo_3O_{10})_4]$, and $BaSO_4$, which consist of large cations and anions, the decrease of the corrosion of lead–antimony alloys on passing from water to water–dioxan mixtures[29], the failure of zinc electrode potentials in $ZnCl_2$ solutions in acetonitrile to obey the Nernst equation[30], and the non-uniform variation of the conductivity of aluminium chloride with concentration in butyl ether[31].

In the vast majority of cases, electrolytes behave in non-aqueous solutions differently than in water. For example, thorium nitrate in acetonitrile has a low conductivity; $CuCl_2$ in acetone has a dark-yellow colour[32]; aluminium bromide dissolves in acetone with evolution of heat[33] and the solutions formed darken after a time and their conductivity increases.

The above and also many other data concerning the solubilities of certain salts in alcohols[34-36], dimethylformamide[37,38], acetone[35,39], pyridine[40-42], sulphur dioxide[43], etc.[44,45] show that the dissolution process is determined by the chemical nature of the solvent and the solute rather than by their physical properties. This is why Izmailov[15,16,46] concluded that the dependence of salt solubilities on the dielectric constant corresponding to Eqn. (3) is characteristic only of a series of solvents of the same chemical type, such as, for example, alcohols.

Numerous experimental data have shown that the dielectric constant is not a characteristic which determines solvent power. Thus CuH is insoluble in water but forms a red solution in pyridine (Py), for which ϵ = 12.3, i.e. is lower than for water[47]. Copper iodide also dissolves in this solvent and, when the latter is distilled off, crystallises in the form of $[CuPy_2]I$.[48] The solubilities of many metal halides in pyridine decrease on passing from iodides to chlorides[44].

Hydrazine (ϵ = 51.7) dissolves many salts at 25°C more effectively than does water (ϵ = 81) and liquid HCN (ϵ = 123 at 15.6°C). For example, HgI_2 dissolves in hydrazine more readily than $HgCl_2$ and $Cu(NO_3)_2$ is only sparingly soluble in this solvent[49]. It is difficult to account for the insolubility of CuCN, AgCl, $Ba(NO_3)_2$, $CuSO_4$, HgI_2, and $Ca(NO_3)_2$ and for the low solubilities of AgCN, CdI_2, $CoCl_2$, $HgCl_2$ and $HgBr_2$ in liquid HCN.

The above data show that the formation of the solution and its properties depends mainly on the chemical nature of the corresponding solvents, including stereochemical factors[51]. The rate of dissolution of the solid is higher the lower the activation energy for the transfer of surface species to the solution, which, apart from depending on temperature, is also a function of the strength of bonding between these species and solvent molecules.

Other conditions being equal, substances with a molecular lattice should exhibit the highest solubility and should be followed in this respect by ionic compounds, since, in order to overcome dispersion forces or to dissociate an ionic linkage, it is necessary to expend less energy than for the disruption of atomic or metallic lattices. In particular, it has been noted that the activation energy for the dissolution process is less than 10 kcal mole^{-1} for compounds with ionic bonding[52], while for molecular crystals it is even lower. The dissolution of substances with a molecular lattice is probably preceded by dispersion interaction between molecules of different kinds, which is possible also in the so called indifferent solvents (CCl_4, C_6H_6, etc.).

The first stage in the dissolution of ionic crystals is apparently ion–dipole attraction. The solubilities of salts are therefore usually higher in polar solvents than in non-polar solvents. Substances with a molecular lattice, such as, for example $ThOx_4$, where Ox is the 8-hydroxyquinoline residue, dissolve, while ionic crystals, such as ThF_4, do not dissolve in solvents of the carbon tetrachloride type[53]. Compared with the ionic compound NaNCO, the covalent compound $Hg(OCN)_2$ dissolves more readily not only in alcohols, ethers, and ketones, but also in cyclohexane[54]. For this reason, neutral molecules should be more effectively extracted by solvents immiscible with water, which is in fact observed experimentally[35-57]. It is easier to replace one dispersion interaction by another than to dissociate an ionic linkage or polar molecules into ions.

However, despite its importance when the phases first come into contact, the ion–dipole interaction is not of decisive significance in the general assessment of solvent powers. This is seen from a comparison of the solubilities in water of calcium and cadmium sulphates, the ionic charges and radii of which are the same, and of sodium and copper(I) chlorides in liquid ammonia. Although the radii of the Na^+ (0.95 Å) and Cu^+ (0.95 Å) ions are the same, the solubilities of their salts are by no means identical. Only 3 g of NaCl dissolves in 100 g of ammonia at −35°C,[44,58] while the solubility of CuCl is much higher. In water, alcohols, acetone, etc. the solubilities of these compounds vary in the opposite sense, which cannot be explained by taking into account electrostatic concepts alone.

Sodium perchlorate dissolves readily in ethylenediamine ($\epsilon = 12.9$ at 25°C) and forms with the latter the solvate $NaClO_4.3C_2H_4(NH_2)_2$.[59] On the other hand, this salt dissolves less readily in liquid sulphur dioxide ($\epsilon = 12.35$ at 22°C); the corresponding solvate has not been obtained either[60]. Niobium and tantalum pentachlorides are very sparingly soluble in benzene, carbon tetrachloride, and chloroform[61] and are somewhat more soluble in ethers, ketones (acetone), tributyl phosphate[62], and acetonitrile[63]. For example, it has been shown that, when acetonitrile dissolves niobium pentachloride, it decomposes its polymeric molecules and forms the solvato-complex $[Cl_5NbNCCH_3]$.[63] Zirconium and hafnium tetrachlorides dissolve in many solvents with high solvating capacities[64,65], for example in alcohols and acetonitrile, with which they form the compounds $ECl_4.2Solv$.[64-66] The formation of E–Solv bonds has been confirmed by infrared spectroscopic[67] and thermochemical[68] data. The compounds ECl_4 do not dissolve in liquid hydrocarbons and carbon tetrachlorides, since they do not form adducts with these solvents[70,71]. Aluminium chloride forms more stable solvates and is therefore more effectively dissolved by acetone than by pyridine[58].

III. THE SOLVATION OF INORGANIC SUBSTANCES

It is seen from the above data that the main condition for dissolution is solvation of the species to be dissolved. Solvents with high solvent power in relation to inorganic substances can be divided into two groups: donor and acceptor. The former effectively solvate ions or molecules of the acceptor type and the latter those of the donor type.

Numerous reviews have been devoted to ion solvation[46,72-76], but they are almost exclusively concerned with aqueous systems. In these communications there is unfortunately no indication of the role of the chemical nature of the solvent in the formation of the solvation shells of ions.

Conway and Bockris[74] and also Samoilov[76] developed for aqueous salt solutions interesting ideas concerning primary and secondary ion hydration, suggesting the existence of different types of bonds in solvates. It is quite reasonable that in primary solvation the solute may undergo a significant change in its electrolytic properties. Thus iodine forms with pyridine conducting solutions, from which it is possible to isolate the compound $Py.2I_2$,[77] or more precisely $[IPy][I.I_2]$.

Owing to solvation, the covalent compound $TiCl_4$ dissociates in acetonitrile[78]:

$$2\,TiCl_4 + 4CH_3CN \rightleftarrows [TiCl_3(CH_3CN)_3]^+ + [TiCl_5(CH_3CN)]^-.$$

When $TiCl_4$ dissolves in dimethylformamide (DMF) and dimethyl sulphoxide (DMSO), the molecules of the latter are attached to the titanium atom, expelling chloride ions to the outer sphere. This process takes place even more readily with $ZrCl_4$ and $HfCl_4$, which form with DMSO the compounds $ECl_4.9DMSO$.[79] Since the conductivities of dimethyl sulphoxide solutions of ECl_4 are high, they presumably contain the solvato-complexes $[E(DMSO)_8]^{4+}$ or $[E(DMSO)_6]^{4+}$. On being dissolved in tetramethylene sulphone (TMS), cobalt(II) perchlorate forms red conducting solutions, from which it is possible to isolate the compound $Co(ClO_4)_2.3TMS$, whose electronic spectrum resembles that of $[Co(H_2O)_6]^{2+}$.[80]

In contrast to primary solvation, secondary solvation arises as a result of the electrostatic attraction of dipoles or via hydrogen bonding. On the other hand, the formation of the first solvation layer around the solute species apparently plays a dominant role in the dissolution process, since the decrease of enthalpy on dissolution is in fact associated with this factor[82-84].

Since solvation processes in non-aqueous solutions have been studied much less thoroughly than in water, the problem of the relative stabilities of cations and anions in relation to solvation has not yet been solved unambiguously. Gutman[51] suggests that "... the solvation of anions by acceptor solvents usually takes place to a lesser extent than the solvation of cations by donor solvents", and, according to other workers[85-88], anions have higher hydration energies than cations of the same size. The latter is true of potassium, ammonium, rubidium, and caesium fluorides, which dissolve in water with evolution of heat. The same investigators[85-88] nevertheless stipulate that in aprotic solvents, which do not form hydrogen bonds with anions, the latter are less solvated than cations. It is difficult to agree with this view, firstly because in solvents with a high solvent power solvent molecules form the most compact structure around cations[89,90]. Secondly, the energy of the hydrogen bond is low compared with the energy manifested in real solvates, which are in most cases typical complexes.

Comparison of the radii of cations and anions found on the basis of the Stokes law with their crystal-chemical values led Prue and Sherrington[87] to the conclusion that in dimethylformamide and dimethyl sulphoxide cations have a larger solvation shell than anions. The same workers noted that in water and methanol anions have the same conductivities as cations with similar crystal-chemical radii. It has likewise been established that in many other solvents cations are much more solvated than anions[91-95]. On the other hand, for weakly solvated cations, salt solubilities increase in the following sequence of anions:

$$Cl^- < NO_3^- < Br^- < ClO_4^- < I^-,$$

The higher solubilities of potassium and certain other metal iodides compared with their chlorides in hydrazine, liquid sulphur dioxide, acetonitrile, and pyridine are due to the more effective solvation of the iodide ion. The dissolution of KCl in iodine monochloride can be hardly accounted for otherwise than by the solvation of the anion:

$$KCl + ICl = K[ICl_2].$$

This is in fact responsible for the higher conductivity of the solution compared with the pure solvent. When $[(C_2H_5)_4N]Cl$ dissolves in $POCl_3$, a similar interaction takes place[96].

Taking into account the solvation of both the cation and anion, it has been concluded[22] that a total solvation limit exists at which the number of moles of the solvent per mole of the salt is equal to the sum of the coordination numbers of the ions. Since the actual salt solubilities are in many solvents higher than the total solvation limits, an insufficiency of the solvent leads to competition between the ions for the solvating molecules with advantage going to the more active acceptors. According to Mishchenko and Sukhotin[22], the energy of hydration of bivalent cations exceeds by a factor of 5–7 the energy of hydration of anions. A higher degree of solvation is also indicated by many other data[97].

It is clear from the foregoing that the effect of the interionic interaction and structural packing density play an extremely significant role in the solubility of electrolytes in addition to ion solvation. In particular, this leads to the sparing solubility of salts consisting of small cations and small anions. The increase of the solubilities of alkali, alkaline earth, and many transition metal halides in the series from chlorides, to bromides, and to iodides can be accounted for by the decrease of the cation–anion interaction energy.

Even the solubilities of salts comprising the anions SO_4^{2-} and ClO_4^-, which have the same structures, are different. For readily solvated cations, the solubility of perchlorate is appreciably higher than that of sulphates. At 25°C the [saturated?] $NiSO_4.6H_2O$ solution contains 29.36% of the salt and the [saturated?] $Ni(ClO_4)_2.6H_2O$ solution 52.87%;[45] this is due to the different strengths of binding of coordinated water to their anions[98].

Thus the solubility of salts depends also on the mutual substitution of anions and solvent molecules in the first and second solvation layers of the cations owing to the different abilities of the anions to form covalent linkages with the cations and different strengths of the hydrogen bonds between a solvent molecule in the solvato-complex and a free solvent molecule, on the one hand, and between a coordinated solvent molecule and an anion, on the other. If the latter predominates over the former, then, when the contribution of the covalent component to the interionic interaction is appreciable, the salt will dissolve less effectively.

For the majority of chlorides, the strength with which water, dimethylformamide, dimethyl sulphoxide, and even alcohol molecules are bound to metal cations is greater than that for the chloride ion. For this reason, the molecules of these solvents displace chloride ions from the coordination spheres of many complexes[99]. Dimethyl sulphoxide is capable of substituting even covalently bound iodide ions; SbI_3, BiI_3 and PbI_2 form conducting solutions in this solvent[100].

The different capacities of salts for dissociation in different solvents are well known; they have in fact led to the concept of differentiating solvents[101]. Later, Parker[85], who gave preference to electrostatic interaction and hydrogen bonding, considered only two groups of solvents in his assessment of their different behaviour with respect to electrolytes: protic and dipolar aprotic solvents. However, although this approach has been successful in a few instances, it is too narrow and Miller and Parker therefore attempted to reconcile the differentiating action of solvents with solvation effects[86]. They put forward the following hypothesis: the degree of solvation of anions by protic solvents decreases with increase of their radii:

$$OH^-, F^- > Cl^- > Br^- > N_3^- > I^- > NCS^- > ClO_4^-,$$

while the degree of solvation by aprotic solvents decreases in the opposite sequence. In the former case, the strong solvation can be accounted for by the enhanced ability of the anions to form hydrogen bonds with small anions and in the latter by the polarising action of the aprotic dipoles on the large anions. Consequently, the greater the polarity of the solvent the stronger its interaction with anions (particularly large anions). Nevertheless, this hypothesis conflicts with many factors. In fact, the lower solubilities of many salts in nitromethane compared with acetonitrile (see Section II) are due to the greater ease of formation of salt solvates in acetonitrile and not to the difference between the polarities of their molecules[102]. In conflict with Miller and Parker's hypothesis[86], in acetone the silver ion combines more strongly with the iodide ion than with the chloride ion[103] and the solubility of metal halides in ammonia (a protic solvent) increases on passing from fluorides to iodides[51]. Furthermore, among the hydrates $NaHal.2H_2O$, $NaI.2H_2O$ is the most stable, while KI does not form stable hydrates at all. Consequently the effect of salt solvation depends more on the nature of the cation than on that of the anion. Miller and Parker's explanation of solvation processes and solubility is based on an electrostatic concept, which, however, cannot be adopted without significant improvements. From the point of view under consideration, anions of the F^- type should interact vigorously with aprotic solvents, since they have comparatively high field strengths; for this reason, LiF should be more soluble than KF even in water, which is not the case.

IV. THE QUANTUM-CHEMICAL ASPECT OF SOLVATION

The majority of known instances of high solubilities of inorganic substances in various solvents[57,67,77-80] cannot be explained without taking into account the donor–acceptor interaction of solvent molecules with both ions and neutral molecules of the solute. An intense absorption band at 3000 Å, indicating the occurrence of interaction between the system components, has been observed even for a solution of iodine in benzene[104]. The formation of a solvato-complex in this solution is also indicated by the increased dipole moment (1.8 D)[105] caused by charge transfer from benzene to iodine[105,106].

If it is assumed that this complex exists in two mesomeric forms, i.e.

$$C_6H_6 \cdot I_2 \leftrightarrow C_6H_6^+ - I_2^-,$$

then the system in the ground state can be described by a wave function of the following type:

$$\psi_N = a\psi_0(C_6H_6 \cdot I_2) + b\psi_1(C_6H_6^+ - I_5^-). \tag{5}$$

Since the C_6H_6–I_2 bond is weak, the relation between the coefficients a and b is given by the inequality

$$a^2 \gg b^2. \tag{5a}$$

For the excited state, in which the ionic form of the complex should predominate, the expression defining the wave function ψ_E is similar to Eqn. (5), but the coefficients a' and b' are different and the second term $b'\psi_1(C_6H_6^- - I_2^+)$ has a minus sign. The following relations hold between the coefficients a and b and between a' and b':

$$\begin{gathered} a^2 + b^2 + 2abS_{01} = 1; \\ a'^2 + b'^2 - 2a'b'S_{01} = 1, \end{gathered} \tag{5b}$$

where S_{01} is the overlap integral for the wave functions ψ_0 and ψ_1, which is proportional to the interaction integral between the orbital of the solvent molecule and the orbital of the solute species.

Using the Schroedinger equation, the ground state of the solvato-complex can be represented by the relation

$$H(a\psi_0 + b\psi_1) = E(a\psi_0 + b\psi_1), \tag{6}$$

where H is the Hamiltonian and E the energy. The following equations can be obtained by the variational method:

$$\begin{gathered} a(E_0 - E) + b(H_{01} - ES_{01}) = 0; \\ a(H_{01} - ES_{01}) + b(E_1 - E) = 0, \end{gathered} \tag{7}$$

where $E_0 = \int\psi_0 H\psi_0 d\tau$, $H_{01} = \int\psi_0 H\psi_1 d\tau$, and $E_1 = \int\psi_1 H\psi_1 d\tau$. The expressions

$$E = E_0 - \frac{(H_{01} - ES_{01})^2}{E_1 - E}; \tag{7a}$$

$$\frac{b}{a} = \frac{H_{01} - ES_{01}}{E_1 - E}, \tag{7b}$$

can be found from Eqn. (7). To facilitate the calculation, it is assumed that the degree of charge transfer in the ground state of the solvato-complex defined by the wave function ψ_N is low. E can then be replaced by E_0 in Eqns. (7a) and (7b):

$$E_N = E_0 - \frac{(H_{01} - E_0S_{01})^2}{E_1 - E_0}; \tag{7c}$$

$$\frac{b}{a} = -\frac{H_{01} - E_0S_{01}}{E_1 - E_0}. \tag{7d}$$

The energy of the solvato-complex E_N in the ground state is equal to the heat of its formation from the components; E_0 is the energy of the electrostatic interaction between the solvent and solute molecules. The second term in Eqn. (7c) defines the covalent component of the A–Solv linkage. For the complex $I_2.C_6H_6$, both terms in Eqn. (7c) are comparable in magnitude. For more stable solvato-complexes, E_0 is very low and may be neglected. The heat of formation of the complex is then given by the expression

$$\Delta H = -\frac{(H_{01} - E_0S_{01})^2}{E_1 - E_0}, \tag{8}$$

or, after substituting Eqn. (7d),

$$\Delta H = -(E_1 - E_0)\frac{b^2}{a^2}. \tag{8a}$$

The transition from the ground to the excited state, to which corresponds the characteristic absorption band of the complex $I_2.C_6H_6$, is accompanied by electron transfer from the benzene molecule to the iodine molecule:

$$h\nu = E_E - E_N, \tag{9}$$

which transforms into the following expression when account is taken of Eqn. (7c) and the analogous expression for the energy of the excited state E_E:

$$h\nu = (E_1 - E)\left[1 + \left(\frac{b'}{a'}\right)^2 + \left(\frac{b}{a}\right)^2\right]. \tag{9a}$$

The expression for the energy $h\nu$ of the charge-transfer band of the solvato-complex can also be formulated in a different way:

$$h\nu = I_{C_6H_6} - F_{I_2} + J, \tag{9b}$$

where $I_{C_6H_6}$ is the ionisation potential of the benzene molecule, E_{I_2} the electron affinity of the I_2 molecule, and J a constant.

The energy $h\nu$ is related to the stability of the solvato-complex. For a given solute, for example, iodine, there is a linear relation between $h\nu$ for solvates formed with different solvents and their ionisation potentials.

As stated above, the nature of the interaction between the solute and the solvent can be inferred also from the change in the dipole moment of the solution. Thus, in a benzene solution of iodine, the admixture of $C_6H_6^+$–I_2^- to the ground state explains the polarity of the complex[107].

The dipole moment of the solvato-complex in the ground state is defined by the relation

$$\mu = e\int\psi_N \sum r_i d\tau, \tag{10}$$

where e is the electronic charge and r_i the vector-distance of the ith electron. Taking into account Eqns. (5) and (5b), Eqn. (10) can be written in the following form:

$$\mu_N = a^2\mu_0 + b^2\mu_1 + 2ab\mu_{01}, \tag{10a}$$

where μ_0 and μ_1 correspond to Eqn. (10) and $\mu_{01} = e\int\psi_0\Sigma r_i\psi_1 d\tau = 1/2S_{01}(\mu_0 + \mu_1)$. Ultimately one obtains

$$\mu_N = a^2\mu_0 + b^2\mu_1 + abS_{01}(\mu_0 + \mu_1). \tag{10b}$$

Taking into account Eqn. (5b) and the known dipole moment of the solvato-complex (μ_N), the overlap integral S_{01}, the induced dipole moment (μ_0), and the dipole moment of the solv$^+$–A$^-$ state of the solvato-complex (μ_1), it is possible to calculate from Eqn. (10b) the wave function coefficients a and b. For complexes of the type $I_2.C_6H_6$, the dipole moments of the components are assumed to be zero ($\mu_0 = 0$) and $\mu_1 = er$. Having adopted $r = 3$ Å, calculation yields $\mu_1 \simeq 15$ D. If the overlap integral $S_{01} = 0.1$, μ_N for the solvato-complex is equal to the dipole moment of the A = Solv linkage or

$$\frac{\mu_{A\text{-Solv}}}{er} = b^2 + abS_{01}. \tag{10c}$$

Eqn. (10c) expresses the degree of charge transfer in Solv$^+$–A$^-$. It has in fact been shown in this way that the increase of the dipole moment in complexes of the type $I_2.C_6H_6$ is caused by charge transfer.

When the coefficients a, b, a', and b' and the overlap integral S_{01} have been calculated with the aid of Eqns. (5b), (8a), and (9a), then, using the experimental values of ΔH and $h\nu$ (for different values of $E_1 - E_0$), it is possible to estimate the dipole moment of the solvato-complex. For example, it has been found that $\mu_N = 2.1$ D for $I_2.O(C_2H_5)_2$ when $E_1 - E_0 = 4.2$ eV and $r = 3.0$ Å, which agrees well with experiment (1.9 D).[108] Thus, quantum-chemical calculations have shown that the solvation process is accompanied by a redistribution of electrons characteristic of chemical interaction.

Bernal and Fowler[23] already noted that the solvation energy of a given cation approaches the overall ionisation potential of the corresponding atom. Although the authors adhered to the electrostatic point of view, they nevertheless explained this fact correctly by the return of the missing electrons to the ion (via none other than a donor–acceptor interaction). The validity of this conclusion also becomes evident when the solvation effects for ions bearing the same charges and having similar radii are compared. For example, the solvation energies of Cd^{2+} (0.92 Å) and Ca^{2+} (0.94 Å) are respectively 532 and 346 kcal g-ion^{-1} in ammonia, 430 and 367 kcal g-ion^{-1} in water, and 412 and 309 kcal g-ion^{-1} in formic acid[46]. A similar difference between solvation energies has been observed for Na^+ and Ag^+.[109]

The high solvation energies of cadmium, zinc, and silver ions in ammonia, water, and other electron-donating solvents can be more correctly attributed to the formation of coordinate bonds[81,92,109] rather than to a simple ion–dipole interaction. This is particularly evident from the fact that high solvation effects are observed for cations which usually behave as active complex-forming agents. A similar view has been defended also by other investigators[13,110], who identify solvation with interaction between Lewis acids and bases. However, according to Pearson[13] the bonds formed by Al^{3+}, La^{3+}, Ti^{4+}, Cr^{3+} and other so called hard acids with water, alcohols, and amines are electrostatic, which conflicts with experimental findings.

Solvents with a high donor capacity usually form stable solvato-complexes with cations, as a result of which conducting systems are produced[77-80]. For example, many compounds and even metals[111] which are insoluble in water dissolve in liquid ammonia; on the other hand, calcium chloride is almost insoluble in this solvent[112].

Since the ionic component of the bond does not exceed 50% even in compounds of the MgO type[113], in the solvato-complexes $[Zr(DMSO)_6]^{4+}$, $[Ag(CH_3CN)_2]^+$, etc. its contribution is even smaller. According to some data[114-116], the solvation energy cannot be reliably calculated on the basis of the electrostatic model. The interaction of solute species with solvent molecules can be regarded as ordinary complex formation. Solvation and the properties of solvato-complexes can then be reliably accounted for by the molecular orbital method. In fact, the ion solvates formed in solution can be described by a set of wave functions of the central ion (sp^3d^i) with certain hybrid functions of the solvent molecules:

$$\psi = a\psi_c + b\Phi, \tag{11}$$

where ψ_c are the wave functions of the atomic orbitals of the central atom involved in the formation of bonds and Φ is an average wave function of the solvent molecules attached to the central atom. The solvates of the simplest ions are usually more susceptible to a quantum-chemical interpretation. For example, calculations on the aquo-complexes of lithium and sodium by the LCAO-MO method have been carried out in a number of studies[117-121] and some investigators[119,120] examined only the simplest systems $Li...OH_2^+$, $Na...OH_2^+$, and $H_2O...Li...OH_2^+$.

Calculations have been made[122] by Hoffmann and Lipscomb's method[123] for different internuclear distances and it has been found that the equilibrium distances for Li^+ and Na^+ are appreciably lower than the sum of the crystal-chemical radii of the M^+ ions and water molecules for all values of m in $M(H_2O)_m^+$, which indicates an appreciable contribution of the covalent bond character in these aquo-complexes. The internuclear distances for the potassium aquo-ion are closer to the sum of the crystal-chemical radii. However, it appears somewhat strange that the hydration shells of lithium consisting of six molecules and those of sodium and potassium consisting of eight molecules are more favourable than the tetrahydrate and hexahydrate shells respectively.

Unfortunately, at the present time quantum-chemical calculations on solvation have not gone beyond the limits of aqueous systems. In contrast to water, certain non-aqueous solvents can form π bonds in addition to σ bonds with solute ions or molecules. In this case, the atomic orbitals of solute molecules should be used to calculate yet another molecular wave function Φ', which may combine with the atomic functions of the central ion ψ_c on formation of a π bond. Evidently solvents of the second type, such as, for example, DMSO, should possess an enhanced solvent power.

Chatt[124] took a view similar to the concepts just described; he believes that the enhanced solubilities of certain transition and d^{10} metal salts in π-acceptor solvents can be accounted for by the presence of the weakly held external d^i electrons of the cation. Using these ideas, it is possible to explain many instances of different types of behaviour of salts in different solvents[125-127], for example, the behaviour of $CaCl_2$ and $ZnCl_2$ in $POCl_3$.[127]

The solvent power and the dissociating capacity of the solvent should depend on the relative energy levels of the electrons of solvent molecules and the corresponding ion making the greatest contribution to the bonds formed.

V. DETERMINATION OF SOLVATE-ION NUMBERS

The study of mixed solutions is extremely fruitful in the determination of the composition of solvates. It is then possible not only to establish the composition of the solvent but also to estimate the relative capacities for solvation of a particular pair of solvents and to show which of them interacts with the solute in the presence of the other. The method of solubility has also proved useful in such cases[128-130].

In a mixture of two solvents, one of which hardly dissolves the given substance A and the other readily dissolves it, equilibrium is established following saturation:

$$\mathrm{A} + m\,\mathrm{Solv} \rightleftarrows \mathrm{A}\cdot m\,\mathrm{Solv}.$$

The constant

$$K = \frac{[\mathrm{A}\cdot m\,\mathrm{Solv}]}{[\mathrm{Solv}]^m} \tag{12}$$

is a quantitative characteristic of the capacity of the substance for solvation by the given solvent in the presence of the other. By taking logarithms in Eqn. (12), we obtain the relation

$$\lg[\mathrm{A}\cdot m\,\mathrm{Solv}] = m\lg[\mathrm{Solv}] + \lg K, \tag{12a}$$

which represents a straight line with a conventional slope m. Assuming that $[\mathrm{Solv}] = lc_{\mathrm{solv}}$, where l is a proportionality coefficient and c_{solv} the overall concentration of the solvent, it is possible to determine the solvation number via a combined graphical and analytical method and then also the equilibrium constant

$$K = \frac{[A\cdot m\,\mathrm{Solv}]}{\{c_{\mathrm{solv}} - m[\mathrm{A}\cdot m\,\mathrm{Solv}]\}^m} \tag{12b}$$

itself.

By studying the solubility of $CuCl_2$ in dioxan–solvent (alcohols, dimethylformamide, water) mixtures, it was found that $m = 2$. Table 1 presents the solvation numbers found by the solubility method for a series of other salts. In most instances these numbers agree with the usual coordination numbers of the cations. The lower values of the solvate-ion numbers suggest that salt anions and in some cases also molecules of the second solvent enter into the coordination sphere.

Table 1. The solvation numbers of salts based on their solubilities in dioxan–solvent systems.

The solvation numbers of undissociated molecules or salts with weakly solvated anions can be most effectively determined by this method. On the other hand, when the salt solvation proceeds in accordance with equilibrium

$$AB_l + n\,\text{Solv} \rightleftarrows A \cdot m\,\text{Solv}^{+l} + l\,B\,i\,\text{Solv}^-,$$

Eqn. (12a) becomes

$$\lg[A \cdot m\,\text{Solv}^{+l}] = \frac{n}{l+1}\lg[\text{Solv}] + D, \tag{13}$$

where D is a constant. In this case the plot based on Eqn. (13) yields the slope

$$\frac{n}{l+1} = \text{slope}, \tag{14}$$

and hence gives only an approximate idea about the solvation of the salt. In order to determine the solvation number of the cation, it is necessary to have additional data concerning the number of molecules i of the solvating solvent attached to the anion. Then,

$$m = \text{slope}\,(l+1) - i. \tag{14a}$$

To determine the solvation number in mixed solvents, one can sometimes use successfully also the spectrophotometric method[132] in conjunction with the Bjerrum procedure[135] or by plotting the simpler relation

$$\lg\frac{D_x}{D_{\max} - D_r}\, m \lg[\text{Solv}] + \lg K, \tag{15}$$

where D_X and $D_{\max}$ are the optical densities of solutions with partial and complete solvation of the solute and

$$K = \frac{[A \cdot m\,\text{Solv}]}{[A][\text{Solv}]^m}. \tag{16}$$

The compositions and formation constants of the dimethylformamide solvates of $CoCl_2$, $NiCl_2$, and $CuCl_2$ in methanol and ethanol were determined by this method[136,137]. It was found that $m = 4$ (moderate DMF concentrations) and $m = 6$ (high concentrations of the solvating solvent) for the first two salts. Under analogous conditions, $m = 2$ and 4 for $CuCl_2$.

In a spectrophotometric study of UO_2Cl_2 solutions in a carbon tetrachloride–tributyl phosphate (TBP) mixture, plots based on Eqn. (15) established the existence of the solvato-complexes [UO_2Cl_2.3TBP] and [UO_2Cl_2.2TBP].[138] The addition of two molecules of pyridine to $CoCl_2$ was established by the same method in the presence of acetone[139,140]. The solvation numbers have been determined spectrophotometrically in a number of investigations[141-145]. Those of neodymium, amounting to 6–8[144] and 4[145], have been found for aqueous alcoholic solutions of $NdCl_3$. The latter number must be regarded as too low, since the solvation shell of neodymium probably incorporates alcohol molecules as well as those of water[140,147]. Other literature values of the solvation numbers of neodymium are 6[148] and 8–9.[149-151]

In order to determine the composition of solvato-complexes by the Bjerrum method, the average solvation number $\bar{m}$ can be calculated for two series of solutions with constant but different salt concentrations and uniformly increasing contents of the solvating solvent:

$$\bar{m} = \frac{c''_{\text{Solv}} - c'_{\text{Solv}}}{c''_A - c'_A}, \tag{17}$$

where c''_A and c'_A, on the one hand, and c''_{Solv} and c'_{Solv}, on the other, are the overall concentrations of the components in two solutions belonging to two different series. In order to evaluate the formation constants, one calculates initially the equilibrium concentration of the solvating solvent:

$$[\text{Solv}] = \frac{c''_A c'_{\text{Solv}} - c'_A c''_{\text{Solv}}}{c''_A - c'_A}, \tag{18}$$

and then one plots the relation

$$m = f(\lg[\text{Solv}]). \tag{18a}$$

By studying the electronic spectra, one can follow the formation of complexes with different solvation numbers (up to the maximum value) and one can observe also the variation of the actual geometry of the solvato-complex. The vibrational spectra (infrared and Raman spectra) can be used to investigate solvation, like the electronic spectra. Compared with the pure solvent, the infrared spectra of solvato-complexes show new bands corresponding to the stretching and deformation vibrations of the bonds and reveal shifts of the vibrational wavenumbers and changes in the intensities of certain absorption bands of the solvating solvent. Since solvates dissociate in solution, the measured vibrational spectra show absorption bands referring both to the complex itself and to free solvent molecules. With increase of solvate concentration, the intensity of the former increases and that of the latter falls. In order to determine the composition of solvates, the vibrational spectroscopic results can therefore be treated similarly to electronic spectra. For example, the addition of one ethyl oxalate and one ethyl malonate molecule to $SnCl_4$ was demonstrated by the change in intensity of the stretching vibration band of the bound and free C=O groups in a benzene solution[152].

In a study of the infrared spectra of acetone solutions of MI and $MClO_4$ (M = Li or Na), it was noted that the C=O stretching vibration band shifts towards lower wavenumbers by 3 cm^{-1} for Na^+ and by 8 cm^{-1} for Li^+.[191] Since this shift is independent of the nature of the anion, it was natural to conclude that the cations are solvated much more intensely than the anions[192] and that the capacity for solvation increases from Na^+ to Li^+.

Conductimetric[153] and cryoscopic[154-163] measurements are sometimes used in the study of salt solvates. Thus the solvation of Al_2Br_6 by acetone and nitrobenzene leads to the formation of two compounds: $AlBr_3$.Solv and $AlBr_3$.2Solv.[164] The decrease of the conductivity of an ethereal solution of $AlCl_3$ with increase of the chloride concentration[31] can be accounted for by the conversion of the more complicated partly dissociated solvato-complex into the less complicated compound $[Cl_3Al.O(C_2H_5)_2]$, which agrees with the literature[165,166].

When cryoscopic measurements are used, it is first necessary to determine the association factor of the solvating solvent:

$$F_c = \frac{\Delta t}{\Delta t'}, \tag{19}$$

where $\Delta t'$ and Δt are the freezing point depressions of the solutions found experimentally and calculated theoretically. It is convenient to use dioxan, in which many solvents are not associated, as the inert solvent[131]. The variation of the freezing point depressions of solutions of the solvating solvent and the test substance in dioxan yields

$$\Delta t_1 = qc_1; \tag{20}$$

$$\Delta t_2 = qc_2, \tag{20a}$$

where c_1 and c_2 are the molar concentrations of the solvating solvent and the solute respectively. When solvato-complexes involving the addition of m solvent molecules are formed, the overall freezing point depression is

$$\Delta t = q(c_1 - mc_2 + c_2), \tag{21}$$

whence

$$m = \frac{qc_1 + qc_2 - \Delta t}{qc_2}. \tag{22}$$

The addition of one $POCl_3$ molecule to $FeCl_3$ and $AlCl_3$ in nitrobenzene[167] has been demonstrated cryoscopically.

A frequently used method for the determination of solvation numbers is that of Stokes. By following the movement of the solvated ion in an external electric field, it is possible to calculate the radius of the solvato-complex as follows:

$$r = \frac{0.82z}{\eta\lambda}, \tag{23}$$

where z is the absolute charge of the ion, λ the limiting equivalent conductance of the solution, η the viscosity of the solvent.

In order to find a more accurate value of the radius of the solvated ion, the following equation has been proposed[168]:

$$r' = \frac{0.82z}{\eta\lambda} \cdot \frac{r_{cr}}{r}, \tag{24}$$

where r' is the exact radius of the solvato-complex and r_{cr} the crystal-chemical radius of the ion investigated.

Table 2 shows that the radii of the solvated ions calculated by Eqn. (24) are higher than the Stokes values. Furthermore, according to Della Monica and Senatore[169], the solvation of cations should take place more vigorously than that of anions, since the radii of the solvato-complexes of the latter are smaller.

The volume of the solvation shell can be found from the radii of the solvated ions by means of the equation

$$V_{Solv} = \frac{4}{3}\pi(r^3 - r^3_{cr}), \tag{25}$$

and then the solvation number can be obtained:

$$m = \frac{V_{Solv}}{V}, \tag{26}$$

where V is the volume of one solvent molecule. Calculation based on Eqns. (24)–(26) led to the determination of the solvation numbers of Li^+: 4.6 (in water); 5 (in acetone); 6 (in acetonitrile); 11 (in ethanol). We believe these values to be too high.

Table 2. The radii r and r' (Å) of certain solvated ions in a number of solvents calculated by Eqns. (23) and (24).[169]

Ion	Methanol		Acetonitrile		DMF		Sulpholane		Nitrobenzene		Formamide	
	r	r'	r	r'	r	r'	r	r'	r	r'	r	r'
Li^+	3.77	4.74	2.98	4.13	4.12	5.10	1.92	3.74	—	—	2.92	4.36
Na^+	3.32	4.46	3.10	4.24	3.45	4.46	2.30	4.23	2.78	3.99	2.46	3.99

Cl^-	2.86	4.16	2.54	3.76	1.87	3.00	0.89	1.98	2.04	3.32	1.45	3.14
I^-	2.39	3.88	2.38	3.56	1.97	3.09	1.15	2.47	2.22	3.49	1.45	3.21
NO_3^-	2.80	4.14	2.24	3.48	1.80	2.92	—	—	2.00	3.30	1.44	3.14

In order to investigate ion solvation, a potentiometric method was proposed in 1958[92,93,95] whereby it is possible to deduce the existence of both homogeneous and mixed solvato-complexes. As in the usual complex-forming systems[170-172], the inert solvent should possess some ionising capacity and the metal corresponding to the salt should form an effective electrode of the first kind. If the solvating solvent binds metal ions into solvates more effectively than the inert solvent, its introduction into the system leads to a decrease of the electrode potential. Knowing the overall concentration of metal ions c_M and having determined its equilibrium value [M] potentiometrically, it is possible to calculate the solvation number of the ion:

$$m = \frac{d \lg \frac{c_M - [M]}{[M]}}{d \lg [Solv]}, \tag{27}$$

where [Solv] is the concentration of the solvating solvent. The formation constant of the solvato-complex can be calculated from Eqn. (16), having assumed that $[A.m\,Solv] = c_M - [M]$ and having replaced [A] by [M].

A combined graphical and analytical treatment of the potentiometric data[95,172] established that the hydration of lead and silver ions changes by 3–4 coordination sites as high concentrations of dioxan and acetone are reduced in the presence of water[93,170]. This is due to the formation of mixed solvates. Homogeneous hydrates of lead ions $[Pb(H_2O)_6]^{2+}$ are detected at high water concentrations in the $Pb(ClO_4)_2$–CH_3OH–H_2O system[173] and the solvates $[M(DMF)_6]$ are detected[174] in the $M(ClO_4)_n$–DMF–H_2O systems, where M = Cd, In, or Sn.

The formation of solvato-complexes can be observed also in a direct study of the properties of solvent molecules. This is achieved best with the aid of the NMR method[175-177] using the chemical shift δ. When the experiments are performed at a fixed frequency $\nu_{av} \simeq \nu_0$, the distance between the signals of the test and standard solutions being determined, the chemical shifts can be estimated as follows:

$$\delta_i = \frac{\nu_i - \nu_{av}}{\nu_{av}} = \frac{\nu_i - \nu_{i\,av}}{\nu_0}. \tag{28}$$

If the solvent molecules with resonating nuclei are attached to a solute molecule or ion, the chemical shift of the nuclei is displaced relative to that of the free solvent molecules. In the absence of exchange between the solvato-complex and free molecules or when its rate is low, the NMR spectrum shows lines due to the resonance of the nuclei of the coordinated and free solvent molecules. By measuring the integral signal intensities, it is possible to determine the concentrations of the bound and free solvent and to calculate from the known concentration of the solute the solvation number and the equilibrium constant for the formation of the solvato-complex[175-188]. In particular, the solvation number can be calculated[184,185] with the aid of the equation

$$m = i\frac{S_c}{S_c + S_f}, \tag{29}$$

where i is the total number of moles of the solvent per mole of the solute and S_c and S_f are the areas under the signals due to the bound and free solvent. Using Eqn. (29), Yatsimirskii et al.[186] found that five water molecules are retained by Lu^{3+} in an acetone solution of $Lu(NO_3)_3.6H_2O$. However, the overall coordination number of lutetium reaches at least 8, since the conductivity of the test solution at a concentration of 0.01 M is extremely low.

On the other hand, when there is an appreciable exchange between the free and bound components of the solvato-complex, the NMR spectrum reveals a single signal:

$$\delta = \delta_1\frac{c_1}{c} + m\frac{c_m}{c}\delta_m, \tag{30}$$

where δ is the average chemical shift of the solvent molecules, δ_1 and δ_m are the chemical shifts of the atoms in the free solvent and the solvent bound in the complex, m is the solvation number, and c_1, c_m, and c are the concentrations of the free solvent, the bound solvent, and the entire active solvent in the system. In particular, the presence of the complexes $[Gd(H_2O)_9]^{3+}$,[182] $[ThCl_4.2DMF]$,[94] and $[Al(DMF)_6]^{3+}$[188] has been established using Eqn. (30). The solvation numbers found for Mg^{2+} are 5 in liquid ammonia[183] and 5 with respect to methanol and 5.7 (with respect to water) in water–methanol mixtures. The authors explained the deviation of the overall solvation number of magnesium from 6 by the partial incorporation of perchlorate ions in the coordination sphere[184]. The more vigorous solvation of Li^+ was established in a study of the NMR spectra of solutions of lithium and sodium salts in DMSO.[187]

In the course of solvation, it is possible to determine the chemical shift of the solvent also in the presence of paramagnetic ions, which influence the NMR spectra as a result of the exciting effect of the unpaired electron on the electronic structure of the solvent molecule. The chemical shift can then be defined as follows:

$$\delta = \frac{8\pi|\psi(0)|^2}{3p}c_{Solv}, \tag{31}$$

where $|\psi(0)|$ is the probability that the unpaired electrons are located near the solvent protons, c_{Solv} the concentration of the solvating solvent in solution, and p a quantity which includes the solvation number of the metal ion. The hexasolvates of nickel and cobalt(II) in acetonitrile have been detected with the aid of Eqn. (31).[189,190]

The X-ray diffraction method is promising for the detection of solvato-complexes. It has been stated[193-196] that there is an analogy between the structures of solids and the corresponding liquid systems. In particular, an octahedral environment has been demonstrated for copper, cobalt, and nickel cations in aqueous solutions[194]. The intensities of X-ray scattering by the solvent and the solution are usually determined by this method and data for the structure of the liquid are obtained by analysing the areas under the maximum of the atomic-electronic density distribution function. The position of the maximum on the distribution curve yields the average distance between the coordinated species. Having measured the area under the maximum on the experimental distribution curve, it is possible to determine the coordination number of the species. Although X-ray diffraction analysis does not always lead to an accurate determination of the bond lengths and valence angles, nevertheless, it has shown that hexasolvate cations are formed in 2–2.5 M $CuCl_2$ and $CoCl_2$ solutions in methanol, ethanol, and dimethylformamide. The chloride ions are then distributed in the secondary solvation shell[136,137].

In order to confirm the conclusions concerning the possible solvates in solution, their preparative study is extremely useful[128,197,198]. As in the physicochemical study of solutions, the synthesis of solvates from different solvents does not by any means always yield the same solvation numbers. This is due to the nature of the solvating solvent and the specific conditions governing the applicability of the research technique.

VI. THE DONOR ACTIVITY OF SOLVENTS

Data concerning the displacement of molecules of one solvent by another in solvato-complexes[92,200-202] can serve as a basis for the estimation of their donor activity. In this respect, valuable information is provided by infrared spectroscopy. For example, the decrease of the solvating capacity of alcohols with respect to Co^{2+} in the following sequence has been demonstrated on the basis of the shift of the absorption band due to the stretching vibrations of the OH group[203]:

$$CH_3CH((OH)CH_3 > (CH_3)_3COH > C_2H_5OH > CH_3(CH_2)_2OH \simeq CH_3(CH_2)_3OH >$$
$$> CH_3CH(OH)C_2H_5 > CH_3(CH_2)_4OH.$$

The solvating capacity of solvents is sometimes estimated from their basicity:

$$H^+ + Solv \rightleftarrows HSolv^+.$$

The higher the constant K_a for the above equilibrium the higher the donor activity of the solvent. Thus the pK_a values for acetone (7.2) and acetonitrile (10.13), which in most cases behave as weakly solvating solvents, are appreciably lower [higher?] than that for dimethyl sulphoxide (0.00).[204]

The sequence of solvent basicities indicated above is consistent with the sequence of solvating capacities determined by other methods. Thus the following sequence in the variation of the donor activities of solvents has been established by NMR from the concentration variation of the chemical shift δ[Eqns. (30) and (31)] of the water protons in water–non-aqueous solvent mixtures in the presence of $AlCl_3$, $TiCl_4$, or $CoCl_2$:[205]

$$DMSO > CH_3OH > C_2H_5OH > [(CH_3)_2N]_2CO \simeq THF > (CH_3)_2CO \simeq CH_3CN \simeq C_4H_8O_2.$$

As was to be expected, the values of δ for the solvating solvent protons are not correlated with their dipole moments and the dielectric constant ϵ.

To compare the abilities of various ions to combine with the same solvent, Izmailov[206] determined their solvation energies assuming them to be similar for isoelectronic ions and assuming that they decrease with increase of the square of the principal quantum number (n^2) of the vacant orbitals. The determination of the solvation energy of the ion reduces to the extrapolation of the almost linear function

$$\Phi = \frac{1}{2}\left[Q_{\text{ion}} + (Q_{\text{Hal}} - Q_{\text{M}^+})\right]. \tag{32}$$

The calculations are performed for $n = 3$, 4, 5, or 6 and Eqn. (32) is then extrapolated to $1/n^2 = 0$. In this case, M^+ is the alkali metal ion. The corresponding sums and differences are determined from the e.m.f.'s of cells with and without transport:

$$\lim \Phi = Q_{\text{ion}} \text{ when } \frac{1}{n^2} \to 0.$$

The values of Q for M^+ and Hal^- in water, ammonia, methanol, and ethanol were calculated from the experimental data. The results of the calculation for the same metal ion lead to the conclusion that the donor activities of the solvents vary.

A comparative assessment of the solvating capacities of the solvents can be made also by comparing the equilibrium constants for the dissolution of substances in mixed solvents evaluated by Eqn. (12). Thus it has been shown for dioxan–solvent mixtures[128,190] that the solvating capacity varies in the following sequence: ethanol < methanol < dimethylformamide.

Table 3 shows that the negative logarithms of the constants for the equilibrium

$$CuCl_2 + 2Solv \rightleftarrows CuCl_2 \cdot 2Solv$$

in dioxan solution increase from dimethylformamide to ethanol. According to the p*K* value, water follows ethanol in this sequence, which appears to show that its solvating activity is weak. This can be accounted for by the ability of dioxan[207] to form strong hydrogen bonds with water. Bearing this in mind, the method under consideration cannot be regarded as universal for the estimation of the donor activities of solvents. The method based on the comparison of the formation constants of solvates calculated by Eqn. (16) and other methods involving the use of an inert solvent suffer from the same disadvantage.

Table 3. The negative logarithms of the formation constants of the solvates $MCl_5.2Solv$ in dioxan solutions.

Solvent	ε	p*K*		
		$CuCl_2$	$CdCl_2$	$NiCl_2$
Methanol	32.6	2.30	3.67	2.62
Ethanol	24.3	2.36	3.75	2.72
Dimethylformamide	36.1	1.44	3.58	2.51
Water	81	2.89	4,36	—

Depending on the donor activity of the solvent, the heat of the solvation reaction

$$A + m\text{Solv} = A \cdot m\text{Solv} + \Delta H$$

will be different. Makarova and Pominov demonstrated in this way the different solvating capacities of alcohols, acetone, and acetonitrile in relation to $CoCl_2$.[208] However, here too one cannot estimate the absolute solvent activities. For this reason, Lindquist and Zackrisson[209] suggested that the donor capacity be determined relative to a standard acceptor ($SbCl_5$ or $SnCl_4$) with which the given donor is combined in 1 : 1 proportions (this should entail the same entropy change). The authors established calorimetrically the following series of solvents based on their decreasing donor capacities:

$$(CH_3O)_3PO > (CH_3)_2SO > (CH_3)_2CO > POCl_3 > SOCl_2.$$

Gutmann and Wychera used the same considerations and introduced the concept of the donor number, which is understood as the numerical value of the enthalpy of addition of a solvent molecule to a molecule of antimony pentachloride in dichloroethane[210]:

$$DN_{SbCl_5} = -\Delta H_{Solv.SbCl_5}. \tag{33}$$

Table 4 shows that the dielectric constant and the donor number of the solvent do not vary in parallel. This shows that the covalent interaction predominates over the electrostatic interaction in solvation processes.

Table 4. The donor numbers and the dielectric constants of certain solvents[51].

Solvent	ε	DN_{SbCl_5}	Solvent	ε	DN_{SbCl_5}
1,2-Dichloroethane	10.1	—	Ethyl ether	4.3	19.2
Nitromethane	35.9	2.7	Tetrahydrofuran	7.6	20.0
Acetonitrile	38.0	14.1	Tributyl phosphate	6.8	23.6
Tetramethylene sulphone (sulpholane)	42.0	14.8	Dimethylformamide	36.1	26.6
Acetone	20.7	17.0	Dimethyl sulphoxide	45.0	29.8
Ethyl acetate	6.0	17.1	Pyridine	12.3	33.1
Water	81	18	Hexamethylphosphoramide	30.0	38.8

A calorimetric study of the solvation of ECl_4, where E = Zr or Hf, in nitromethane established[211] the following series based on the donor activities of solvents:

$$(CH_3)_2SO > (CH_3)_2NCOH > CH_3CN > CH_3NO_2,$$

It agrees with the data in Table 4.

Nevertheless, the same solvent can manifest different solvating capacities with respect to different solutes. Because of this, the solvating capacities of solvents cannot be treated as non-relative quantities and Gutmann's donor numbers cannot be treated as absolute solvent characteristics. For example, acetonitrile does not possess a high capacity for the formation of compounds with Na^+, Pb^{2+}, and Ca^{2+} ions, but it forms solvato-complexes with $AlCl_3$, $GaBr_3$, BF_3, $SnCl_4$, and $TiBr_4$ (without substituting halide ions).[87]

In contrast to the available donor numbers of acetone, ethyl ether, and other ethers (Table 4), the energy of solvation of $NbCl_5$ by acetonitrile (−37.8 kcal) is much higher than the energy of solvation by ethyl and butyl ethers (−21.0 kcal), dioxan, and esters[212]. These findings suggest that the donor activities of solvents are determined not only by their individual properties but also by the specific features of their interaction with the solute.

For a more objective determination of the donor activities of solvents, one can isolate the solvates and determine thermochemically the solvation energies[128,130]. Such a calculation can be performed in connection with the determination of the integral heats of solution of the solvate (ΔH_3), the substance in the absence of the solvating solvent (ΔH_2), and the corresponding solvents (ΔH_1) in water or another liquid in which all the substances enumerated dissolve. The solvation energy can be calculated from the equation

$$\Delta H = \Delta H_1 + m\Delta H_2 - \Delta H_3. \tag{34}$$

Table 5 shows that the solvating capacity of dimethylformamide is highest, water occupying the second place as regards donor activity. The value of the hydration energy obtained for $CuCl_2.2Solv$ is somewhat difficult to understand[130].

Table 5. The solvation energies (kcal) of certain metal chlorides.

Solvent	$CuCl_2\cdot 2Solv$	$CaCl_2\cdot 2Solv$	$ZnCl_2\cdot 2Solv$	$NiCl_2\cdot 2Solv$
Methanol	7.41	4.16	8.20	5.68
Ethanol	7.32	4.49	—	5.62
Dimethylformamide	10.32	7.14	13.13	9.78
Water	7.20	6.10	—	8.47

VII. COMPLEX FORMATION REACTIONS IN NON-AQUEOUS AND MIXED SOLUTIONS

In contrast to aqueous solutions, in the interaction of ions in non-aqueous solutions a multiplicity of anomalies are observed. In the presence of water, the stability of the halides of $s^2p^6d^{10}$ and $s^2p^6d^{10}s^2$ cations decreases in the sequence $I^- > Br^- > Cl^-$. On the other hand, according to a number of workers[213-215], the variation of the conductivities of halides in pyridine solutions follows the opposite sequence. However, if one employs a series of salts with the same anion, then their conductivities in pyridine decrease in the sequence

$$Ag^+ > Li^+ > K^+ > Na^+,$$

i.e. in conformity with the ability of the cations to form pyridine complexes. Only the position of potassium in this series is somewhat incomprehensible, since K^+ is usually less solvated than Na^+. Since potassium ions form relatively unstable solvato-complexes with pyridine, the interaction of $AgNO_3$ with KSCN and even with K_2HgI_4 in this solvent takes place only in consequence of the precipitation of KNO_3.[40,41]

The role of non-aqueous solutions in complex-formation processes involving readily hydrolysed ions is especially great. In particular, the study of the majority of metal selenocyanates involves considerable difficulties. The $\mathrm{C}\overline{\cdots}\mathrm{Se}$ bond in the selenocyanate ion $\mathrm{N}\overline{\overline{\cdots}}\mathrm{C}\overline{\cdots}\mathrm{Se}^-$ is weak and the ion therefore decomposes with elimination of selenium both under the influence of light and in an acid medium. It is quite reasonable that $NCSe^-$ should be stabilised when the electron density of selenium is increased, i.e. when the selenocyanate ligand is bound to a central atom with an enhanced π-donor capacity. Mainly $s^2p^6d^{10}$ ions in the Fifth and Sixth Periods of the Periodic System possess this property. This is why it is possible to detect in aqueous solutions the selenocyanate complexes of silver, mercury, cadmium, gold and one or two more metals with electronic structures similar to that indicated above. On the other hand, La^{3+}, Cr^{3+}, V^{3+}, Mn^{2+}, Zr^{4+}, etc. exhibit only a weak capacity for the formation of dative bonds and, in contrast to the metals listed above, form only unstable E–NCSe linkages, which cannot compete with the $E-OH_2$ or E–OH linkages arising in consequence of hydrolysis. A decrease of pH results in the decomposition of the selenocyanate ligand in such systems and the efficiency of the formation of transition metal selenocyanates can therefore be increased only in non-aqueous solutions[216,217]. Similar effects occur in the study of complex-formation reactions between polyvalent cations and nitrite ions and other weak acid anions[218].

Interesting data have been obtained for the influence of solvents on the complex-formation reaction[61] when silver halides are dissolved in the presence of $AgNO_3$ and $AgClO_4$.[103] The Ag_3I^{2+} dissociation constant varies as a function of the nature of the solvent in the following way:

$(CH_3)_2CO$	H_2O	$(CH_3)_2SO$	CH_3CN
10^{-19}	$10^{-14,1}$	$10^{-10,8}$	10^{-10}

It is seen from these results that dimethyl sulphoxide, in its role as an active solvating agent (with a donor number of 29.8), promotes to a greater extent than water the dissociation of the complex, while acetone tends to stabilise it, although the donor number of acetone is close to that of water (Table 4). On the other hand, acetonitrile has a much lower donor capacity (a donor number of 14.1) and the stability of the complex Ag_3I^{2+} in this solvent is lower than in other solvents. Similar facts have been quoted by Surpina et al.,[219] who noted that in acetonitrile the interaction of $NbCl_5$ with azoles and Schiff bases proceeds with greater difficulty than in esters. This demonstrates yet again that Gutmann's donor numbers are relative[51].

Like dissolution, complex formation depends wholly on the solvation of the central ion and the ligands. The greater the strength of their bonds with solvent molecules, the more difficult it is to make them come together. On the other hand, if the solvent molecules can be removed from the solvato-complexes by binding them to another solvent, then an interionic linkage is formed more readily. This is why it has been possible to detect in aqueous dioxan solution the complex $[Cd(SCN)_6]^{4-}$, which is not formed in water, other conditions being equal[95]. The study of complex-forming systems in mixed and purely non-aqueous solutions permits the formulation of the rule governing the composition of the complexes: the addition to an aqueous solution of a donor-active solvent at moderate and high concentrations of the latter permits the formation of complicated complexes, but, following the attainment of a concentration of 90—100%, the number of acido-ligands in the coordination sphere falls again[95,173,220]. This rule operates in the study of not unduly stable complexes and can be explained by the fact that, at moderate concentrations of the non-aqueous solvent, the latter binds water and facilitates the incorporation of acido-ligands in the coordination sphere in place of water. When its concentration is higher, the non-aqueous solvent itself combines with the central atom and prevents the addition of other ligands.

As a result of the formation of stable dioxan–water compounds[205,220], the activity of water falls and lead–antimony alloys cease to be corroded in the mixed solvent[29]. An increased solvation effect prevents the formation of nickel and cobalt hexaselenocyanate and even tetraselenocyanate complexes in pure dimethylformamide[221], of anionic copper(II) complexes in dimethyl sulphoxide[222], and of molybdenum(V) complexes in hexamethylphosphoramide[223]. Tin forms only $[Sn(NCS)_3]^-$ in dimethylformamide, while the complex in methanol and acetonitrile is $[Sn(NCS)_4]^{2-}$.[174,224] On the other hand, cadmium combines with four thiocyanate ligand species in methanol and dimethylformamide and with six such species in acetonitrile. The stability of cadmium, indium, and tin thiocyanate complexes increases on passing from dimethylformamide to acetonitrile via methanol[225,226].

The examples examined above show that, contrary to the conclusion reached in the literature[227,228], the chemical nature of the solvent has a greater influence on complex formation than the dielectric constant. In solvents which form stable solvates with metal ions, the combination of these ions with other ligands proceeds with greater difficulty. In acetonitrile, $ZnCl_2$ behaves as a stable complex because Zn^{2+} is only weakly solvated by the molecules of this solvent. As a result, the variation of the zinc electrode potential with the concentration of such a solution is anomalous[30]. In acetonitrile, zinc forms anionic chloro-complexes more readily than highly solvated mercury(II). $HgCl_2$, which forms stable solvato-complexes is converted into $[HgCl_4]^{2-}$ in acetonitrile with greater difficulty than in water[229], although the donor number of water is higher[51].

Depending on the nature of the solvent, the sequence of ligands in the series based on the stability of the given metal complexes can also change. For example, the stability of cadmium and lead halide complexes in alcohols and water increases from the chlorides to the iodides, while in dimethylformamide the variation is in the opposite sequence[230-233]. The inversion of the stability sequence of lead halides can be readily accounted for by the enhancement of the solvation of the anions by dimethylformamide and by the increase of their radii. That this is indeed so can be seen from the fact that NaI dissolves more readily in dimethylformamide (and formamide) than NaCl. Furthermore, the enthalpies of solution of metal halides in DMSO vary in the sequence[234]

$$Cl^- > Br^- > I^-.$$

The study of mercury(II) halides in DMF[235], DMSO[236], and dimethylacetamide (DMA)[237], which have very similar donor numbers, has revealed an appreciable variation of the stabilities of these complexes in the following sequence of solvents:

$$DMSO < DMF < DMA < H_2O.$$

The explanation of the dependence of the complex formation reaction on the nature of the solvent taking into account solvation has been confirmed in numerous experiments[220-226,238-244]. The electronic absorption spectrum of the $Co(ClO_4)_2$–NaNCSe–DMF solution with a monomolecular or bimolecular proportion of selenocyanate has a band at 525 nm, i.e. in the region corresponding to the absorption by the octahedral complexes $[Co(NCSe)(DMF)_5]^+$ formed (only the optical density increases). On the other hand, in the presence of a large excess of $NCSe^-$, a new band appears at 625 nm,[243] which is due to the tetrahedral complex $[Co(NCSe)_4]^{2-}$.

In choosing a solvent promoting complex formation, one must take into account both its solvent power with respect to the reactants and the nature of its interaction with the complex formed. The most marked effect of complex formation can be achieved when the donor activity of the solvent is low. For example, in acetone mercury(II) nitrate behaves as a stable complex[242]. Whereas, in acetone, acetonitrile, and other similar solvents Pb^{2+}, Cu^{2+}, Co^{2+}, Zn^{2+}, Cd^{2+}, and In^{3+} ions form readily hexa- and tetra-halogeno- and hexa- and tetrathiocyanato-complexes, in dimethylformamide and dimethyl sulphoxide complexes with low coordination numbers are formed even in the presence of an excess of acido-ligand[221,224,244]. In DMSO, even the proton is very strongly bound[245].

The study of the Raman laser spectra and the freezing points of the solutions showed that, depending on the concentration, phosphorus pentachloride forms the following complexes in acetonitrile, nitromethane and nitrobenzene:

$$2PCl_5 \rightleftarrows [PCl_4]^+ + [PCl_6]^- \qquad (> 0.03\ M)$$

or

$$PCl_5 \rightleftarrows [PCl_4]^+ + Cl^-. \qquad (< 0.03\ M).$$

On the other hand, in solvents such as benzene and carbon tetrachloride, it behaves as the neutral complex $[PCl_5]$.[246]

By selecting solvents in accordance with the above relations, it is possible to detect in non-aqueous solutions numerous complexes which are not formed in aqueous solutions.

VIII. THE INFLUENCE OF SUPPORTING ELECTROLYTE IONS AND "STEPWISE" COMPLEX FORMATION

In many non-aqueous solutions, the initial electrolytes exist as ion pairs, but it is nevertheless possible to demonstrate in such solutions the formation of complexes with substances capable of forming strong bonds with the ions of the given electrolyte. The composition of the complexes in such systems can be readily determined by physicochemical methods and it is even possible to calculate conventional equilibrium constants for the complex-formation reactions. However, depending on the nature of the initial salt of the given metal, the equilibrium constants are not the same in the particular solvent. Thus, the formation of the complex $[Co(NCSe)_4]^{2-}$ with a conventional equilibrium constant of 7.0×10^{-14} was established in the $Co(ClO_4)_2$–NaNCSe–$(CH_3)_2CO$ system[240], while in the presence of cobalt nitrate the equilibrium constant for the same complex proved to be higher.

On the other hand, if the initial salt includes anions which can be bound strongly to the given cation, then the determination of the composition of the complexes yields a low number of ligand species incorporated. This can be explained by the formation of mixed complexes. In particular, a study of the $MoOCl_3$–NaNCSe–$(CH_3)_2CO$ system established the existence of the complex $[MoOCl_3(NCSe)]^{2-}$, which is then converted into $[MoOCl_2(NCSe)_3]^{2-}$ and $[MoOCl(NCSe)_4]^{2-}$.[247]

The formation of a large number of mixed complexes in both aqueous[248] and non-aqueous[245-253] solutions has now been demonstrated. In many instances, mixed complexes are formed more readily than homogeneous complexes. This is apparently due to an energy gain in consequence of the formation of an asymmetric structure, as happens in platinum complexes in accordance with the *trans*-influence principle[254]. When mixed complexes are formed, both the mutual influence of the ligands and the nature of the solvent play an extremely significant role. It is appropriate to note here that the $O(C_2H_5)_2$ molecule combines with BF_3 more readily than the fluoride ion[256,257] in consequence of "chemical symbiosis".[255]

Attempts are sometimes made to explain why mixed complexes are favoured by thermodynamic factors on the basis of the concept of hard and soft acids and bases[13]. In terms of Pearson's rule, the bonds formed by Be^{2+} and

Al^{3+} with acetate ions as well as those formed by the proton with OH^- and F^- should be regarded as ionic, the hydride ion should readily combine with Hg^{2+}, and the Cl^- ion in complexes should behave like the fluoride ion.

In reality this is not so. The formation of hydrides is not characteristic of silver, gold, and mercury. The chloride ion behaves similarly to bromide, iodide, and even thiocyanate. This is why there is a possibility of their mutual substitution with formation of mixed complexes[248,258,259].

For example, the formation of mixed complexes of the type $[E(NCS)_2Cl_2(Solv)_2]$ by zirconium and hafnium can be demonstrated by conductimetric study of the ECl_4–NaNCS–CH_3CN system[260] and $[E(OH)_2(NCS)_2(Solv)_2]$ can be detected when $E(OH)_2Cl_2.7H_2O$ is ground with NH_4NCS in the presence of tributyl phosphate or cyclohexanone[261]. The fact that these are coordination compounds is confirmed by infrared spectra.

If no account is taken of the formation of mixed complexes, then the result of physicochemical study of the corresponding system might lead to the conclusion that the simplest complexes are produced. In reality coordination saturation always takes place in solution owing to the formation of mixed complexes.

The view that complex formation takes place in steps has been firmly established in the literature[135,262-266]. The appearance of each new complex is attributed solely to the kinetic factor, i.e. to the displacement of the equilibrium caused by the increase of ligand concentration. However, this approach is valid only for relatively unstable complexes and provided that account is taken of the incorporation of solvent molecules in the coordination sphere when the E–L and E–Solv bond energies are similar. On the other hand, if $Q(E\text{-}L) \gg Q(E\text{-}Solv)$, then homogeneous complexes EL_n with $n \gg 1$ may be formed even at low ligand concentrations. Under these conditions, only complexes corresponding to the greatest decrease of Gibbs free energy are as a rule produced. Consequently, the thermodynamic and not the kinetic factor is more significant in the formation of stable complexes. Thus when Cu^{2+} interacts with ammonia, the first four NH_3 molecules are bound to the central atom equally strongly, while the fifth molecule combines less effectively[135]. This fact is satisfactorily accounted for by the Jahn–Teller theorem.

Bearing in mind that the incorporation of new ligand species in the complex results in its rearrangement, strengthening some and weakening other bonds, the breakdown of a rigorous sequence based on the increase in the number of species in the complexes with increasing concentration of the corresponding ligand, is quite reasonable. This is why Bjerrum's method has frequently proved unsuitable in the study of non-aqueous solutions[135]. In its general form, this method appears to give a positive result and the relation defined by Eqn. (18a), in which [Solv] has been replaced by the concentration of the acido-ligand, is smooth with distinct horizontal plateaux indicating a high probability of individual complexes. For example, only complexes with $m = 2$, 4, or 6 have been clearly detected in the $E(ClO_4)_2$–NaNCSe–CH_3OH systems, where E = Co or Ni.

It is very remarkable that in methanol, where the stability of nickel selenocyanate complexes is low, the formation function varies more uniformly than in acetone[243]. The formation curve for the cobalt complex reveals the presence of steps also in methanol for $NCSe^- : Co^{2+} = 2$, 4, and 6.[240] More distinct inflections occur in the curve for the acetone solutions, where the stability of the complex is higher.

In contrast to the dimethylformamide solution, an intense band at 400 nm and a weak band at 630 nm appear in the spectrum of the acetonitrile solution already for $Co^{2+} : NCSe^- = 1 : 1$.[243] Bjerrum's formation curve clearly reveals only two steps with $\bar{n} = 1$ and $\bar{n} = 4$. Palladium coordination numbers of 4 and 2 are most clearly manifested in the $PdCl_2$–NaNCSe–DMF system. The latter corresponds to the mixed complex $[PdCl_2(SeCN)_2]^{2-}$.[267]

The formation of only HgI_2 and $[HgI_4]^{2-}$, which are thermodynamically more stable than HgI^+ and HgI_3^-, can be demonstrated in the $Hg(ClO_4)_2$–NaI–solvent systems, where the solvent is an alcohol, acetonitrile, etc.

In dimethyl sulphoxide, Fe^{3+} ions react with CN^- to form only $Fe(CN)_2^+$, $Fe(CN)_3$, and $Fe(CN)_4^-$, or, more precisely, mixed complexes, while the reaction with the fluoride ion yields $[FeF_4(DMSO)_2]^-$.[268] It is of interest that in such cases there are no complexes with six acido-ligands. On the other hand, cobalt chloride forms two complexes in dimethylacetamide: $[CoCl(DMA)_5]^+$ and $[CoCl_3(DMA)_3]^-$.[269]

A series of complexes up to $[E(NCS)_8]^{4-}$ were detected in a study of ECl_4–KNCS systems in acetonitrile and dimethylformamide by Bjerrum's method[260], but they are not all equally probable. This is why the presence of $E(NCS)_4$ is established in experiments involving isomolar series of solutions in dimethylformamide, while $[E(NCS)_6]^{2-}$ is found in acetonitrile. The higher solvating capacity of dimethylformamide under the same conditions leads to the formation of complexes with a smaller number of NCS ligand species than in acetonitrile. It would appear that $E(NCS)_4$ are simple complexes with a coordination number of 4. However, this is not the case, because the complexes $E(NCS)_4.4DMF$, where according to infrared spectra the NCS groups and solvent molecules are coordinated to the metal atom, are isolated from solution[260].

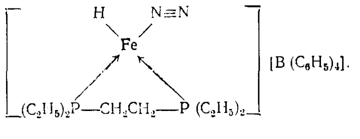
The study of non-aqueous solutions demonstrated the possibility of the coordination of ions which do not usually form complexes in aqueous solutions. In particular, the nitrate ion hardly behaves as a ligand in consequence of its hydration in dilute aqueous solutions. Only at high concentrations of NO_3^- does the potential of the lead electrode decrease[270]. In acetone and even in alcohols, which combine with the nitrate ion less effectively than water, the nitrate ion ceases to be indifferent[44,60]. The coordination compound $[K_2Pb(NO_2)_3(NO_3)]$, in which the nitrate ions behave as a ligand, can be obtained from methanol[271].

Bearing in mind that in many non-aqueous solutions the so called indifferent anions are only slightly dissociated from the corresponding complex-forming agent, in the determination of the compositions of the most involved anionic complexes, one must employ series of solutions with a constant concentration of the initial salt. The study of isomolar series in many instances leads to the determination of the simplest complexes, which are in reality mixed complexes[267,272,273]. The complex $[Pd(SeCN)_4]^{2-}$ has been detected spectrophotometrically in the $PdCl_2$–NaNCSe–DMF system at a constant palladium concentration and variable NaNCSe concentrations, while in the isomolar series of solutions only $[PdCl_2(SeCN)_2]^{2-}$ was detected[267]. Similar results have been obtained also for thorium thiocyanate[273].

Valuable information can be obtained by studying complex formation using the solubility method. In contrast to other methods, the application of which requires a constant concentration of the central atom, in this case both the concentration of the ligand and of the central atom is varied from mixture to mixture. This is why in systems where the ligand and the central atom are capable of forming strong bonds, the solubility method leads to the detection of complexes with a lower component ratio than other methods. This rule[220,274,275] has been confirmed in a large number of experiments[274-283]. While the anionic complexes $[Pb(XCN)_6]^{4-}$ have been detected potentiometrically in methanol[274,282], only the complexes $[Pb(XCN)_4]^{2-}$, where X = S or Se, have been detected by the solubility method and in acetone only the complexes $[Pb(XCN)_3]^-$ have been found[277,283]. In aqueous acetone solution with an acetone concentration of 7 M, the complex $[Ag(SCN)_4]^{3-}$ has been detected potentiometrically at a constant silver concentration, while, according to the results obtained by the solubility method, the complex $[Ag(SCN)_2]^-$ predominates in acetone[277]. Copper[279], silver[280], palladium[267], mercury(II),[281] and lead[282-284] iodides and selenocyanates behave similarly.

IX. NON-AQUEOUS SOLUTIONS IN PREPARATIVE INORGANIC CHEMISTRY

The use of non-aqueous solutions has greatly extended the scope of inorganic synthesis in the field of organometallic compounds[285-287], metal polycarbonyls and their derivatives[288], metal and semimetal hydrides[289-291], salt-like inorganic compounds which are extremely sensitive to water and atmospheric oxygen[292,293], boron compounds with organic ligands[294], and coordination compounds of transition metals with molecular nitrogen[295-297] and carbon dioxide[298]. For example, the iron compound[294]



has been obtained in acetone.

The reaction of cyclopentadiene with metallic potassium in benzene was discovered as early as the beginning of the present century[285]. On the other hand, NaC_5H_5 was not obtained until 50 years later in DMF, THF and 1,2-dimethoxyethane. The so called sandwich compounds of transition metals were synthesised by exchange reactions between NaC_5H_5 and metal halides in tetrahydrofuran or other similar solvents[300] and then also mixed compounds, for example $C_5H_5Fe(CO)_3$.[301] The reactions of metal polycarbonyls with halides[302], isonitriles[291,300], amines, and cyanides[303,304] made it possible to obtain many mixed coordination compounds.

Since several reviews have been devoted to the problem of the synthesis of the above and other compounds, one need consider only the general characteristics of the preparation and crystallisation of coordination compounds from non-aqueous media taking into account solvation effects. In particular, diborane reacts with LiH to form $LiBH_4$ only because the lithium ion can be solvated by ethyl ether, but there is no interaction between diborane and NaH.[305]

Interesting data have been obtained for the synthesis of coordination compounds from boranes[306-308]. Thus diborane reacts with sodium amalgam in ether to form the triboranide NaB_3H_8 (together with sodium tetrahydroborate), while tetraborane reacts with ammonia to give $[(NH_3)_2BH_2][B_3H_8]$ and $[H_3NB_3H_7]$,[306] and with $(C_6H_5)_3P$ to give $[(C_6H_5)_3PB_3H_7]$. Solvents with a higher donor activity than ether decompose the triborane skeleton[308,309].

Another no less important factor concerns the structure of the solvents in which the synthesis is carried out. While the dissolution of salts in water reduces initially to the formation of the hydrates of cations and anions within the limits of the water structure, the majority of even dilute non-aqueous systems consist of combinations of mixed solvato-complexes, where the immediate environment of the cation consists not only of solvent molecules, but also of salt anions behaving as ligands.

At a high concentration of the non-aqueous solution, its structure approaches increasingly that of the corresponding solvate or the pure solute, depending on the solvating properties of the solvent. If in the given solution solvent molecules are not bound very strongly to salt ions, the introduction of another solvent having the same solvating capacity but forming hydrogen or dipolar bonds with the first solvent can lead to the formation of salt crystals without solvent molecules. This is very important for the synthesis of anhydrous salts such as nitrates, perchlorates and others, the hydrates of which undergo hydrolytic decomposition on heating.

When salt solutions in solvents with a high donor activity (DMSO, DMF, etc.) are concentrated, the formation of crystalline structures is preceded by the appearance of comparatively weak forces in the interaction between anions and the molecules of the solvate environment or by electrostatic attraction to the solvated cation. Solvates with a comparatively large (in the case of weakly coordinated anions) or small (if the anions give rise to fairly stable coordinate bonds) content of solvent molecules should be formed from such a solution. For example, copper, cobalt, zinc, aluminium, gallium, indium and many other metal nitrates and perchlorates crystallise in the form of the complexes $MB_n.6Solv$, e.g. $Al(ClO_4)_3.$ $.6DMF$,[188] while the halides, thiocyanates, and selenocyanates of these metals form crystals of $MB_2.4Solv$[221,224] and $ML_3.3Solv$ and $CuCl_2.2Solv$.[222] Solvates of this type are produced from a solvent with a lower donor activity also by nitrates and even perchlorates: $Zn(NO_3)_2.2CH_3CN$, $Sn(ClO_4)_2.2CH_3CN$, $Ni(NO_3)_2.2CH_3CN$,[311] and $Ni(ClO_4)_2.$ $.2CH_3CN$.[312]

In contrast to the perchlorates, an increase of the concentration of the solution leads in the case of halides, thiocyanates, and selenocyanates to a more appreciable substitution of solvent molecules in the solvation shell of the cation by the anions. Such mutual ordering of the ions and solvent molecules with increase of concentration is completed by the separation from the solution of solvates with a reduced content of the solvent, for example: $CdCl_2.2(CH_3)_2CO$,[313] $InBr_3.3N_2H_4$,[314] $ZnPy_2(NCSe)_2$,[315] $Co(NCS)_2.3N_2H_4$,[316] and $Sn(NCO)_2.2C_4H_8O_2$.[316] If a solvent with a high σ-donor activity hinders crystallisation, then active acido-ligands readily enter into the inner sphere and therefore give rise to crystals with a low content of the solvent: $SbCl_3.CH_3COOH$,[317] $SnBr_4.CH_3COOH$,[318] $In(NCS)_3.0.5CH_3CN$,[225] $Sn(NCS)_2.OP(C_6H_5)_3$,[319] $Ga(NCO)_3.$ $.THF$,[316] and $MoOCl_3.2THF$.[310]

When the anion is strongly bound to the cation, the solvent molecules may be completely displaced by the anions. The crystallisation structure then involves short-range order with participation of desolvated ions, which is observed in the formation of the solid phase in an ethereal solution of HgI_2 or $Hg(OCN)_2$[99] and in a formamide solution of $PbCl_2$.[320] Potassium chloride crystallises from dimethylformamide in the unsolvated form and $MgCl_2$ with four solvent molecules[131]. Consequently, the influence of the solvent, hindering crystallisation, is regulated both by the strength of the bonding between its molecules and ions and by interionic forces. As a rule, by selecting the right solvent, it is easy to synthesise many simple and coordination compounds unstable in the presence of water, for example, selenocyanates[216,217,321-326], cyanates[327-330], and mixed coordination compounds each containing two or more different ligands[327-336].

Since the introduction of a non-aqueous solvent miscible with water weakens hydrolysis, the stability of readily decomposed compounds of certain metals can be appreciably increased even in mixed solutions. The influence of the non-aqueous solvent is more appreciable when the E–L bonding is weaker and hydration of the central ion competes appreciably with it. This is why transition metal and aluminium, gallium, bismuth, etc. isothiocyanates, cyanates, and particularly selenocyanates, which are unstable in water, can be isolated from non-aqueous or even aqueous–non-aqueous systems. The use of non-aqueous solvents in the case of lanthanides makes it possible to prevent the decomposition of the selenocyanate ion. However, the solvation of cations is not then prevented. In order to weaken the influence of the latter and to accelerate the separation of the corresponding compounds, it is useful to employ the chelation effect. In particular the following reactions

$$3\,\mathrm{KNCSe} + \mathrm{RCl_3} = 3\,\mathrm{KCl} + \mathrm{R\,(NCSe)_3},$$

where R = Sc, Y or lanthanides, can be achieved in a series of solvents. However, after the separation of KCl, $R(NCSe)_3$ is virtually impossible to crystallise in view of the high stability of the complex species $[R(Solv)_n]^{3+}$. If 2,2′-bipyridyl (bipy), 1,10-phenanthroline (phen) and diantipyrinylmethane (dant) are introduced into such a solution, compounds of the type $[R(NCSe)_3(bipy)_2]$, $[R(NCSe)(dant)_4](NCSe)_2$, and $[R(NCSe)_3(phen)_3]$ are formed immediately[325-327].

The synthesis of zirconium and hafnium selenocyanates $[E(NCSe)_4(bipy)_2]$ from acetonitrile solutions[321], the thiocyanates $R(NCS)_2Ox.6CH_3OH$ from methanol solutions[334], and the complexes MB_2Ox,[335,336] where B = NO_2^-, NO_3^-, Cl^-, NCS^-, or ClO_4^-, R = lanthanide, Al, or Ga, and Ox is the 8-hydroxyquinoline residue, is based on the same principle.

With cations which form less stable solvato-complexes than lanthanides, it is possible to obtain many selenocyanates and mixed coordination compounds $Cat_n[E(NCX)_mB_l]$, where X = O, S, or Se, B = Br, I or Py, and Cat are univalent cations, even from acetone[326-331], methanol, acetone–dioxan, and aqueous methanol[332] solutions.

When the double decomposition reaction between ECl_n and AgNCO is carried out in methanol and AgCl is separated, then, using the chelation effect, it is possible to obtain $[In(NCO)_3phen]$, $[In(NCO)_3bipy]$, $[In(phen)_3](NCO)_3$,[329] $[E(NCO)_2(phen)_2]$, and $[E(NCO)_2(bipy)_2]$,[332,333] where E = Mn, Co, Ni, Zn, or Cu. When a solution containing large outer-sphere cations is added to a methanol solution of $In(NCO)_3$, the compound $Cat[In(NCO)_4]$ is formed[324]. $K_n[Pb(NCO)_{n+2}]$ and $K_2[Pb(NCO)_2(NCS)_2]$,[337] where n = 1, 2 or 3, can be obtained from dimethylformamide.

When $(C_5H_5)_2ZrCl_2$ was allowed to react with AgNCO, the compound $[(C_5H_5)_2Zr(NCO)_2]_2O$ was obtained from acetone solution, and, when gaseous HNCO was passed into the above solution of dicyclopentadienylzirconium chloride, the compound $[(C_5H_5)_2Zr(NCO)_2]$ was formed[338]. The latter as well as $[(C_5H_5)_2Zr(NCS)_2]$ can be obtained also by double decomposition reactions of $(C_5H_5)_2ZrCl_2$ with AgNCO or AgSCN, but in this case in dichloroethane solution[339]. In the latter case the stabilisation of zirconium cyanates is achieved by sandwich-type chelation. It is remarkable that in acetone HOx reacts with $ThCl_4$ to give only the adducts $ThCl_4.mHOx$, where m = 1, 2, 4 or 6, with different coordination numbers. Infrared spectra failed to reveal the presence of free HOx in these compounds; its addition takes place via the nitrogen atom. On the other hand, when a solution of $Th(NCS)_4$ is prepared in the same solvent and an acetone solution of HOx is added, a compound having a different composition is produced: $[Th(NCS)_n(Ox)_{4-n}].nHOx$.[340]

Depending on the nature of the solvent, the same starting materials interact differently. For example, the reaction of $Ni(NCS)_2$ with $[(C_6H_5)_4P]N(CN)_2$ or $[(C_6H_5)_4As]N(CN)_2$, taken in proportions of 1 : 2, results in the formation of $(Cat)_2\{Ni[N(CN)_2]_2(NCS)_2\}$ in methanol and $(Cat)\{Ni[N(CN)_2]_3\}$ and $(Cat)_2[Ni(NCS)_4]$ in acetone[341].

On the other hand, when $Co[N(CN)_2]_2$ interacts with $[(C_6H_5)_4P]NCS$, $(Cat)_2\{Co[N(CN)_2]_2(NCS)_2\}$ is formed in acetone and $(Cat)_2\{Co[N(CN)_2]\}(NCS)_3$ and tetrathiocyanatocobaltate(II) in methanol[342]. [This should be Ref. 341 (Ed. of Translation.]

The influence of the solvent on the structure of the compounds formed merits special attention[218]. In particular, the same starting materials KNCO and AgNCO form $K[Ag(NCO)_2]$ following their interaction in DMF and potassium difulminatoargentate(I) $K[Ag(CNO)_2]$ after interaction in acetone, i.e. a compound having a different structure[343].

X. CONCLUSION

The present development of industry and the associated reduced amount of fresh water available per member of the population have stimulated attempts to place chemical industry on a non-aqueous basis[344]. The problem of solid-phase reactions, the use of fused salt systems, for example the synthesis of monosilane from $SiCl_4$ and LiH in the KCl–LiCl eutectic mixture[345], and of other solutions to carry out various chemical processes with subsequent regeneration of the solvent is already extremely urgent.

Compared with water, the nature of the chemical reaction[50] and the properties of the various substances[223,239] are radically different in many non-aqueous solvents. Thus the solubilities of silver halides in liquid ammonia, acetonitrile, DMSO, and pyridine are much higher than in water. Solubility determinations[346] have shown that the solvent power in relation to AgCl, AgBr, and AgI decreases in the sequence

$$\mathrm{CH_3CN > (CH_3)_2SO > (CN_3)_2CO > C_2H_5NO_2 > CH_3OH.}$$

It is interesting that this sequence is inconsistent with the variation of the donor numbers of solvents (Table 4). This is very important both for the solution of preparative problems (for example, the synthesis of anhydrous salts[347]) and in connection with the use in homogeneous catalysis of certain compounds insoluble in water.

The donor (acceptor) activity of the solvent is the most important factor (compared with others) determining its influence on the corresponding processes. However, such activity may vary with the nature of the solute. The higher the activity, the greater the difficulty of the interaction of the complex-forming agent with other ligands and the greater the ease of formation of mixed solvato-complexes. In the presence of two different acido-ligands, mixed complexes involving them are usually formed more readily in solvents with a lower donor activity. Consequently, depending on the latter, the composition of the complexes of a given central atom with the same ligands should vary in different ways in different solvents.

The influence of the solvent on oxidation-reduction reactions merits attention. Thus, bromine reacts with hydrogen sulphide with liberation of sulphur in the presence of water and with formation of thiohypobromous acid in chloroform[348]:

$$H_2S + Br_2 \rightleftarrows HBr + HSBr.$$

This is associated with different degrees of solvation and hence dissociation of the corresponding compounds in different solutions (as well as the different behaviour of PCl_5 in acetonitrile, nitromethane, and nitrobenzene on the one hand and in benzene and carbon tetrachloride on the other[246]). The unusual influence of the medium has, in fact, made it possible to obtain many at first sight uncommon coordination compounds, including those with zero and negative degrees of oxidation of the central metal atom[349,350]. In the presence of aluminium chloride, fused bismuth chloride is reduced in accordance with the equation

$$BiCl_3 + 2Bi + 3AlCl_3 = 3Bi[AlCl_4].$$

Bismuth tetrachloroaluminate has a melting point of 253 °C.[351] Gallium(I) and cadmium(I) salts can be obtained similarly.

In view of the enhanced specificity of the reactions when water is replaced by other solvents, many [non-aqueous?] solutions are being increasingly used not only in syntheses but also in titrimetric analysis[352-354]. One is then usually dealing with complex-formation reactions.

The study of complex-formation reactions in non-aqueous solutions has greatly extended the range of these reactions[355-358] and permitted the formulation and to some extent also the solution of a number of new problems. It is therefore extremely important to seek an objective characteristic of the solvent which will make possible a more complete prediction than can be done at present of its solvent power in relation to various substances, its influence on complex-formation reactions, and the possibility of synthesising new compounds.

When account is taken of the σ-donor and π-acceptor activities of solvents and also of the ability of various ligands to be coordinated to the corresponding metal atoms, it is possible to predict the dissolution in a number of liquid multicomponent systems under the usual conditions of many substances, such as, for example, oxides, sulphides, selenides, and even metals, which are usually regarded as absolutely insoluble in water, alcohols, ketones, and similar liquids. This problem is of considerable interest from both theoretical and practical points of view.

The State of Physicochemical Research on Ferroelectric Films

Yu.Ya.Tomashpol'skii

The review deals with studies on films of complex oxides with unusual dielectric properties. The principal methods for their preparation are described and studies on thin films of barium titanate and solid solutions based on it are considered in detail: the structures at the atomic and supra-atomic levels, the composition of condensed films, structural defects, properties as a function of structure and composition, etc. Data are presented for other ferroelectric complex oxide films as well as thin ferromagnetic layers. Their possible applications are briefly enumerated.
The bibliography includes 257 references.

CONTENTS

I. INTRODUCTION

The continuous development of engineering requires new materials with specified physicochemical properties. Among the materials supplied by chemical industry to meet the requirements of electronic engineering, substances with unusual electrical and magnetic properties (ferroelectric, piezoelectric, and pyroelectric materials, ferrites, etc.) occupy an important place. In recent years increasing attention has been devoted to a research on films of these materials, which are of both theoretical and practical importance.

The principal advantages of electronic devices containing a thin-layer element is simplicity of the technology of their manufacture, microminiaturisation, rapid action, and reduction of the energy consumed and of the controlling fields. On the other hand, a film constitutes a unique model for the investigation of the nature of spontaneous polarisation, side effects, the influence of structural defects on spontaneous deformation, and lattice dynamics, A thin layer is a convenient object for the investigation of the domain and atomic structures of the ferroelectric material up to the determination of atomic coordinates.

The physicochemical properties of films are determined by their chemical composition and atomic-electronic structure. The composition of thin ferroelectric layers is usually more complex than that of metallic, dielectric, and semiconducting films. In the case of mixed oxides, the system consists of 3, 4, and more components, which significantly complicates the mechanism of structure formation, aggravates the phase and structural non-uniformity of the condensed layers, and gives rise to problem of stoichiometry. As a result of the development of electronic probe methods for the analysis of composition and structure, ways have been outlined for determining the compositions of condensates and for optimising the conditions governing the formation of the crystal structure. The role of defects is being more thoroughly investigated. It has become evident that the imperfection of the structure can obscure the true size effects.

After the discovery of barium titanate as a ferroelectric material in the USSR by Vul and Gol'dman[1] (and independently in the USA and Japan), the science of ferroelectricity began to develop rapidly. The relevant monographs[2-10] cover numerous aspects of ferroelectricity, but, with the exception of comparatively short reviews[11-14], the literature on ferroelectric films contains no systematic accounts of data scattered in journal articles, the number of which has sharply increased in recent years.

This review deals with films of oxide ferroelectric materials, which have been the subject of the vast majority of studies on thin ferroelectric layers. Mixed (binary and ternary) oxides have the advantage over other classes of ferroelectric substances as regards relative structural simplicity and the relative simplicity of the technology required to prepare the relevant devices. Ferroelectric materials of the type of barium titanate (with the perovskite structure) have a particularly simple structure, which makes it possible to interpret their properties on a structural basis, and have found extensive practical applications. The restriction of the scope of the review to a discussion of complex oxide films does not rule out the applicability of the fundamental relations of ferroelectricity in thin layers to other classes of materials exhibiting spontaneous polarisation.

II. METHODS FOR THE PREPARATION OF THE FILMS

The problems of the thin layer begin already in the preparation stage, since the structure, properties, and frequently the very presence of the ferroelectric effect depend decisively on the method of synthesis.

There are many methods for the preparation of thin layers: mechanical grinding, chemical etching, slip casting, various kinds of sedimentation, vacuum condensation, etc. The choice of the method depends on the specific problem. For example, the method of deposition on to a support of a suspension of microcrystallites obtained by grinding the starting material is convenient for the structural analysis of the film by electron diffraction. Grinding, casting, and sedimentation are used for the preparation of thick films. Studies on thin films require methods such as vacuum condensation, etc.

A simple method for reducing the thickness of films is mechanical grinding, but this yields high-quality films with a thickness not less than 50–100 μm. Thinner films (15–20 μm) are prepared by slip casting[15-17]. The slip is prepared from a fine-grained powder synthesised beforehand and having the specified composition. The main fraction of the powder must consist of particles smaller by a factor of 5–10 than the thickness of the cast film. The composition of the binder is chosen on the basis of the conditions governing the optimal formation of the slip, adequate elasticity, and fluidity. The slip is spread on a cleaned support and after drying the film is sintered. The method requires an apparatus for vacuum treating the slip and is used in the mass production of film devices.

One of the sedimentation methods is cataphoresis[18,19] which involves the deposition of the powder from a suspension and subsequent sintering of the layer. The deposition is sometimes carried out in an electric field[20–23] or with the aid of a centrifuge[24]. Films with thicknesses ranging from 5 μm upwards can be prepared by fusion. The initial material is fused on a platinum foil in a specific atmosphere and spreads on the support with formation of a strong single-crystal film[26]. An unusual method involves evaporation from solution; a thin layer of barium titanate consisting of individual crystallites has been prepared in this way[27].

The decrease in thickness by chemical etching involves treatment of a massive specimen (or a single-crystal plate), subjected to preliminary grinding, with a solvent capable of slow dissolution of the material. Hot orthophosphoric acid is used for barium titanate. The method makes it possible to obtain films with a thickness down to 500 Å, but it is then extremely difficult to achieve a uniform thickness. Such layers are used in electron microscopy[28–30]. Single-crystal films with a thickness of several hundreds of ångströms have been prepared by a suspension method[31], but this procedure cannot yield layers with a smoothly varying thickness. The preparation of vitreous layers in a high-temperature flame has been described[32,33].

Methods involving vacuum condensation on a thoroughly cleaned support have found extensive application in the preparation of ferroelectric films. There is a large literature (monographs, reviews, articles; see for example, Refs. 34–36) on this problem. The thickness of the condensate is varied within wide limits, including monatomic layers.

Depending on the method of sputtering of the initial ferroelectric substance, the following procedures can be distinguished:

1. Thermal sputtering by high-temperature heating using a resistance furnace and electron or laser beams[37–40].
2. Cathodic sputtering in which evaporation is achieved by bombarding the substance with inert gas atoms accelerated by a constant field generated by two electrodes (diode sputtering[41]) and by the fields of radiofrequency (RF-sputtering) or high-frequency (HF-sputtering) generators[42–48,68]. When a gas is added to the inert plasma, reactive sputtering takes place[49,50].

We shall now compare the characteristics of thermal and cathodic sputtering. Films prepared by cathodic sputtering require a smaller amount of the starting material, since the target is used repeatedly. Compared with the thermal method of evaporation, cathodic sputtering of compounds having a complex composition ensures a somewhat better stoichiometric composition. Having established the required atmosphere, the second method makes it easier to obtain, for example, oxide films free from an oxygen deficiency. Finally, substances can be subjected to cathodic sputtering over a wide range of temperatures.

On the other hand, the method of thermal sputtering has many undoubted advantages. A simpler equipment is used without the need for a high voltage and exact metering of the gaseous atmosphere, without the difficulties associated with the regulation of the discharge, and without field interference. The rate of condensation is appreciably higher than in cathodic sputtering. Homogeneous films of complex geometry and with a thickness varying in accordance with a specific law are more readily obtained. The thickness of the films is more easily regulated and reproducibility and continuous process control can be more readily achieved. It is significant that thermal evaporation yields purer films compared with cathodic sputtering, in which the rate of adsorption of residual gases may exceed the rate of adsorption of the material condensed. Thus the choice of the method of vacuum condensation depends on the specific material, the specific properties of the films, and technical feasibility.

In the thermal evaporation of ferroelectric materials of complex composition, the so called method of "discrete" evaporation, sometimes referred to as the "instantaneous", "explosive", or "grain-by-grain" method, is most common. It was first used to prepare brass films[51] and was then extended to many materials, including complex oxides with a perovskite structure[52].

The essential feature of the method is that the substance is supplied to the evaporator in small discrete doses. Because of its low heat capacity, each dose vaporises fairly rapidly, creating a vapour with a nearly stoichiometric composition. The condensation of this vapour on the support should give a stoichiometric composition. Under specific condensation conditions, there are additional parameters influencing the composition. For this reason, a modification of the method is used (involving a change in the form of the evaporator, variation of the rate of supply of the material, variation of the composition of the starting material, the introduction of oxygen into the growing film, etc.[39,53,54]).

Compared with other procedures for the preparation of thin films, the vacuum condensation methods have advantages, such as the possibility of smooth control of the thickness (which can reach that of a monatomic layer) and other characteristics of the film by changing the type of support, its temperature, the rate of deposition, etc. The methods of vacuum condensation have been applied on a technological scale and can be used in mass production. A common disadvantage of these methods involves the problem of stoichiometry and structural ordering, which arise from the non-equilibrium conditions in the condensation process.

On the other hand, vacuum condensates have a structure which frequently cannot be generated by other methods (ultrasmall ordered regions with strong disorientation, saturation by defects). This makes it possible to use such films as model systems for the investigation of the influence of the degree of order, the proportion of defects, and other factors on the ferroelectric properties of the substance.

III. THIN BARIUM TITANATE FILMS

1. Atomic and Supra-atomic Structures

Films prepared by methods which do not involve the cleavage of the starting material to the atomic-molecular level (as in vacuum condensation) do not exhibit appreciable changes in atomic structure within the framework of the structural motif. They can be single crystals, can be obtained by chemical etching of crystals, or by the fusion method, or they can have a polycrystalline structure if they are prepared, for example, by sedimentation methods. While it is evident that the perovskite motif is retained in such barium titanate layers, the problem of spontaneous deformation (c/a) in the thin film is not so clear. It is known[55] that low-temperature synthesis of $BaTiO_3$ leads to a cubic cell ($c/a = 1.00$) and not to a tetragonal cell. The grain dimensions then do not exceed 0.1 μm,[39,56] but suppression of spontaneous deformation is not attributed to the small size of the structural elements but to structural defects in the substance: lattice vacancies[55] and layers of the hexagonal phase[39].

On the other hand, the decrease of the normal spontaneous deformation in particles having a diameter less than 1 μm has been explained[57] by a kind of domain configuration of such very small grains. In the same study an anomaly was observed in the spontaneous deformation in a surface layer 100 Å thick, where c/a exceeded the normal value for barium titanate. This anomaly persists up to 600°C. A similar effect has been described in a study[58] where the tetragonal structure of the surface layer did not disappear up to 430°C. This situation was accounted for by the presence of a thin layer of space charge[59]. Another interpretation[60] involves a change in the composition of the atomic layers near the surface, which becomes close to that of TiO_2 in consequence of the opposed shifts of the Ti and O atoms. However, it remains obscure why the increase of c/a in the thin layer is not manifested in small $BaTiO_3$ crystals, where the role of the surface layer should be considerable.

Electron microscope and electron microdiffraction studies on thin (about 500 Å) barium titanate films[28,29,61] failed to reveal anomalies in c/a or significant deviations from the positions of the atoms in the lattice relative to massive material. This can indicate either errors in the earlier experiments[57] owing to the inadequate resolution of the electron diffraction pattern, as suggested by Tanaka and Honjo[28], or an effect operating in a layer several ångströms thick. On the other hand, appreciable structural changes in the surface layer may be caused by the applied electric field owing to the non-linear distribution of potential[62]. The layer of inhomogeneous deformation caused by the increase of the parameter c and the decrease of a expands with increase of field strength. This fact can explain the contradictions between electrophysical and structural studies (the former revealed anomalies in the surface layer and the latter did not) and also between the data of different workers concerning the thickness of the anomalous layer.

In contrast to the group of studies discussed above, investigation of the structure of vacuum condensates revealed the possibility, in principle, of a dependence of their structure on the conditions of synthesis. Depending on the type and temperature of the support, the rate of condensation, and the stoichiometry, different degrees of ordering, and different types of variation of the size, shape, and orientation of the grains are obtained[38,43,52,63-67,69-73]. In condensation on a cold (t_{room}) support, a disordered structure arises in the $BaTiO_3$ film and the diffraction lines on the X-ray and electron diffraction patterns are diffuse. The nature of the structure of such a film remained obscure for a long time; it was not clear whether it is a result of random shifts of the atoms from their normal positions within the limits of each unit cell (intrinsically amorphous state) or whether it is a normal atomic configuration within the limits of several unit cells with distortion of long-range order (a highly dispersed state). A direct study of the structure by the radial distribution method in combination with high-resolution electron transmission microscopy[74,75] established that the film consists of disoriented regions whose size amounts to several tens of ångströms. The perovskite motif persists within each region, but the interatomic distances deviate somewhat (up to 5%) from their values in the crystalline film as the coordination sphere increases (Fig. 1). The structure of amorphous films with an excess of barium is appreciably different[76].

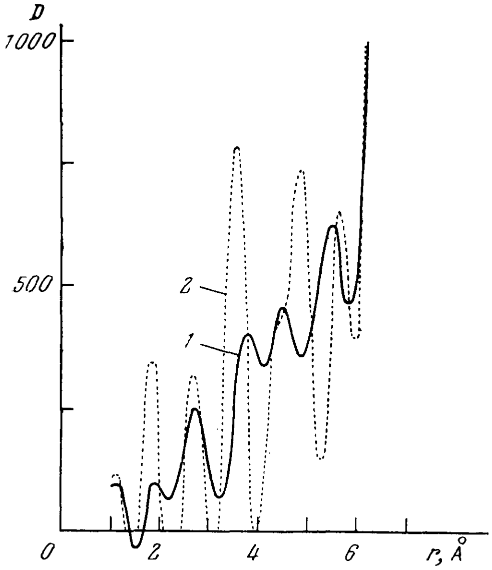

Figure 1. Atomic radial distribution functions D in disordered (curve *1*) and crystalline (curve *2*) barium titanate condensates[74,75].

Structural ordering leading to crystallisation is mainly initiated by the action of heat on the condensate, which the latter can experience during film growth or subsequently. The nature of the crystallisation is different in the two instances and different temperatures are required for the same degree of crystallisation: during subsequent annealing, the temperature must be higher by several hundreds of degrees than the temperature of the support during condensation[38,74,76]. The formation of the structure of the $BaTiO_3$ film on a heated support has been studied by many workers[52,63,65,74,77,78]. At a certain temperature of the support (130–500°C), which depends on its type, the rate of condensation, and the residual atmosphere, crystallites, usually rectangular in shape, begin to develop in the disordered matrix. With increase of temperature, the crystallites grow, filling the matrix, and lose their crystallographic outline in the plane of the film. The orientation of these formations on supports made of ionic crystals is as a rule $\langle 100\rangle \parallel \langle 100\rangle$. $\{111\}$ twins on an LiF support[79] and the $\langle 111\rangle \parallel \langle 111\rangle$ orientation on a platinum foil[18] have also been noted. In crystalline regions, the interatomic distances in the pseudocubic approximation are close to those for the massive crystal[74,76,80]. Thus the condensate obtained on a heated support has a characteristic microstructure: it comprises single crystal regions distributed in a disordered matrix. In many cases the single-crystal "islands" have the same azimuthal orientation, giving rise to an epitaxial effect[52,74,76,77,79] (Fig. 2).

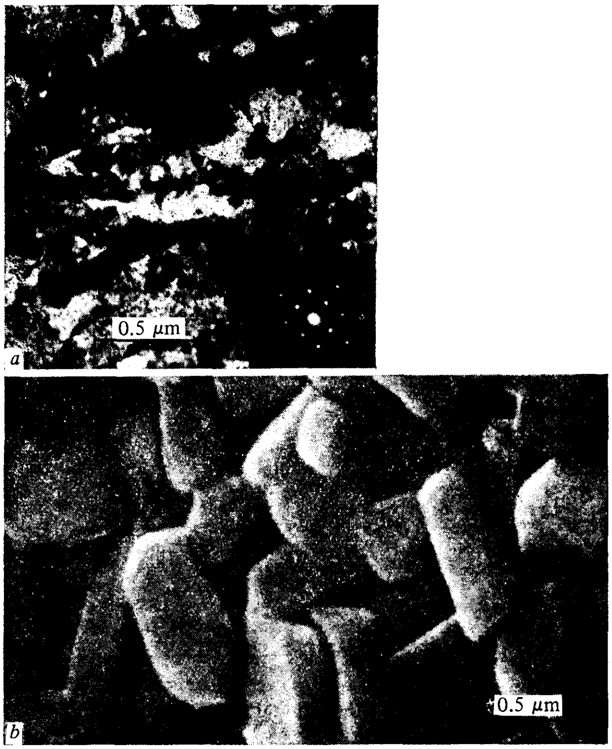

Figure 2. Photomicrographs of a section of barium titanate condensate obtained in different ways: *a*) on a lithium fluoride support heated to 850°C (the diffraction pattern is shown in the lower right-hand corner); *b*) on a cold platinum support with subsequent annealing at 1300°C for 2 h.[74,80]

The causes of the partial retention of disorder in the matrix lie in the considerable proportion of defects in the condensate which are not eliminated by heating. The defects are due primarily to the non-stoichiometry of the film, admixtures of the evaporator material, and other factors[39,74]. Some of the defects serve as centres for the formation of sections with a random orientation.

Heat treatment (starting from $t = 500-1000°C$ [38,64,74,81]) of the condensates obtained on a cold support ensures more homogeneous crystallisation, which is revealed by X-ray diffraction. Annealing at 1200–1400°C tends to order the structure, promoting the transition from the cubic to the tetragonal modification and the growth of grains, the size of which can reach between a few tenths of a micrometre to tens and hundreds of micrometres depending on the thickness of the film[39,74,78,82,83] (Fig. 2). The negative influence of high-temperature annealing consists in the growth of crystals of an impurity, which is present in the matrix in a finely dispersed state after condensation[74,84], and also in the formation of cavities between the crystallites in consequence of intense coalescence processes[64,74,81].

The condensates obtained have a polycrystalline or orientated structure with the direction of texture <100> or <111>.[18,38,39,46,83,85]

The high degree of order does not always guarantee the occurrence of spontaneous deformation in the condensate. In many instances[38,39,86,41,47] the formation of a cubic and not a tetragonal phase at room temperature has been claimed. The transition from the disordered state to a tetragonal structure probably proceeds via the cubic modification. In massive barium titanate, the conversion of the cubic cell into the tetragonal cell occurs at 800° to 1050°C,[39,55,74] while in thin condensed films the transition is delayed, so that $c/a = 1.00$ in some regions of the film even after annealing at 1200–1300°C.[38,41] The quenching of the high-temperature cubic phase in the films can be explained by the appreciable degree of supercooling in the condensation process[84,86,87]. The degree of spontaneous deformation in thin layers is as a rule close to the normal value (~1%),[38,39,41,65,88] although the possibility of the variation of c/a in some cases is not ruled out[83].

The absolute values of the unit cell parameters in the films are usually close to the parameters of the massive material in the pseudocubic approximation. At room temperature, $a = 4.01 \pm 0.02$ Å,[41,88] 4.000–4.030 Å,[39] and 3.99–4.02 ± 0.01 Å.[74] An increase of the parameter by up to 2% after condensation on a support at $t < 900°C$ has been noted[41] (Fig. 3).

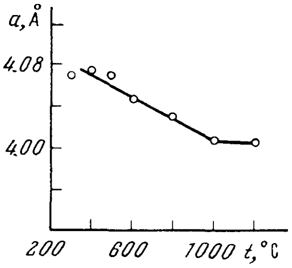

Figure 3. Variation of the unit cell parameter a (in the pseudocubic approximation) of barium titanate films with the temperature of the support t (according to Shintani and Tada's data[41]).

On the whole, one must emphasise that the inadequate resolution of the X-ray diffraction patterns of the condensates preclude a rigorous analysis of the multiplicity of the lines and accurate measurements of the parameters. It is therefore possible that fine structural effects are undetected.

2. Composition

The problem of the composition, which is particularly important for condensed films, did not receive adequate attention for a long time. There is reason to believe, for example, that the stoichiometry of the thin layers obtained in the frequently quoted investigations[89,90] was appreciably distorted. The suppression of the ferroelectric effect in consequence of the imperfection of the composition and structure of the condensates masks size phenomena. The gap in studies on the compositions of thin barium titanate layers was probably due to the lack of a suitable measuring technique.

In recent years, following the development of electronic probe analysis, a wide variety of X-ray microspectroscopic studies on thin condensates have become possible (the study of the local and total composition, of the distribution of elements, of the thickness, etc.). Methods have been developed for the absolute determination of the stoichiometry in terms of the concentrations of the individual elements of the film [91,92] as well as simpler methods in which the composition of the film is compared with a standard using the ratio of the intensities of the spectral lines [66,93]. It is convenient to employ for $BaTiO_3$ the ratio of the Ba $L\alpha$ and Ti $K\alpha$ lines. The standard value is $I_{\text{Ba}\,L\alpha}/I_{\text{Ti}\,K\alpha} = 0.83 \pm 0.05$ for an accelerating potential of 20 kV. [66] The thickness of the layer is determined at the same time from the intensity of the spectral lines of the constituent elements of the film or the support [93,96].

The stoichiometry of the condensates depends on the composition of the molecular vapour, the rate of condensation, the type and temperature of the support, the residual atmosphere, and other parameters. Although the mechanism of evaporation has not been completely elucidated, mass-spectrometric data [82,99] and other considerations [66] indicate a complex composition of the vapour, which contains, together with $BaTiO_3$ "molecules", also BaO, TiO_2, and reduced "fragments", down to metal ions (Tables 1 and 2). Naturally, the complex composition of the vapour phase must have a significant influence on the stoichiometry of the barium titanate condensates. Indeed, there is evidence for the presence of an excess of barium oxide [39,88] in condensed films of the higher oxides $BaO.nTiO_2$ ($n = 2-4$), Ba_2TiO_4, and $BaWO_4$. [38,64,97] The non-stoichiometry of the $BaTiO_3$ condensates prepared by discrete evaporation has been investigated in detail [66,74,98].

Table 1. Composition of the barium titanate vapour under "stationary" conditions* determined mass-spectrometrically (according to the data of Verbitskaya et al. [32]).

Evaporation temp., °C	Material of evaporator	Composition	
		effusion chamber	open surface
2200	Tungsten cell	BaO^+, TiO_2^+, TiO^+, WO_2^+, Ba^+, $BaTiO_3^+$	—
1820	Tungsten cell and strip	BaO^+, TiO_2^+, TiO^+, WO_2^+, Ba^{+2}	BaO^+, TiO_2^+, TiO^+, Ba^+
1980	Iridium strip	—	BaO^+, TiO_2^+, TiO^+, Ba^+

*Under "pulse" (discrete) evaporation conditions, the $BaTiO_3^+$ concentration increases by a factor of 10.

Regardless of the condensation parameters, the films contain different amounts of excess barium ($I_{\text{Ba}\,L\alpha}/I_{\text{Ti}\,K\alpha} > 0.8$), which has an unfavourable influence on the microstructure, being segregated in the form of droplike inclusions. When material with an excess of titanium introduced beforehand is evaporated [53], oxides with a high titanium content are distributed in the matrix without hindering the growth of the perovskite $BaTiO_3$ phase. This can be explained by the crystallisation of $BaTiO_3$ over a wide range of existence, according to the $BaO-TiO_2$ phase diagram [100].

Table 2. Mass-spectrometric composition of the vapour of barium titanate evaporated by the discrete method (according to Nurriddinov's data [99] and the studies quoted in his paper).

Ion	Ba^+	BaO^+	TiO^+	TiO_2^+	$BaTiO_2^+$	$BaTiO_3^+$	WO_3^+	WO_2^+
Relative intensity	0.8	1.0	0.3	0.1	0.06	0.1	0.1	0.08

The favourable role of the excess titanium had been noted earlier [38,101], albeit without any explanation of its causes, for films obtained by evaporation from individual BaO and TiO_2 sources as well as by Feldman's method [37,102]. Films with an excess of titanium ($I_{\text{Ba}\,L\alpha}/I_{\text{Ti}\,K\alpha} = 0.3$ to 0.8) have a structure fairly close to ideality and exhibit ferroelectric properties. Impurities can be identified after high-temperature annealing. As a result of local fluctuations, BaO, Ba_2TiO_4, $BaTi_2O_5$, $BaTi_3O_7$, $BaTi_4O_9$, and sometimes an impurity from the evaporator material have been detected in $BaTiO_3$ condensates. General analysis of the problem of the stoichiometry of $BaTiO_3$ condensates [98] has shown that it is apparently extremely difficult to obtain a rigorously stoichiometric composition.

In addition to the deviation from the stoichiometric proportions of barium and titanium, a deficiency of oxygen is frequently observed in the films, oxygen being lost partly on evaporation of the initial powder and partly on condensation, particularly on a hot support. As a result of the loss of oxygen, some of the Ti^{4+} species are reduced with formation of "defect electrons" and an increase of electronic conductivity. The oxygen deficiency can be eliminated by annealing the film in air or in oxygen at temperatures up to 500°C.

3. Structural Defects

The films, particularly those obtained by condensation, contain an appreciable amount of structural defects. An attempt to give a systematic account of the lattice defects in barium titanate vacuum condensates has been made [74].

Point, linear, and three-dimensional defects are formed during preparation. The first type includes (a) atoms displaced from normal positions and "frozen" following condensation on a cold support, (b) impurity atoms, including "excess" structural atoms present due to non-stoichiometry (local X-ray spectroscopic analysis has revealed between 0.1 and 1 wt.% of the evaporator material), and (c) oxygen vacancies formed under reducing condensation conditions. Other types of defects include the boundaries between the crystallites and the disordered matrix and between the grains as well as microscopic cracks arising in consequence of the relaxation of microstresses as well as cavities produced by coalescence processes.

---

*d = thickness, ϵ = dielectric constant at room temperature, tan δ = dielectric losses at room temperature, f = frequency, P_s = spontaneous polarisation at room temperature, E_c = coercive field, and E' = dielectric strength.

Structural defects impair and in many cases suppress the ferroelectric properties of the thin layer, the mechanisms of the influence of the defects being various. Presumably the inhibition of the transition from the cubic to the tetragonal structure of the condensate[86] is caused particularly by defects of the point type. There is apparently an analogy between the cubic phase of the films and the radiation-induced cubic modification of massive barium titanate, arising after irradiation with neutrons above the threshold dose of about 10^{18} neutrons cm^{-1}.[103-106] This phase does not exhibit a low-temperature transition to the polarised state and probably lacks ferroelectric properties[103]. The cause of the transition to the cubic phase and of the stabilisation of the latter is believed to be the point defects formed after mixing the atoms. Only prolonged annealing at 1100—1200°C restores the tetragonal structure of the material[105]. Under these conditions, some of the defects are not annealed, which is indicated by an increase in the lattice parameters. Presumably similar processes occur also in condensates.

4. Ferroelectric Properties

The degrees of spontaneous polarisation, dielectric constants and losses, coercive fields, and other ferroelectric parameters of the barium titanate films, based on the data of different investigators, are presented in Table 3. The scatter of the results can be explained by the very great sensitivity of the properties of the thin layer to its previous history (the technology of the preparation and attachment of the electrodes, the electrode material, and the conditions of the measurements). It is necessary to distinguish clearly technological factors, which determine the proportion of structural defects in the films, from size effects.

The influence of structural defects. The "impairment" of the ferroelectric properties of the thin layer compared with the initial barium titanate (the decrease in the degree of spontaneous polarisation, the increase of the coercive field and the dielectric losses, the blurring of the phase transition, etc.) are due primarily to the "dilution" of the ferroelectric phase by regions which are incapable or only partly capable of transpolarisation—the regions of the lattice with zero spontaneous deformation, non-stoichiometric phases, and extraneous inclusions[74,86,98,108].

The dielectric constants of the films depend significantly on relaxation polarisation processes of different types and on the surface states[117, 118]. Monomolecular gaseous and organic films on the surface of a ferroelectric material form surface layers with unstable characteristics. The removal of these layers before the deposition of electrodes ensures an adequate reproducibility of the properties[107]. The role of the relaxation mechanisms is manifested in the low frequency dispersion of ε and tan δ characteristic of condensates[38,40,44,78,89,118]. The decrease of the dielectric constant and dielectric losses with increase of frequency may be considerable (Fig. 4).

The nature of the ferroelectric phase transition in a thin layer, particularly a condensed layer, is not quite so marked as in massive $BaTiO_3$. The degree of blurring of the transition is determined by heterophase fluctuations in composition (for condensates) or other fluctuations. However, with the exception of cases where a solid solution based on $BaTiO_3$ is formed in the condensate, the Curie temperature T_C (120°C) is maintained to within 5 to 10 K.[97,102,107,116,117] This fact indicates the existence in the condensates, in addition to the defective regions, of highly ordered regions with spontaneous nearly normal deformation ($c/a = 1.01$). Thus, in contrast to radiation-induced damage, the structural defects are not distributed homogeneously in the condensates. This factor can in fact explain the different types of behaviour of T_C in the films and in irradiated ferroelectric materials. The defects in the condensates influence the degree of blurring of the phase transition, without altering T_C significantly; on the other hand, radiation damages each cell, causing a decrease of c/a and an appreciable shift of T_C towards lower temperatures.

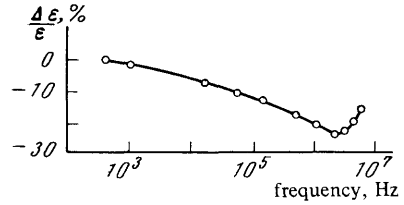

Figure 4. Variation of the dielectric constant of the $BaTiO_3$ condensate with frequency[44].

Size effects in films. The results of studies on the ferroelectric parameters of thin films, which may be treated as the manifestation of dimensional effects, although in many instances technological factors cannot apparently be fully ignored, are considered below.

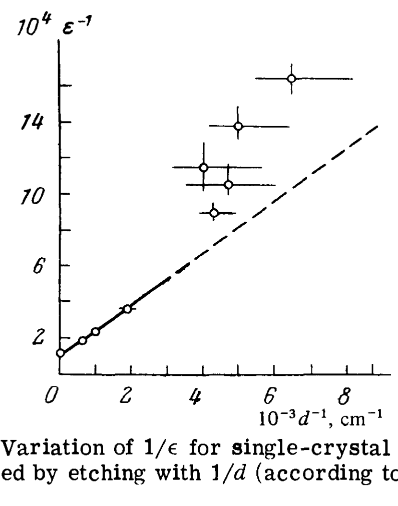

Figure 5. Variation of $1/\varepsilon$ for single-crystal $BaTiO_3$ films obtained by etching with $1/d$ (according to Makarov's data[107]).

The dependence of the dielectric constant on the thickness of single crystal films obtained by the attenuation method has been studied in a series of investigations[25,26,107,119-122]. At an early stage it was concluded that ϵ increases as the thickness of the layer is reduced[26], but subsequent studies by the same and other investigators showed that the variation of ϵ with d is linear down to $d \simeq 3.5$ μm, a deviation from the relation being observed below this limit[107,119,123,124] (Fig. 5). The decrease of ϵ is caused by the decrease of the effective Curie–Weiss temperature[107]. The Curie–Weiss constant is independent of the thickness of the crystal in the range $1 \geqslant d \geqslant 4000$ μm.

The coercive field in the tetragonal phase increases with decrease of d,[25,122] but in low-temperature modifications the increase is not quite so great. An increase of P_s in a thin layer (up to 6 μm) relative to a thicker film has been observed[121]. However, later the same authors concluded[25,119] that the dependence of P_s on thickness is weak for $d \geqslant 1$ μm. According to these data, the tetragonal structure and transpolarisation persist down to 1 μm in accessible fields. The absolute degree of spontaneous polarisation is appreciably reduced compared with massive $BaTiO_3$. The decrease of P_s in films prepared by deposition followed by sintering has also been noted by other investigators[18], although in this case the defects probably played an appreciable role. In layers with $d \leqslant 10$ μm, obtained by etching, a monotonic decrease of the degree of spontaneous polarisation with thickness was demonstrated[108].

The smoothing of the $\epsilon(t)$ relation with decrease of thickness has been noted[121]. For $d = 1$ μm, the maximum in the $\epsilon(t)$ relation at 120°C disappears, but reappears in a stronger field, albeit in a diffuse form. The retention of $T_C \simeq 120$°C for $d \geqslant 1$ μm is significant[120].

The smoothing of the maximum in the $\epsilon(t)$ relation near 120°C with decrease of d has been noted[25]. A similar effect has also been observed in thinner layers prepared by condensation[117] (Fig. 6). For a $BaTiO_3$ vacuum condensate with a thickness of 100 ± 20 Å, the $\epsilon(t)$ maximum in the region of 120°C is completely smoothed out, while both low-temperature maxima are retained.

It must be emphasised that the increased proportion of defects in condensed layers does not rule out the possibility of using them for the investigation of size effects, for example, the dependence of dielectric parameters on thickness. A set of films with different thicknesses, obtained under similar condensation conditions (identical proportions of defects), made it possible to determine the $P_s(d)$ relation in the range $100 \leqslant d \leqslant 1400$ Å (Fig. 7).[117] At room temperature, P_s decreases with thickness from about 10 μc cm^{-2} ($d \geqslant 1400$ Å) to approximately zero for $d \simeq 100$ Å. The thinnest ferroelectric layers (100–200 Å) have apparently been obtained in a study by the present author and Sevost'yanov[117].

5. The Theory of Size Effects in $BaTiO_3$

The decrease in the size of an object below a certain limit leads to a change in its properties (the size effect). The critical size is different for different properties.

The theory of the size effect in ferroelectric materials is based on thermodynamic and microscopic concepts, which permit a qualitative (at best semiquantitative) description of the critical phenomenon. For ferroelectric materials, the concept of the critical size is related to parameters such as spontaneous induction D_s (polarisation P_s) and deformation, the Curie temperature T_C, the dielectric constant ϵ, the domain structure, etc.

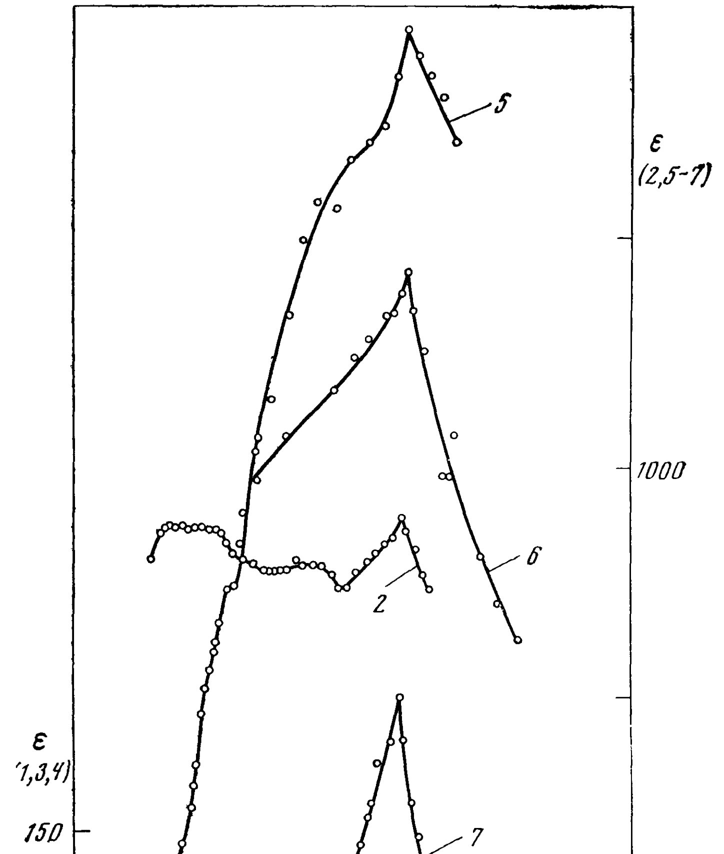

Figure 6. Temperature variation of ε for barium titanate condensates with different thicknesses (Å): 1) 100; 2) 230; 3) 430; 4) 450; 5) 680; 6) 800; 7) 5000 (according to Tomashpol'skii and Sevost'yanov's data[117]).

In depolarisation field models[125–132], the presence of an incompletely shielded depolarisation field E_{det}, directed in opposition to P_s, is postulated in a thin C-domain crystal. Ivanchik[125] took into account the mechanism of shielding by free carriers alone. At equilibrium, characterised by a minimum in the free energy F, the latter is expanded as a series (the usual procedure in a formal thermodynamic treatment) in terms of the spontaneous induction D_s (polarisation) with retention of higher terms and differentiation with respect to the expansion parameter.

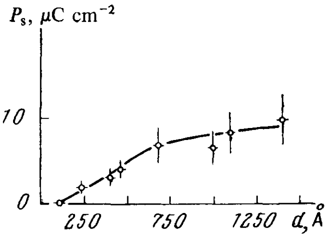

Figure 7. Experimental variation of P_s with d for barium titanate condensates (according to Tomashpol'skii and Sevost'yanov's data[117]).

The assumption of partial conductivity of the crystal makes it possible to express the electric field E in terms of the charge density, which is in its turn a function of D_s. Thus a closed equation, the solution of which determines the dependence of the ferroelectric parameters on the thickness of the crystals d, is obtained for D_s (or P_s). Apart from the semiconductor shielding mechanism, others, for example, mechanisms associated with structural defects, have also been proposed[126].

Ivanchik's ideas[125] were subsequently extended to a ferroelectric–electrode system with a distributed space charge[127–131], more detailed account being taken of the influence of the electrical contact conditions: the material of the contacts and methods for achieving them.

The depolarisation field model yields a relation between P_s, T_C, and d. An estimate of the critical thickness (corresponding to the complete disappearance of the effect) leads to 200–500 Å for barium titanate[125,132]. This approach explains qualitatively the experimentally observed decrease with thickness of P_s and the pyrocoefficient γ and the blurring of the phase transition. However, the model is not free from disadvantages, which hinder a quantitative interpretation of experimental data. The assumption of semiconducting properties implies the presence in the ferroelectric of a definite number of free carriers, which contribute to the shielding E_{dep} and promote its "dissipation". It has been noted[133] that a prolonged action of E_{dep} in conducting crystals is unlikely and its numerical value is "the subject of a major controversy"[130]. Furthermore, the theoretical conclusion that T_C is appreciably displaced towards lower temperatures with decrease of d has not been confirmed experimentally for $BaTiO_3$ down to thicknesses of about 200 Å.[117,119] No account is taken in the model of surface states[134], which can have an appreciable influence on the redistribution of polarisation charges owing to their partial or complete compensation on the surface[135]. Finally, the model is valid only for the C-domain state, whereas in reality one encounters, apart from the C-domain configurations[136,137], also A-domain thin layers[29,111,119], for which the influence of E_{dep} is not significant[138].

According to the dynamic model[119,120], in which the lattice vibrations of a ferroelectric plate with a limited thickness d in the z direction are considered under the conditions of a transverse frequency ω_t, the dielectric constant ϵ_z should decrease with decrease of d, while ϵ_x and ϵ_y should remain invariant. T_C does not change significantly.

In a monoaxial ferroelectric ($P_s \| z$), a phase transition would be impossible for a certain thickness. In the case of $BaTiO_3$ the presence of three equally valid directions of P_s should lead to the conversion of the thin layer into the A-domain form and only a weak variation of P_s with thickness. Thus the dynamic model does not predict significant changes of P_s for thin crystals of the $BaTiO_3$ type or a shift of T_C with decrease of film thickness. According to the model, the Curie–Weiss temperature and the dielectric constant decrease for low values of d, while the $\varepsilon(t)$ relation is smoothed out owing to the ϵ_z component. The limitations of the model involve, in particular, the fact that its conclusions are valid only for the thickness range $1 \leqslant d \leqslant 300$ μm.[120]

In the electrostatic model of the thin layer of a ferroelectric material[117,139], one considers the dependence on thickness d of fields due to dipoles and charges and the Lorentz (E_{Lor}) and depolarisation (E_{dep}) fields in C- and A-domain films of the barium titanate type. The behaviour of the internal electric fields E_i and of spontaneous polarisation P_s with decrease of d is determined by the relative contributions of the opposed E_{Lor} and E_{dep} fields. The Lorentz field begins to decrease with decrease of the thickness below the critical value, which has been estimated as 300–500 Å, depending on the chosen size of the Lorentz cavity. When $d <$ 300–500 Å, the model predicts an appreciable decrease of E_i and P_s. If $E_{dep} = -4\pi P$ (P is the polarisation), i.e. is not shielded, then $P_s \rightarrow 0$ when a = 80–100 Å for a C-domain film. When E_{dep} is weakened or absent (an A-domain crystal), a low value of P_s persists for $d < 100$ Å. The model does not rule out the occurrence of spontaneous polarisation in layers with a thickness below 1000 Å and yields a $P_s(d)$ relation which can be reconciled with experimental data[117] for a suitable choice of parameters. The inadequate rigour of the criteria governing the choice of the critical thickness makes the model semiquantitative.

A fairly simple model, which explains the anomalies in the ferroelectric properties of thin crystals, is that of the surface layer[57,112,123], based on experimental evidence for its existence. Regardless of their nature, surface layers are considered anomalous from the standpoint of ferroelectric behaviour. A thin crystal is treated as a layer condenser, the internal component of which consists of the "normal" ferroelectric and the outer regions consist of the "anomalous" material (with a low value of ϵ, a high coercive field, etc.)[123,124]. The overall value of ϵ, which decreases with decrease of film thickness for a constant depth of the surface layer, is calculated in terms of this scheme.

The model explains the decrease of ϵ, the smoothing of the $\epsilon(t)$ relation in the region of the phase transition, the increase of the coercive field, and other anomalies in the film. However, one must point out certain experimental data which are difficult to account for within the framework of this model. Kanzig and coworkers[57] suggested that the surface layer model is based on the structural distortions within the cell. On the other hand, electron microscope[28], electron microdiffraction[61,140,141], and X-ray[142] studies failed to reveal such distortions in the crystals (with thicknesses down to 500 Å) and in the surface layer of $BaTiO_3$ with a thickness of hundreds of ångströms. The presence of a strong electric field in the surface layer[62,143,144] should lead to an increase of the concentration of C-domains near the surface. However, as stated above, experimental data indicate a tendency by thin films (where the surface layers should have an appreciable negative volume) towards conversion into the A-domain form[29,111,119]. In the surface layer model, its non-ferroelectric nature (low values of ϵ, high coercive fields, the absence of transpolarisation, etc.) is usually emphasised. Direct observation of the domain structure of $BaTiO_3$ with the aid of a scanning electron microscope[145] indicates a ferroelectric behaviour of the regions near the surface. Finally, the results of different studies concerning the depth of the surface layer h and its dielectric constant ϵ are characteristically contradictory (h = 0.01 to 25 μm, ϵ = 5–1080).[59,112,123,124,135,146-152]

Evidently the depth of the surface layer (if it exists) is not a single-valued film parameter, depending on many factors (mechanical treatment, heat treatment, the applied field, irradiation with light, etc.)[3,58,153]. It has been noted correctly[120] that the surface layer model is very flexible, because it operates with a number of adjustable parameters. However, the uncertainty of the parameters introduced precludes the use of the model for a rigorous quantitative comparison with experiment.

The ferroelectric characteristics of thin layers (in particular vacuum condensates) can be calculated using a model the ferroelectric properties of which are determined by the degree of "dilution" of the ferroelectric phase by non-polarised regions, without specifying the nature of the latter: this may be a quenched high-temperature phase, defective regions where there is no transpolarisation, and extraneous impurities. P_s for such a mixture can be calculated within the framework of the electrostatic model from the effective atomic shifts[74,86] and the dielectric constant can be found from the formulae of Grossman and Isard[154].

Thus theoretical analysis explains the dimensional effect in thin ferroelectric layers: the decrease of P_s, ϵ, and γ, the blurring and shift of the phase transition (T_C), and the change in the lattice vibration spectrum.

The theory predicts a critical film thickness, below which $P_s = 0$. The specific form of the relations between the ferroelectric characteristics and the critical size on the one hand and d on the other is a function of a number of parameters (conductivity, electrode material, the surface state, the domain structure, etc.). In the depolarisation field model, the critical thickness is 200–500 Å and in the electrostatic model 80–100 Å (for a C-domain film in the absence of shielding from the depolarisation field).

6. $BaTiO_3$ Films as Models in Studies of the Ferroelectric State

Determination of the critical size of ferroelectric "nuclei". In the model of ferroelectric nuclei[155], it is assumed that small regions of the tetragonal modification arise in the deep paraphase, grow with decrease of temperature to T_C, reaching the critical size, and below T_C are converted into a system of 180-degree domains. Bearing in mind that the cessation of the growth of the "nuclei" before the attainment of the critical size (when the latter exists) owing to restriction by the natural grain boundaries should lead to the suppression of the "normal" ferroelectric behaviour (dimensional effect), an attempt has been made[156] at an experimental determination of the critical size of the region of the tetragonal phase in barium titanate. Condensed films where there is a possibility of an extensive variation of the grain size, from tens of ängströms to hundreds of micrometres are unique models for such research.

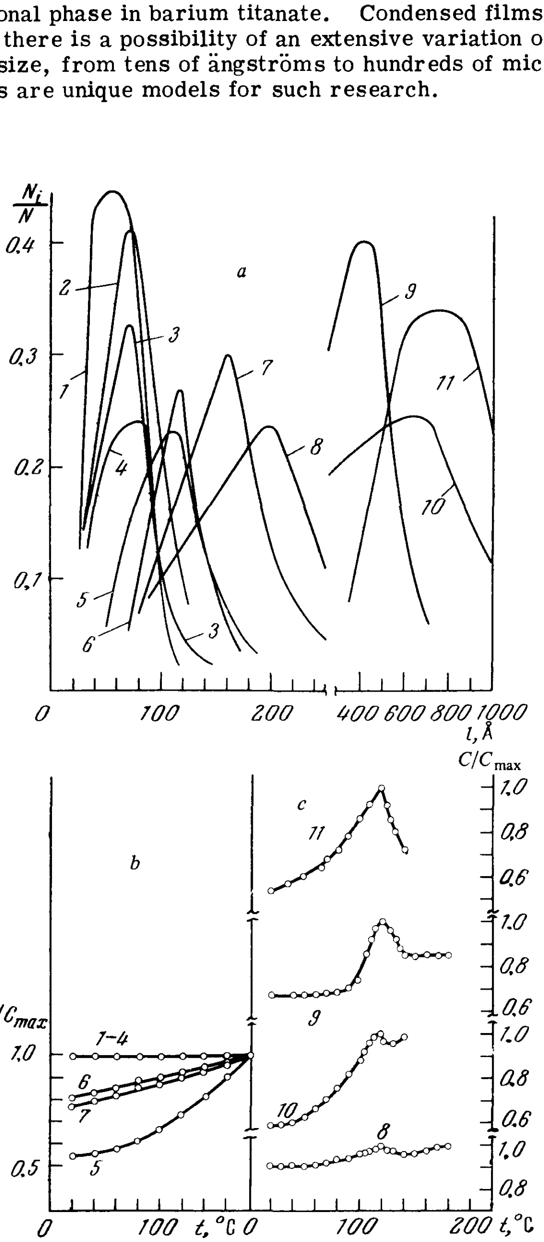

Figure 8. Distribution of grains (N_i/N) with respect to size (a) and temperature variation of the relative capacitance C/C_{max} (b and c) of condensed barium titanate layers (according to Tomashpol'skii and Sevost'yanov's data[156]); the numerals opposite the curves in the lower part of the figure correspond to the numerals in its upper part.

Fig. 8 presents the results of dielectric measurements on films with different average grain sizes, which show that there exists a limiting grain size $l \simeq 180-250$ Å, below which there are no ferroelectric anomalies and which may be compared with the critical "nucleus". The experimental critical size is satisfactorily correlated with the size of the fluctuation regions in the vicinity of T_C, observed by Kanzig[157] and calculated theoretically in a number of investigations[158–161].

Determination of the group velocity of phonons in the ferroelectric mode. The decrease of the dielectric constant has been explained by a change in the bulk-phase vibrations in thin ferroelectric layers[119]. In this approach, the experimental study of the size effect in films makes it possible to determine certain parameters of the dynamic model for those regions of the phonon spectrum where ultrahigh-frequency and neutron spectroscopic methods are ineffective. A high velocity of phonons has been obtained from the dielectric constant of single-crystal barium titanate films: $\sqrt{B} \simeq 10^7$ cm s^{-1} (B is a constant related to long-range forces in the dynamic theory)[107].

IV. FILMS OF SOLID SOLUTIONS BASED ON BARIUM TITANATE

The characteristics of films of the solid solutions Ba(Ti, Sn)O_3 and (Ba, Sr)TiO_3 with a thickness in the range 10–500 μm, obtained by the slip casting method, have been investigated in a number of studies[124,162,174], while others, prepared by the grinding method (30–35 μm thick), by etching (with a thickness from 40 μm upwards), and by cataphoresis (approximately 80 μm thick), have been investigated by Morozov[163], Burfoot and Sensordenker[164], and Yamanaka et al.[165] respectively. For $d \geqslant 30$ μm, the coefficient of non-linearity, ϵ, and P_S remain high[162,174]. However, for $d < 30$ μm, the coefficient of non-linearity and other parameters decrease. As the thickness is reduced below 500 μm, the controlling potential falls, which makes it possible to employ non-linear film elements based on (Ba, Sr)TiO_3 in semiconductor circuits[124]. The ultrahigh frequency dispersion in the ferroelectric phase and the maintenance of the validity of the Curie–Weiss law in the paraphase have been observed[163]. Certain optical characteristics of thick films with 25% Sr have been published[164].

In the preparation of solid solution vacuum condensates, additional problems associated with stoichiometry arise. The contradictory nature of the data obtained for condensed films is associated primarily with the inadequate control of their composition and structure. Thus, an increase of the dielectric constant with decrease of thickness from 1.6 to 0.1 μm, has been reported[89], the absolute value of ϵ amounting to several thousands. $\epsilon < 50$ has been obtained for similar films in another study[90]. The validity of the results of a particular investigator is difficult to establish, since the composition of the condensate was not followed in either study. (Ba, Sr)TiO_3 films 2–3 μm thick have been obtained[78] by the method of discrete evaporation and $\epsilon(t)$ maxima, displaced towards lower temperatures compared with pure BaTiO_3, have been observed. Low-frequency dispersion has been found in the range 10^2-10^6 Hz. $P_S < 1$ μC cm^{-2} has been obtained at room temperature for a $(Ba_{0.95}Sr_{0.05})TiO_3$ film 2.4 μm thick.

(Ba, Sr)TiO_3 vacuum condensates with a thickness less than 1 μm have been obtained and investigated in a series of studies[118,166–168]. The structures and compositions were determined by X-ray diffraction and by local X-ray spectroscopic analysis. In order to correct for the excess barium and strontium, the initial material had a composition with a barium deficiency[53]. The structure of the films was of the perovskite type with parameters close to that of the starting material, provided that the multiplicity of the X-ray lines was disregarded. The ferroelectric behaviour of the solid solution condensates was confirmed by the dielectric hysteresis [$\epsilon(t)$ peaks], which disappeared at temperatures above those of the phase transitions. As for massive specimens, the $\epsilon(t)$ maxima shifted towards lower temperatures with increase of the strontium content. The limiting thickness of the solid solution film in which transpolarisation was still observed amounted to about 700 Å.

The decisive influence of structural ordering and stoichiometric factors on ferroelectric properties has been demonstrated and it has been shown that the structural defects in the films initiate relaxation processes. Spontaneous polarisation coexists under the conditions with relaxation polarisation, the contribution of which may be fairly high. A characteristic feature of the films is a high value of $\tan\delta$ (amounting to several tenths at low frequencies), low frequency dispersion, and the blurring of phase transitions.

(Ba, Ca)TiO_3, Ba(Ti, Sn)O_3, Ba(Ti, Zr)O_3, and (Ba, La)TiO_3 condensates have been investigated[42,167,169]. After heat treatment, admixtures of TiO_2 and other phases are detected in the films together with the perovskite modification. Following the addition of 14% La or Ca, T_C falls to room temperature. The difference between the values of ϵ for the film and the massive material does not exceed 5% and the dielectric losses amount to 0.01 to 0.03. For (Ba, La)TiO_3 condensates obtained by cathodic sputtering[169], $\epsilon \simeq 200$ (at a frequency of 1.5 kHz) and $\tan\delta \simeq 0.02$ dielectric strength $\simeq 10^5$ V cm^{-1}.

V. OTHER COMPLEX OXIDE FILMS

1. Strontium Titanate ($SrTiO_3$)

The preparation of strontium titanate vacuum condensates among other perovskites materials was reported for the first time by Muller et al.[52] Thin layers obtained by cathodic sputtering were investigated in greater detail by Pennebaker[49], who found that, when this method is used, the properties of the films are influenced mainly by the size of the crystallites and the oxygen pressure. Although many properties of the condensate proved to be similar to those of the starting material, nevertheless ϵ amounted to 65% of the value for massive $SrTiO_3$ and the losses were appreciably higher. The variation of ϵ and $\tan\delta$ with thickness and dielectric strength of 500 kV cm^{-1} have been observed[170] for films obtained by the same method.

The structures and properties of strontium titanate films 0.05–1 μm thick, prepared by the method of discrete evaporation, have been investigated in detail[171-173]. The principal parameter determining the stoichiometry with respect to strontium and titantium is the rate of condensation, which leads to an excess concentration of strontium when it exceeds the optimum value ($\leqslant 1$ Å s^{-1}). Condensation on a heated support is responsible for the appreciable losses of oxygen from the film compared with condensates deposited on a cold support. The oxygen deficiency can be partly or completely compensated by subsequent annealing in air or in oxygen.

In the disordered state, the film consists of a collection of arbitrarily oriented regions whose size amounts to several tens of ängströms. Within each region, the perovskite motif is maintained but the interatomic distances are somewhat different from those in the massive crystal. High-temperature treatment results in ordering processes leading to crystallisation. In the crystalline state, the unit cell parameters are close to the initial values (for the massive specimen). At low temperature, the behaviour of the $\epsilon(t)$ relation is different for the disordered and crystalline films. For the former, ϵ falls slowly with decrease of temperature, and for the latter it increases, although more slowly than the value for the initial crystal. At −100°C and a frequency of 1 kHz, $\tan\delta = 0.01-0.001$ in disordered films and the dielectric strength is $\sim 10^6$ V cm^{-1}.

2. Lead Titanate ($PbTiO_3$)

Condensates 0.1–0.3 μm thick have been prepared by the cathodic sputtering method[175]. In order to achieve a stoichiometric composition, the lead content in the target did not exceed 5%. The dielectric constants ϵ of these films amounted to several tens. Films with structures closer to ideality, prepared by the same method, had dielectric constants which depended on the molar ratio Pb : Ti and amounted to about 500 in the optimum case (1 : 1).

3. Lead Zirconate ($PbZrO_3$)

Thick $PbZrO_3$ layers have been prepared by deposition in a constant electric field[22,176]. Their dielectric constants are several times smaller than the values for polycrystalline specimens and the dielectric losses are higher in consequence of the porosity of the layers. A shift of T_C towards higher temperatures has been observed.

4. $(Pb_{0.92}Bi_{0.07}La_{0.01})(Fe_{0.405}Nb_{0.325}Zr_{0.27})O_3$

Films 2–16 μm thick with a perovskite structure and having the above complex composition have been obtained by deposition followed by sintering[177]. For these layers, $\epsilon \simeq 1000$ and $T_C = 150$°C. The degree of spontaneous polarisation amounts to 10–20 μC cm^{-2} and the coercive field is $\geqslant 15$ kV cm^{-1} with a satisfactorily rectangular hysteresis loop. One of the films of this series withstood 2×10^{11} switchings lasting 300 ns at a potential of 20 V.

Studies on films of the same composition, prepared by radiofrequency sputtering, have been reported recently[178]. For films 4.5 μm thick, it has been found that $\epsilon \simeq 1600$, $P_S = 3-15$ μC cm^{-2}, the coercive field is 5–10 kV cm^{-1}, $T_C \simeq 80$°C, and the resistance is $\sim 10^{14}$ Ω cm. The condensates withstood 10^{11} switchings lasting 200–600 ns without appreciable changes in P_S and the coercive field.

5. Calcium Titanate ($CaTiO_3$)

Vacuum condensates 0.1–0.3 μm thick with $\epsilon = 20-60$ have been obtained[179]. Their high dielectric strength (up to 10^7 V cm^{-1}) is striking. The structures and properties of the films, prepared by discrete evaporation, have been studied[180]. The unit cell parameter in the pseudocubic approximation is $a = 3.90 \pm 0.05$ Å, which somewhat exceeds the values for massive $CaTiO_3$ ($a = c = 3.819$ Å and $b = 3.815$ Å); the dielectric constant is 500–700 (for the initial ceramic, $\epsilon = 200$), but the dielectric losses in the films are higher ($\tan\delta = 0.5$ against 0.2 in the massive specimen). The electret properties of ceramic calcium titanate films have been studied[181]. An electric field has not been detected in the films in the presence of an appreciable space charge.

6. Tungsten Trioxide (WO_3)

The microstructure and certain physical properties of WO_3 condensates have been described[182]. The films were deposited *in vacuo* (10^{-5} mmHg) on glass supports. The observed characteristics are complex functions of technological parameters.

7. Lithium Niobate ($LiNbO_3$) and Lithium Tantalate ($LiTaO_3$)

Foster[183] reported studies on lithium niobate films 2–4 μm thick obtained by cathodic sputtering. The condensates proved to be weakly textured, had $\epsilon = 65$ at a frequency of 1 kHz and a piezoelectric coefficient of about 0.08, which is about 50% of the value for a single crystal along the z axis. The preparation of $LiNbO_3$ and $LiTaO_3$ films by high-frequency sputtering has been described[47,184]. The authors observed a deficiency of lithium in the film and enriched the target in lithium for the purpose of compensation. The ferroelectric properties of these condensates are weak: $\epsilon = 80-100$ and $\tan\delta \simeq 0.1$.[47] The elements of the epitaxial growth of $LiNbO_3$ condensates with the (001) orientation, prepared by discrete evaporation on a single crystal layer of silver, have been determined[185]. Attempts have been made to grow single-crystal $LiNbO_3$ films for optical purposes[186].

8. Ferroelectric Niobates

Thin layers having the $KNaNb_2O_6$, $Ba_2NaNb_5O_{15}$, $K_3Li_2Nb_5O_{15}$, and $PbNb_2O_6$ compositions have been obtained by cathodic sputtering on SiO_2 supports coated with gold[187]. The stoichiometry was maintained to within 10–15%. A weak piezoelectric effect was observed in some of the films.

9. Bismuth Titanate ($Bi_4Ti_3O_{12}$)

Epitaxial layers of bismuth titanate have been obtained[188–191]. The condensation temperature was varied from 400° to 700°C and the target consisted of a ceramic with an excess of bismuth to compensate for its losses. The thickness of the films on MgO and platinum supports was 0.2–4.5 μm. The dielectric characteristics, including the degree of spontaneous polarisation, agree well with the values for the massive crystals. Domain boundaries were observed in films 12–32 μm thick[189].

10. Lead Germanate

The discovery of the ferroelectric effect in lead germanate was reported recently[192,193]. The new ferroelectric belongs to the trigonal system, the threefold axis is polar, and $T_C = 170-180$°C. According to the authors[192,193], the formula of the ferroelectric crystal is $5PbO.3GeO_2$, but one cannot rule out a somewhat different composition, namely $3PbO.2GeO_2$.[194,195] Polycrystalline lead germanate films with a thickness <1 μm and having a structure and composition close to those of the initial single crystal have been prepared by discrete evaporation and investigated[196]. An anomaly in the $\epsilon(t)$ relation, corresponding to the phase transition in the massive crystal (T_C), and a dielectric hysteresis loop were observed. The degree of spontaneous polarisation is about 70% of its value for the single crystal.

11. Strontium Tellurate ($SrTeO_3$)

A characteristic feature of this new ferroelectric is that its ferroelectric properties are observed in the temperature range 312–485°C.[197] Films about 0.1 μm thick were obtained by the vacuum evaporation of the comminuted ceramic $SrTeO_3$, for which the temperature range of the polarised state was found to be 325–470°C.[198] Polycrystalline layers can be made even when the support is at room temperature. Heat treatment of the films in air leads to a distinct maximum on the $\epsilon-t$ curve at 470°C, corresponding to T_C for the ceramic. A lower limit of the ferroelectric region was not observed.

12. Antimony Orthoniobate ($SbNbO_4$)

Antimony orthoniobate, a new ferroelectric material, has $T_C = 403$°C and $P_S = 15$ μC cm^{-2} at room temperature, according to Lobachev et al.[199] $SbNbO_4$ vacuum condensates, obtained by discrete evaporation, have a polycrystalline structure[200]. The $\epsilon(t)$ relation has a maximum in the region of 380°C. For the films with the composition closest to stoichiometry, dielectric hysteresis was observed at room temperature; $P_S = 7.4$ μC cm^{-2} and $\tan\delta = 0.1-0.5$.

It has been reported recently[201] that $SbNbO_4$ is an antiferroelectric above 403°C and that the transition to the paraelectric region (T_C) occurs at 600°C.

VI. FERROMAGNETIC VACUUM CONDENSATES

The combination of ferroelectric and ferromagnetic dipoles in a structure of the perovskite type has been achieved in a ceramic consisting of solid solutions of ferroelectric–ferromagnetic systems[202,203], one of the components of which is the $Sr_{0.3}La_{0.7}MnO_3$ solid solution with the magnetic Curie point $T_C^M = 90-120$°C.[204,205]

Condensates of the $BaTiO_3-Sr_{0.3}La_{0.7}MnO_3$ system have been investigated[206]. Films approximately 1000 Å thick with the composition close to $(Ba_{0.9}Sr_{0.03}La_{0.07})(Ti_{0.9}Mn_{0.1})O_3$ were prepared by discrete evaporation, varying the composition of the starting material and subjecting the film to heat treatment during and after condensation. The composition and structure were investigated by local X-ray spectroscopic and X-ray diffraction analyses.

Fig. 9 illustrates the temperature variation of the relative dielectric constants ϵ/ϵ_{max} and of the half-widths ΔH of electron spin resonance lines for films of the initial components $BaTiO_3$ and $Sr_{0.3}La_{0.7}MnO_3$ as well as the condensate of the above composition. The $\epsilon/\epsilon_{max}(t)$ maximum, corresponding to the ferroelectric Curie point T_C, is displaced from 120°C for the pure $BaTiO_3$ film towards lower temperatures following the addition of $Sr_{0.3}La_{0.7}MnO_3$. The $\Delta H(t)$ minimum, corresponding to T_C^M (90°C)[207] for the $Sr_{0.3}La_{0.7}MnO_3$ condensate, also moves to the region of lower temperatures. Thus $T_C^M = -120$°C and $T_C^E \leqslant -130$°C were obtained for the $(Ba_{0.9}.Sr_{0.03}La_{0.07})(Ti_{0.9}Mn_{0.1})O_3$ films. Compared with a ceramic of similar composition and also with films of the initial components, the transitions in the ferromagnetic film are diffuse and occur at lower temperatures, probably owing to fluctuations in composition.

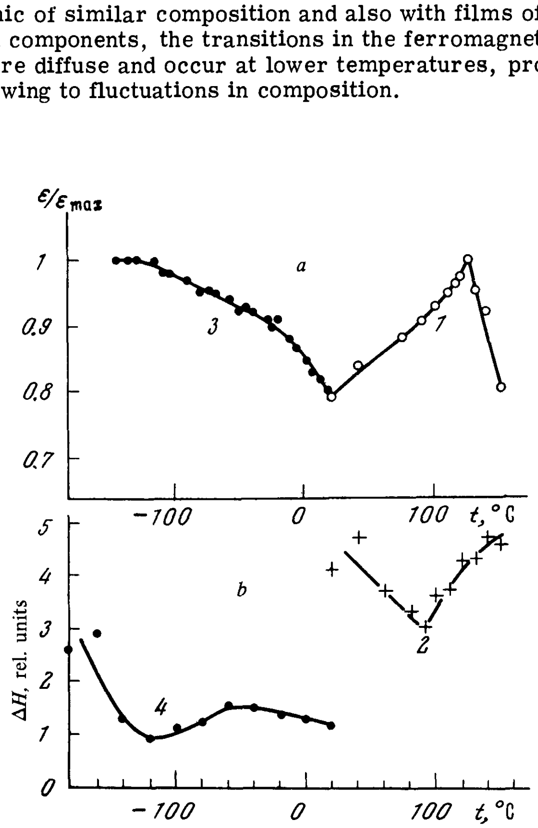

Figure 9. Temperature variation of the relative dielectric constant ϵ/ϵ_{max} (*a*) and electron spin resonance line half-width ΔH for the manganese ion (*b*) in films of the initial components $BaTiO_3$ (curve *1*) and $Sr_{0.3}La_{0.7}MnO_3$ (curve *2*) and the condensate $(Ba_{0.9}Sr_{0.03}La_{0.07})(Ti_{0.9}Mn_{0.1})O_3$ (curves *3* and *4*)[206].

VII. CERTAIN APPLICATIONS OF THIN FERROELECTRIC LAYERS

The need for thin ferroelectric layers in a wide variety of electrical and optical instruments as condensers, pyroelectric detectors, piezoelectric transducers, memory elements, and indicator elements is fairly considerable[13,14]. It has been concluded[208] that one of the important applications of ferroelectric films may be their use as condensers for microwave amplifiers in multimodular systems. The requirement for a high value of ϵ and a low value of $\tan\delta$ at high frequencies is important here. $BaTiO_3$ and $PbTiO_3$ films are therefore less suitable for such purposes than, for example, $Bi_4Ti_3O_{12}$ condensates. The latter ensure a high capacitance (0.02–0.2 μF) and low dielectric losses up to frequencies of about 10^9 Hz. Condensed $SrTiO_3$ films with $\epsilon = 200$ also exhibit low dielectric losses up to 10^9 Hz.[49] Thus bismuth and strontium titanate films can be used as microwave condensers by virtue of their frequency characteristics and the comparatively low temperature at which they are prepared (<600°C), which is compatible with other technological operations.

It has been established[209] that thin layers of ferroelectric oxides with added lanthanum, having high and positive temperature coefficients of resistivity, can be used as sensitive detectors of infrared radiation. After annealing at 1400°C, a $Ba_{0.600}Sr_{0.397}La_{0.003}TiO_3$ film 10 μm thick had a resistivity of $\sim 10^6\ \Omega$ cm and a temperature coefficient of resistivity of ~6%. High annealing temperatures are an obstacle in the technology of the preparation of such elements for infrared video devices, but in the search for new thermistor compositions, technological progress should lead to the solution of this problem[210].

The pyroelectric materials usually employed as sensitive thermodetectors and in thermal vision systems consist of single crystals or ceramics, but the optimum thickness of such elements in thermal vision is 10–15 μm, i.e. the element should be a film. A decrease of thickness gives a higher sensitivity, a better resolution, and low inertia[211]. One of the problems arising in connection with the use of pyroelectric materials in such devices involves difficulties in the preparation of electrically and optically homogeneous elements of large size.

Piezoelectric elements made of massive ferroelectric materials are widely used as electromechanical transducers in acoustic arrest lines, but their comparatively large size limits their use to low frequencies. It has been shown[212] that elements ~1 μm thick are necessary in devices where the transducer operates as a generator or detector of ultrasonic waves at frequencies of ~10^9 Hz.

Thus ferroelectric films with high electromechanical coupling coefficients, such as $LiNbO_3$, lead zirconate-titanate, and alkali and alkaline earth metal niobates with the structure of tungsten bronzes can be used in such applications. Positive results have been obtained[183] on oriented $LiNbO_3$ films prepared by cathodic sputtering, in which the (012) plane of the hexagonal structure is inclined at an angle of 40° to the support. Piezoelectric measurements on thin films yielded a piezoelectric coefficient of 0.08, which amounts to about 50% of its value for the single crystal. The reasons for the difference are probably associated with the non-stoichiometry and inadequate structural ordering of the condensates.

By analogy with ferromagnetic materials, the ferroelectric hysteresis loop has a potential application in memory devices. It has been shown[177,213-216] that memories with capacities up to 10^9 bits can be achieved with the aid of thin photoconducting and ferroelectric layers. The thickness of the $(Pb_{0.92}Bi_{0.07}La_{0.01})(Fe_{0.405}Nb_{0.325}Zr_{0.27})O_3$ layers used, prepared by ceramic casting and sputtering[217], reached several micrometres, the ferroelectric films exhibiting a rectangular hysteresis loop and satisfactory thermal scattering. The memory device was charged by means of a light spot focussed on the screen of a cathode ray tube.

The use of thin ferroelectric layers in image-producing devices requires structures in which the contrast of the image, caused by the variation of double refraction under the influence of an electron beam modulated by the video signal, is not too sensitive to the thickness of the element. Here the most suitable material is bismuth titanate in which the optimum contrast can be achieved for a particular growth orientation. Since natural $Bi_4Ti_3O_{12}$ crystals do not grow in the required [crystal] habit, a solution was found to the problem when layers of the *A–C*-domain crystal with a large area (1 cm²) were grown on MgO and $MgAl_2O_4$ single crystals[188,189,191]. An example of the use of a non-linear ferroelectric capacitance and of hysteresis properties in image-producing devices is provided by a system comprising a liquid-crystal matrix and a thin transparent plate of a CTS ceramic with added lanthanum[218].

Among other applications, mention should be made of the use of ferroelectric films as indicator devices[219] and light modulators ($LiNbO_3$ and $LiTaO_3$)[220,221] and also for dielectric thermostabilisers and other purposes[222].

In conclusion one should note that, as a result of the efforts made in recent years to study the mechanisms of growth and ordering processes and to extend and improve preparative methods, there has been a clear progress in the technology of the preparation of highly ordered ferroelectric films, including epitaxial layers. However, many problems, on the solution of which depends the attainment of optimum properties (stoichiometry and homogeneity of composition, epitaxial growth, physical material of the electrodes, and methods of their deposition), are still far from a complete solution. There is a need for more far-reaching studies of the surface phenomena in ferroelectric materials, the role of which is particularly significant in a thin layer.

There has been an appreciable increase in the number of new ferroelectric films. Whereas the vast majority of studies were previously concerned with barium titanate, in recent years more than 20 new compounds and solid solutions have been obtained as films, including bismuth titanate, lead germanate, and antimony orthoniobate. Here efforts should be directed towards the search for compositions which do not require high temperatures of synthesis and which possess the necessary properties.

In practical applications there has been a transition from the predictive stage to the incorporation of thin-layer ferroelectric elements in solid state devices. The optimum technology has been developing vigorously recently. Further progress in research on thin ferroelectric layers will reveal new fields for their application.

---o0o---

During the preparation of the manuscript for the press, numerous studies were published on the synthesis and applications of thin lithium niobate layers. $LiNbO_3$ films have been prepared by decomposing the vapours of organometallic compounds on lithium tantalate supports[226], by dipping the support in an $LiNbO_3$ melt[227], by diffusion into the region of the surface layer of the crystal[228-234], and by ion exchange[235]. Similar systems have been proposed as optical and acoustic waveguides and electro-optical modulators[230,231,236-246]. The applications of films as waveguides have been reviewed[247,248].

Memory devices based on films with an epitaxial structure (bismuth titanate), synthesised by high-frequency sputtering, have been made[249,250]. The possibility of devising capacitive film heat sensors has been demonstrated[251]. New data for size effects in ferroelectrics and their treatment in thin layers have been published[252,253] as well as data obtained in studies on $SrTiO_3$ and (Ba, Sr)TiO_3 vacuum condensates[254-256]. Methods have been developed for the measurements of the dielectric parameters of ferroelectric films in the ultrahigh frequency range[257].

Intramolecular Coordination in Organic Derivatives of Non-transition Elements

A.K.Prokof'ev

The problem of intramolecular coordination in organic derivatives of non-transition elements is surveyed and critically considered. Only those inner complexes (in an unreacting molecule or in the transition state)where the chain with the donor atom is linked to the element only via carbon atoms are considered. The data are treated systematically on the basis of the type of ligand. It is shown that intramolecular coordination is the driving force in various molecular rearrangements and many elimination reactions involving organic derivatives of the elements.
The bibliography includes 331 references.

CONTENTS

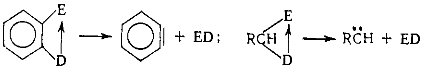
I. INTRODUCTION

Twenty years have elapsed since the synthesis of the first stable organic derivatives of the elements with intramolecular coordinate bonding in which the chain containing the donor atom is linked to the non-transition acceptor element only via carbon atoms. They have been called inner complex organic derivatives of the elements[1]. The comparatively sluggish development of this field can be explained both by the lack of clear-cut criteria concerning the understanding of the very concept of intramolecular coordination (IAMC) and by the defects of the current physical and physicochemical methods for the determination of the structure of matter and the consequent serious difficulties in the detection and demonstration of IAMC.

IAMC should be understood as a donor-acceptor interaction with charge transfer within the limits of a single molecule taking place through space, by-passing the conjugation chain, and involving the formation of a new single D-E bond in the limiting case (D is the electron-donating atom and E the non-transition acceptor element). Naturally one excludes from consideration a similar interaction between two adjacent atoms of the type of $d_\pi - p_\pi$ conjugation, for example in aminoboranes and silylamines, which might be regarded as a special case of IAMC resulting in only an increase of bond order.

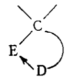
The strength of IAMC in a non-reacting molecule is unknown, since no inner complex for which the conformational equilibrium constant has been determined has so far been described. Nevertheless most investigators suggest that intramolecular coordination interaction is energetically close to hydrogen bonding. The limits of its manifestation are fairly wide: from complete charge transfer, as, for example, in γ-aminopropyl compounds of boron, to closed structures in which IAMC occurs only in the transition state.

The available data on the properties of organic derivatives of the elements with IAMC were reviewed for the first time in 1970[2]. Their importance for theory and practice in the chemistry of organic derivatives of the elements was already noted at the time. In subsequent years these compounds were successfully used in the synthesis of reactive and unstable species such as carbenes and arynes, the synthesis of which by other methods is in many instances impossible. Reactions of this kind, proceeding via IAMC, have been described by Nefedov et al.[3]:



In the present review we shall therefore not consider β-elimination in aromatic systems with formation of arynes and α-elimination in aliphatic systems with formation of carbenes.

The aim of the present review is to survey data on the physical and chemical properties of organic derivatives of non-transition elements with IAMC. We shall consider only compounds in which the chain containing the donor atom is linked to the acceptor element via carbon atoms, i.e. true organic derivatives of the elements with IAMC:



The data reviewed are arranged systematically on the basis of the type of ligand, which we believe to be most convenient for the detection of differences in the acceptor properties of elements, and are dealt with in order of decreasing electron-donating capacity of the ligand subgroups in the sequence $\geqslant$N >-O- >-Hal π-systems. This series is purely conventional and changes markedly as a function of the element and the reaction conditions for ligand atoms, belonging to different subgroups, linked to the same hydrocarbon groups. At the same time practice has shown that the ease of formation and the stabilities of many organic derivatives of the elements increase in this sequence. Each type of ligand is discussed in order of increasing size of the rings formed in IAMC, the elements being considered in order of their increasing valence within a Period and downwards within the limits of a single subgroup. The chemical consequences of IAMC are surveyed after coordination in non-reacting molecules has been examined.

Particular attention is devoted in this review to X-ray diffraction studies of compounds with IAMC, since the geometrical criterion—the distance between the donor and acceptor atoms—is one of the most clear-cut pieces of evidence for the presence or absence of coordination.

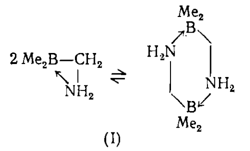
However, this criterion cannot be always justified experimentally owing to the lack of the exact values of the van der Waals radii of the elements in their organic compounds[4]. Furthermore, the radius depends on the hybridisation of the element and can therefore change. Naturally experimental accuracy is frequently the decisive factor and for this reason all studies where it is not indicated have been excluded from this review.

II. INNER COMPLEXES WITH NITROGEN-SUBGROUP LIGANDS

The synthesis of nitrogen-containing organic derivatives of the elements frequently presents considerable difficulties because of the electron-donating capacity of amine and nitrogen and its tendency to form intermolecular complexes. Their number and variety are therefore greatly inferior to similar derivatives of the oxygen and fluorine subgroups.

The presence of IAMC has a significant influence on the physical and spectroscopic properties of organic derivatives of the elements. It is very important to have at ones disposal consistent data obtained by different methods, since only then can one decide sufficiently unambiguously whether or not IAMC is present. This is also associated with the necessity to separate interfering factors such as intermolecular coordination (IRMC), crystal and field effects, solvation, inductive and resonance effects, etc.

Measurements of the molecular weight in the gas phase (13.8% of the dimer at 0°C and pure monomer at temperature exceeding 40°C up to 75°C) and the temperature variation of the ^{11}B NMR spectrum in the liquid phase (decrease of the degree of dimerisation from 84.3% at −25°C to 24.3% at 35°C with a heat of dimerisation of about 9 kcal $mole^{-1}$) have shown that aminomethylboron (I) is involved in a dimer–monomer equilibrium, the amount of monomer increasing with temperature[5]:

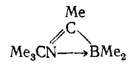


(I)

The study of the dissociation of complexes (I) with trimethylboron and ammonia has shown unambiguously that complex (I) is a weaker acid and a weaker Lewis base than the corresponding monofunctional derivatives. According to ^{11}B and ^{1}H NMR spectroscopic data, the electron density at the boron atom in complex (I) is enhanced compared with trialkylboron and the δ_{CH_2} signal is strongly displaced towards a lower field (by 0.24 p.p.m.; 0.20 p.p.m. in cyclopropane). The combined data quoted above provide serious grounds for the assumption that B ← N intramolecular coordination obtains in the monomeric state of compound (I).

It is noteworthy that[6] dimethylaminomethylboron exists only in the dimeric form up to 170°C. The authors explain this difference from compound (I) by the greater electron-donating capacity of nitrogen in $RNMe_2$ compared with RNH_2, which is in turn manifested by a decrease of the acid properties of dimethylaminoboranes.

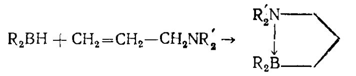
The three-membered inner complex obtained in a quantitative yield at room temperature when the product of the addition of trimethylboron to t-butyl isocyanide $Me_3C\overset{+}{N}{\equiv}C\overset{-}{B}Me_3$ isomerises proved to be resistant to the action of oxygen and moisture[7]. The ^{1}H NMR spectrum of the complex was found to contain three signals of the CH_3 group with the line intensity ratios 1:2:3, while the infrared spectrum contains a band with $\nu(N{=}C) = 1548\ cm^{-1}$, but there is no band with $\nu(\overset{+}{N}{\equiv}C) = 2247\ cm^{-1}$. Furthermore, it has been established (by mass spectrometry) that the gas phase contains only the monomeric form of the complex. All these findings confirm the proposed structure[7]:



The steric factor is the decisive cause of the formation of the three-membered ring, since the reaction between less hindered isonitriles and boranes leads to the formation of dimeric products—2,5-dibora-2,5-dihydropyrazines[8].

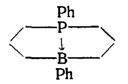
The coordination capacity of the element E in the R_2ECH_2X system (X = Si, Ge, or Sn and X = N, O, S, or a halogen) is extremely low and only one complex, formed by trifluoromethyltrimethyltin with hexamethylphosphoramide[9], has been isolated and weak adduct formed by chloromethyltrimethyltin with dimethylformamide in solution has been described[10]. The latter complex was detected by Mössbauer spectroscopy, although in the organotin compound itself there is no Sn ← Cl intramolecular coordination, as can be seen from the nuclear quadrupole resonance (NQR) spectra[11], Mössbauer spectra[12], and dipole moments[13]. Furthermore, the basicity sequence of the amino-derivatives (Ge > Sn > Si) is consistent with the adopted electronegativity scale of the elements E [14] and there is therefore no coordination even in these compounds. For this reason, the claim[15,16] concerning the occurrence of IAMC in the above system (or the "α-effect") is invalid. According to infrared and ultraviolet spectra, IAMC is also absent from 2-substituted pyridines (E = Si, Ge, or Sn)[17]:

γ-Aminopropyl derivatives of Group III elements cyclise extremely readily to five-membered rings via E ← N intramolecular coordination; in most cases they are obtained by the addition of hydrides to allylamines[18-24]:



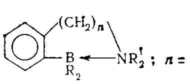
These complexes are relatively resistant to cold water[18], solutions of alkalis[24], disproportionation[22], peroxides[21], mercaptans[23], and heat[22]. Furthermore, they are stable in air and do not react with ammonia and phosphine[21]. In the gas phase, they exist as monomers[21]. The high dipole moments (4.0–4.2 D)[23], high refractions[21], infrared spectroscopic data [$\nu(B \leftarrow N) = 1266\ cm^{-1}$][19], ^{11}B and ^{1}H NMR data[19-21,24], and mass spectra[19,20,24] also indicate the occurrence of IAMC. When the hydrogen atom attached to nitrogen is replaced by alkyl groups or when an alkoxy-group is attached to a boron atom, the strength of the B ← N bond decreases appreciably and in the compound $(EtO)_2BCH_2CH_2CH_2NEt_2$ (μ = 1.44 D) the bond probably does not exist at all[23].

The phosphorus analogue probably also exists in a cyclic form[25]:



This is shown by its stability in air and on heating and by ^{11}B and ^{1}H NMR data.

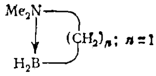
Compounds of the type



; $n = 1, 2$; $R' =$ Alk, Ar; $R = H, NMe_2$, O—

have also been described[26-28]. They too are relatively resistant to hydrolysis and, when $R = H$, do not react with olefins, which is characteristic of complexes with an intermolecular N → B bond[28].

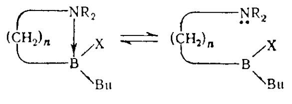
It has been suggested[29] that all compounds of the type



$n = 1$-10

in general involve intramolecular coordination, since their dipole moments are approximately 4 D and the fragments $(M - 1)^+$, where M is the molecular weight, give rise to high intensities in the mass-spectra, this being characteristic of compounds having such a structure; the expected infrared and ^1H NMR spectroscopic properties have also been obtained.

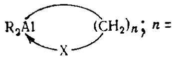
A detailed study of compounds of this class by the ^{11}B and ^1H NMR methods showed that, both in the pure state and in solutions, they consist of an equilibrium mixture of cyclic and linear forms[30-32]:



; $n = 3, 4$; $R =$ Alk; $X =$ Alk, OAlk, SAlk .

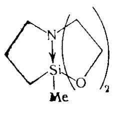
The breakdown and occurrence of intramolecular coordination take place at a rate exceeding $10^3\ s^{-1}$, which enabled the authors[30] to call these compounds a "pulsating" system. The equilibrium position depends on n, R, and X as well as temperature. With increase of temperature, the equilibrium is displaced towards the linear form (as shown by the temperature variation of the ^{11}B NMR spectra and the dipole moments). The equilibrium constants and heats of reaction were calculated from these results.

Similar aluminium compounds are also inner complexes[1,33-35], which are monomeric in hydrocarbons, distil *in vacuo* without decomposition, do not form adducts with ether (for X = OR), and do not form quaternary compounds with methyl iodide (for $X = NR_2$)[1]:

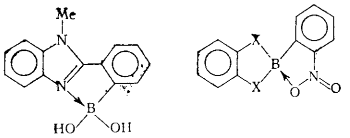


; $n = 3, 4$; $X = NR_2$, OR, SR, Hal .

X-Ray diffraction analysis of methyl(2,2′,3-nitrilodiethoxypropyl)silane confirms the occurrence of IAMC in γ-aminopropyl compounds of non-transition elements even for a relatively poor acceptor such as the silicon atom (reliability index $R = 4.6\%$).[36] The molecule of this compound consists of a distorted trigonal bypyramid with the nitrogen atom and the methyl group at the vertices. The Si–N bond length (2.336 Å) is much smaller than the sum of the van der Waals radii (3.5 Å), but greatly exceeds the length of the covalent bond (1.74–1.78 Å). Steric factors decrease the CNSi angle from the tetrahedral value to 102°, which makes the N → Si linkage relatively long.

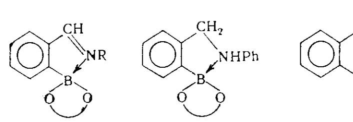


Inner-complex coordination has been put forward to account for the anomalous ultraviolet spectra of the compounds[37,38]



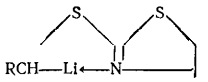
; X = NH, O,

the infrared[39-41] and ^1H NMR spectra[40,41] of the compounds

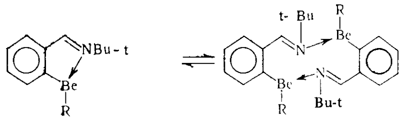


; E=Al, Ga ,

and for the formation of the anomalous products of the reactions of lithiothiazoline[42]:

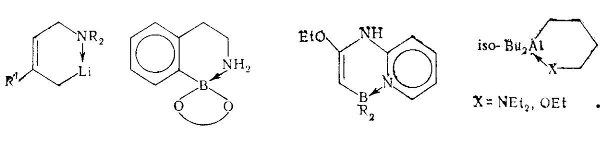


Such coordination is apparently the cause of the *ortho*-metallation of azomethines by dialkylberyllium[43]; in this case, when R = t-Bu, the degree of association of the reaction product in benzene is 1.55–1.65, which suggests the equilibrium



It is also responsible for the *ortho*-metallation of azobenzenes by mercury acetate[44]. These compounds are widely used in the chemistry of transition metals[45].

The formation of six-membered rings as a result of N → E intramolecular coordination takes place with much greater difficulty because of the appreciable angular ring strain. Such ring structures have been proposed for compounds of lithium[46] (on the basis of the stereoselectivity of the reaction products), boron [$\nu(N \rightarrow B) = 1240\ cm^{-1}$,[47] on the basis of infrared and ^{11}B NMR spectroscopic data[48,49]], and aluminium[34]; they are monomeric in benzene solution and thermally stable:

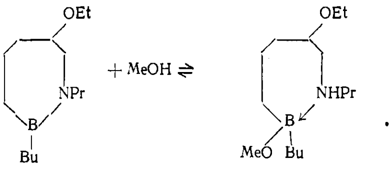


X = NEt₂, OEt .

The instability of the coordinate bond in six- and even seven-membered rings is illustrated by the fact that stable products of the hydroboration of but-3-enyl derivatives containing functional substituents are readily oxidised to alcohols[50]:

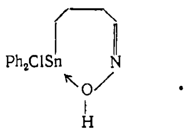
$$CH_2{=}CHCH_2CH_2X \xrightarrow{BH_3} {>}B(CH_2)_4X \xrightarrow{[O]} \text{alcohol};$$
$$X{=}NR_2, OR, SR, OAc, Cl.$$

The rapid dissociation and formation of the N → B intramolecular coordinate bond in substituted 1,2-azaborepanes are reversible and depend both on the concentration of methanol in hexane solutions of the compound and on temperature, as shown[51] by the signal shifts in the ^{11}B NMR spectrum:



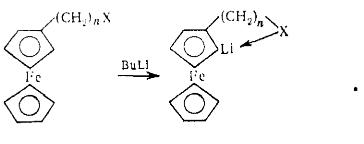
Similar aluminium compounds, iso-$Bu_2Al(CH_2)_5X$ ($X = NEt_2$ or OEt), contain associated species with intermolecular bonds together with seven-membered IAMC structures[34].

A seven-membered ring is probably formed in δ-stannyloximes, whose infrared spectra, both in the solid state and in solution, contain a $\nu(OH) = 3475\ cm^{-1}$ band, and none due to the hydroxy-groups involved in hydrogen bonding are present. Furthermore, when treated with PCl_5, they undergo a Beckmann rearrangement with exchange of the hydroxy- and stannylpropyl groups, which should therefore be located in the *syn*-positions relative to one another:



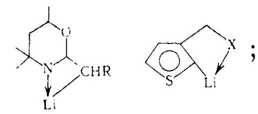
When chlorine attached to tin is replaced by a phenyl group, the compounds behave as the usual ketoximes and do not exhibit the above anomalies[52].

The *ortho*-metallation reactions of ferrocenes and benzenes, with substituents containing atoms having unshared electron pairs (X), and also of heterocycles with the aid of alkyl derivatives of lithium, sodium, and magnesium are of great practical importance from the synthetic standpoint. The high selectivity and high yields of the reaction products can probably be accounted for by the formation of a strong M ← X intermolecular coordinate bond in the initial stages with subsequent metallation in the *ortho*-position and stabilisation of the resulting complexes by an M ← X intramolecular coordinate bond. In most cases lithium alkyls are used as the metallating agents.



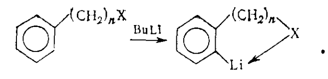
Direct metallation has been investigated in detail for the following amino-derivatives of ferrocene: $n = 1$, $X = NMe_2$,[53] $\langle N(CH_2)_m\rangle$ (m = 4 or 5),[54] or [55]; $n = 2$, $X = NMe_2$.[56] The reactions proceed much more readily than for unsubstituted ferrocene[53]. The evidence for coordination is provided indirectly by the condensation products. These reactions are described in greater detail elsewhere[57,58].

Dihydro-1,3-oxazines[59] and thiophens[60] are just as readily metallated[60]:



; X = NMe_2, OMe .

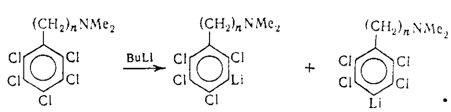
Aminobenzenes are metallated in the *ortho*-position much more slowly and under much more severe conditions than the ferrocene analogues in consequence of the reduced acidity of the protons:



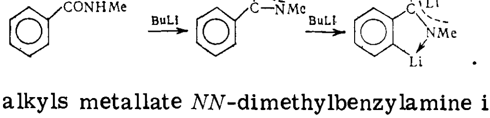
Substituted benzenes have been investigated: $n = 0$, $X = NMe_2$ [61,62]; $n = 1$, $X = NMe_2$ [63]; $X = AsR_2$ [64]; $n = 2$, $X = NMe_2$.[65,66]

The presence of the N → Li intramolecular coordinate bond in such compounds is confirmed by the infrared spectroscopic study[67] of the ^6Li- and ^7Li-labelled benzene complexes ($n = 1$, $X = NMe_2$) in addition to the isolation of *ortho*-substituted reaction products. The $\nu(C-Li) = 355\ cm^{-1}$ and $\nu(N \rightarrow Li) = 494\ cm^{-1}$ bands in the spectrum of the compound with ^7Li were displaced to 370 and 500 cm^{-1} respectively following the introduction of ^6Li. This isotopic shift is characteristic of the N → Li intermolecular coordinate bond and the Li–C bond in ordinary lithium alkyls. Cryoscopic determination of the molecular weight in DMSO showed that at minimal concentrations the degree of association of these complexes is less than 1 but at high concentrations it exceeds 4. An N → Li intermolecular bond is probably formed in the compounds together with the intramolecular coordinate bond. The coordination is confirmed also by the ready removal of DMSO, a powerful solvating solvent, at room temperature *in vacuo*, while ordinary lithium alkyls form stable complexes under these conditions even with ether.

The sharp decrease of the Lewis basicity of the amino-group in *NN*-dimethylamino(alkyl)perchlorobenzenes as a result of the strong electronegativity of the perchlorophenyl group and the impossibility of the formation of an intermolecular coordinate bond with butyl-lithium (particularly in the presence of solvating solvents) lead to their metallation only in the *meta*- and *para*-positions and not the *ortho*-position with respect to substituent[68,69]:

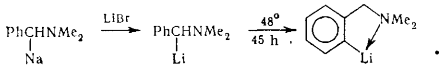


Secondary amines[70], amides[71], and sulphonamides[72] are metallated initially at the nitrogen and only then in the *ortho*-position (in the presence of an excess butyl-lithium), for example:



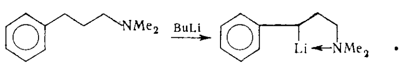
Sodium alkyls metallate *NN*-dimethylbenzylamine in the *ortho*-position with subsequent spontaneous isomerisation to the derivative with the metal in the α-position with respect to the amino-group[73]:

When sodium in the last compound is replaced by lithium, the *ortho*-metallated product can be reformed after prolonged heat treatment, although at room temperature the α-lithio-compound is stable:

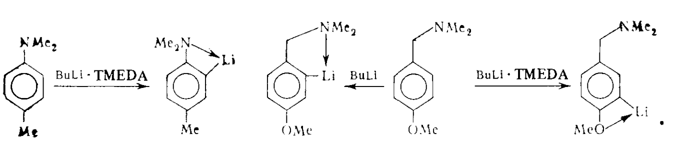


The reasons for these isomerisations are obscure.

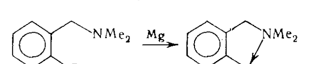
The metallation of *NN*-dimethyl-3-phenylpropylamine proceeds in the chain with formation of a five-membered ring[74]:



One should note that *ortho*-metallation by butyl-lithium proceeds comparatively slowly (11–21 h), but is sharply accelerated (1–2 h) when its complex with tetramethylethylenediamine (TMEDA) is used[75]. On the other hand, the lithium atom in the complex BuLi.TMEDA lacks electron-accepting properties and cannot therefore be involved in an intermolecular coordinate bond with the nitrogen atom of the amino-derivatives of benzene, ferrocene, and heterocycles, which is the main cause of the metallation of the 2-position, and not of the more acidic methylprotons in *NN*-dimethyl-*p*-toluidine [75], and of the *ortho*-position relative to the methoxy-group in *p*-methoxy-*NN*-dimethylbenzylamine. [76] In these compounds the *ortho*- and *para*-directing effects of the dimethylamino- and methoxy-groups exceed respectively those of the methyl and dimethylaminomethyl groups:

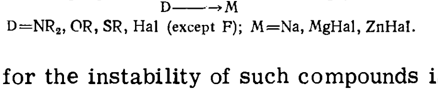


Grignard reagents are also formed very readily (in quantitative yields) from 2-bromobenzyl-*NN*-dimethylamine, while the 3- and 4-bromo-derivatives do not react under analogous conditions[77]:



The chemical manifestations of intramolecular coordination are extremely varied and frequently involve "anomalous" elimination reactions and rearrangements, which do not occur with related compounds where coordination is known to be absent. Furthermore, the metal–carbon σ-bond is polarised under the influence of coordination and therefore becomes more reactive. Such processes are particularly frequent in aliphatic systems.

When alkyl halides containing a heteroatom in the β-position are acted upon by reactive metals, extremely unstable organometallic compounds are formed and decompose at the instant of formation as a result of easy β-elimination[78,79]:

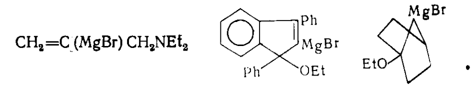


D=NR$_2$, OR, SR, Hal (except F); M=Na, MgHal, ZnHal.

The reason for the instability of such compounds is probably a D → M intramolecular coordinate bond, although this has not been specially investigated.

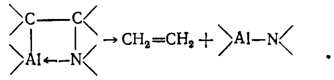
Numerous studies have shown that β-elimination in Grignard reagents cannot be prevented either by very low temperatures or by the protection of functional groups[79].

There are only a few instances of the successful formation of Grignard reagents of this type where either the activation energy for the formation of allenes is unduly high[80,81] or the elimination reaction is forbidden by Bredt's rule[82]:

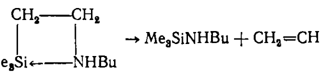


Halogenoamines $R_2N(CH_2)_nHal$ form organomagnesium compounds in THF with $n \geq 3$.[79,83]

The β-aminoethyl derivatives of aluminium, which begin to decompose with formation of ethylene already during their formation when vinylamines add to aluminium hydrides (at 20–60°C), are also unstable[84]:

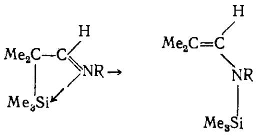


The similar silicon compounds are much more stable, and silanes with tertiary amino-groups are not decomposed on prolonged heat treatment up to 300°C, while those with secondary amino-groups eliminate ethylene at this temperature with a 30% yield[85]:



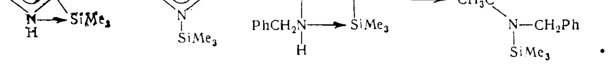
Quaternary salts decompose in the same way, but silylamines with alkoxy-groups at the silicon atom are stable.

Organosilicon derivatives of aldimines rearrange very slowly at room temperature to the corresponding *N*-derivatives[86]:

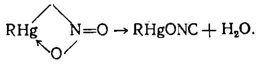


The isomerisation is sharply accelerated in the presence of 10 mole % of trimethylsilyl bromide and depends markedly on steric factors; for example, with R = t-Bu or iso-Pr there is no isomerisation. It is very probable that the non-catalysed rearrangement takes place intramolecularly, by analogy with the keto–enol isomerisation (see Section III).

Diatropic rearrangements with exchange of the trimethylsilyl group for hydrogen in 2-trimethylsilylpyrrole at room temperature[87] and in silylacetamidines at 95–200°C[88] apparently take place in the same way, although their mechanism has not been investigated (these rearrangements are considered in greater detail in Section III):



Kashutina and Okhlobystin[89] suggest that this is why α-nitromethyl derivatives of mercury decompose at the instant of formation to fulminate and water:

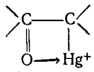


It is interesting to note that trinitromethyl compounds of mercury are fairly stable and it is believed[89] that the possibility of dehydration is a necessary condition for the rearrangement.

III. COMPLEXES WITH OXYGEN-SUBGROUP LIGANDS

1. Aldehydes and Ketones

The carbonyl group in α-carbonyl organic derivatives of the elements has "anomalous" spectroscopic properties compared with carbon analogues—its absorption in the infrared and ultraviolet spectra is displaced towards longer wavelengths and the band intensities are greatly enhanced. These findings have been explained by σ,π conjugation[90]. However, the even greater shift of the ν(CO) wavenumber (to 1645 cm^{-1}), while ν(CH) retains its normal value in the $RHgCH_2CHO$ (R = Cl or CH_2CHO) spectra would be difficult to understand in terms of conjugation, which led to the hypothesis[91] that both intramolecular and intermolecular CO → Hg coordinate bonds are formed in these compounds. The IAMC hypothesis, leading to a decrease of the positive charge on the metal, was put forward to explain the low rate constant for the electrochemical reduction of α-carbonyl derivatives of mercury[92]:



.

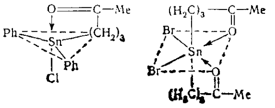
Attempts have been made in a number of studies to determine the main effect responsible for these anomalies. The increase of the intensity of the *n* → π* transition band by a factor of 4–5 in the spectra of α-silylketones compared with the carbon analogues confirmed, according to Musker and Ashby[93], the presence of a CO → Si intramolecular coordinate bond and could not be explained by steric and inductive effects. However, the exaltation of the *n* → π* transition is observed in many other ketones and may be due to factors which do not affect the absorption by the carbonyl group. The significant difference between the observed and calculated wavenumbers of the carbonyl group in the spectra of α-silylketones and their carbon analogues cannot serve as proof of a greater contribution by IAMC compared with the inductive effect of the trialkylsilyl group, since no account was taken in the calculations of the influence of the field and other factors which may be more important than the inductive effects[94]. Furthermore, it follows from the infrared spectra of α-silylketones in the gas phase [the bathochromic shift of ν(CO)][95] that there is no intermolecular coordination in these compounds.

There are probably concerted effects of the CO → Si intramolecular coordinate bond and the inductive effect of the R_2Si-group in α-silylketones, since the ν(CO) band in the spectrum of α-triphenylsilylcyclohexanone is split in carbon tetrachloride into two components, the intensities of which vary with temperature, but the splitting itself is independent of concentration and can therefore be accounted for by a conformational equilibrium[94]. Intramolecular coordination probably obtains also in α-stannylketones, since an appreciable quadrupole splitting (Δ) is observed in their Mössbauer spectra and furthermore such interaction is not inconsistent with mass-spectrometric data[10].

Coordination of this kind is absent from β- and γ-stannylketones[10,96] but becomes appreciable when the hydrocarbon groups at the tin atom in these compounds are replaced by powerful electronegative groups—halogens (see Table)[96].

The values of ν(CO) permit the existence of an Sn ← OC intramolecular coordinate bond in compounds (III), (IV), and (VII) but not in (II) and (V), since the tin atom in compounds of the latter type does not usually exhibit coordinating properties.

When complexes (IV), (VI), and (VII) with bipyridyl are formed, the intramolecular coordinate bond is ruptured and the ν(CO) wavenumbers become characteristic of the free carbonyl group. The occurrence of intramolecular coordination is confirmed also by the analysis of the chemical shifts of the protons in the methylene group linked to the carbonyl group. The signals of compounds (II) and (V) are located in the region of τ = 7.55 p.p.m. The replacement of the phenyl group by a halogen in these compounds causes their downfield shift in consequence of the appearance of IAMC, which reduces magnetic shielding. On the other hand, in the bipyridyl complexes (IV), (VI), and (VII) the carbonyl group is liberated and the proton signals again appear in the region of τ = 7.55 p.p.m. There is no intermolecular coordination in these compounds, since compounds (III) and (VII) are monomeric in benzene. There is no splitting Δ in the Mössbauer spectra of compounds (II) and (V), which is as a rule a characteristic feature of tetracoordinate organotin compounds, but it is appreciable in the spectra of compounds (III) and (VII). The magnitude and sign of Δ suggest the following structure of these compounds:



.

The occurrence of intramolecular or intermolecular coordination in non-reacting organic derivatives of the elements with α-carbonyl groups should facilitate the possible elementotropic rearrangements, since such interaction lowers the activation energy for the transition complex. Indeed α-silylketones rearrange to the isomeric siloxyalkenes on heating to 160–180°C for 2–3 h [97] or on standing in the presence of catalytic amounts of mercury and zinc salts and halogenosilanes[98]: $R_3SiCH_2COR' \rightarrow R_3SiOC(R') = CH_2$, where R and R′ = alkyl or aryl.

The thermal rearrangement is a process common to these compounds and takes place intramolecularly via a four-membered transition state[97]:

.

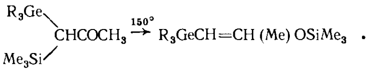
This is proved by the following findings: (a) the retention of configuration in the thermolysis of the optically active ketone (+)-α-(methylphenyl-1-naphthylsilyl)benzophenone[97]; (b) the absence of intermolecular interaction products in the thermolysis of a mixture of α-trimethylsilylacetophenone and triethylsilylacetone[98]; (c) the first order of the reaction[97]. The activation energy for the rearrangement is 26–33 kcal $mole^{-1}$ depending on R and R′.[99] On the other hand, catalytic isomerisation is an intermolecular process[98].

Silylmethyl sulphoxides, which are heteroanalogues of α-silylketones, undergo a remarkable rearrangement[100]:

$$Me_3SiCH_2\underset{\overset{\|}{O}}{S}R \xrightarrow{60°} Me_3SiOCH_2SR.$$

Its mechanism is obscure. The germanium analogue does not isomerise under these conditions and the phosphorus analogue $Me_3SiCH_2P(O)Ph_2$ is stable even at 180°C.

αα-Dimetallated ketones also isomerise on heating. Thus germyl silyl ketones are converted into *C*-silylated germyl-substituted enols[101] at a higher rate than α-monosilylketones:



$$\begin{matrix}\mathrm{R_3Ge}\diagdown & \\ & \mathrm{CHCOCH_3}\xrightarrow{150^\circ}\mathrm{R_3GeCH{=}CH(Me)OSiMe_3}\ . \\ \mathrm{Me_3Si}\diagup & \end{matrix}$$

A phosphonate ester rearranges similarly (to the extent of 50% in the presence of 2% orthophosphoric acid and to the extent of only 1% in the absence of a catalyst)[102]:

$$\underset{\mathrm{O}}{\overset{}{\mathrm{(EtO)_2\overset{}{P}}}}\mathrm{CH_2COCH_3}\xrightarrow{170^\circ}\underset{\mathrm{O}}{\mathrm{(EtO)_2P}}\mathrm{OC(CH_3){=}CH_2}\ .$$

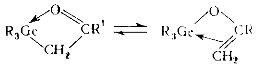
It is believed that the rearrangement proceeds intramolecularly, since it is unaffected by the addition of 2-butanone.

Spectroscopic properties of γ-stannylketones.[96]

Compound	ν(CO), cm^{-1} (in liq. paraffin)	τ_{CH_2CO}, p.p.m. (in $CDCl_3$)	δ for SnO_2, mm s^{-1}	Δ, mm s^{-1}
(II) $Ph_3Sn(CH_2)_3COMe$	1705	7,55	1.73	0
(III) $Ph_2ClSn(CH_2)_3COMe$	1669	7,46	1.38	−3.30
(IV) $PhCl_2Sn(CH_2)_3COMe$	1670	7,30	—	—
$PhCl_2Sn(CH_2)_3COMe\cdot$bipy *	1710	7.55	—	—
(V) $Ph_2Sn[(CH_2)_3COMe]_2$	1709	7,55	1,41	0
(VI) $Cl_2Sn[(CH_2)_3COMe]_2$	1680	7.23	—	—
$Cl_2Sn[(CH_2)_3COMe]_2\cdot$bipy	1705	7.42	—	—
(VII) $Br_2Sn[(CH_2)_3COMe]_2$	1675	7.27	1,66	+3.83
$Br_2Sn[(CH_2)_3COMe]_2\cdot$bipy	1703	7,55	1.56	+3.80

*bipy = 2,2′-bipyridyl.

True elementotropic tautomerism occurs in the case of α-germylketones[103], the equilibrium position depending strongly on temperature, an increase of which increases the content of the *O*-isomer. The equilibrium between the isomers is established slowly (in about one month)[104] at room temperature and much faster following the addition of bromogermanes. Presumably this reversible rearrangement proceeds via a coordination complex:

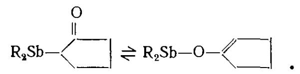


The contents of the *C*- and *O*-isomers depend strongly on the substituent linked to the keto-group. Thus, at 20°C and with R = CH_3, the equilibrium mixture contains 3% of the *O*-isomer for R′ = CH_3 [105] and 33.7% for R′ = *p*-ClC_6H_4.[106] The germanotropic equilibrium constant is satisfactorily correlated with Hammett's σ constant (ρ = 1.67). Consequently electron-donating substituents in the aromatic ring decrease and electron-accepting substituents increase the concentration of the *O*-isomer in the equilibrium mixture, which occurs in prototropic keto–enol systems, but in a series of organic derivatives of the elements, this influence is much stronger. The thermodynamic parameters of the isomerisation reaction have been calculated from the temperature variation of the equilibrium constants; for example $\Delta H = 2.64 \pm 0.05$ kcal mole^{-1} and $\Delta S = 2.1 \pm 0.1$ kcal mole^{-1} K^{-1} for R = R′ = CH_3.[106] Fractionation of the mixture of isomers can displace the equilibrium almost completely towards the more volatile *O*-isomer.

Stannylmethyl ketones and the corresponding *O*-stannylenols undergo interconversions at much higher rates than their germanium analogues. The rearrangement is also reversible but proceeds intermolecularly[105,107] and is greatly accelerated following the addition of trialkyltin halides (the average lifetime of the isomers is 10^{-1}–10^{-3} s). Depending on the substituents R and R′, the equilibrium mixture may contain 6–23% of the *O*-isomers, the amount of which is frequently independent of temperature.

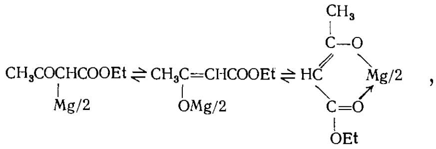
$$\mathrm{R_3SnCH_2COR'} \rightleftharpoons \mathrm{R_3SnOC(R')C{=}CH_2}\ .$$

In the series of similar antimony compounds, the rate of equilibration depends on the structure of the ketone. In the antimony derivatives of cyclohexanone, the rate is approximately the same as for stannylmethyl ketones, while the cyclopentanone compound of antimony isomerises much more slowly. With increase of temperature, the content of the *O*-isomer in the equilibrium mixture rises: for example from 20% at 20°C to 30% at 113°C for the latter compound[108]:

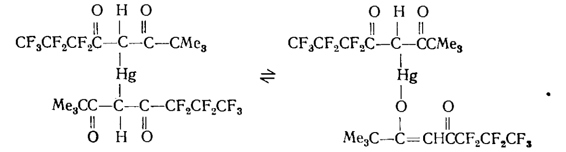


The mechanism of this rearrangement is unknown.

Keto-enol tautomerism probably occurs in the magnesium derivatives of acetoacetic ester, the infrared spectra of which depend markedly on the solvent and concentration[109]:



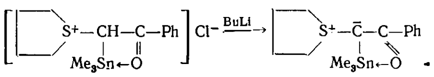
and also in the mercury derivatives of β-diketones (two different constants $J_{^1H-C-^{199}Hg}$ have been obtained in acetone at −75°C, namely 257 and 273 Hz):[110]



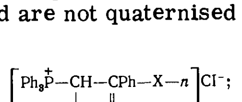
It is believed that the interaction of trialkylsilylketens with trialkyl phosphites and phosphorothioites (X = O or S) proceeds via intermediate ketophosphinate esters, which then isomerise intramolecularly to the corresponding siloxyvinyl compounds with 70–85% yields[111]:

Silylmethylsulphonium chloride [ν(CO) = 1675 cm^{-1} in carbon tetrachloride] behaves similarly, rearranging slowly to siloxyvinyl sulphide at room temperature[112]:

The tin analogue is stable, but the marked decrease of ν(CO) (to 1524 and 1487 cm^{-1} in KBr) suggests the existence of an $\mathrm{Sn} \leftarrow \mathrm{OC}\langle$ intramolecular coordinate linkage in this compound. When it is acted upon by butyl-lithium in THF, butane is evolved: the former coordination is probably regained in the resulting ylid $[\nu(\mathrm{CO}) = 1528\ \mathrm{cm^{-1}}]$[112]:



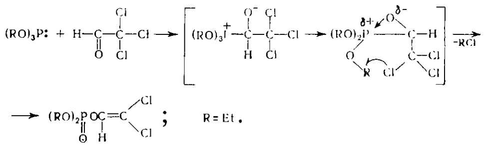
The same type of interaction has been suggested also for phosphoranes $[\nu(\mathrm{CO}) = 1470{-}1495\ \mathrm{cm^{-1}}$ in KBr]. Furthermore, these compounds are resistant to hydrolysis and methanolysis and are not quaternised by methyl iodide[113].



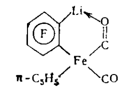
$$\left[\mathrm{Ph_3\overset{+}{P}{-}\underset{\underset{R_3Sn\leftarrow}{|}}{CH}{-}\underset{\underset{O}{\|}}{C}Ph{-}X{-}}n\right]\mathrm{Cl^-};$$

X=H, Me, OMe, Cl, Br.

A remarkable example of the influence of the possible intramolecular coordination on reactivity is the Perkow reaction—the interaction of triethyl phosphite with chloral to form ββ-dichlorovinyl diethyl phosphate. According to one of the proposed mechanisms, the reaction proceeds via phosphonium salts[114]:

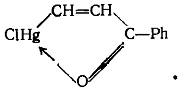


Intramolecular coordination is the cause of the unusually high stability of complex (VIII)[115]:



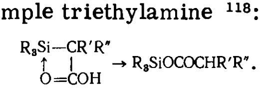
ortho-Fluorolithio-derivatives of aromatic compounds are known to be thermally unstable and to form arynes readily[3]. However the corresponding aryne has not been observed (the Diels-Alder reaction with furan leads to the *ortho*-hydrotetrafluorophenyl derivative in quantitative yield) for compound (VIII) (containing an iron atom in the *ortho*-position), while the *meta*- and *para*-isomers give rise to the normal addition products. A similar difference has been observed also between the exchange reactions involving $(\pi\text{-}\mathrm{C_5H_5})(\mathrm{CO})_2\mathrm{FeI}$. The coordination in this compound breaks down following the addition of $\mathrm{D_2O}$ (the *o*-deutero-isomer has been isolated quantitatively).

The higher stability of *cis*-β-oxovinylmercury halides compared with the *trans*-analogues has been explained similarly[116]. X-Ray diffraction analysis of *cis*-β-benzoylvinylmercury chloride demonstrated a cisoid conformation of the molecule in which the oxygen atom is directed towards the mercury atom (R = 13.6%; $l_{\mathrm{Hg...O}} = 2.88$ Å). The Hg...O distance and the sum of the van der Waals radii (2.9–3.1 Å) are within the limits of experimental accuracy. However, the decrease of the ClHgC angle, located opposite the oxygen atom, to 173° ± 2° and the conformation of the molecule suggest the following coordination[117]:



2. Acids and Their Derivatives

Silylacetic acids rearrange to the isomeric acyloxysilanes at the melting point and also under very mild conditions, frequently at 25°C, in the presence of basic catalysts, for example triethylamine [118]:



$$\mathrm{\underset{\underset{O=}{\uparrow}}{R_3Si}{-}\underset{\underset{COH}{|}}{C}R'R''\rightarrow R_3SiOCOCHR'R''}.$$

The thermal isomerisation proceeds intermolecularly while the catalytic isomerisation can be both intermolecular and intramolecular. However, in highly dilute solutions, where the extent of bimolecular reactions is reduced to a minimum, only the intramolecular pathway operates, since optically active vinylacetic acids are converted into the corresponding acetoxysilanes with retention of configuration at the silicon atom[119].

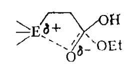
Silyl derivatives of carboxylic acids and their esters are readily decarboxylated at 150–230°C via an intramolecular mechanism, which has been demonstrated by kinetic data and also by the finding that the thermolysis of a mixture of the esters does not lead to intermolecular interaction products[99]:

The ester of stannylated phenylacetic acid reacts with $\mathrm{SiCl_4}$ to form a keten acetal, which readily isomerises in 2–3 days at room temperature to the carbon derivative until the attainment of equilibrium[120]:

$$\mathrm{R_3SiCH(Ph)COOMe\xrightarrow{SiCl_4}\underset{5\%}{PhCH{=}C(OMe)OSiCl_3}\rightleftharpoons\underset{95\%}{Cl_3SiCH(Ph)COOMe}}.$$

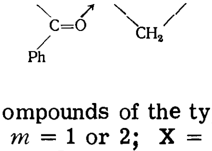
This is the first instance of silylotropism. Distillation of the equilibrium mixture leads to a slight shift of equilibrium towards the *O*-isomer, but the initial equilibrium position is restored after the period stated above.

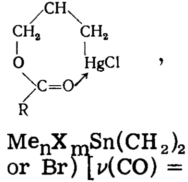
The esters $\mathrm{Et_3E(CH_2)_2COOEt}$ (E = Si, Ge, or Sn) hydrolyse much faster than ethyl butyrate or $\mathrm{Et_3E(CH_2)_3.COOEt}$, which cannot be accounted for solely by the inductive effect of the $\mathrm{Et_3E}$ groups. It is believed[121] that the higher rate of hydrolysis can be explained by the formation of intermediate complexes:



Such stabilisation of the transition state is absent for $\mathrm{Et_3Sn(CH_2)_3COOEt}$, since five-membered rings are frequently formed at a higher rate than six-membered rings.

In view of the reduced values of ν(CO), intramolecular coordination has been suggested for bis(benzoyloxymethyl)zinc $[\nu(\mathrm{CO}) = 1645\ \mathrm{cm^{-1}}]$ [122] and carboxypropyl derivatives of mercury $[\nu(\mathrm{CO}) = 1680{-}1710\ \mathrm{cm^{-1}}]$ [123]:





and also in compounds of the type $\mathrm{Me}_n\mathrm{X}_m\mathrm{Sn(CH_2)_2COOMe}$ (n = 1 or 2; m = 1 or 2; X = Cl or Br) $[\nu(\mathrm{CO}) = 1656$ to $1680\ \mathrm{cm^{-1}}$ in KBr] [124], the τ_{MeO} signal in the ^{1}H NMR spectra of which undergoes a downfield shift. It is suggested that a trigonal bypyramidal structure occurs in these compounds, one of its vertices being occupied by the acetoxy-group[124].

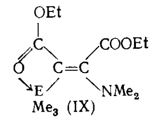
It is noteworthy that intramolecular coordination occurs in R_3SnCH_2COOMe but not in R_3SnCH_2OCOMe (according to Mössbauer spectra)[95], which is probably associated with the greater inductive effect of the methoxycarbonyl group compared with the acetoxy-group.

Internal coordination has been suggested also for diazoesters:

$$R_{4-n}Sn\,[C(N_2)COOEt]_n \text{ (where } n=1,2) \text{ and } YC(N_2)COOEt\ ,$$

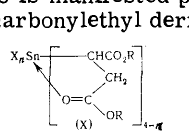
where Y = Me_3Si, Me_3Ge, Me_3Pb, or RHg, in view of the high dipole moment $\mu = 2.2$ D (for $n = 1$ and R = Me), the monomeric state of the compounds in benzene (for tin compounds), and the appreciably reduced values of ν(CO) (1640–1675 cm^{-1}) and ν(N≡N) (2045–2070 cm^{-1}) compared with the carbon analogues[125]. The coordination in diazoesters is probably stronger than in α-ketones and α-carboxyesters, since the shift of ν(CO) in the latter compounds is smaller.

The occurrence of intramolecular coordination is the cause of the splitting of the ν(CO) bands (1735 and 1680 cm^{-1} for E = Si, 1739 and 1698 cm^{-1} for E = Ge, and 1740 and 1705 cm^{-1} for E = Sn) and ν(C=C) bands (1570 and 1550 cm^{-1} for E = Si, 1590 and 1555 cm^{-1} for E = Ge, and 1625 and 1590 cm^{-1} for E = Sn) in the infrared spectra of compounds of type (IX)[126] (see also Riviera-Boudet and Satge[127]):



(IX)

The difference between the coordinated and covalently linked carbonyl groups is manifested particularly clearly in organotin diethoxycarbonylethyl derivatives (X),



(X)

X = Hal; n = 2, 3

the spectra of which contain ν(CO) bands in the ranges 1634–1660 and 1692–1718 cm^{-1}.[128,129] A trigonal bipyramid with the ethoxycarbonyl group at one of the vertices has been proposed for n = 3.[129] Two isomers have been isolated for n = 2 and X = Br and their crystal structures have been determined[130,131]. They both (R = 9.8 and 16.7%) have distorted octahedral structures. The two bromine atoms are in the *cis*-positions and the 1,2-di(ethoxycarbonyl)ethyl groups are linked to the tin atom via oxygen and carbon atoms with formation of five-membered rings. The Sn–O bond length (2.44–2.49 Å) greatly exceeds the sum of the covalent radii (2.06 Å) and the Sn ← OC coordination is therefore fairly weak.

In consequence of amide conjugation, the organic acid amide derivatives of the elements are much more labile than the corresponding α-ketones and α-acids and therefore rearrange under more severe conditions[132–134]; secondary amides rearrange to the N-isomers, while acylated N-alkylamides rearrange to the O-isomers. These isomerisations probably also proceed via an intramolecular mechanism:

$$R_3ECH_2CONHR' \xrightarrow{140-200°} R_3EN(R')COCH_3; \text{ E = Si, Ge,}$$

$$Et_3SiCH_2CON(Me)COR \xrightarrow{160-180°} Et_3SiOC[N(Me)COR]{=}CH_2.$$

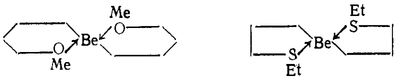
It is believed that intermediates with intramolecular coordination of the type

are formed in the hydroboration of N-alkenylureas and N-alkenylcarbamates, which reduces the reactivity of H_2B groups, prevents further hydroboration, and after hydrolysis leads to high yields of the corresponding alkylboronic acids, while in the case of terminal olefins trialkylboron compounds are formed exclusively[135].

3. Alcohols and Ethers

Alcohol and ether derivatives of the elements frequently exhibit reduced thermal stability as a result of O → E intermolecular coordination and evolve comparatively readily ethylene and cyclopropane (CP) or their derivatives, particularly in those cases where the functional group is in the β- and γ-positions with respect to the element. Such ready β- and γ-elimination is undoubtedly associated with the higher strength (energy) of E–O bonds compared with E–C bonds. In some cases such compounds could be isolated under mild conditions.

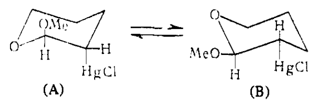
The stability of di-(δ-methoxybutyl)- and di-(γ-ethylthiopropyl)-beryllium on distillation in a high vacuum suggested that these compounds exist as inner-complex salts[136]:



In solutions *cis*-β-mercurated alicyclic alcohols are probably also involved in intramolecular coordination, since the OH absorption band in the infrared spectra is displaced towards longer wavelengths by 18–22 cm^{-1} compared with the carbon analogues[137], while the shift for the *trans*-isomers is only 6–10 cm^{-1}. However, it is not altogether clear whether this approach can be used for open-chain compounds or compounds with conformationally mobile rings. The study of the conformation equilibria of the mercury derivatives of tetrahydropyran in acetonitrile,

$$(A) \rightleftharpoons (B)$$

showed that the strength of the coordinate bond in these compounds is low[138]. It has been found from ^1H NMR spectra that the equilibrium mixture contains at least 56% of conformation (B) (ΔG = −0.14 kcal $mole^{-1}$):

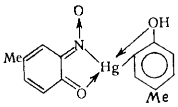


Since ΔG for HgX groups is equal or close to zero, intramolecular coordination stabilises conformation (B) with an energy of about 1 kcal $mole^{-1}$. It has been suggested[138] that the intramolecular stabilisation of unstable conformations is common to all compounds with substituents between which appreciable coordination interaction is possible.

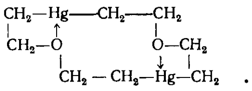
This conclusion was confirmed in a study of the dipole moments of β-substituted mercury compounds of the type $HalHgCH_2CH_2X$ [Hal = Cl, Br, or I; X = OMe, OCOMe, CF_3, or $C(NO_2)_3$].[139] In the series of these compounds, intramolecular coordination occurs in benzene only for X = OMe or OCOMe and in the former case is so weak that it breaks down following the addition of ethyl acetate. The capacity for intramolecular coordination decreases in the following sequence of substituents X: MeOCO > MeO ≫ CF_3 > $C(NO_2)_3$. For the last two substituents, this conclusion had been made earlier on the grounds that, when these compounds are acted upon by nucleophiles, ethylene is not evolved owing to the absence of electron-donating groups capable of coordination, while the presence in the β-position of substituents with an unshared electron pair (OR, OCOR, and NR_2) leads under the same conditions to complete β-elimination. Furthermore, when X = CF_3, the constant $J_{(CF_3...Hg)}$ for the ^{19}F NMR spectrum in carbon tetrachloride is extremely low[140, 141].

However, in the crystalline state there is no intramolecular coordination at all in the mercury compounds, which has been shown convincingly by X-ray diffraction. Thus the mutual orientation of the substituents relative to the cyclohexane ring in the α(*dd*, *ll*) and β(*dl*, *dl*) diastereoisomers of 2-methoxycyclohexylmercury chloride proved to be different, the intramolecular Hg...O distances in the α-isomer (4.06 Å) and in the β-isomer (3.06 Å) virtually ruling out intramolecular coordination[142].

The Hg...O distance in the 2-hydroxy-5-methylphenylmercury derivative of 5-methylnitrosophenol is 3.00 Å, the C–N and N–O linkages are close to double bonds, and the mercury atom is joined covalently to the carbon atoms of the phenolic ring and the nitrogen atom of benzoquinone (*R* = 11%).[143] However, in this case the very weak Hg ← O interaction is largely determined by the rigidity of the molecular geometry:

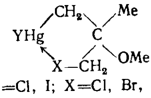


Hg ← N intermolecular coordination (2.77 Å) with almost planar conformation of the –Hg–C–C–N group (*R* = 5.6%) obtains even in *N*-[2-(chloromercuri)ethyl]-diethylamine[144]. An exception is the dimeric molecule of ββ'-oxidodiethylmercury[145]:



Here intramolecular coordination leads to the formation of a tricyclic structure (l_{HgO} = 2.21 ± 0.06 Å). However, following a slight decrease of the CHgC angle (to 176°), the hybrisation of the mercury atom remains virtually unchanged, which indicates a low accuracy of the above investigation.

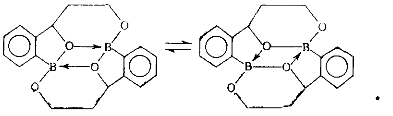
When organomercury compounds contain an atom with a free electron pair in both β- and γ-positions, intramolecular coordination occurs with formation of a five-membered ring in consequence of smaller angular strain. This is the cause of the non-equivalence of the methylene protons in the ^1H NMR spectra of compound (XI):



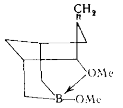
Y=Cl, I; X=Cl, Br, OH.
(XI)

[Y = Cl; X = Cl or Br; $\Delta\nu(CH_2Br)$ = 19.1 Hz; $\Delta\nu(CH_2Hg)$ = 13.6 Hz]; the non-equivalence diminishes sharply in the presence of solvents which break the coordinate bond, for example pyridine, and this leads in its turn to a decrease of J_{HgCCCH_3} (it amounts to 36 Hz in $CDCl_3$ and 20 Hz in pyridine)[146]. When Y = I and X = OH, a temperature variation of J_{HCOH} is observed in $CDCl_3$ and ν(OH) in the infrared spectrum falls to 3584 cm^{-1}.[147] The non-equivalence of the methylene protons in compounds of the type $BrHgCH_2CR(OR')COX$ (R = Me, Ph, OBu-t, or Me and X = Me or OMe) is even more pronounced [$\nu(CH_2Hg)$ = 8.7–29.7 Hz in carbon tetrachloride]. However, it is difficult to determine in this instance which oxygen atom is involved in the Hg ← O intramolecular coordination: peroxide, carbonyl, or ester oxygen[148].

Internal coordination is responsible for the enhanced hydrolytic and chemical stability (there is no reaction with 2-aminoethanol and *o*-phenylenediamine under mild conditions) of the boronate diester[149]:



The doublet of signals in the ^{11}B NMR spectrum (with chemical shifts of –30.5 and –51.3 p.p.m. relative to $Et_2O.BF_3$) corresponds to the coordinated and free boron atoms in the bicyclic ester (XII),



(XII)

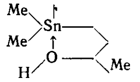
which evidently exists in the form of an equilibrium mixture of chair-boat and chair-chair conformers, the proportions of which have been found to be 65 : 35.[150]

The enhanced acidity of silyl (germyl)-substituted cyclohexanols (XIII)

(XIII)
(E = Si, Ge)

relative to carbon analogues, which has been established on the basis of the large shifts of the ν(OH) bands in the infrared spectra following the addition of DMSO and THF, can be accounted for by E ← O intramolecular coordination, since the electropositive influence of silicon and germanium should reduce the acidity of these alcohols[94]. On the other hand, the acidity of 1,1,1-triphenylethanol derivatives of silicon and germanium is normal[151]. The large difference clearly demonstrates the influence of conformation on the proximity of the electron-donating and electron-accepting atoms.

The coordination in γ-stannylethanol (XIV)



(XIV)

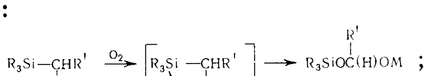
probably takes place as a result of the very high value of $J_{^{117}/^{119}Sn\text{-}CH_3}$ in the ^1H NMR spectrum, which amounts to 60.6/63.4 Hz in 0.32 M solution in carbon tetrachloride in the presence of added tris(dipivaloylmethanato)europium[152].

In the presence of basic catalysts (active metals, organometallic compounds, or amines), silylmethanols readily rearrange to alkoxysilanes[153-156] via a pseudo-first-order reaction[157]. Its rate is very sensitive to the nature of the group at the methanol centre and the activation energy is 8–11 kcal $mole^{-1}$. The basic catalyst removes the acid proton and the resulting α-hydroxy-ion then undergoes an intramolecular rearrangement with formation of a stronger Si–O bond and the fixation of the negative charge at the carbon atom. The carbanion formed is rapidly protonated to alkoxysilane:

$$R_3Si-\underset{\underset{OH}{|}}{C}R'_2 + :B \rightleftharpoons R_3Si-\underset{O^-\cdots HB^+}{C}R'_2 \rightleftharpoons R_3Si\underset{O}{\quad}\bar{C}R'_2 \underset{HB^+}{\rightleftharpoons} R_3SiOCHR'_2 + :B\ .$$

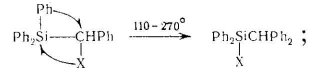
This isomerisation proceeds with retention of configuration at the chiral Si centre[158] and with its inversion at the chiral carbinol centre[159].

The products of the oxidation of the Si–C bond in α-trialkylsilyl organometallic compounds, i.e. hydroperoxy-salts[160], undergo a similar rearrangement and are converted as a result of hydrolysis into silanols and siloxanes:



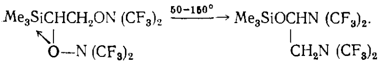
$$R_3Si-\underset{\underset{M}{|}}{C}HR' \xrightarrow{O_2} \left[R_3Si-\underset{\underset{OOM}{|}}{C}HR'\right] \longrightarrow R_3SiO\overset{\overset{R'}{|}}{C}(H)OM\ ;\quad M = MgCl,\ AlBu_2\ .$$

The thermal rearrangements of α-substituted benzyltriphenylsilanes probably proceed via an intramolecular mechanism with migration of the substituent X to the silicon atom accompanied by the transfer of the phenyl group from silicon to carbon[161]:



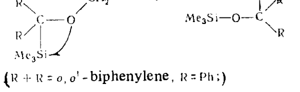
X = OAc, OTs, F, Cl .

This also happens in the thermal rearrangement of trifluoromethylaminoxyalkylsilanes with dissociation of the Si–C and N–O bonds and the formation of stronger Si–O and N–C bonds[162]:



$$Me_3Si\underset{\underset{O-N(CF_3)_2}{|}}{C}HCH_2ON(CF_3)_2 \xrightarrow{50-150^\circ} Me_3SiO\underset{\underset{CH_2N(CF_3)_2}{|}}{C}HN(CF_3)_2.$$

These isomerisations, which take place almost quantitatively (the latter is a first-order reaction), are examples of diatropic rearrangements in which two σ bonds change places as a result of the cyclic process. A study of the kinetics of the conversion of allyl silylmethyl ether to a silylether[163]

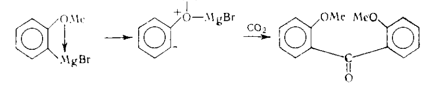


(R + R = o,o'-biphenylene, R = Ph;)

showed that the rearrangement does not proceed via a single mechanism. For example, when R + R = oo'-biphenylene, the silyl group migrates intramolecularly to the extent of 100%, while the allyl group migrates via this mechanism only to the extent of 72%. The isomerisation proceed via a first-order reaction and depends only slightly on the solvent. The activation parameters (in benzene) are $E_a = 32.3 \pm 0.6$ kcal $mole^{-1}$, $\Delta H^{\neq} = 31.4 \pm 0.6$ kcal $mole^{-1}$, and $\Delta S^{\neq} = -8.9 \pm 0.8$ cal K^{-1}.

β-Metallated alcohols and ethers are fairly stable in solution in aromatic compounds. Like aminoferrocenes (aminobenzenes), alkoxyferrocenes (alkoxybenzenes) are therefore metallated by butyl-lithium only at the site adjoining the substituent owing to Li ← OR intramolecular coordination, benzene derivatives reacting much more slowly. Substituted ferrocenes with X = CPh_2OH,[164] OMe,[165,166] CH_2OR,[167] or Cl[166] and benzenes with X = OMe[168] or SO_2CMe_3[169] have been used. In the case of thioanisole[170], the α-position of the ring is metallated with subsequent transfer of the lithium atom to the methyl group, probably as a result of *trans*-metallation.

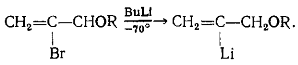
Internal coordination has also been proposed to account for the anomalous reactions between CO_2 and Grignard reagents derived from o-bromomethoxy(methylthio-, dimethylamino-)benzenes, as a result of which both acids and ketones have been obtained[171-173]. The formation of the latter can be understood on the basis of this scheme



Aliphatic β-lithioethers very readily eliminate lithium alkoxides owing to the Li ← OR intramolecular coordination and can therefore be obtained only at very low temperatures[174,175]. For example, when β-iodoethers are acted upon by butyl-lithium, the main product is ethylene with only a 5% yield of the desired product[174]:

$$ICH_2CH_2OR \xrightarrow{BuLi} Li\overset{CH_2CH_2}{\longleftarrow}OR \rightarrow CH_2{=}CH_2 + LiOR.$$

Similar α-vinyl-lithium compounds are much more stable and can be obtained in a preparative yield, for example[176,177]:



$$CH_2{=}\underset{\underset{Br}{|}}{C}-CHOR \xrightarrow[-70^\circ]{BuLi} CH_2{=}\underset{\underset{Li}{|}}{C}-CH_2OR.$$

β-Alkoxyethylmagnesium compounds are extremely unstable (see Section II).

It is interesting to note that ethers [and sulphides] of the type $ROCH_2MgCl$ and $PhCH_2SCH_2MgCl$ are stable at −30° and 0°C respectively, but [at higher temperatures?] decompose with elimination of ethylene[178]:

$$2ROCH_2MgCl \rightarrow CH_2{=}CH_2 + 2ROMgCl.$$

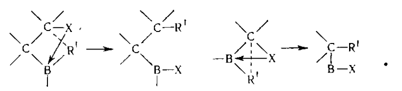
However, in the presence of cyclohexene their decomposition does not lead to the formation of norcarane[178], so that the elimination of ethylene most probably proceeds via intermolecular coordination.

β-Alkoxyethyl derivatives of boron are also thermally unstable. For example, tris-(2-alkoxyethyl)boron begins to evolve ethylene at a temperature as low as −10°C. However, the stability of these compounds increases as the 2-alkoxyethyl groups are substituted by alkoxy-groups and 2-alkoxydiethoxyboron decomposes only at 160–170°C.[179]

It has been shown that the ease of elimination of olefins from the compounds $R_2B\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}X$ depends on X. When X = OTs, OBz, OAc, or Cl, the decomposition takes place below 0°C, while for X = OAlk(Ar) the compound can be isolated[180,181].

It has been shown for deuterated[182] and cyclohexane[183] derivatives of boron that thermal β-elimination takes place via an intramolecular mechanism. Under comparable conditions, β-alkoxylethylboron compounds form olefins more readily than the analogous sulphur derivatives[182,184].

β-Elimination may be accompanied also by a β-transition (a new type of diatropic rearrangement), which likewise proceeds intramolecularly[185,186]. α-Transition reactions proceed similarly[183,185]:

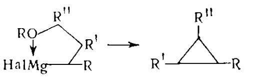


X = OR, SR.

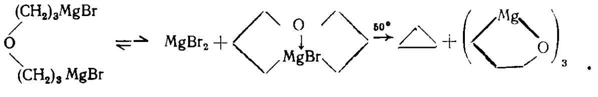
Al ← OR intramolecular coordination is probably the cause of the thermal instability also of β-alkoxyethyl derivatives of aluminium[33,187].

Similar silicon compounds decompose only under severe conditions and eliminate olefins quantitatively via a first-order reaction[188] (see also Tsurugi et al.[189]), for example:

There is no doubt that the thermal instability of 3-alkoxy(aryloxy)-derivatives of Grignard reagents can be accounted for by Mg ← OR intramolecular coordination[190–193]. This reaction can serve as a preparative method for the preparation of substituted cyclopropanes (yield of about 50%):

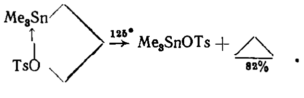


Bifunctional Grignard reagents disproportionate fully in THF into cyclic monomeric compounds (their degrees of association have been determined), which eliminate cyclopropane on thermolysis[194]:



On thermolysis, the compounds iso-$Bu_2Al(CH_2)_2OR$ (n = 3 or 4) form cyclopropane[34,195,196] and cyclobutane[34] respectively.

Tin compounds $Me_3Sn(CH_2)_nOTs$ ($n = 3$ or 4) behave in different ways depending on the value of n.[197] When $n = 3$, the thermolysis leads to cyclopropane, while in the case of n = 4–6 olefins are mainly produced, although 10% of cyclopentane has been obtained for $n = 5$:

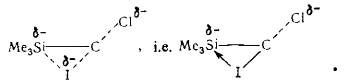


Presumably compounds of the type $E(CH_2)_nOR$ ($n > 3$) do not form cyclic products on thermolysis even when they contain reactive metals. For example, γ-ethoxybutylmagnesium bromide decomposes only with elimination of butyl ethyl ether[191].

IV. COMPLEXES WITH HALIDE LIGANDS

The extensive employment of many types of alkyl (aryl) halides and their derivatives in direct metallation reaction has led to the synthesis of numerous classes of organic derivatives of the elements with possible Hal – M intramolecular coordination and in the case of reactive metals most of them are extremely unstable at room temperature and readily decompose as a result of α- and β-elimination with formation of carbenes and arynes respectively[3]. In this part of the review we shall consider only compounds where intramolecular coordination is postulated in a non-reacting molecule, the transition state, or in thermolysis with formation of olefins and cycloalkanes.

Such coordination was postulated for the first time in the transition state to account for the sharp acceleration of the exchange (by a factor of 13) of the chlorine atom in trialkylchloromethylsilanes for an iodine atom in dry acetone (the Finkelstein reaction) in relation to the carbon analogues[198,199]:



This concept was subsequently used to explain the unusually easy nucleophilic substitution of the chlorine atom for I, OR, and SR in α-chloromethyl derivatives of mercury (the exchange is accelerated by a factor of 10^6 compared with n-BuCl)[200], boron[201], germanium, and tin[202]. It is noteworthy that there is no intramolecular coordination of this type in a non-reacting molecule (see Section I).

When alkyl substituents at the central atom are replaced by powerful electronegative groups capable of exciting the vacant orbitals of the central atom, intramolecular coordination takes place, as shown for trichloromethyl derivatives of mercury Cl_3CHgX (X = Cl, Br, or CCl_3). In ^{35}Cl NQR spectra there is appreciable (>2%) splitting of the lines due to the chlorine atoms in the CCl_3 group, which has been explained by an intramolecular interaction of one of the chlorine atoms with the mercury atom[203]. The authors believe[203] that such coordination has been confirmed by the X-ray diffraction analysis of Cl_3CHgBr in which Hg...Cl distances proved to be different—two of them are 3.21 Å and one is 3.15 Å. However, since the difference is within the limits of experimental error, the above conclusion cannot be regarded as reliable. Coordination in the above compounds breaks down when dimethoxyethane is added (the pronounced line splitting disappears), but not in the presence of ether[204].

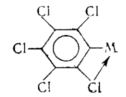
Cl → Sn intermolecular coordination probably also occurs in chloromethyltrichlorotin. Thus its mass spectrum[205] reveals the presence of rearranged fragments formed as a result of the ejection of carbene via a three-membered transition state, while the ^{35}Cl NQR spectrum of the $SnCl_3$ group[206] was found to consist of two lines with an intensity ratio of 1 : 2 and a splitting of about 6%, which exceeds by a factor of three the maximum possible crystallographic splitting. The non-equivalence of chlorine atoms has been explained by the possible coordination interaction between chlorine and tin, which can be both intermolecular and intramolecular. Cryoscopic determination of the molecular weight in benzene showed that there is no association. Furthermore, on reaction with an excess of relatively weak electron donors such as ether and benzene, the compound forms 1 : 1 (and not 1 : 2) complexes, existing only in solution (according to ^{35}Cl NQR spectra), which is not a characteristic feature of organotin compounds with powerful electronegative groups. This shows that the intramolecular coordination is stronger than the intermolecular coordination with ether and benzene. It was therefore assumed that these complexes have the configuration of a trigonal bipyramid with the tin atom in the centre and the three chlorine atoms in the equatorial plane; one of the vertices is occupied by the chlorine atom of the chloromethyl group and the other by a molecule of ether or benzene[2].

Ethyl acetate causes only a partial breakdown coordination in Cl_3SnCH_2Cl (according to dipole moment measurements), while pyridine destroys it completely with formation of a 1 : 2 complex; calorimetric data made it possible to estimate the energy of the intermolecular coordination as approximately 5 kcal mole^{-1}, which is typical for a hydrogen bond[13].

Finally, electron diffraction study of this compound in the vapour phase (R = 12.3%)[207] showed that its molecule is a distorted octahedron with hindered rotation about the Sn–C bond. However, one cannot conclude directly from these data that the Cl → Sn intramolecular coordinate bond is present.

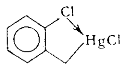
It is interesting to note that dichlorobis(chloromethyl)tin consists in the crystalline state of infinite chains with intermolecular Sn ← Cl bonds (X-ray diffraction analysis, R = 17.7%).[208]

The pentachlorophenyl derivatives of the number of metals have anomalous spectroscopic properties, which suggested the occurrence of intermolecular coordination:



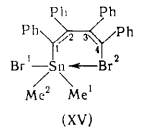
The compound with M = HgC_6Cl_5 melts at a much higher temperature than the corresponding pentafluorophenyl derivative[209]. The splitting of the frequencies of the *ortho*-chlorine atoms and their appreciable shift relative to the *meta*- and *para*-atoms have been observed in the ^{35}Cl NQR spectrum. The same characteristics have been found also for M = HgR (R = Cl, Me, or Ph).[210] Furthermore, low electrochemical reduction rate constants have been obtained for these compounds[92]. According to ultraviolet spectroscopic data, the pentafluorophenyl derivatives of silicon and tin have $\lambda_{max} \simeq 200$ nm, and a much higher molar absorption than their hydrogen-containing analogues[211]. *o*-Halogenophenyl derivatives of alkali and alkaline earth metals are extremely unstable owing to intramolecular coordination and the ease of formation of arynes, which is of great importance for synthesis[3]. The corresponding ferrocene derivatives are entirely stable (see Section III).

The absorption band corresponding to the vibrations of the Hg–Cl bond in the infrared spectrum of *o*-chlorobenzylmercury chloride is split into three components owing to the existence of several rotational isomers. The most intense component at 314 cm^{-1} has been attributed to the conformation with possible intramolecular coordination[212]:



A very interesting variation of the influence of substituents on intramolecular coordination has been observed in butadienyltin derivatives[213]. A doublet of equally intense signals due to the methyl protons (δ = 0.48 and 0.98 p.p.m., 36°C), merging into a singlet on heating to 87°C, has been found in the ^{1}H NMR spectrum of 4-bromo-1,2,3,4-tetraphenyl-*cis,cis*-buta-1,3-dienyldimethyltin bromide (XV). The addition of basic solvents, for example ether or pyridine, has a similar influence. To explain the non-equivalence of the methyl protons in the diene, Sn ← Br intramolecular coordination was postulated: it stabilises the non-planar distorted cisoid conformation and hinders the rotation about the $C_{(2)}-C_{(3)}$ bond with a barrier of 18.3 ± 0.23 kcal mole^{-1} (according to ^{1}H NMR spectra) at room temperature and in non-basic solvents. Consequently intramolecular coordination can be disrupted by heating the specimen or by adding basic solvents.

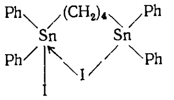
The proposed conformation of the diene (XV) in solution proved to be the same as in the crystalline state, as shown by X-ray diffraction (R = 10.7%).[213,214] The Sn ← Br bond length is 3.77 Å, which is smaller by 0.4 Å than the sum of the van der Waals radii of tin and bromine atoms. To ensure such coordination, the $C_{(1)}$–Sn–Me^1 angle has increased to 129° (from the tetrahedral angle of 109.5°) and the torsional angle in the butadiene fragment has increased to 68.1°:



(XV)

The introduction of the phenyl group in place of bromine and tin atoms should cause the breakdown of intramolecular coordination, since a tin atom linked to four carbon atoms does not usually exhibit coordinating properties. X-Ray diffraction analysis of this compound[215] confirmed this hypothesis: the Sn ← Br bond length is 4.346 Å and the $C_{(1)}$–Sn–Me^1 angle is 117.1°.

The conformation of the molecule can be very different in the crystalline state and in solution. For example, 1,4-bis(iododiphenylstannyl)butane has a high dipole moment in benzene (5.24 D), which is believed[216] to be associated with the existence of the inner complex (XVI):



(XVI)

However, in the crystalline state the molecule proved to be symmetrical with a tetrahedral configuration of the tin atom (X-ray diffraction analysis; R = 9.6%).[217] At the same time, when iodine in compound (XVI) is replaced by hydroxy- and acetoxy-groups, the compounds probably exist in the crystalline state as inner complexes—their Mössbauer spectra show appreciable quadrupole splittings compared with the iodine analogue and the tin atom is undoubtedly pentacoordinate[218].

The influence of intramolecular coordination on the physical and chemical properties of organic derivatives of the elements has been studied in particularly great detail in relation to *cis*-β-chlorovinylmercury chloride. A singlet at 33.132 MHz was observed in the ^{35}Cl NQR spectrum, its position apparently indicating the absence of intermolecular coordination, as happens in the *trans*-isomer[219]. Whereas the dipole moment of the *trans*-isomer agrees well with the calculation, for the *cis*-isomer there is a sharp discrepancy between the observed and calculated moments in benzene (2.92 and 3.57 D respectively), which is believed[220] to be caused solely by the appreciable decrease of the ClCC and CCHg angles in consequence of the intramolecular coordination. Using different solvents (benzene, dioxan, and ethyl acetate), it has been shown by the same method that the strength of the Cl → Hg intramolecular coordinate bond in *cis*-ClCH = CHHgHal decreases in the sequence Cl > Br > I,[221] while strong intermolecular Hal → Hg bonds have been observed in the corresponding *trans*-analogues (on the basis of Hal NQR spectra)[222]. Intramolecular coordination probably occurs also in di(*cis*-β-chlorovinyl)mercury, since $J_{^{13}C-^{199}Hg}$ in the ^{13}C NMR spectrum is appreciably higher than for symmetrical mercury compounds, where coordination is known to be ruled out[223].

Finally, the *cis*-β-chlorovinylmercury chloride molecule has been investigated by gas electron diffraction (R = 11.5%)[224]. The intramolecular non-valent Hg...Cl distance proved to be 3.27 Å, while the sum of the van der Waals radii is 3.3–3.5 Å. Consequently the electron-diffraction data are consistent with the occurrence of extremely weak intramolecular coordination, but cannot be regarded as unambiguous proof. The decrease of the CHgCl angle, located opposite the additional chlorine atom, to 168.5° might also indicate intramolecular coordination, but it is not clear in which direction the Hg–Cl bond is "bent". Presumably the intramolecular coordination is largely determined by the rigidity of the molecular geometry:

Nevertheless the mercury atom in the *cis*-isomer is coordination-saturated and the *cis*-chloride does not therefore form complexes with pyridine[225], TMEDA, and di(mercaptomethyl)ethane[226], in contrast to the *trans*-chloride. For this reason, nucleophilic attack on the mercury atom should be hindered in the *cis*-isomer, which in turn hinders the nucleophilic cooperation in electrophilic substitution at the carbon atom.

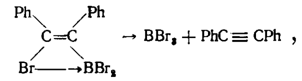
Apart from considerable resistance to electrophilic substitution, *cis*-β-chlorovinylmercury chloride does not eliminate acetylene even when acted upon by powerful nucleophilic agents, i.e. lacks completely the capacity to transfer the reaction centre and therefore lacks "dual" reactivity. For example, whereas the *trans*-isomer immediately evolves acetylene even when acted upon by a weak nucleophilic agent such as dibutylmercury, the *cis*-isomer is readily alkylated by Grignard reagents[226-228]:

R=Me, Ph, etc.

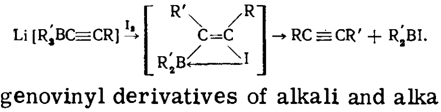
It has been shown that the *cis*-compound is also smoothly symmetrised on treatment with iodide ions, in contrast to the *trans*-compound, which immediately evolves acetylene[227,228]. Both stereoisomers react with diazomethane without the evolution of acetylene and with formation of the corresponding β-chlorovinyl(chloromethyl)mercury compound, which then eliminates acetylene under thermodynamically-controlled conditions[226-228].

The study of the thermolysis of β-chlorovinyl derivatives of mercury has shown[229] that the stability of *cis*-ClCH-CHHgHal decreases in the sequence Cl > Br > I, while the inverse series holds for the *trans*-isomers. However, this behaviour in the case of the *cis*-compounds is inconsistent with the decrease of the strength of intramolecular coordination in the sequence observed in the measurement of dipole moments[221]. The mass spectra of the *cis*- and *trans*-compounds are qualitatively the same, but the *cis*-isomers are more stable under electron impact.

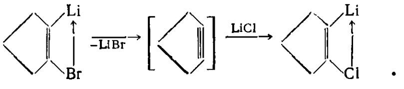
Unfortunately the strength of intramolecular coordination has not been investigated for different halogens in the halogenovinyl group, since such compounds could not be synthesised despite numerous attempts. Nevertheless the strength of intramolecular coordination should presumably increase in the sequence Cl < Br < I, by analogy with boron derivatives. The series is fairly clear for the latter. Indeed *cis*-β-chlorovinylboron distills *in vacuo* without decomposition and is smoothly arylated by di-(*p*-anisyl)mercury to *cis*-β-chlorovinyl(dianisyl)boron.[226] β-Bromovinyl compounds decompose to acetylenes on slow heating *in vacuo*[230]:



while β-iodovinyl compounds cannot be isolated at all because they are converted quantitatively into acetylenes even under mild conditions (–78°C)[231]:

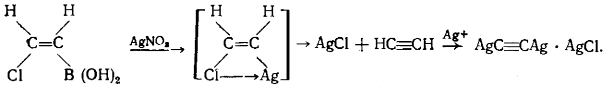


β-Halogenovinyl derivatives of alkali and alkaline earth metals are still less stable. Thus 2-bromo-1-lithiocyclopentane eliminates a very unstable monomolecular cyclopentyne at a temperature as low as 20°C (this has been established on the basis of the concentration variation of the salt effects and the reversibility of the formation of lithium bromide) via a first-order reaction with an activation energy of 24 kcal mole⁻¹ (± 10%). In its thermolysis in the presence of 2,5-diphenyl-3,4-benzofuran, the product of addition to cyclopentyne, the formation of which in the course of the reaction had been demonstrated kinetically, was isolated. Lithium chloride adds to cyclopentyne with formation of 2-chloro-1-lithiocyclopentene:[232]

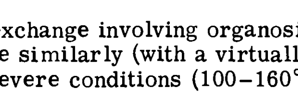


Cyclohexyne and cycloheptyne have been obtained under mild conditions from 2-fluoro-1-lithiocyclohexene and a Grignard reagent, based on 1,2-dibromocycloheptene, respectively[233,234]. Their formation has been demonstrated by condensation and trimerisation reactions and is undoubtedly due to M ← Hal intramolecular coordination (M = Li or MgHal).

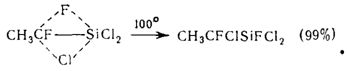
β-Chlorovinyl derivatives of silver are also extremely unstable. When an attempt was made to obtain them by treating stereochemically pure *cis*- and *trans*-β-chlorovinylboronic acids with aqueous silver nitrate solution, only the complex of silver carbide with silver chloride AgC≡CAg.AgCl was isolated. The initial state probably involves the formation of *cis*- and *trans*-β-chlorovinyl derivatives of silver, which eliminate acetylene as a result of Ag ← Cl intramolecular or intermolecular coordination, and the acetylene is metallated by the excess silver ions[235]:



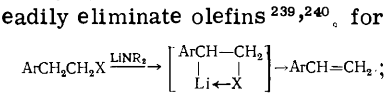
When the chemical consequences of intramolecular coordination in aliphatic systems are considered, one must remember the spontaneous diatropic intramolecular rearrangement of α-halogeno-organoboranes with hydride substitution of halogen and the formation of alkylhalogenoboranes, which proceeds via a first-order reaction with inversion of configuration[236,237]:



An analogous exchange involving organosilicon compounds takes place similarly (with a virtually quantitative yield) but under severe conditions (100–160°C) when there are different halogens at the silicon and α-carbon atoms, for example[238] (see also Brook and Jones[161]):



β-Halogeno-derivatives of alkali metals are extremely unstable and readily eliminate olefins[239,240], for example:

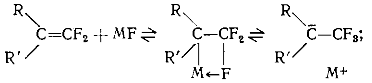


$$\mathrm{ArCH_2CH_2X}\xrightarrow{\mathrm{LiNR_2}}\left[\begin{matrix}\mathrm{ArCH{-}CH_2}\\ |\qquad |\\ \mathrm{Li\leftarrow X}\end{matrix}\right]\rightarrow\mathrm{ArCH{=}CH_2};$$

X=Cl, Br, OSO_2, Ph.

These compounds can be obtained at very low temperatures with a yield not exceeding several per cent[174].

In the case of organofluorine compounds β-elimination may be in equilibrium with the reaction involving the addition of the metal fluoride to the olefin:



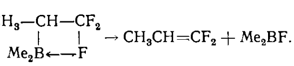
M = metal .

The position of such equilibrium depends on many factors, but probably mainly on the M–F bond energy. In fact LiF and NaF, which hardly add to fluoro-olefins, have a much higher M–F bond energy than KF and CsF, which readily form carbanions on interaction with perfluoro-isobutene and perfluoropropene.

Aliphatic Grignard reagents can be obtained only when there is no heteroatom other than fluorine in the β-position (see Section I and also Ballard and Gilman[241]).

Organozinc compounds possess the same properties[242,243]; one should note that β-elimination takes place much more readily than α-elimination even in the case of relatively unreactive halogens[243]:

β-Halogenoboron compounds are extremely unstable and usually decompose already at the instant of formation[244-249]. Even the most stable of the compounds described remain stable only at −78°C and begins to decompose slowly at room temperature and rapidly at 100°C [246]:



$$\begin{matrix}\mathrm{CH_3{-}CH{-}CF_2}\\ |\qquad\ |\\ \mathrm{Me_2B\longleftarrow F}\end{matrix}\rightarrow\mathrm{CH_3CH{=}CF_2+Me_2BF}.$$

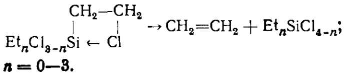
β-Fluoroethylsilanes eliminate ethylene in the gas phase only at 150–320°C via a first-order reaction. The rate of reaction is independent of the surface to volume ratio of the reaction vessel, pressure, and the presence of radical traps—cyclohexene and nitric oxide[250-254]:

$$\begin{matrix}\mathrm{CH_2{-}CHF}\\ |\qquad |\\ \mathrm{X_3Si\longleftarrow F}\end{matrix}\rightarrow\mathrm{X_3SiF+CH_2{=}CHF};$$

X=F, OMe, OBu, Me.

The liquid-phase decomposition of siloxane with X = OBu in a silicone oil proceeds via the same mechanism[255]. β-Fluoroethylpolysiloxanes of the type $[CHF_2CH_2SiO_{1.5}]_n$ behave similarly[255-256].

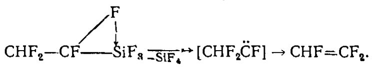
β-Chloroethylsilanes decompose in the gas phase at 300–400°C also via a first-order reaction, the rate of reaction increasing on replacement of alkyl substituents at the silicon atom by chlorine[257-260]:



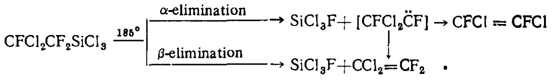
$$\begin{matrix}\mathrm{CH_2{-}CH_2}\\ |\qquad |\\ \mathrm{Et_nCl_{3-n}Si\leftarrow Cl}\end{matrix}\rightarrow\mathrm{CH_2{=}CH_2+Et_nSiCl_{4-n}};$$

$n = 0$–3.

When fluorine atoms are present simultaneously in the α- and β-positions with respect to silicon, α-elimination takes place exclusively[251,261-263], for example;



On the other hand, when different halogens are present in the α- and β-positions in the molecule, α-elimination clearly predominates over the possible β-elimination or the 1,2-shift of the fluorine atom in the carbene formed (the yields of olefins are 80 and 7% respectively)[263,264]:



It is difficult to account for this mode of thermolysis. Purely conformational factors probably play a decisive role here.

Mixed polyfluoroethyl derivatives of the type $Me_3SnCF_2CFHEMe_3$ (E = Si, Ge, or Sn) decompose at much lower temperatures (55°C, 20°C, and at the instant of preparation) and exclusively via β-elimination[265,266]:

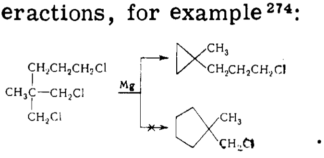
$$\begin{matrix}\mathrm{Me_3Sn{-}CF_2}\\ \uparrow\qquad |\\ \mathrm{F{-}CHEMe_3}\end{matrix}\rightarrow\mathrm{CF_2{=}CHEMe_3+Me_3SnF}.$$

These findings can be accounted for both by a decrease of the E–C bond energy in the sequence Si > Ge > Sn and by the sharp increase of the coordinating capacity of E in the reverse sequence. Conformational factors probably also play a significant role, since $l_{\mathrm{Sn-F}_\alpha} > l_{\mathrm{Sn-F}_\beta}$.

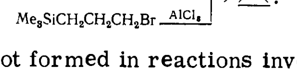
Compounds of the type $Me_3ECF_2CHFM(CO)_5$ (where E = Ge or Sn and M = Mn or Re) also decompose similarly at the instant of formation[267-269].

If the fluorine atom is in the γ-position, then organic derivatives of the elements (for example, derivatives of magnesium[270], boron[270], and silicon[271]) acquire enhanced stability and decompose via a radical-chain mechanism[271]. The lack of coordinating capacity by the fluorine atom in the γ-position has not been satisfactorily explained.

On the other hand, other halogens in the γ-position decrease sharply the stability of organometallic compounds and it is actually impossible to isolate them in the case of reactive metals. For example, magnesium[272-275], zinc[276], and aluminium[245] compounds readily eliminate substituted cyclopropanes. The tendency towards intramolecular 1,3-interaction is very great and clearly predominates over 1,4- and 1,5-interactions, for example[274]:

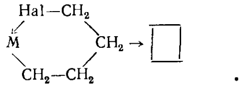


It is interesting that γ-halogenopropyl derivatives of boron[244] and silicon[277] are thermally stable. Nevertheless cyclopropane is readily formed from the silicon compounds[277] either as a result of a base-catalysed elimination (in which the carbanion formed in the ionisation of the Si–C bond undergoes intramolecular nucleophilic substitution) or under the influence of aluminium chloride, which involves the intramolecular electrophilic substitution of the carbonium ion formed on ionisation of the C–Hal bond:



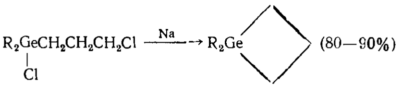
Cyclopropane is not formed in reactions involving the exchange of the reactants.

δ-Halogenobutyl derivatives of reactive metals (sodium, lithium, magnesium[278], and aluminium[196]) decompose only at elevated temperatures with slight (11–13%) elimination of cyclobutane (CB):

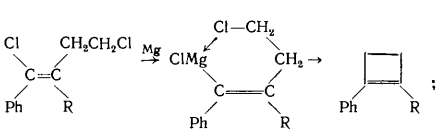


However, similar aluminium compounds have been found[245] to give rise on decomposition exclusively to methylcyclopropane and but-1-ene, but not cyclobutane.

An exception to this rule is the cyclisation of γ-halogenopropyl-silanes and -germanes[279,280] under the influence of sodium in boiling toluene, for example:

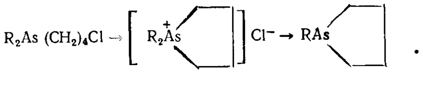


and of an unusual Grignard reagent formed from 1,4-dichlorobut-1-enes in ether (the yield of cyclobutene reaches 90%) where magnesium reacts with the vinyl chlorine and not the primary chlorine[281]:

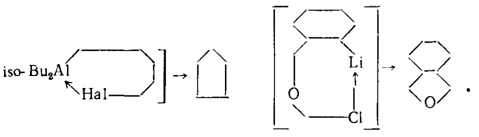


R=H, Ph.

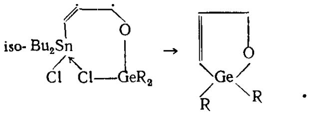
δ-Cyclobutyl derivatives of arsenic form five-membered rings at 160–170°C in 80% yield[282,283], while compounds with longer or shorter aliphatic chains are thermally stable:



Cyclisation reactions of ε-halogeno-derivatives of lithium[284], and aluminium[196] have also been described; these have not been isolated, but a Hal → M linkage has been postulated on the basis of the high yields of reaction products (70 and 75% respectively):



The reactions of γ-siloxy(germyloxy)chlorostannanes at temperatures exceeding 130°C with formation of oxametallocyclo-alkanes and -alkenes[285] have also been described, for example:

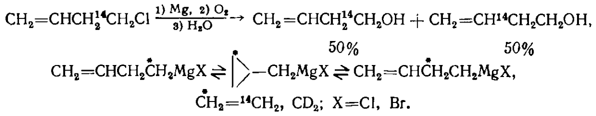


V. COMPLEXES WITH π-LIGANDS

In contrast to transition metals, which readily form stable π-complexes playing an extremely important role in modern chemistry, particularly in the stereochemically controlled reactions of π-electron systems, such complexes of non-transition metals have been obtained only recently for bivalent germanium, tin, and lead (see, for example, the paper by Doe et al.[286] and the references quoted there). At the same time, it has been shown in numerous investigations that, although many ω-unsaturated organometallic compounds derived from Group IA–IIIA metals cannot in fact be isolated in a pure state, they are undoubtedly formed as intermediates in solutions and cyclise very rapidly as a result of M ← π-ligand intramolecular coordination.

1. Olefins

This new branch of the chemistry of organometallic compounds was begun by a study[287] in which the Grignard reagent obtained from the deuterium-labelled or [^{14}C] allylmethyl chlorde (bromide) was oxidised by oxygen in ethereal solution. The distribution of the label along the chain in the unsaturated alcohols obtained demonstrated unambiguously that the Grignard reagent cyclises before its oxidation to the alcohol:



The ^1H NMR spectra show that ⩾ 99% of the Grignard reagent from arylmethyl chloride (bromide) and from cyclopropylmethyl chloride has the allylmethyl structure. This had been established by the author in an earlier study[288]. The time of 50% equilibration between the isomeric acyclic forms of the Grignard reagent is 30 h at 27°C and 40 h at 55°C and corresponds to an activation energy of 23 kcal mole^{-1}.

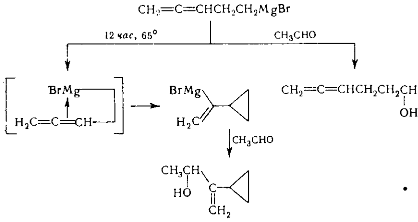
The existence of the cyclic form has been demonstrated by the fact that treatment of cyclopropylmethyl bromide (chloride) with magnesium in methyl ether (–24°C) or in ethyl ether (36°C) in the presence of traces of benzoic acid yielded methylcyclopropane, the content of which reached 55% in the case of the bromide[289]. This amount should correspond to the initial cyclic form, whose protonation is much faster than its rearrangement. The rearrangement proceeds via a first-order reaction and its 50% reaction time is about 2 h at –24°C, which corresponds to a free energy of activation of 19 kcal mole^{-1}.

The study of the influence of substituents in the γ- and δ-positions on the rearrangement of allylmethyl Grignard reagents showed that the vinyl group or two phenyl groups in the δ-position appreciably accelerate the rearrangement in consequence of the stabilisation of the partial negative charge in the cyclic forms. Thus, when phenyl groups are present, the distribution of the deuterium label between the α- and β-positions was completed in 5 h at room temperature, the content of the cyclic form being less than 0.3%.[290] Conversely, the phenyl group in the γ-position appreciably retards the formation of the cyclic form, probably in consequence of the destabilisation of the cyclopropane ring. According to ^1H NMR spectra, compound (XVII) is stable in ethers at room temperature and rearranges to (XVIII) only after 8 h at 100°C.[291] The study of the reversible isomerisation (XVII) ⇌ (XVIII), i.e.

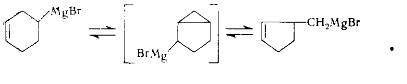
(XVII) (XVIII) R = Me; M = Li, MgBr.

by ^{1}H NMR [292] showed that the rate of equilibration depends on the following factors: (1) the structure of the organic group; (2) temperature; (3) the electronegativity of the metal (it decreases in the sequence Li $\gg R_2Mg > RMgX$); (4) the solvent (in more polar solvents, the isomerisation is retarded for magnesium compounds but accelerated for lithium compounds); (5) the concentration (it increases linearly for Grignard reagents, the proportionality constant depending particularly strongly on the temperature, solvent, and substituents; on the other hand, for the lithium compound it depends appreciably on the concentration); (6) the presence of salts in solution [$MgBr_2$ accelerates the rearrangement of (XVII), while lithium alkoxides retard it]. Furthermore, compounds (XVIII) predominate in the equilibrium mixture in consequence of the very pronounced thermodynamic secondary isotope effect and the (XVII) $\rightleftharpoons$ (XVIII) equilibrium constant depends on the physical conditions. The authors explain [292] the results by the existence of two different mechanisms of the reversible isomerisation (XVII) $\rightleftharpoons$ (XVIII): an ionisation-recombination process for lithium compounds and a bimolecular process for organomagnesium compounds, probably via an *at* complex.

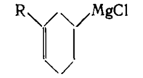
The allene system apparently constitutes the limiting case of the stabilisation of the cyclic form (because of the absence of decyclisation) and it is therefore of preparative importance for the synthesis of vinylcyclopropanes. For example, the yields of the Grignard reagent from 5-bromopenta-1,2-diene in THF and of the cyclic and straight-chain alcohols derived from it (respectively after refluxing for 12 h and without heating, with subsequent treatment with acetaldehyde) proved to be 25%, which indicates a quantitative cyclisation reaction with a 50% decomposition period of about 4 days at 25°C [293]:



The rearrangements of cyclic allylmethyl Grignard reagents have also been investigated. While the cyclopentene compound decomposes on heating without change in ring size, the cyclohexene and methylcyclopentene Grignard reagents undergo interconversions, the latter greatly predominating in the equilibrium mixture (about 90% after several hours at 80°C) [294-296]:



It has been shown with the aid of deuterium labels that the rearrangement proceeds via a bicyclic intermediate, which, however, cannot be determined in the equilibrium mixture. The authors believe that the driving force of the ring contraction process [294-296] is the difference between the stabilities of the primary and secondary Grignard reagent, which they estimated as 3.7 kcal mole^{-1}. The equilibrium constant depends strongly on the solvent and concentration, and a secondary entropy-controlled isotope effect is observed for the deuterated compounds:



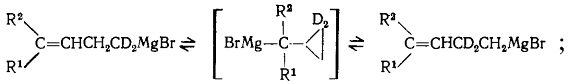
;

R=H, Ph, p-MeC_6H_4, m-$CF_3C_6H_4$.

(XIX)

Comparison of the rates of rearrangement to compound (XIX) showed that an aryl group decreases and electronegative substituents slightly increase the rate. These results correspond best to isomerisation with ClMg ← ‖ intramolecular coordination via a bicyclic intermediate, which is formed at a lower rate than that of its decomposition to the cyclopentene ring [297]. Furthermore, the signals of the olefinic protons in the ^{1}H NMR spectra of the initial Grignard reagents are located in a lower field compared with the corresponding hydrocarbons, which the authors [297] believe may serve as evidence for the formation of π-complexes.

This mechanism was confirmed in a study of the kinetics of the reversible isomerisation (XX) $\underset{k_2}{\overset{k_1}{\rightleftharpoons}}$ (XXII), i.e.

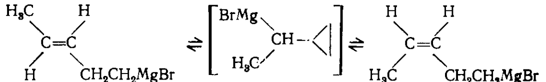


(XX) (XXI)

(a) R^1=H, R^2=Me; (b) R^1=R^2=Me ,

(XXII)

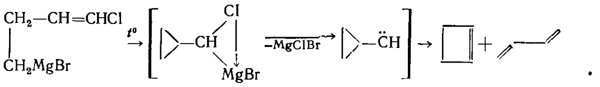
by ^{1}H NMR in ether [298]. It was found that compound (XXa) (*cis* : *trans* = 42 : 58) is in equilibrium with compound (XXII) only after 775 h at 100°C. The rearrangement is retarded even more after the introduction of a second methyl group in the δ-position: compound (XXb) gives rise to (XXIIb) after 900 h at this temperature with a yield of only 20%. These results conflict with a radical mechanism. To demonstrate the involvement of the intermediate (XXI), which cannot be detected in the equilibrium mixture, a study was made of the kinetics of the *cis*-*trans* isomerisation (XXIII) $\rightleftharpoons$ (XXV) with gas-liquid chromatographic identification of the carboxylated reaction products in the form of their methyl esters. Regardless of the initial compound, (XIII) or (XXV), the isomerisation was described by a first-order equation and always led to the same mixture of *cis*- and *trans*-products (21 : 79). Since the sums $k_1 + k_2$ for the equilibria (XXa) (XXIIa) and (XXIII) (XXV) are of the same order of magnitude, (XXI) and (XXIV) are true intermediates, in which the single bond between the carbanionic centre and the cyclopropane ring has sufficient time for free rotation. The *cis*-*trans* isomerisation (XXIII) $\overset{k_1}{\rightleftharpoons}$ (XXV) therefore proceeds via the same mechanism as the reversible isomerisation involving the α- and β-positions in the (XX) $\rightleftharpoons$ (XXII) process [298]:



(XXIII) (XXIV) (XXV) .

When a chlorine atom is introduced into the δ-position, the Cl → Mg intramolecular coordination occurs with formation of cyclopropylcarbene, since thermolysis of the Grignard reagent in ethers yielded cyclobutene in 80% yield together with a small amount of buta-1,3-diene (detected by ^{1}H NMR) [299]. The 50% decomposition period of the initial compound in THF is 500 h at 61.5°C and 2 h at

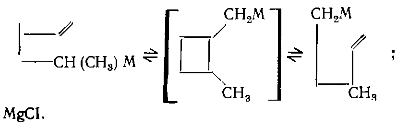
107°C, which corresponds to an activation energy of 30 kcal mole^{-1}:



The dependence of the cyclisation–decyclisation reaction on the amount of ionic character of the metal–carbon bond has been investigated[300]. When the allylmethyl compound of mercury is added to the sodium–potassium alloy in THF, a dark cherry-red solution of the cyclic anion is formed immediately, giving rise after carboxylation to phenylcyclopropylacetic acid in 80% yield. The replacement of potassium by sodium also leads to the cyclic product only:

Its stability is explained by the stabilisation of the electron pair by the benzene rings. On the other hand, when the potassium in ether is replaced by lithium or magnesium, which form stronger covalent bonds with carbon, there is an immediate reverse rearrangement to the corresponding acyclic products. These rearrangements are reversible. For example, diphenylcyclopropylmethyl-lithium is stable in THF, while in ether it isomerises completely to $\gamma\gamma$-diphenylallylmethyl-lithium. The reverse rearrangement can be induced by the simple addition of THF to an ethereal solution the compound.

In systems containing a four-membered ring there is also equilibrium between the acyclic and cyclic forms of the organometallic compounds, for example[301]:



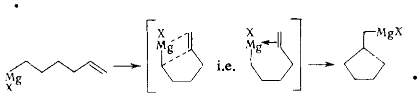
M=Li, MgCl.

In THF, the Grignard reagent rearranges much more slowly than the sodium and lithium compounds, despite the use of less polar hydrocarbons as solvents for the latter. The equilibrium mixture obtained for the organolithium derivative contains more than 99% of the primary compound, which indicates its higher stability compared with the isomeric secondary compounds. It is believed that this isomerisation proceeds via a four-membered cyclic intermediate.

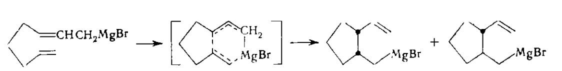
Equilibrium is established in such systems at a very high rate. For example, it is 3×10^{-6} s^{-1} at 140°C and 3.5×10^{-5} s^{-1} at 160°C (obtained from the rate of appearance of α-protons in the ^{1}H NMR spectrum) for deuterated organomagnesium compounds, the isomer concentrations at equilibrium being in proportions of 3 : 2.[302]

It is important to note that cyclobutane does not form even in trace amounts in the isomerisation of allylmethyl compounds[290,291].

Because of the low angular ring strain, cyclopentyl derivatives of metals are fairly stable, but their stability depends strongly on the nature of the organic group. Thus the primary Grignard reagent obtained from 7-bromohept-1-ene forms 7% of methylcyclohexane [303], while the secondary Grignard reagent (from 6-chlorohept-1-ene) gives after hydrolysis a mixture of *cis*- and *trans*-1,2-dimethylcyclopentanes in proportions of 1 : 4 with a yield of 88% [304]:

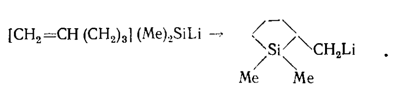


The secondary Grignard cyclises faster than the primary or tertiary reagent in THF at 100°C, all the rearrangements proceeding via first-order reactions. The observed ratios of the *cis*- and *trans*-products undoubtedly indicate an intramolecular mechanism of these reactions (an intermolecular interaction of a Grignard reagent with an isolated double bond is unknown with the exception of the addition of ethylene to allylmagnesium chloride)[305]:

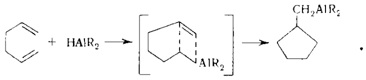


The isomerisation is highly stereoselective. Thus, when an ethereal solution of diene was refluxed, it cyclised smoothly with formation of *cis*- and *trans*-products in yields of 90 and 3% respectively and a 50% decomposition period of 2 h.[306]

Cyclisation involving the formation of cyclopentanes also occurs in the series of organolithium compounds, for example with $CH_2 = CH(CH_2)_3CHRLi$ (R = H or Me) [307], norbornene systems[308], and silicon-lithium derivatives[309], the process being quantitative in the last instance:

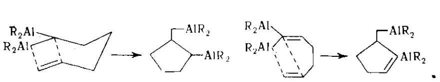


Organic derivatives of Group III metals, particularly aluminium compounds, play an important role in the formation of cyclopentanes. Using these, Ziegler[310] achieved for the first time the cyclisation reaction in the chemistry of ω-unsaturated organometallic compounds. He showed that the interaction of dialkylaluminium hydride with hexa 1,5-dienes gives a quantitative yield of α-aluminomethylcyclopentanes:



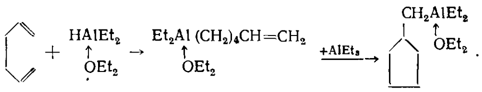
Subsequently this reaction was extended to strained 1,5-dienes[311].

The mode of hydroalumination of vinylacetylenes with subsequent cyclisation can be controlled by choosing an appropriate solvent. For example, the reaction involving hex-1-en-5-yne in ether with subsequent hydrolysis gave the cyclopentane derivative an 80% yield, while in triethylamine the reaction leads to cyclopentenes with the same yield[312]:



The reaction of trialkylaluminium with buta-1,3-dienes also leads to cyclopentanes (yield 27%).[313]

All the reactions described above proved to be feasible only because the cyclisation is faster, even at low temperatures, than the intramolecular addition of dialkylaluminium hydrides to the terminal double bonds. However, such cyclisation can be prevented with the aid of specific coordination. For example, it does not occur with the $Et_2AlH \leftarrow OEt_2$ ether adduct, the acyclic product being formed in 93% yield ($>$Al ← ‖ intramolecular coordination is impossible), but the adduct can cyclise quantitatively following the addition of a catalytic amount of triethylaluminium, which decomposes the complex and liberates the ω-unsaturated organoaluminium compound[314]:



A general method has been proposed for the cyclisation of hex-5-enyl organometallic compounds based on the exchange reaction between dihex-5-enylmercury and the corresponding metal[315]:

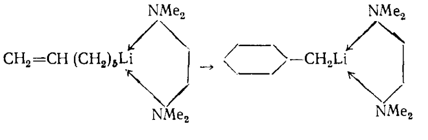
$$\frac{n}{2}\,\mathrm{Hg}\,[(\mathrm{CH_2})_4\mathrm{CH{=}CH_2}]_2 + mM \rightarrow mM\,[(\mathrm{CH_2})_4\mathrm{CH{=}CH_2}]_n \rightarrow$$
$$\rightarrow mM\,[\mathrm{CH_2}\,(\text{cyclo- }\mathrm{C_5H_{12}})]_n;$$
$$M{=}\mathrm{Li,\ Mg,\ Al,\ Ga,\ In.}$$

In non-coordinating solvents, the formation of a ring requires between 1 h and 8 days at 25°C for M = Li (depending on the solvent; 1 h in ether), 24 h at 110°C for M = Mg, 48 h at 40°C for M = Al, 3 weeks at 95°C for M = Ga, and 3 weeks at 110°C for M = In (the reaction times were determined from ^{1}H NMR spectra). The solvent plays a major role in determining the rate of exchange and cyclisation[316]. For lithium, the rate increases in the sequence cyclopentane $<$ benzene $\ll$ ethyl ether (8 days, 96 h, and 1 h respectively); the aluminium compound could not be isolated from hydrocarbons, while in THF the reaction does not proceed at all and in ethyl and phenyl ethers it occurs to the extent of 4.9 and 95% respectively. These results are consistent with the known behaviour of organolithium compounds in basic media, where intermolecular linkages are broken, which leads to an increase of their reactivity. The opposite effect is observed for aluminium compounds.

It is remarkable that these rearrangements proceed much more readily than the analogous intermolecular reactions. However, they do not occur with but-3-enyl and pent-4-enyl derivatives of metals because of the high strain in the three- and four-membered rings[315].

The ease of cyclisation of hexenyl derivatives of metals decreases in the sequence Al $>$ Mg $>$ Li $>$ Zn $\gg$ Hg[317] (for zinc, the cyclisation takes place to a very slight extent). This sequence is probably determined by the presence of vacant orbitals in the metal and the polarity of the M–C bond.

On the other hand, the heptenyl derivatives of lithium and magnesium do not form six-membered rings either in ether or in THF, but in the presence of TMEDA, which greatly increases the polarity of the M–C bond, they cyclise readily and irreversibly (special experiments showed that the cyclopentylmethyl and cyclohexylmethyl derivatives of lithium and magnesium are not decyclised in the presence of TMEDA)[307]:



Similar aluminium compounds form cyclohexanes at an elevated temperature[318] in yields up to 70%[316], while octenyl derivatives of aluminium do not cyclise to cycloheptanes.[316]

The comparatively ready cyclisation of ω-unsaturated organometallic compounds should be preceded in many instances by M $\leftarrow \|$ intramolecular coordination in non-reacting molecules, which has been studied in a number of investigations using various physicochemical methods.

Weak Li $\leftarrow \|$ intramolecular coordination has been postulated in but-3-enyl-lithium[319] on the basis of ^{7}Li and ^{1}H NMR and infrared and ultraviolet spectroscopic data, which indicate anomalous properties of the double bond.

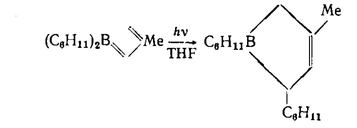
The chain length in olefins has little influence on the electronic environment of the double bond, but the introduction of groups in the terminal positions alters the chemical shifts of the olefinic protons, which are in general correlated with the electron-donating or electron-accepting properties of the substituents. For example, dibut-3-enyl- and dihex-5-enyl-zinc have the normal parameters of the ^{1}H NMR spectrum (the signals of the olefinic protons are located in the same region as for the corresponding pure alkenes) and there is no coordination interaction in these compounds. On the other hand, the spectrum of dipent-4-enylzinc is anomalous: compared with pent-1-ene, the chemical shifts due to the protons of the olefinic and α-carbon atoms are displaced downfield owing to the decreased electron density at the double bond. Furthermore, the signals due to the α-protons are displaced downfield even more at –70°C or on formation of a complex with 2,2′-bipyridyl. These data suggested the existence of weak Zn $\leftarrow \|$ intramolecular coordination[317,320]. It was impossible to study dipent-4-enylmagnesium by a similar procedure because of its insolubility in coordinating solvents, and in the analogous mercury compound there is no such coordination[320].

Alkenyl derivatives of Group III metals exhibit the same characteristics. For example, in the infrared spectra of alk-4-enyl derivatives of aluminium the band due to the ν(CH) deformation vibrations of the olefinic linkage is displaced by 30–38 cm^{-1} towards shorter wavelengths and the band due to the ν(C=C) vibrations is displaced by 22–23 cm^{-1} towards longer wavelengths compared with the initial olefins. The compounds are monomeric in benzene and their spectra change following dilution by hydrocarbons. However, the $\geqslant$Al $\leftarrow \|$ intramolecular coordinate linkage is ruptured under the influence of Lewis acids, since ether adducts, for example, have the normal ν(CH) and ν(C=C) frequencies. Intramolecular coordination in non-reacting alk-4-enylaluminium compounds (cyclisation occurs only at elevated temperatures) is confirmed additionally by ^{1}H NMR spectra where the $\delta_{\mathrm{CH=CH}}$ signals are displaced downfield by 0.3 p.p.m., while the $\delta_{\mathrm{CH_2}}$ signals of the isobutyl groups are displaced upfield by 0.15 p.p.m., compared with the 6- and 7-enyl homologues of aluminium, in which there is no coordination (no frequency shifts were observed in the spectra)[321].

It is interesting to note that the signals of the olefinic protons are displaced upfield also on formation of a complex with trimethylamine, and the shifts are independent of concentration. This clearly indicates an intramolecular mechanism of these processes. The energy of the $\geqslant$Al $\leftarrow \|$ intramolecular coordinate bond has been estimated as at least 2–5 kcal mole^{-1}.[322]

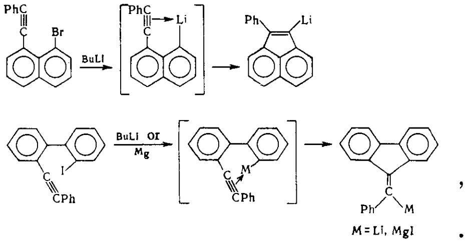
^{1}H, ^{13}C, and ^{119}Sn NMR and infrared and Mössbauer spectra have shown[323,324] that there is no M $\leftarrow \|$ coordination in the alkenyl derivatives of Group IV elements of type $\geqslant\mathrm{M(CH_2)}_n\mathrm{CH = CHR}$ (M = Si, Ge, or Sn; n = 1 or 2; R = H or Ph).

The photochemical cyclisation of dienylboranes to boracyclopent-3-ene is exceptional [ν(C=C) = 1635 cm^{-1}; monomeric state in benzene[325]] and probably proceeds via intramolecular coordination:

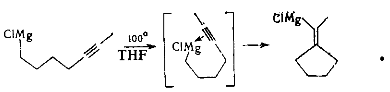


2. Acetylenes

The intramolecular addition of organometallic compounds to an isolated acetylenic bond has been little investigated, but is of considerable practical interest for the synthesis of various classes of vinyl compounds. It has been shown that such interaction in rigidly fixed systems depends on the relative positions of the C≡C triple bond and the M–C bond.[326,327] For example, when 8-bromo-1-phenylethynylnaphthalene is metallated with butyl-lithium, it cyclises, but the cyclisation reaction does not proceed with the corresponding Grignard reagent. The difference is undoubtedly associated with the much higher polarity of the C–Li bond compared with C–Mg. The carbon skeleton of 2-chloro-1-phenylethynylbenzene does not change when chlorine is replaced by lithium or magnesium, while treatment of 2-iodo-2′-phenylethynylbiphenyl with butyl-lithium or magnesium results in cyclisation to a five-membered ring:



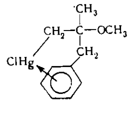
Aliphatic systems with triple bonds may be of preparative importance for the synthesis of ethylidenecyclopentanes. For example, when the Grignard reagent derived from 7-chlorohept-2-yne is refluxed for 6 days at 100°C with subsequent hydrolysis, the yield is 90%; however, the yield falls to several per cent in the absence of refluxing. There is no doubt that the isomerisation takes place after the formation of the Grignard reagent, the 50% cyclisation period of which is 50 h at 100°C:[328]

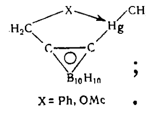


Similar reactions with 7-halogeno-oct-2-ynes yield substituted ethylidenecyclopentanes, the 50% cyclisation period for the bromide, amounting to about 15 h at 100°C. Like the alkenyl derivatives, secondary alkynyl Grignard reagents cyclise faster than the primary reagents, the smaller of the two possible rings being formed, i.e. ethylidenecyclopentanes and not the more stable methylcyclohexenes.[305,328]

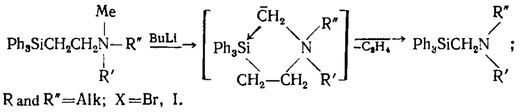
3. Aromatic Compounds and Carbanions

According to ^1H NMR spectra, Hgintramolecular coordination probably occurs in 2-methoxy-2-methyl-3-phenylpropylmercury, since the methylene protons are found to be non-equivalent, the non-equivalence diminishing sharply when strong solvating solvents, for example pyridine, capable of breaking the coordinate linkage, are used[329]. J_{HgCCCH_3} changes in the same way. A similar interaction has also been proposed for methylmercury derivatives of carboranes in view of the similar influence of solvents on $J_{^{199}Hg-C-^{1}H}$.[330]





A very rare instance of possible intramolecular coordination with a carbanion has been described recently. Three base-catalysed rearrangements of quaternary ammonium salts are known—the Stevens, Sommelet-Hauser, and Hofmann rearrangements. On the other hand, a specific rearrangement of the molecular skeleton of silicon derivatives takes place. When silylethylammonium salts were treated with an excess of butyl-lithium and then with water, silylmethylamines were obtained as the main product[331] and the Stevens rearrangement was not observed:



The amines are probably formed as a result of intramolecular attack by the negative charge on the silicon atom in the intermediate carbanion, which leads to the ejection of ethylene. In the case of R″ = Ph, there is no rearrangement and only *NN*-dimethylaniline has been isolated.

o0o

The data described demonstrate convincingly the increasing importance of intramolecular coordination for the understanding of many aspects of the structure and reactivity of organic derivatives of the elements, and particularly its decisive involvement in preparative syntheses of many classes of organic compounds, the preparation of which by other methods is either difficult or impossible. On the other hand, the concept of intramolecular coordination has not been justified theoretically and it is often difficult to demonstrate it experimentally. However, this field of the chemistry of organic derivatives of the elements began to develop vigorously only recently and holds out much promise for the immediate future.

Advances in the Synthesis of Heteroadamantanes

N.V.Averina and N.S.Zefirov

Typical formal schemes for the synthesis of heteroadamantane structures and the limits of applicability and synthetic scope of various methods are discussed and described systematically.
The bibliography includes 207 references.

CONTENTS

I. INTRODUCTION

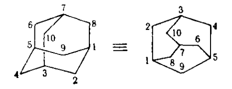
More than 1000 publications have been devoted to the synthesis and study of the properties of adamantane and its derivatives and their number has been continuously increasing. Such persistent interest by chemists is due to a set of unique properties of compounds of the adamantane series, which makes this class interesting from both theoretical and practical points of view. A large number of reviews have been devoted to the chemistry of adamantane, some of which are concerned only with synthetic aspects[1-4], while others deal more or less completely with the entire set of problems in the chemistry of adamantanes and their practical applications[5,6]. Heteroanalogues of adamantane constitute an important class of compounds. There are two reviews on heteroadamantanes covering the literature up to 1961, but these are to a large extent obsolete[1,4]. Although other reviews[7,8] were published later (partly covering the literature up to 1967), they are insufficiently complete. There has been recently a considerable growth of the number of publications dealing with the synthesis of heteroadamantanes and the search for novel methods of synthesising them and with the study of the chemical properties of the products[9-17]. Studies concerned with theoretical problems, which are solved using heteroadamantanes as model compounds, are being published systematically[18-22]. Bearing in mind also the great practical value[23-26] and physiological activity[27-42] of these compounds, it is useful to survey the new advances in this branch of synthetic organic chemistry.

We classified the literature data on the basis of the formal synthetic schemes rather than the type of heteroatoms. Such treatment makes it possible to discuss simultaneously the synthesis of adamantane heteroanalogues containing various heteroatoms and thus find the genetic relation between these structures. An undoubted advantage of this type of arrangement of data is the possibility of using a formal scheme for the synthesis of heteroadamantane which have not yet been described, containing, for example, rarely encountered heteroatoms.

II. FORMAL SCHEMES FOR THE SYNTHESIS OF HETERO-ADAMANTANE STRUCTURES

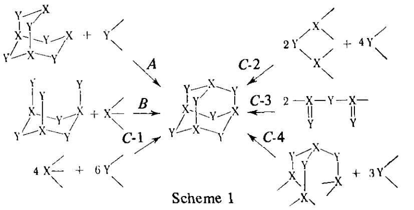
The formal schemes for the synthesis of adamantane heteroanalogues can be divided into several types: (1) synthesis from bicyclic structures; (2) synthesis from monocyclic structures; (3) synthesis from acyclic structures. Furthermore, methods of synthesis based on the transformation of the skeletons of other polycyclic skeletal structures constitute a class on its own to some extent. The data in this review are classified in accordance with these types.

A few words must be said about the nomenclature of heteroadamantanes. According to IUPAC rules[43], the atoms of the adamantane skeleton should be numbered in a sequence such that the heteroatoms have the lowest possible numbers. The general numbering of the skeleton is the same as that adopted for adamantane itself[44,45]. When several heteroatoms of different types are present, the numbering sequence must be as follows: O, S, SE, N, P,. . . , Si, Ge,. . .



When typical synthetic schemes are considered, one must bear in mind the following characteristic of heteroadamantane structures: tervalent and quadrivalent atoms (boron, nitrogen, phosphorus, and silicon) can occupy any position in the adamantane nucleus, while bivalent atoms (oxygen and sulphur) are known *a priori* to be incapable of occupying bridgehead positions. Before oxygen or sulphur can occupy the 1-, 3-, 5-, and 7- bridgehead positions in the adamantane structure, they must be converted into the onium state. For this reason, the introduction of a heteroatom into a bridgehead position is usually fairly specific, while the methods for the introduction of heteroatoms into the 2-, 4-, etc., positions in the adamantane skeleton have much in common.

The most convenient and most frequently employed starting materials for the synthesis of the adamantane skeleton are derivatives of bicyclo[3,3,1]nonane (pathway *A*). The availability of compounds of this series[46,47] and the possibility of extensive modification of the substituents and reactive groups makes this synthetic pathway extremely promising. The method of synthesis from monocylic fragments (pathway *B*) is less general and reduces mainly to the synthesis of adamantanes with heteroatoms in the 1-, 2-, 9-, and 10-positions. Finally, there is a whole series of synthetic approaches to heteroadamantanes based on the condensation of aliphatic compounds (pathways *C*-1–*C*-4). All these variants are presented in Scheme 1.



Scheme 1

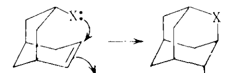
The synthetic pathways *C*-1–*C*-4 can include the formation of mono- or bi-functional compounds at intermediate stages. However, in the present review we shall not consider the detailed mechanisms of such condensations. This would be fairly difficult because their mechanisms are so far unknown in most instances and furthermore a formal treatment makes it possible to give a systematic account of data on the basis of the types of initial structures employed. Such treatment significantly facilitates the search for synthetic pathways to new heteroadamantane structures regardless of the type of heteroatom.

III. SYNTHESIS OF HETEROADAMANTANES FROM BICYCLO[3,3,1]NONANE SYSTEMS

The greatest number of heterocylic systems having the adamantane structure have been synthesised from bicyclo-[3,3,1]-nonane derivatives. This synthetic pathway may be difficult because the synthesis of the initial bicyclic structures is in many cases fairly laborious.

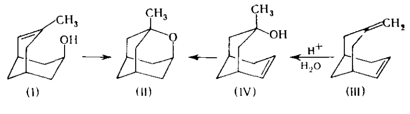
1. Synthesis Involving Multiple Bonds in the Ring

When the bicyclo[3,3,1]non-2-ene molecule contains a functional group in the *endo*-7-position, intramolecular cyclisation via Scheme 2 is possible in principle:



Scheme 2

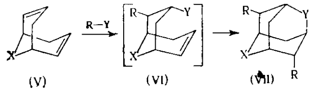
By virtue of steric factors, cyclisation of this type should occur extremely readily and the problem reduces to modifications of the method for the introduction of a double bond or a functional group into the ring or to the synthesis of the bicyclononane skeleton itself. However, examples of cyclisations of this kind are so far known only for adamantane itself[48,49] and for homoadamantane heteroanalogues[50–53]. A characteristic example of reactions of this type is the cyclisation of 7-hydroxy-3-methylbicyclo[3,3,1]non-2-ene (1) to 1-methyl-2-oxa-adamantane (II) in an acid medium[54,55]:



(I) (II) (IV) (III)

The ring closure of the diene (III) to a tricyclic system should be included in the same type of cyclisation, since oxa-adamantane (II) is formed in an acid medium via compound (IV).[56]

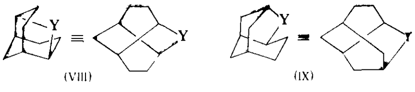
One of the commonest procedures for the introduction of a heteroatom involves electrophilic addition to multiple bonds in the bicyclo[3,3,1]nona-2,6-diene system via Scheme 3:



(V) (VI) (VII)

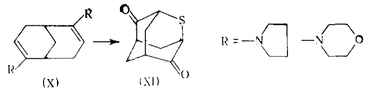
Scheme 3

In practice the reaction product is always a derivative of the adamantane structure (VII) and the intermediate monofunctional derivative of type (VI) cannot be isolated. The reaction is sometimes accompanied by the formation of twistane (VIII) and isoadamantane (IX) derivates[57]:



(VIII) (IX)

The initial diene structure of type (V) is usually synthesised by a method involving the transformation of the functional groups of 3,7- and 2,6-disubstituted bicyclononane derivatives. Dehydrohalogenation[58–60] or dehydration[61] reactions as well as the formation of enol or enamine derivatives from diketones[62,63] are most frequently used. Electrophilic addition to the diene (V) in water proceeds via a mixed addition mechanism and leads to 4,8-disubstituted derivatives (VII). A whole series of mono- and diheteroadamantanes, listed in Table 1, have been obtained on the basis of this reaction. The reaction of the diene (V) with sulphur dichloride proceeds via the same electrophilic addition mechanism. When the 2,6-disubstituted diene (X) is treated with sulphur dichloride, 4,8-dioxo-2-thia-adamantane (XI) is formed. It has been used as the starting material for the preparation of a series of 2-thia-adamantane derivatives[19,64,65]:



(X) (XI)

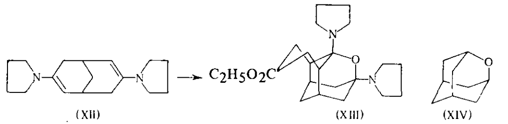
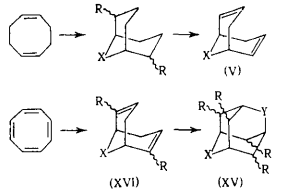
The condensation of the bisenamine (XII) with ethyl bromomethylacrylate leads to the pentacyclic structure (XIII), which is based on the 2-oxa-adamantane skeleton[63]:



(XII) (XIII) (XIV)

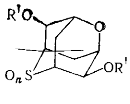
It is noteworthy that the hydration of the diene (V, X = CH_2) with sulphuric acid gives the unsubstituted 2-oxa-adamantane (XIV) in 26% yield[59]. The formation of the dioxa-adamantane (VII, X = Y = O, R = H) as a side product in the synthesis of 2,7-dioxatwistane from 9-oxabicyclo[3,3,1]nonane-2,6-diol has been explained by the same reaction of the diene (V, X = O) with sulphuric acid[66].

The synthesis of 2,6-diheteroadamantanes is based on bicyclic dienes (V) with the heteroatom in the 9-position as the starting compounds. A convenient version of the synthesis of the latter involves reactions based on unsaturated cyclo-octane derivatives via Scheme 4:



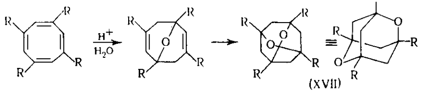
Scheme 4

When cyclo-octatetraene was treated twice with sulphur dichloride, tetrachlorodithia-adamantane (XV, X = Y = S, R = Cl) was obtained[67,68] and the addition of selenium monochloride to the dichlorothia-derivative (XVI, X = S, R = Cl) leads to the thiaselena-adamantane (XV, X = S, Y = Se, R = Cl).[69] A detailed study of the ^1H NMR spectra of oxide derivatives of 2-oxa-6-thia-adamantane (XVII, X = SO_n, Y = O, R = OR′)[78] and also of heteroadamantanes of type (VII, X = O, Y = O or N-Tos; X = N-Tos, Y = CH_2, O, or N-Tos),[61,74] synthesised from *cis*, *cis*-cyclo-octa-1,5-diene, showed that the elementary stage is *trans*-addition, which determines the configuration of the substituted heteroadamantanes obtained:



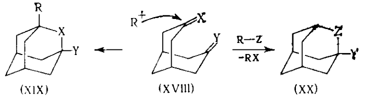
n = 1, R′ = H;
n = 2, R′ = H, Ac .

Treatment of 1,3,5,7-tetra-alkoxycyclo-octatetraene with alcohol containing a small amount of hydrogen chloride leads to the formation of 1,3,5,7-tetra-alkoxy-2,6-dioxa-adamantane (XVII),[70] the structure of which was demonstrated by X-ray diffraction[71].



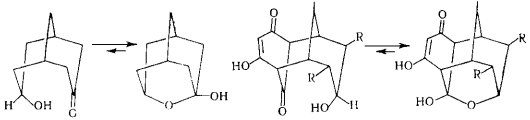
2. Condensation Involving Exocyclic Multiple Bonds

This type of formation of heteroadamantane systems can be represented schematically as follows:



Scheme 5

The basic idea of this scheme consists of the intermediate formation of *endo*-functional derivatives capable of an intramolecular reaction via the second multiple bond. The tendency towards intramolecular cyclisation is also caused by the steric proximity of the fragments at $C_{(3)}$ and $C_{(7)}$. For example, we may note that the ketoalcohol (XXI) exists in the hemiacetal form (XXII).[80] This is true also for more complex polycyclic structures. For example, the derivative of 2-oxa-adamantane (XXIV) is the hemiacetal form of compound (XXIII)[81,83]:



Bicyclononane derivatives with exocylic multiple bonds in the 3- and 7-positions, as in compound (XVIII, X = O or CH_2, Y = O or CH_2), are the most convenient starting compounds for condensations of this type. The difficulty of the method arises from the laborious synthesis of the initial bicyclic structures, which are obtained mainly by the cleavage of the adamantane skeleton[83-87]. A series of 2-oxa- and 2-aza-adamantanes (XIX), listed in Table 2, have been obtained from bicyclic derivatives (XVIII) via Scheme 5.

Table 2. 1,3-Disubstituted 2-heteroadamantanes of type (XIX) synthesised from unsaturated bicyclic compounds (XVIII).

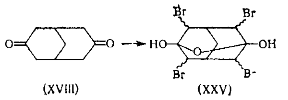
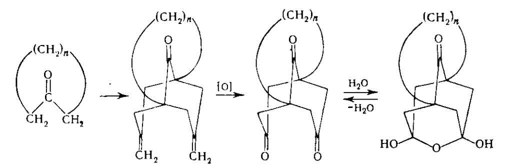
Bromination of the diketone (XVIII, X = Y = O) in acetic acid with four equivalents of bromine yields 4a, 8a, 9a, 10a-tetrabromo-1,3-dihydroxy-2-oxa-adamantane (XXV). On the other hand, bromination with 4.5 equivalents of trimethylphenylammonium tribromide in CH_2Cl_2 leads to a mixture of 4e, 8e, 9a, 10a-tetrabromo-derivative (XXV) and 2,6-dibromotriasterane-3,7-dione, which are separated chromatographically[92]. The authors assume that the oxa-adamantane system is formed via a tetrabromodiketone stage:



The presence of bromine atoms in both positions adjoining the C=O groups can enhance the electrophilic properties of these groups so much that the hydrated forms are stabilised and the latter can subsequently cyclise spontaneously to the oxa-adamantane system.

A study of the condensation of the cycloalkanones (XXVI, n = 9 or 10) and αα′-dichloroisobutene demonstrated[93] the formation of a considerable amount of the dimethylene derivative (XXVII). The oxidation of the olefin (XXVII) with potassium permanganate followed by treatment with lead tetra-acetate gives a 13% yield of the triketone (XXVIII), which is converted into the oxa-adamantane (XXIX):

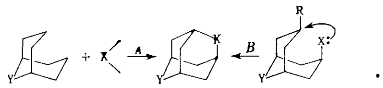


(XXVI) (XXVII) (XXVIII) (XXIX)

The authors concluded that the mobile decamethylene chain not only does not interfere with the formation of the oxa-adamantane system but actually promotes it, since it should favour the double chair conformation in the conformational equilibrium of the bicyclo[3,3,1]nonane system[94].

3. Condensation Without the Involvement of Multiple Bonds and Heteroatoms

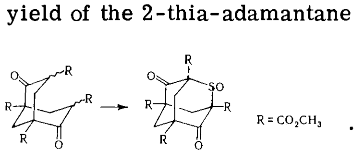
The reactions involving cyclisation to the adamantane structure of initial bicyclo[3,3,1]nonane derivatives without multiple bonds or heteroatoms participating in the formation of a tricyclic system are presented in Scheme 6.



(XXX) (XXXI) (XXXII)

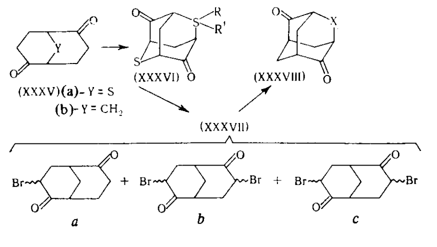
Scheme 6

This scheme (pathway *A*) applies when the so called "Meerwein ester" (XXXIII) reacts with thionyl chloride[82]. This gives rise to a 71% yield of the 2-thia-adamantane system (XXXIV):

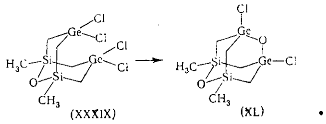


(XXXIII) (XXXIV)

An analogous tricylic system [XXXVI, (RR') = CH_2; R = CH_3, R' = OH or OAc] has been obtained by the reaction of the diketone (XXXVa) with acetic anhydride in a highly acid medium[95]. On bromination with pyridine hydrobromide perbromide, the diketone (XXXVb) gives a mixture of the mono- and di-bromo-derivatives (XXXVII, a–c).[98] On treatment with ammonia in absolute dioxan, 2-aza-adamantane-4,8-dione (XXXVIII, X = NH) was obtained from this mixture of bromo-derivatives:

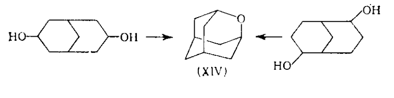


The replacement of ammonia by methylamine leads to the *N*-methyl derivative of 2-aza-adamantane (XXXVIII, X = NCH_3). Reduction of the dibromo-derivative (XXXVIIc) with sodium tetrahydroborate in aqueous alcoholic solutions leads to 2-oxa-adamantane-4,8-diol and, in the presence of catalytic amounts of alkali, to the oxa-adamantane (XXXVIII, X = O).[97] Heteroadamantanes (XL) containing O, Si, and Ge have been obtained via the same pathway *A* by treating the chlorogermane (XXXIX) with water[98]:



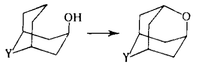
(XXXIX) (XL)

The formation of mono-oxa-adamantane (XIV) from bicyclo[3,3,1]nonane-3,7-diol under the influence of concentrated sulphuric acid is an example of type *B* condensations of bicylic compounds[83,84]. 2-Oxa-adamantane can be obtained by the same pathway from the readily available bicyclo-[3,3,1]nonane-2,6-diol[99,100]. Evidently the formation of 2-oxa-adamantane in the latter case requires a series of hydride shifts:



(XIV)

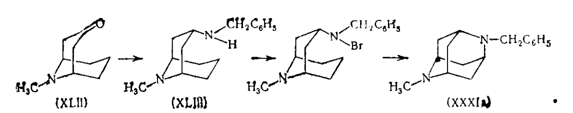
Treatment of the *endo*-alcohol (XLI, Y = CH_2) with lead tetra-acetate in boiling benzene or its oxidation with a mixture of iodine and mercury(II) oxide in carbon tetrachloride give rise to oxa-adamantane (XIV)[101] in yields of 89 and 60% respectively. The *exo*-isomer (XLI, Y = CH_2) is unreactive with respect to lead tetra-acetate and the main product of its oxidation with mercury(II) oxide was the corresponding ketone:



(XLI) (XXXI), X = O

6-Oxa-2-phospha-adamantane (XXXI, X = O, Y = PC_6H_{11}, $\overset{O}{\overset{\|}{P}}CH_2PH$, or $PPhCH_2$)[102] and 6-oxa-2-aza-adamantane (XXXI, X = O, Y = $NCOCH_3$)[103] skeletons have been obtained by a similar method. The attempts to synthesise the oxa-aza-adamantane system by the cyclisation of the benzylamino-derivative (XLI, Y = NCH_2Ph) have been unsuccessful, while refluxing of the acetamido-derivative (XLI, Y = NCH_3CO) in benzene in the presence of lead tetra-acetate leads smoothly to 6-oxa-2-aza-adamantane (XXXI, X = O, Y = $NCOCH_3$). The same heteroadamantane system (XXXI, X = O, Y = NCH_3) was obtained at 85% yield by the acid cyclisation of 7-ethoxy-*N*-methyl-3α-granatanol (XXXII, X = OH, Y = NCH_3, R = OC_2H_5) with hydrobromic acid[104].

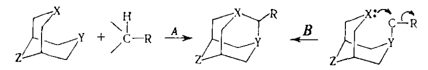
The Hofmann–Löffler reaction was used for the first time in 1973 to synthesise the 2,6-diaza-adamantane system[105]. Reductive amination of the ketone (XLII) in the presence of benzylamine leads to the amine (XLIII), which is converted into the diaza-adamantane derivative (XXXIa) by subsequent bromination and cyclisation in sulphuric acid:



(XLII) (XLIII) (XXXIa)

4. Condensations Involving the Heteroatoms of Bicyclo-[3,3,1]nonane Derivatives

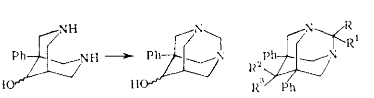
Reactions of this type are used to synthesise mono- and di-heteroadamantanes with heteroatoms in the 1- and 3-positions, which can be represented schematically as follows:



(XLIV) (XLV) (XLVI) .

Scheme 7

Reactions of this kind are used most typically in the synthesis of diaza-adamantane systems (pathway *A*). The simplest instance is the condensation of 3,7-diazabicyclo[3,3,1]nonane (bispidine) (XLIV, X = Y = NH, Z = CH_2) with formaldehyde. The problem of the synthesis of the diaza-adamantanes essentially reduces therefore to the problem of the synthesis of bispidine and similar structures. Likewise the condensation of bispidinol (XLVII) with paraformaldehyde in alcohol yields 1,3-diaza-adamantanol (XLVIII)[106]:



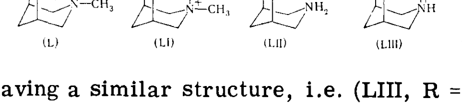
(XLVII) (XLVIII) (XLIX) .

When 1,5-diphenylbispidin-9-ol and 1,5-diphenylbispidin-9-one were treated with the corresponding aldehydes or ketones, a series of biologically active 2-substituted diaza-adamantanes of type (XLIX) were obtained[107] (listed in Table 3).

Table 3. 1,3-Diaza-adamantanes (XLIX) obtained by the condensation of bispidine derivatives with formaldehyde[107]

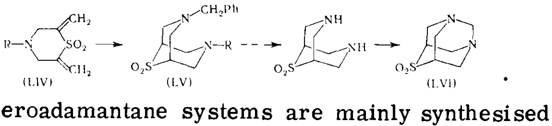
R^2	R^3	R	R^1
H	OH	H, Me, Et	Me, Et, Pr, iso-Pr, Ph, p-$MeOC_6H_4$, 2-furyl, Me, Et, Pr
$(R^2R^3) = O$		H, Me, Et	iso-Pr, Ph, p-$MeOC_6H_4$, 2-furyl, 4,3-$HO(MeO)C_6H_3$

A flattened double chair conformation has been found for *NN'*-dimethylbispidines[108], which promotes the formation of intramolecular hydrogen bonds in salts of bispidine derivatives (for example, perchlorates) and this results in the formation of the adamantane-like structure (L). When *NN'*-dimethylbispidine was treated with methylene iodide, a high yield of diaza-adamantane (LI) was obtained[109]:



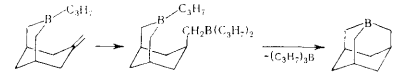
(L) (LI) (LII) (LIII) .

Products having a similar structure, i.e. (LIII, R = H or CH_3), are also obtained when bispidine salts (LII) are treated with formaldehyde and formic acid[110]. 6-Oxa-1,3-diaza-adamantane (XLV, X = Y = N, Z = O, R = H) has been synthesised from diallylamine via the intermediate formation of 9-oxabispidine (XLIV, X = Y = NH, Z = O).[111] The reaction of the diallylamide of benzenesulphonic acid with mercury acetate gives rise to the morpholine system, which is converted into 9-oxabispidine on treatment with ammonia. The condensation of the bispidine derivative with paraformaldehyde leads to the oxadiazo-adamantane (XLV, X = Y = N, Z = O, R = H). The 6-thia-1,3-diaza-adamantane system has been synthesised by an analogous sequence of reactions[112]. The reaction of sulphur dichloride with *NN*-diallybenzene-sulphonamide results in cyclisation to the thiomorpholine system (LIV). Similar cyclisation reactions have been described previously[113]. Subsequent interaction with benzylamine leads to the cyclisation of the thiomorpholine system to the thiobispidine system (LV), which is converted in several stages, involving subsequent condensation with formaldehyde, into 6-thia- 1,3-diaza-adamantane (LVI):



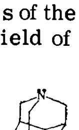
(LIV) (LV) (LVI) .

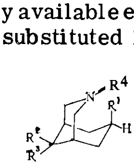
1-Heteroadamantane systems are mainly synthesised via pathway *B* (Scheme 7). Bicyclononane derivatives (XLVI) substituted in the 3- (at the heteroatom) and 7-positions of the bicyclononane molecule are convenient starting materials for this pathway. The synthesis of 1-bora-adamantanes is an example of condensations of this kind. The hydroboration of 7-methylene-3-propyl-3-borobicyclo[3,3,1]nonane (LVII) with tetra-n-propyldiborane leads to compound (LVIII), the cyclisation of which with elimination of 3-propylborane yields 1-bora-adamantane (LIX).[114,115] When compound (LVIII) interacts with pyridine, the pyridine adduct of 1-bora-adamantane is formed[116]. We may note that the geometry of bora-adamantane should simulate the structure of the 1-adamantyl carbonium ion:



(LVII) (LVIII) (LIX) .

The starting compound for the synthesis of the aza-adamantane (LXa) is the 3-azabicyclononane derivative (LXI), synthesised by the condensation of ethyl α-bromomethacrylate or its precursor ββ'-dibromoisobutyrate with the enamine derived from *N*-toluenesulphonylpiperidin-4-one[117] or other *N*-substituted piperidin-4-ones[118,119]. The reduction of the ketoester (LXIa) with lithium tetrahydroaluminate gives the diol (LXId), which is smoothly detosylated under the influence of a mixture of hydrochloric and acetic acids to give 4-hydroxy-1-aza-adamantane (LX, R = OH). Catalytic hydrogenolysis of the readily available ethylene acetal (LXIe) gives a high yield of 2,6-disubstituted 1-aza-adamantane[118]:





(LX) (a)-R = OH, H, NH_2; R^1 = H;
(b)-R = H; R^1 = CH_2OH

(LXI)	a	b	c	d	e
R^1	CO_2Et	CO_2Et	CO_2Et	CH_2OH	CO_2Et
R^2	$\}=O$	OH	H	OH	R^3		H	OH	H	
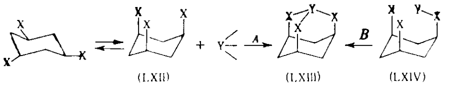
R^4	Tos	Tos	Tos	Tos	CO_2CH_2Ph

.

IV. CONDENSATION AND INTRAMOLECULAR CYCLISATION OF *CIS*, *CIS*-1,3,5-TRISUBSTITUTED CYCLOHEXANES

The general scheme for the synthesis of 2,4,10-triheteroadamantanes involves the condensation of *cis*, *cis*-1,3,5-trisubstituted cyclohexanes with compounds containing a fragment Y capable of condensing with three functional groups at once to form single bonds in accordance with Scheme 8 (pathway *A*):

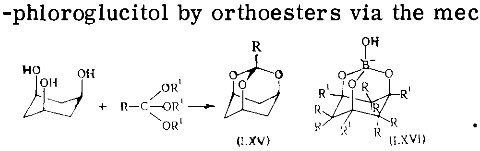


(LXII) (LXIII) (LXIV)

Scheme 8

It is possible to suggest a version of the general scheme where the tervalent component is already combined with one of the functional groups, as shown in Scheme 8 (pathway *B*). Possibly in the synthesis of triheteroadamantanes via pathway *A*, stage *B* is included as an intermediate step and the two versions are indistinguishable. However, it is methodologically useful to distinguish pathway *B*, since it is suitable also for the synthesis of 2,4-diheteroadamantanes.

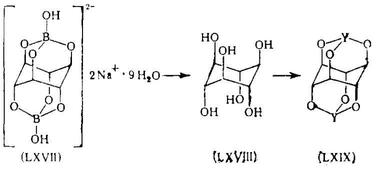
This type of condensation was used for the first time to synthesise the 2,4,10-trioxa-adamantane system (LXIII, X = O, Y = CH).[126] The synthesis involves the esterification of *cis*-phloroglucitol by orthoesters via the mechanism



(LXV) (LXVI)

cis-Phloroglucitol has proved to be a very readily available starting compound and is frequently used in similar syntheses[30,31,121-124]. For example, we may note that its condensation with the tetraethyl ester of orthomalonic acid in the presence of boron trichloride yielded 3-ethoxycarbonylmethyl-2,4,10-trioxa-adamantane (LXV, R = $CH_2CO_2C_2H_5$). Using different condensing agents, a series of trisubstituted trioxa-adamantanes (LXV) have been obtained via a similar mechanism[30,31].

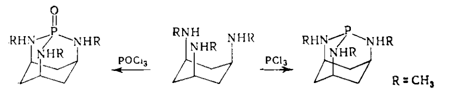
This type of condensation is very suitable for the synthesis of 1-hetero-derivatives of 2,4,10-trioxa-adamantane. In particular, *cis*, *cis*-cyclohexane-1,3,5-triols form stable complexes of type (LXVI) on reaction with sodium metaborate[121]. Evidently this type of condensation is analogous to the well known reaction involving the formation of borate complexes of carbohydrates and polyhydroxy-compounds[125]. It is of interest that *trans*-hexahydroxycyclohexane (scyllitol) (LXVIII) forms a borate complex having the diadamantane structure (LXVII). This reaction is used to isolate scyllitol from natural sources. Scyllitol reacts with triethyl orthoformate in dimethyl sulphoxide (DMSO) to form a polymeric intermediate, which can be converted by pyrolysis into hexaoxadiadamantane (LXIX, Y = CH) in 15% yield. The reaction of compound (LXVIII) with trimethyl phosphite in DMSO or hexamethylphosphoramide yielded diadamantane (LXIX, Y = P)[126]:



(LXVII) (LXVIII) (LXIX)

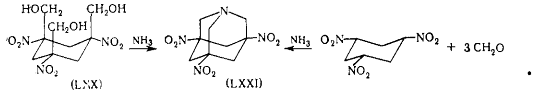
One can also use in this reaction trimethyl phosphate, which reacts with phloroglucitol to give 2,4,10-trioxa-1-phospha-adamantane (LXIII, X = O, Y = P)[122]. The same cyclic system was obtained on treating the *cis*-isomers of cyclohexane-1,3,5-triol derivatives with phosphorus trichloride[121]. The structure of compounds (LXIII, X = O, Y = CH, P, or P=O) has also been studied by ^1H NMR.[127-129]

Similarly to the reaction with *cis*-phloroglucitol, the *cis*-isomer of the triamine (LXII, XR = $NHSO_2C_6H_5$, $NHCH_2C_6H_5$, or $NHCH_3$) condensed with orthoformate in the presence of sulphuric acid to a compound with a 2,4,10-triaza-adamantane structure (LXIII, Y = CH, X = $NSO_2C_6H_5$,[130] $NCH_2C_6H_5$, or NCH_3.[131] Treatment of compound (LXII) with phosphoryl chloride or phosphorus trichloride leads to 2,8,9-triaza-1-phospha-adamantane structures (LXIIIa and LXIIIb):[131]



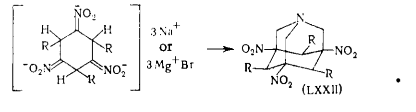
(LXIIIa) (LXIIa) (LXIIIb)

A report[132] of a study of the structure of 1,3,5-trihydroxymethyl-1,3,5-trinitrocyclohexane isomers (LXX) and the synthesis of 3,5,7-trinitro-1-aza-adamantane (LXXI) by the condensation of the triol (LXX) with ammonia in an alkaline medium was published in 1972:



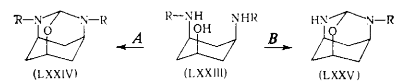
(LXX) (LXXI)

The condensation of 1,3,5-trinitrocyclohexane with ammonia and formaldehyde also led to compound (LXXI). 3,5,7-Trinitro-1-aza-adamantane (LXXI) and a number of its derivatives [LXXII, R = CH_3, C_2H_5, $CH(CH_3)_2$, n-C_4H_9, $CH_2CH(OH)CH_3$, , or ][133] have been obtained by the reduction of 1,3,5-trinitrobenzene with sodium tetrahydroborate or Grignard reagents followed by treatment of the reduction products with formaldehyde and ammonium chloride:



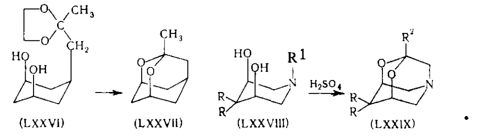
(LXXII)

The condensation of the hydroxyamine (LXXIII) with triethylorthoformate leads to the formation of derivatives of 2-oxa-4,10-diaza-adamantane (LXXIV):[134]



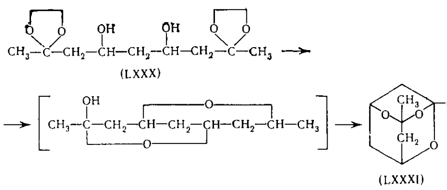
(LXXIV) (LXXIII) (LXXV)

The starting compound (LXXIII) is interesting because its *N*-acyl derivative (R = $COCH_3$) can be converted by intramolecular cyclisation into oxadiaza-adamantane (LXXV) (Scheme 8, pathway *B*). This mechanism can also be illustrated by the following example. Treatment of the ethylene ketal (LXXVI) with sulphuric acid leads to 1-methyl-2,6-dioxa-adamantane (LXXVII)[135] and cyclisation of the *N*-substituted 3,5-dihydroxypiperidine [LXXVIII, R = H, or CH_3, R^1 = $CH_2CH(OC_2H_5)_2$, CH_2Ph, or ] under the influence of sulphuric acid yields a derivative of 4,9-dioxa-1-aza-adamantane (LXXIX, $R^1 = R^2$ = H; R^1 = H, R^2 = CH_3; R^1 = CH_3, R^2 = H)[136]:



(LXXVI) (LXXVII) (LXXVIII) (LXXIX)

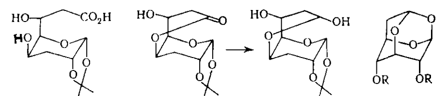
3,5-Dimethyl-2,4,6-trioxa-adamantane (LXXXI) has been obtained by the hydrolysis of the diethylene ketal (LXXX) with a dilute inorganic acid followed by the elimination of water from the non-isolated bicyclohemiketal form[137]:



(LXXX)

(LXXXI)

The 2,4,6-trioxa-adamantane system has also been obtained by the intramolecular cyclisation of compound (LXXXIV)[138,139]. On refluxing with molecular sieves in toluene, the ammonium salt of the acid (LXXXII) yields the lactone (LXXXIII), the hemiacetal (LXXXIV) of which is converted into 6-deoxy-*D*-glucodealdoheptose on hydrolysis. 50% of the latter exists in the cyclic trioxa-adamantane form (LXXXV, R = H):

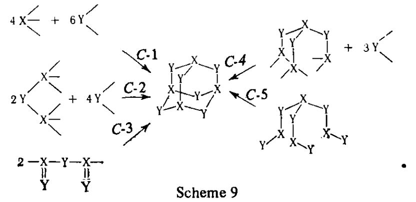


(LXXXII) (LXXXIII) (LXXXIV) (LXXXV)

like *D*-glucuronic acid, 6-deoxy-*D*-glucohepturonic acid is capable of being converted into a lactone[140]. The hemiacetal of this lactone also gives rise to the trioxa-adamantane structure (LXXXV), as shown by ^{1}H NMR.[141,142]

V. SYNTHESIS FROM ACYCLIC COMPOUNDS

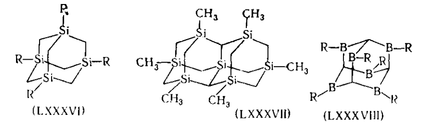
One should note in the first place that almost any heterocyclic system with the adamantane structure can be constructed from acyclic fragments, but the later must contain both atoms capable of occupying the 1-, 3-, 5-, and 7-positions in the adamantane skeleton and bivalent atoms known on *a priori* grounds to be incapable of occupying bridgehead positions. The ratio of the reactants depends on the number of atoms in the initial fragments involved in the construction of the adamantane skeleton. Condensation of this type can therefore be represented by several formal schemes (Scheme 9):



Scheme 9

The simplest initial structures are ammonia and formaldehyde (pathway *C*-1). Their condensation was achieved for the first time in 1860 in the synthesis of hexamethylenetetramine (urotropine or 1,3,5,7-tetra-aza-adamantane)[143], to which the adamantane structure was attributed as early as 1895.[144] The methods of synthesis of urotropine derivatives are not considered in this review, since the chemistry of urotropine constitutes an independent field.

The *C*-2 pathway is frequently followed in the synthesis of sila-adamantanes by the pyrolysis of simple halogenosilanes and silanes with carbon-containing substituents. For example the pyrolysis of tetramethylsilane at 650°C led to the isolation of tetramethyltetrasila-adamantane (LXXXVI, R = Me) from a complex mixture of reaction products[145-149]:



(LXXXVI) (LXXXVII) (LXXXVIII)

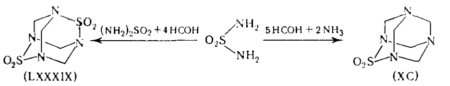
In addition, compound (LXXXVII)[148,150], the structure of which was demonstrated by ^{1}H NMR, was isolated by chromatography. The yield of the tetrasila-adamantane derivative (LXXXVI, R = Me) increased greatly (sometimes to 80%), when 1,3,5-hexamethyl-1,3,5-trisilacyclohexane was introduced into the reaction[151]:

$$2\,(\mathrm{Me_2\overset{|}{S}iCH_2{-}})_3 \xrightarrow{\mathrm{AlBr_3}} [\mathrm{MeSi(CH_2)_{3/2}}]_4 + 2\mathrm{Me_4Si}.$$
(LXXXVI)

Pyrolysis of chlorotrimethylsilane at 700°C leads to a mixture of compounds ranging from fully chlorinated derivatives (LXXXVI, R = Cl) to fully methylated sila-adamantanes (LXXXVI, R = Me), which can be separated chromatographically[149,152]. The tetrachloro-derivative (LXXXVI) was also obtained from chlorotrimethylsilane and tetrachlorosilane in the presence of aluminium chloride at 500°C but in very low yields[153]. The interaction of carbon-containing silanes incorporating Si–Cl groups with $ZnCl_2$ in organic solvents leads to cyclic fluorinated carbon-containing silanes (LXXXVI, R = F) where all the hydrogen atoms can be replaced by chlorine on photochemical chlorination[154]. Bora-adamantanes with a structure of type (LXXXVIII, R = Me) can be obtained via similar reactions on pyrolysis of trimethylboron at 450°C.[155]

Thus pathway *C*-2 is extremely convenient for the synthesis of various tetrasila-adamantanes with structures of type (LXXXVI, R = Cl, Br, or Me) and possibly also structures with heteroatoms such as germanium and tin, when starting compounds having structures containing the $SiCH_2$, CH_2Si, Si_3CH, $GeCH_2$, or $SnCH_2$, etc. fragments are used.

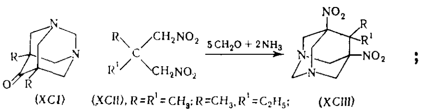
The *C*-3 type of condensation can be illustrated by the synthesis of tetramethylenetetramine disulphone (LXXXIX) on reaction between sulphamide and formaldehyde in proportions of 2 : 4.[156] It is noteworthy that the cyclic disulphone (LXXXIX) is extremely toxic and its action on the central nervous system is five times as potent as that of strychnine[157]:



(LXXXIX) (XC)

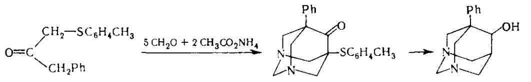
The synthesis of the sulphone (XC) is a kind of combination of pathways *C*-1 and *C*-2 in a single reaction. The condensation of sulphamide, formaldehyde, and ammonia is carried out in an acid medium to give a 90% yield of the sulphone (XC).[158] This type of condensation of acyclic fragments, involved in the construction of the adamantane molecule, constitutes a modified Mannich condensation. The mechanism of the condensation reactions may involve in the initial stages the formation of mono- and bicyclic structures. Although mono- and bicyclic intermediates can be isolated in the Mannich condensation as the main products, depending on the reaction conditions, nevertheless hetero-adamantane structures are usually synthesised without the isolation of the intermediates. We therefore regard this type of condensation as an independent process, bearing in mind the real initial structural units.

The condensation of diethyl acetonedicarboxylate in the presence of ammonium acetate[159] leads to the diaza-adamantane (XCI, R = $CO_2C_2H_5$). The Mannich reaction, which employs dibenzyl ketone and ammonium acetate or dibenzyl ketone, alkylammonium acetate, and ammonium acetate as the starting compounds, gives rise to the diaza-adamantane (XCI, R = Ph) together with a certain amount of bicyclic products[160]:



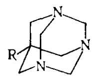
(XCI) (XCII), $R = R^1 = CH_3$; $R = CH_3$, $R^1 = C_2H_5$; $(R, R^1) = -(CH_2)-, -(CH_2)_5-$ (XCIII)

One of the simplest and most convenient methods for the synthesis of 1,3-diaza-adamantane derivatives involves the aminomethylation of compounds containing two active methylene groups with formaldehyde and ammonia salts of weak acids. Thus 2,2-dialkyl-1,3-dinitropropanes (XCII) condense with formaldehyde and ammonium acetate in the presence of ammonium carbonate to form substituted 1,3-diaza-adamantanes (XCIII).[161] Tolylthiophenylacetone is converted by a similar reaction into the diaza-adamantane (XCIV), which is easily reduced by Raney nickel to compound (XLVIII).[105]



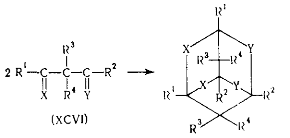
(XCIV) (XLVIII)

The starting compounds used as structural units in the synthesis of substituted 1,3,5-triaza-adamantanes (XCV, R = NO_2 or NH_2) are nitromethane, paraformaldehyde and ammonium acetate[162].



(XCV)

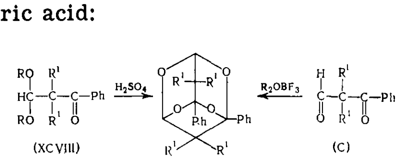
The condensation of β-dicarbonyl compounds and their thioanalogues has a great scope for the synthesis of polyheteroadamantanes. Reactions of this type can be represented schematically as follows:



(XCVI) (XCVII)

Depending on the nature of X and Y, a number of heteroadamantane structures can be synthesised by the "dimerisation" of the initial dicarbonyl compounds or by condensation with other β-dicarbonyl compounds.

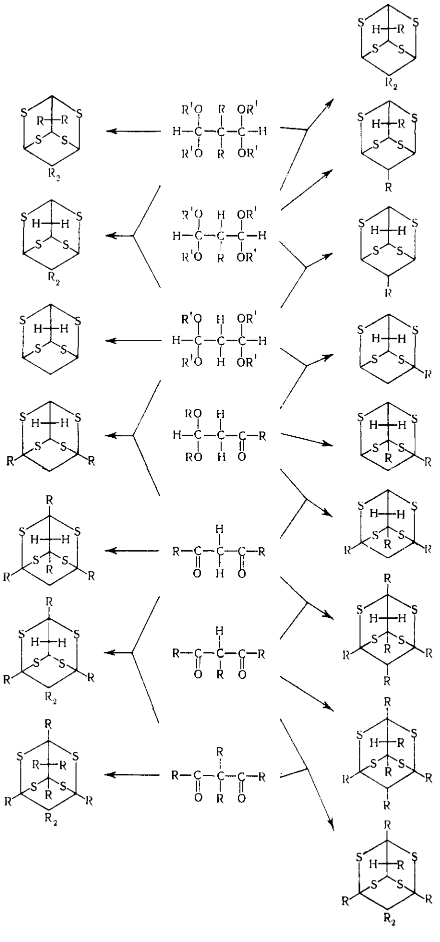
The synthesis of α-formylisobutyrophenone (XCVI, X = Y = O, R^1 = Ph, R^2 = H, $R^3 = R^4$ = Me)[163] from the acetal (XCVIII, R = C_2H_5, R^1 = CH_3) was described in 1959. It was later established[164] that the compound, to which the structure of α-formylisobutyrophenone had been erroneously attributed in the previous study, is in fact the dimer of this aldehyde. The tetraoxa-adamantane structure (XCIX, R^1 = Me) was proposed for it on the basis of spectroscopic data. It was found that the dimer (XCIX) is obtained in almost quantitative yield when the acetal (XCVIII) is treated with 80% sulphuric acid:



(XCVIII) (XCIX) (C)

The dimerisation of certain β-dicarbonyl compounds in the presence of boron triluoride-ether or zinc chloride in glacial acetic acid leads to only slight yields of tetra- and penta-methyl derivatives of tetraoxa-adamantane, the structures of which have been identified by mass spectrometry. In contrast to this, the dimerisation of the ketoaldehyde (C) leads to an almost quantitative yield of tetraoxa-adamantane (XCIX).[165] This type of dimerisation is also characteristic of thioanalogues[166]. All possible versions of the synthesis of polythia-adamantanes are most clearly illustrated by Scheme 10 of Olsson and Almqvist[166], which is reproduced here.

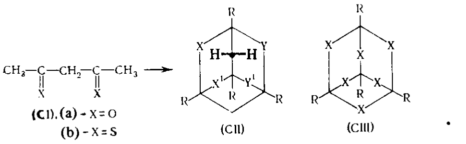
The Syntheses of 2,4,6,8-Tetrathia-adamantane Derivatives[166]



Scheme 10

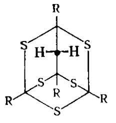
In a strongly acid medium in the presence of hydrogen sulphide, β-diketones, and particularly pentane-2,4-dione (CIa) are converted into derivatives of tetrathia-adamantane (CII, X = Y = X^1 = Y^1 = S) and its mono-oxa- (X = O), dioxa- (X = Y = O), and trioxa-analogues (X = Y = Y^1 = O)

(CII, R = Me).[167] The main product of the reaction of dithioacetylacetone (CIb) was a tetrathia-adamantane (CII, X = Y = X^1 = Y^1 = S, R = Me).[168] The selenium analogue (CII, X = Y = X^1 = Y^1 = Se) was synthesised for the first time in 1969[169] by passing hydrogen selenide through a solution of pentane-2,4-dione in glacial acetic acid in the presence of zinc chloride. In addition the hexaselena-adamantane (CIII, X = Se) was isolated from the mixture of reaction products.

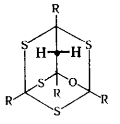


(CI), (a) - X = O
(b) - X = S
(CII) (CIII)

Thiocarboxylic acids and their salts have been used as convenient substitutes of hydrogen sulphide in the synthesis of oxathia-adamantanes. The reaction of β-dicarbonyl compounds with thioacetic acid was carried out for the first time by Brändström[170]. Apart from the tetrathia-adamantane (CII), he obtained two substances, which he regarded without proof as its oxa-analogues (CII, X = O and X = Y = O). The same reaction of β-dicarbonyl compounds (XCVI, X = Y = O; X = Y = S; X = O, Y = S) with thioacetic acid in the presence of zinc chloride led to the synthesis of tetrathia-adamantanes (XCVII), pentathia-adamantanes (CIV), and hexathia-adamantanes (CIII, X = S) in proportions determined by the molar ratios of the initial reactants. Mono-, di-, and tri-oxa-analogues of compound (CII) and the oxatetrathia-adamantane (CV, R = Me) are formed simultaneously[171].



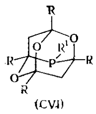
(CIV)



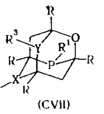
(CV)

Thus β-dicarbonyl compounds react with hydrogen sulphide or thiocarboxylic acids to give isomeric mixtures of thia- and oxathia-adamantanes[2,170], which can be separated by preparative gas–liquid chromatography (GLC) and identified by mass spectrometry[166,172–174].

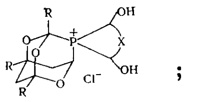
Using phosphine or primary substituted phosphines instead of hydrogen sulphide, it is possible to obtain by a similar reaction phosphorus analogues having structures of type (CII, X = Y = Y^1 = O, X^1 = P)[175] as well as a series of tetra-alkyl-substituted 2,6,9-trioxa-10-phospha-adamantanes (CVI).[176] By varying the amounts of phosphine or primary substituted phosphine taken for the reaction with an alkyl-β-diketone, it is possible to obtain a series of compounds with a structure of type (CVII):



(CVI)



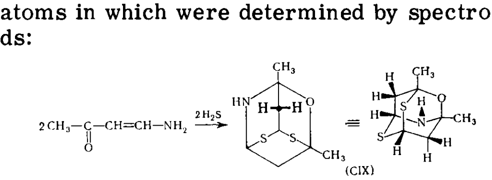
(CVII)



(CVIII), R = Me, X = –(CH$_2$)$_2$–, –(CH$_2$)$_3$–;
R = CF$_3$, X = –CH$_2$(CHOMe)CH$_2$– ;

where X and Y may be oxygen or phosphorus[177]. Thus, when two equivalents of the β-diketone react with one equivalent of phosphine, compound (CVII, X = Y = O) is the product; the reaction with two equivalents of phosphine yields the oxaphospha-derivative (CVII, X = P, Y = O) and the reaction with three equivalents of phosphine gives rise to the phospha-derivative (CVII, X = Y = P). The compounds obtained in this way are listed in Table 4.

The condensation of secondary substituted phosphines with aldehydes (for example glutaraldehyde) leads to structures of type (CVI), (CVII), and (CVIII).[178] The reaction of α-aminovinyl ketone with hydrogen sulphide leads to the polyheteroadamantane (CIX),[179] the positions of the N, O, and S atoms in which were determined by spectroscopic methods:



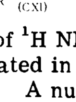
(CIX)

Table 4. Heteroadamantanes with a structure of type (CVII).[177]

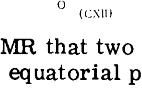
X	Y	R	R^1	R^2	R^3
O	O	Me	H, iso-Bu, Octyl, Pr	—	—
O	O	trifluoromethyl	R^1 = R^2 = tris-(2-hydroxyethyl)		
O	O	Pr	dodecyl	—	—
O	O	1,5-diethyl-3,7-dimethyl	benzyl	—	—
O	O	Bu	2-carboxyethyl	—	—
P	O	Me, Et	R^1 = R^2 = bis-(2-cyanoethyl), allyl, cyclohexyl, bis-(*p*-chlorophenyl)		—
P	P	Me	Ph	Ph	Ph
P	P	trifluoromethyl	R^1 = R^2 = tris(2-hydroxyethyl)		H

Synthetic schemes for the preparation of heteroadamantanes via pathway *C*-4 are based on the use as starting compounds of trifunctional derivatives containing in their structure both atoms capable of occupying bridge-positions and atoms occupying the 2-, 4-, and other analogous positions in the adamantane skeleton. Thus the initial fragment already contains seven atoms needed for the construction of the adamantane skeleton. The missing three units are introduced by condensation or intramolecular cyclisation from the substituents present in the initial molecule (see Scheme 9, pathway *C*-5). The triaza-adamantane structure (CXI, R = Me, R^1 = 2-C$_5$H$_4$N) was demonstrated in 1967 for the product of the condensation of tri(aminomethyl)methane (CX, R = CH$_3$, R^1 = NH$_2$) with piperidine-2-aldehyde[180]:

RC(CH$_2$R^1)$_3$
(CX)



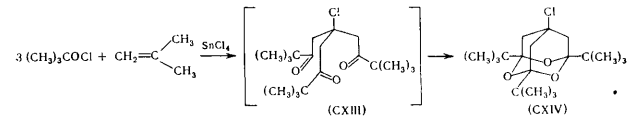
(CXI)



(CXII)

It was shown with the aid of ^{1}H NMR that two pyridyl groups in compound (CXI) are located in equatorial positions and one is in an axial position. A number of mono-substituted derivatives of compound (CXI) with the substituents R = H and R^1 = NO$_2$, NH$_2$, HNOH, N(CH$_3$)$_3$, HNCOCH$_3$, HNCOPh, or HNCH$_2$C(NO$_2$)(CH$_3$)$_2$ have been obtained[181] from tri-(hydroxymethyl)nitromethane (CX, R = NO$_2$, R^1 = OH) ammonia, and formaldehyde. Oxaphospha-adamantane derivatives of type (CXII, X = N, P = O) are formed on intramolecular degradation of nitrilotrimethylenephosphonic acid N(CH$_2$.PO$_3$H$_2$)$_3$ or OP(CH$_2$PO$_3$H$_2$)$_3$ by acetic anhydride[182].

A new type of triacylation in the reactions of pivaloyl halides with isobutene was discovered in 1972.[183] In the presence of tin tetrachloride, this reaction gives rise to the trioxa-adamantane derivative (CXIV), which is probably formed via the triketone (CXIII). The latter is apparently unstable and is spontaneously converted into compound (CXIV):

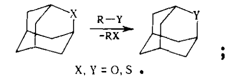


(CXIII) (CXIV)

The data presented show that the pathways to the synthesis of heteroadamantanes from acyclic compounds are extremely varied and numerous and constitute a large field in the synthesis of various heteroanalogues of adamantane.

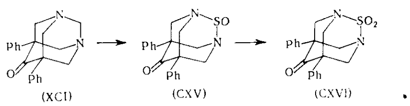
VI. SYNTHESIS BY THE TRANSFORMATION OF POLYCYCLIC STRUCTURES

So far there are few instances in the literature of the formation of heteroadamantane derivatives as a result of the transformation of the skeletons of other polycyclic molecules. However, this method appears fairly promising bearing in mind the advances in the synthesis of a wide variety of polycyclic and skeletal structures. One of the methods formally resembles the Yur'ev reaction[184] (Scheme 11):

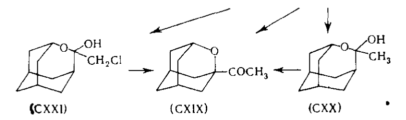


Scheme 11

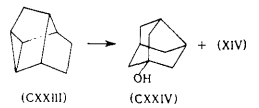
Reactions leading to the substitution of the heteroatom in rings are known also for bicyclo[3,3,1]nonane systems[185–187]. The formation of thiadiaza-adamantane (CXV) from diaza-adamantane (XCI)[188] by treating the latter with $SOCl_2$ in anhydrous pyridine is an example of reactions of this kind involving adamantane structures:



A new pathway to the synthesis of the 2-oxa-adamantane system from derivatives of 2-substituted adamantanols was discovered in 1971.[189] When 2-methyladamantan-2-ol (CXVII, R = Me) was treated with lead tetra-acetate in the presence of iodine, the oxahomoadamantane derivative (CXVIII) was obtained. The di-iodoether (CXVIII) is readily decomposed by dilute hydrochloric acid in DMF to the oxa-adamantane derivative (CXIX). The ketone (CXIX) was also obtained from both homoadamantanes (CXX) and (CXXI) by treatment with iodine in the presence of hydrogen chloride in DMF. Treatment of the adamantanol (CXVII, R = H) with a mixture of yellow or red mercury(II) oxide and iodine, the reaction system being heated or irradiated, leads to a mixture of unsubstituted 2-oxa-adamantane (XIV), and the adamantanone (CXXII).[190] The ratio of the reaction products depends on the molar ratios of the adamantanol, mercury(II) oxide, and iodine and on the reaction temperature:



The unsubstituted oxa-adamantane (XIV) has also been obtained in a low yield (10%) in the reaction of deltacyclane (CXXIII) with concentrated sulphuric acid. Depending on the conditions, the main reaction product is 1-noradamantanol (CXXIV) or 2-noradamantanol[191]:



During the preparation of the manuscript for the press and while it remained with the editors, a number of studies have been published on the synthesis[192–201], properties[202–205], and structure[206–207] of heteroadamantanes containing between one and five heteroatoms in the adamantane structure.

Methods of Synthesis and Properties of Allylboranes

B.M.Mikhailov

The methods of synthesis and chemical properties of allyl derivatives of boron of different types and their applications in organic chemistry, including their use for the synthesis of 1-bora-adamantane and adamantane compounds, are discussed. The bibliography includes 148 references

CONTENTS

I. INTRODUCTION

Studies on the chemical properties of organic boron compounds in recent years have led to the discovery of an increasing number of new fields of application of these substances in organic syntheses. Methods of synthesis based on organoboranes have greatly extended the scope of the applications of organometallic reagents in preparative chemistry, usefully supplementing the available synthetic procedures involving organic derivatives of magnesium, zinc, and alkali metals.

Allyl derivatives of boron, which are highly reactive and exhibit a specific behaviour in relation to different classes of organic compounds, are particularly promising as synthetic reagents. A characteristic feature of triallylborane and some of its analogues is their ability to exist in a state of permanent allyl rearrangement, which takes place at different rates, depending on the nature of the compound and temperature. The high reactivity of allylboranes is manifested in their reactions with water, alcohols, and amines, which occur even at room temperature; this distinguishes them sharply from trialkylboranes, which react with the same substances only at elevated temperatures. Allylboranes react with aldehydes, ketones, quinones, and nitriles like organometallic compounds, their use for synthetic purposes having in many instances considerable advantages compared with magnesium and other metal compounds[1].

A specific feature of allylboranes is their tendency to react with unsaturated compounds. Their reactions with acetylenic and allenic compounds lead to 3-borabicyclo[3,3,1]nonene and 3-borabicyclo[3,3,1]nonane systems, on the basis of which it proved possible to develop a stereospecific method for the synthesis of compounds of the cyclohexene and cyclohexane series, to synthesise unique 1-bora-adamantane systems, and to devise a novel method for the synthesis of adamantane derivatives.

II. METHODS OF SYNTHESIS

Triallylborane was obtained for the first time in 33% yield by the reaction of triallyl borate and allylmagnesium bromide[2]. Triallylborane is also formed from allylmagnesium bromide and n-butyl metaborate[3]. The reaction between allylmagnesium bromide and boron trifluoride-ether constitutes a preparative method for the synthesis of triallylborane[3]:

$$3\,C_3H_5MgBr + BF_3 \rightarrow (C_3H_5)_3B + 3\,MgBrF.$$

The reaction can be carried out in a single stage by adding a mixture of allyl bromide and boron trifluoride-ether to magnesium in an ethereal medium[4,5].

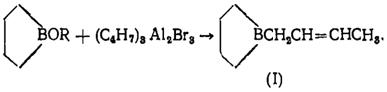
When allylmagnesium chloride and boron trifluoride-ether are used, the yield of triallylborane is 10–47%.[4,6] Allylmagnesium chloride and methyl borate may be used to synthesise triallylborane[7]. Triallylborane can be obtained most conveniently from allylaluminium sesquibromide and n-butyl borate or boron trifluoride-ether[8]:

$$(C_3H_5)_3Al_2Br_3 + BF_3 \xrightarrow[78\%]{} (C_3H_5)_3B + AlF_3 + AlBr_3\ .$$

Tricrotylborane in 75% yield[9] and tri-(2-methylallyl)-borane[10] have been synthesised by the last method.

Mixed organoboranes containing one or two allyl groups are obtained by treating the corresponding acid esters with allyl derivatives of magnesium or aluminium.

1-Crotylboracyclopentane (I) has been synthesised from 1-n-butoxyboracyclopentane[11] or 1-methoxyboracyclopentane[12] and crotylaluminium sesquibromide:



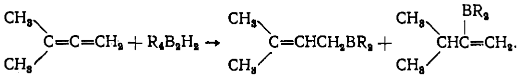
(I)

1-Allylboracyclopentane has been obtained by treating 1-alkoxyboracyclopentane with allylmagnesium bromide or allylaluminium sesquibromide[13]. Dialkylallylboranes[14], alkyldiallylboranes[14], and allyldiarylboranes[15] can be synthesised by this method from dialkylborinic, alkylboronic, or diarylborinic acid esters.

Dialkylallylboranes are also formed when esters of dialkylthioborinic acids are treated with triallylborane[16]:

$$(C_2H_5)_2BSC_6H_{13} \xrightarrow{(CH_2{=}CHCH_2)_3B} (C_2H_5)_2BCH_2CH{=}CH_2.$$

Mixed dialkylallyl compounds of boron can be likewise obtained by adding tetra-alkyldiboranes to allenic hydrocarbons. Dialkyl-(3-methylbut-2-en-1-yl)boranes (II) with an admixture of about 10% of the isomeric compounds (III) have been synthesised by this method[17]:



$$(CH_3)_2C{=}C{=}CH_2 + R_4B_2H_2 \rightarrow (CH_3)_2C{=}CHCH_2BR_2 + (CH_3)_2CHC(BR_2){=}CH_2.$$

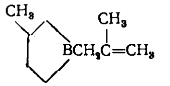
90% (II) 10% (III)

A number of acylic[18] and cyclic[19,20] allenic hydrocarbons have been hydroborated with tetra-(3-methylbut-2-yl)-diborane; the reaction products, containing a mixture of the corresponding substituted dialkylallylboranes and dialkylvinylboranes, were oxidised with hydrogen peroxide.

Alkyldiallylboranes can be obtained by the symmetrisation of dialkylallylboranes. Thus, on being heated above 100°C, diethyl-(3-methylbut-2-en-1-yl)borane is converted into a mixture of triethylborane, ethyldi-(3-methyl-but-2-en-1-yl)borane, and tri-(3-methylbut-2-en-1-yl)borane, which can be separated by fractional distillation[17].

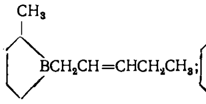
When a 5 : 1 mixture of buta-1,4-diene and diborane reacts in an ethereal medium, a low yield is obtained of a mixture of unsaturated compounds having the composition $C_8H_{15}B$ [together with di-(1-boracyclopentylbutanes)], which consists almost entirely of 1-crotylboracyclopentane[12,21].

The hydroboration of isoprene (using the ratio hydrocarbon : B_2H_6 = 6 : 1) leads to a mixture of 1-alkenyl-3-methylboracyclopentanes [together with di-(3-methylboracyclopentyl)pentanes], which consists to the extent of about 60% of 3-methyl-1-(2-methylbut-2-en-1-yl)boracyclopentane (IV):[22]

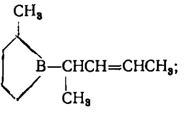


(IV)

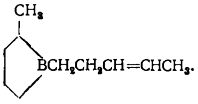
Hydroboration of piperylene yields a mixture of 1-alkenyl-2-methylboracyclopentanes containing about 35% of 2-methyl-1-(pent-2-en-1-yl)boracyclopentane (V), 15% of 2-methyl-1-(pent-3-en-2-yl)boracyclopentane (VI), and 50% of 2-methyl-1-(pent-3-en-1-yl)boracyclopentane (VII):[22]



(V)



(VI)



(VII)

Allyl derivatives of boron with oxygen-containing and other functional groups at the boron atom can be obtained by various methods. A general and preparatively convenient method of synthesis of compounds of this type is based on reactions of triallylboranes, which are highly reactive in relation to different reagents. Allylboronic acids and their esters are formed when allylboranes are treated with water or alcohols at room temperature. Thus triallylborane reacts with water to form allylboronic acid, which is isolated as its anhydride on distillation[3]. Studies on reactions of 1-crotylboracyclopentane[11] and tricrotylborane[9] with water, which lead to the formation of but-1-ene and respectively to 1-hydroxyboracyclopentane and crotylboronic acid established that the protonolysis of the boron–carbon bond takes place with allyl rearrangement. The n-butyl ester of diallylborinic acid can be obtained from triallylborane by treating it with one equivalent of n-butyl alcohol. n-Butyl diallylborinate reacts with n-butyl alcohol to form di-n-butyl allylboronate[3].

When methyl alcohol reacts with diallylborane, the reactants being in proportions of 1 : 1, the dimethyl ester of allylboronic acid is obtained, and not the methyl ester of diallylborinic acid, part of the initial triallylborane being recovered unchanged. This can be explained by the fact that the $(C_3H_5)_2BOCH_3$ formed initially undergoes rapid symmetrisation to $(C_3H_5)B(OCH_3)_2$ and $(C_3H_5)_3B$.[3]

Diethyl[23], di-n-propyl[24,25], di-n-butyl, diallyl, dibenzyl, and diphenyl[24] esters of allylboronic acid have been obtained by treating triallylborane with the corresponding alcohols. Tricrotylborane reacts vigorously with methanol at room temperature to form the methyl ester of dicrotylborinic acid and but-1-ene (98%) with a small admixture of but-2-ene (2%) when the initial reactants are taken in equimolar proportions[9]. Thus the alcoholysis of the B–C bond in allyl derivatives of boron takes place with allyl rearrangement.

In order to convert tricrotylborane into the dimethyl ester of crotylboronic acid, the borane must be heated with methanol[9]. The dimethyl ester of allylboronic acid has been synthesised by treating trimethyl borate with allylzinc or allylaluminium compounds[26]. The reaction of crotylmagnesium bromide and methyl borate with subsequent hydrolysis and transesterification of reaction products with n-hexyl alcohol leads to a mixture of di-n-hexyl esters of 1-methylallylboronic and crotylboronic acids in proportions of 77 : 23, with a 44% overall yield[27]. When crotyl-lithium is used, only the ester of crotylboronic acid is obtained (36%). On standing (for several weeks) or in the presence of magnesium bromide (for 18 h at 55°C), the ester of 1-methylallylboronic acid is slowly converted into the ester of crotylboronic acid. The reaction of hex-2-en-1-ylmagnesium bromide with methyl borate leads to the esters of hex-1-en-3-ylboronic and hex-2-en-1-ylboronic acids in proportions of 86 : 14.[27]

According to patent data[28], the dipentyl ester of allylboronic acid is formed when triallyl borate, allyl bromide, and sodium react with subsequent esterification by pentyl alcohol. A mixture of cyclic esters of allylboronic and isopropenylboronic acids in proportions of 66 : 14 is obtained when allene is heated for a long time at 130°C with 4,4,6-trimethyl-1,3,2-dioxaborinane[29].

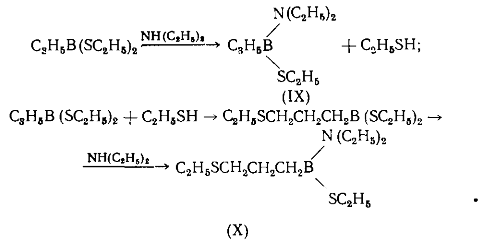
A simple method for the synthesis of dimethyl allylboronate involves heating a 1 : 2 mixture of triallylborane with methyl borate[30]. It has been established by ^{1}H NMR that a 4 : 1 equilibrium mixture of allylboronic and diallylborinic acid esters is obtained from an equimolar mixture of triallylborate and methyl borate, while the proportions of the esters obtained from an initial 2 : 1 mixture are 1 : 2.3.[31] When triallylborane is heated with triisobutyl borate, di-isobutyl allylboronate is obtained[8].

Allylboranes serve as starting materials for the synthesis of allylic thioacids. Triallylborane reacts with ethanethiol at –15°C, the ethyl ester of diallylthioborinic acid and propene being formed from equimolar amounts of the initial reactants[32,33]. When two equivalents of ethanethiol are used, the main reaction product is the diethyl ester of allylthioboronic acid; in addition, the ethyl esters of diallylthioborinic and 3-ethylthio-n-propylthioboronic acids (VIII) are obtained. The latter acid is formed as a result of the addition of ethanethiol to the ester of allylthioboronic acid:

$$(C_3H_5)_3B + C_2H_5SH \xrightarrow[-C_3H_6]{} (C_3H_5)_2BSC_2H_5 \xrightarrow{C_2H_5SH} \underset{\text{(VIII)}}{C_2H_5SCH_2CH_2CH_2B\,(SC_2H_5)_2}.$$

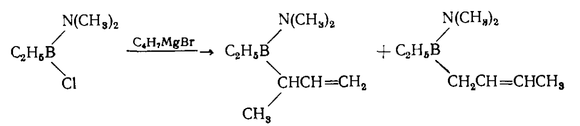
The synthesis of the ethyl esters of diallylthioborinic and allylthioboronic acids has also been described[25].

Like the esters of dialkylthioborinic and alkylthioboronic acids[34–37], those of allylthioboronic acids react readily with various substances. When diethyl allylthioboronate is treated with ammonia, *BBB*-triallylborazole is formed, the reaction with n-butylamine yields allyl-(n-butylamino)-borane, and the reaction with diethylamine leads to the ethyl ester of allyl(diethylamino)thioborinic acid (IX) and to the ethyl ester of (diethylamino)-3-ethylthiopropylthioborinic acid (X):[33]



Allyl-containing amino-derivatives of boron can be obtained from allylboranes. Triallylborane reacts with ammonia and primary and secondary amines to form adducts, which are smoothly converted into diallylaminoborane or its *N*-alkyl derivatives on heating to 100–130°C.[3,38] Diallylaminoborane and alkylaminodiallylboranes have been synthesised by this method[25].

When chloro(ethyl)dimethylaminoborane reacts with crotylmagnesium bromide, a mixture of but-1-en-3-yl-(ethyl)dimethylaminoborane (XI) and but-2-en-1-yl(ethyl)-dimethylaminoborane (XII) is obtained in proportions of 65 : 35:[39]



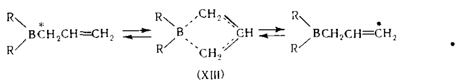
Compound (XI) is comparatively stable at room temperature, but isomerises to compound (XII) at 150°C. The reaction of chlorobis(dimethylamino)borane with crotylmagnesium bromide gives rise to a mixture of but-1-en-3-ylbis(dimethylamino)borane and but-2-en-1-yl-bis(dimethylamino)borane (84 : 16).[40]

Allyldichloroborane is formed when BCl_3 is heated with tetra-allyltin[41].

III. THE PERMANENT ALLYL REARRANGEMENT IN ALLYL DERIVATIVES OF BORON

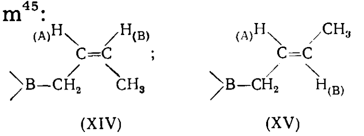
^{1}H NMR studies of triallylborane led to the detection in the latter of a permanent allyl rearrangement[42–44], the activation energy for which proved to be 10 ± 1 kcal mole^{-1}.

The reversible exchange of CH_2 groups in allyl derivatives of boron proceeds via a transition state (XIII) with symmetrically distributed hydrogen atoms in the CH_2 groups relative to the [boron] atom and equivalent B–$\overset{*}{C}$ and B–C bonds.

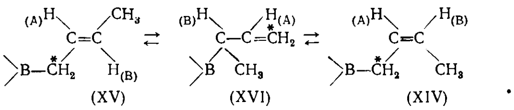


The specific features of the chemical behaviour of triallylborane are undoubtedly associated with the permanent allyl rearrangement occurring in it.

The study of the ^{1}H NMR spectra of tricrotylborane using proton–proton double resonance at frequencies of 60 and 100 HMz shows that this compound exists as a mixture of *cis*- (XIV) and *trans*-isomers (XV) of the but-2-enyl form[45]:



In contrast to triallylborane, there is no permanent allyl rearrangement in tricrotylborane at room temperature. The proton spectrum of the $-CH_{(A)}=CH_{(B)}$ system, obtained using proton–proton double resonance, shows that *trans*-tricrotylborane predominates in the mixture (J_{AB} = 15.0 Hz), its content at room temperature amounting to 70%. The form of the ^{1}H NMR spectrum of tricrotylborane above 150°C indicates the reversible interconversion of the *cis*- and *trans*-isomers at such a rate that the chemical shift and the spin–spin interaction constants of the $H_{(A)}$ and $H_{(B)}$ protons (J = 14 Hz) are averaged. The observed interconversion evidently proceeds via a stage involving the isomerisation of the but-2-enyl form of tricrotylborane (XV) to the but-1-enyl form (XVI), in which there is free rotation about the $H_{(A)}-C-CH_{(B)}$ bond, ensuring the conversion into the *cis*-form of tricrotylborane (XIV):



The interconversions (XV) ⇌ (XVI) and (XVI) ⇌ (XIV) proceed via a transition state of type (XIII).

The study of the ^{1}H NMR spectra of tri-(2-methylallyl)-borane showed[10] that there is a permanent allyl rearrangement in this compound too, occurring more readily than in triallylborane. Thus, at 100°C the rate of rearrangement is 5709 s^{-1}, while in triallylborane at the same temperature it is 2421 s^{-1}. The activation energy for the rearrangement is 9.8 ± 0.5 kcal mole^{-1}.

The permanent allyl rearrangement in tri-(3-methyl-but-2-en-1-yl)borane, 1-allyl-2-(but-2-en-1-yl)5-chloromethylene-4,4-dimethylcyclopentane[46], and 3-allyl derivatives of the 3-borabicyclo[3,3,1]non-6-ene series[47] has been studied by ^{1}H NMR. Permanent intermolecular allyl rearrangements have been detected by ^{11}B and ^{1}H NMR in the exchange reactions of triallylborane, tricrotylborane, and tri-(2-methylallyl)borane with borates[48] and alkyl thioborates[49]. The influence of the permanent allyl rearrangement on the parameters of the NMR spectra of certain allyl derivatives of boron has been studied[50].

IV. CHEMICAL PROPERTIES

1. Capacity for Complex Formation

Triallylborane forms complexes with pyridine[23,51], α-picoline, trimethylamine[51], and diethylamine[38]; a complex of tricrotylborane with pyridine is known[9].

The capacity of triallylborane for complex formation has been studied by ^{1}H and ^{11}B NMR and by boron–proton double resonance[51]. The heats of dissociation of the adducts of triallylborane with trimethylamine, pyridine, 2-methylpyridine, and 3-methylpyridine are respectively 20.6, 25.1, 19.1, and 26.2 kcal mole^{-1}. Reactions involving the substitution of one ligand by another in triallylborane complexes have been investigated by ^{1}H NMR [51] and it has been established that exchange between the free amine and the amine bound in the complex takes place in amine solutions of triallylborane complexes. Tri-(2-methylallyl)borane has a smaller capacity for complex formation than triallylborane[10].

The oxidation of the triethylamine complex of tricrotylborane in an excess of the amine with hydrogen peroxide leads to crotyl alcohol with an admixture of only 2% of

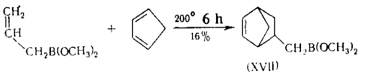
1-methylallyl alcohol, i.e. the oxidative cleavage of the B–C bond takes place without allyl rearrangement[10].

2. Reactions with Organometallic Compounds and Certain Other Reagents

Allyl-lithium adds to triallylborane with formation of lithium tetra-allylborate[52]. Triallylborane, tri-(2-methylallyl)borane, and tricrotylborane enter into exchange reactions with dimethylzinc[53–55] and dimethylcadmium[55,56] with formation of trimethylborane and the corresponding diallyl derivatives of zinc and cadmium. Vanadium tetrachloride forms BCl_3 and allylvanadium trichloride on reaction with triallylborane.

Di-n-butyl allylboronate combines with dichloromethylsilane in the presence of chloroplatinic(II) acid with formation of an ester of 3-methyldichlorosilylpropylboronic acid[58]. In the presence of chloroplatinic(II) acid, triethylsilane adds to the allylboronate ester with much more difficulty. Triethylgermane and triphenylgermane add to dimethyl allylboronate[59] at the double bond of the allyl group linked to $B(OR)_2$ much more readily than to olefinic hydrocarbons and their derivatives having functional groups in the γ-position. The latter substances combine with triethylgermane only in the presence of H_2PtCl_4, while the addition of triethylgermane to the allylboronate ester takes place without catalyst at 110–190°C and leads to the formation of the dimethyl ester of 3-triethylgermylpropylboronic acid in a high yield.

Allylboronate esters are involved in diene condensation with cyclopentadiene and its chloro-derivatives[60]. Dimethyl allylboronate condenses with cyclopentadiene only at a high temperature, forming the ester of *endo*-2-{bicyclo[2,2,1]hept-5-en-1-yl}methylboronic acid (XVII):



(XVII)

The allylboronate ester condenses very readily with hexachlorocyclopentadiene forming the ester of 2-{1,4,5,6,7,7-hexachlorobicyclo[2,2,1]hept-5-en-1-yl]-methylboronic acid. The reaction of the allylboronate ester with 1,2,3,4-tetrachlorocyclopentadiene yields the ester of 2-{1,4,5,6-tetrachlorobicyclo[2,2,1]hept-5-en-1-yl}methylboronic acid.

Triallylborane, tricrotylborane, and tri-(2-methylallyl)borane react with ethyl diazoacetate, forming the esters of $\gamma\delta$-unsaturated acids (XVIII):[61]

$$(RCH{=}CR'CH_2)_3B + N_2CHOOC_2H_5 \xrightarrow[-N_2]{+H_2O} \underset{\text{(XVIII)}}{RCH{=}CR'(CH_2)_2COOC_2H_5};$$

R and R = H or CH_3.

According to some data[23], treatment of triallylborane with bromine at room temperature yields tri-(2,3-dibromopropyl)borane, while according to others[8] the product is 1,2,3-tribromopropane at –35°C. Reaction of di-n-butyl allylboronate with bromine yields the ester of 2,3-dibromopropylboronic acid[62]. In the presence of air, triallylborane forms a polymer containing 25–30% of oxygen[63]. Triallylborane is an active catalyst of the polymerisation of methyl methacrylate[63]. Thermal decomposition of triallylborane leads to the formation of various hydrocarbons and boron-containing products[64,65]. The reaction of triallylborane with tri-isobutylborane at 130–140°C yields butene and a polymer, which are converted on heating with alcohols into 1,5-dialkoxy-1,5-diboracyclo-octanes[66].

3. Reactions with Diborane and Tetra-alkyldiboranes

When triallylborane is treated with diborane (in proportions of 1 : 2) in ethereal solution, a solid polymer is obtained[67]. On being heated with n-butyl alcohol, it gives rise to hydrogen, propene, and liquid products, consisting mainly of 1,5-di-n-butoxy-1,5-diboracyclo-octane and the tetra-n-butyl ester of propane-1,3-diboronic acid. On heating with methyl borate, the solid polymer undergoes exchange reactions as a result of which the tetramethyl ester of propane-1,3-diboronic acid and the methyl ester of di-(3-dimethoxyborylpropyl)boronic acid are obtained[68–70]. When the polymer is heated with boron trichloride, 1,3-dichloroborylpropane is formed[71].

The reaction of triallylborane with triethylamine-borane leads to a polymer, whose pyrolysis gives rise to a complex mixture of products, where the main component is 1,5-diborabicyclo[3,3,3]undecane[72].

Hydroboration of dimethyl allylboronate and subsequent oxidation of the products lead to a mixture of diols containing 97% of propane-1,3-diol and 3% of propane-1,2-diol.[30] The main hydroboration product is tri-(3-dimethoxyborylpropyl)borane (XIX):

$$3\,CH_2{=}CHCH_2B(OCH_3)_2 + \frac{1}{2}B_2H_2 \rightarrow B[CH_2CH_2CH_2B(OCH_3)_2]_3.$$

(XIX)

On treatment with alcohol in the presence of a catalytic amount of a mercaptan, it is converted into the methyl ester of di-(3-dimethoxyborylpropyl)borinic acid and the dimethyl ester of n-propylboronic acid.

In the reaction of diborane with n-butyl diallylboronate, boron is attached to the extent of 97% to the terminal carbon atom of the allyl group[73]. The hydroboration of the ester with the reactants in proportions of 1 : 2 leads to a complex mixture of products whose treatment with n-butyl alcohol leads to the evolution of hydrogen and distillation of the alcoholysis products yields 1,5-di-n-butoxy-1,5-diboracyclo-octane and 1,3-dibutoxyborylpropane. The reaction of tetra-n-propyldiborane with dimethyl allylboronate results in the formation of the unstable dimethyl ester of 3-di-n-propylborylpropylboronic acid[74], which decomposes on heating into methyl di-n-propylboronate and a polymer. On heating with methyl borate in the presence of a small amount of tetrapropyldiborane, which plays the role of the reaction catalyst[75], the polymer is converted into 1,3-bis(dimethoxyboryl)propane. Allylboronate esters behave similarly in relation to tetra-alkylborane [...part of text missing in Russian original (Ed. of Translation)] dimethylester of allylthioboronic acid[74].

4. Reactions with Carbonyl Compounds and Nitriles

It has been reported[23,24] that triallylborane reacts with aldehydes to form the alkyl esters of diallylborinic acid and cyclohexadiene or dialkyl esters of alkylboronic acid, cyclohexadiene, and propene. Subsequently it was shown that the reaction of triallylborane with aldehydes in reality proceeds via the mechanism of organometallic synthesis, i.e. via the addition of allyl groups to the carbon atom and of the BR_2 group to the oxygen atom of the carbonyl group[76]. Depending on the ratio of the initial reactants, the esters of diallylborinic, allylboronic, or boric acids are then obtained. The reaction of triallylborane with ketones stops at the stage involving the formation of allylboronic acid even on heating to 80°C.[76]

Since allylboronate esters and borates are readily hydrolysed and readily undergo transesterification with aminoalcohols, the reaction of triallylborane with aldehydes and ketones can be used to synthesise unsaturated alcohols. The reaction of tricrotylborane with formaldehyde is accompanied by the allyl rearrangement[9]. Triallylborane adds smoothly to $\alpha\beta$-unsaturated aldehydes in the 1,2-positions[77,78]. The reaction of acrolein and triallylborane in 2 : 1 proportions yields the di(hexa-1,5-dien-3-yl)-ester of allylboronic acid[77,78]. The reaction of triallylborane with α-cyclocitral or β-cyclocitral (in proportions of 1 : 3) results in the formation of the corresponding borates, which demonstrates the ability of allylboronate esters to add to aldehydes.

The reactions of triallylborane with $\alpha\beta$-unsaturated ketones have also been investigated[77,79]. In contrast to tri-n-butylborane, which adds to methyl vinyl ketone in the 1,4-positions with formation of oct-2-en-2-yl dialkylborinate (XX):[77]

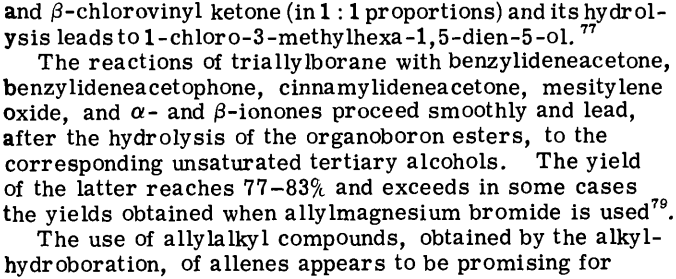
$$(n\text{-}C_4H_9)_3B + CH_2{=}CH\overset{\overset{\displaystyle O}{\|}}{C}CH_3 \rightarrow CH_3(CH_2)_4CH{=}\overset{\overset{\displaystyle OB(C_4H_9\text{-}n)_2}{|}}{C}CH_3,$$

(XX)

triallylborane adds to methyl vinyl ketone in the 1,2-positions with formation of the 3-methylhexa-1,5-dien-3-yl ester of diallylborinic acid, whose hydrolysis gives rise to 3-methylhexa-1,5-dien-3-ol. 1-Chloro-3-methylhexa-1,5-dien-3-yl diallylborinate is obtained from triallylborane and β-chlorovinyl ketone (in 1 : 1 proportions) and its hydrolysis leads to 1-chloro-3-methylhexa-1,5-dien-5-ol.[77]

The reactions of triallylborane with benzylideneacetone, benzylideneacetophone, cinnamylideneacetone, mesitylene oxide, and α- and β-ionones proceed smoothly and lead, after the hydrolysis of the organoboron esters, to the corresponding unsaturated tertiary alcohols. The yield of the latter reaches 77–83% and exceeds in some cases the yields obtained when allylmagnesium bromide is used[79].

The use of allylalkyl compounds, obtained by the alkylhydroboration, of allenes appears to be promising for organic synthesis. When these compounds interact with carbonyl derivatives, the products are the alkyl esters of dialkylborinic acids, whose hydrolysis yields unsaturated alcohols. Thus the esters (XXI) are formed from dialkyl-(3-methylbut-2-en-1-yl)boranes and mesityl oxide, their hydrolysis resulting in the formation of 3,3,4,6-tetramethylhepta-1,5-dien-4-ol (XXII):[17]



$$\begin{matrix}CH_3\\ & C{=}CHCH_2BR_2\\ CH_3\end{matrix} + (CH_3)_2C{=}CH\overset{\overset{\displaystyle O}{\|}}{C}CH_3 \xrightarrow[81\%]{} CH_2{=}CH{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle OBR_2}{|}}{C}}{-}CH{=}C(CH_3)_2 \xrightarrow[86\%]{-H_2O}$$

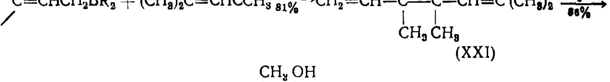
(XXI)

$$\rightarrow CH_2{=}CH{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle OH}{|}}{C}}{-}CH{=}C(CH_3)_2.$$

(XXII)

The reactions with acetone, methyl vinyl ketone, and benzaldehyde take place similarly.

Diallyl-(2-ethoxypenta-1,4-dien-1-yl)borane reacts with acetone to form compound (XXIII):[80]

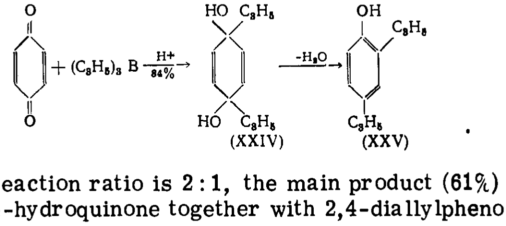


$$(C_3H_5)_2BCH{=}\overset{\overset{\displaystyle OC_2H_5}{|}}{C}{-}CH_2CH{=}CH_2 + 2(CH_3)_2CO \rightarrow CH_2{=}CHCH_2\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}OBCH{=}\overset{\overset{\displaystyle OC_2H_5}{|}}{C}CH_2CH{=}CH_2.$$

(XXIII)

Di-n-hexyl crotylboronate reacts with butyraldehyde and cyclohexanone, the products being the corresponding 1-methylallylmethanols[27].

The reactions of triallylborane with various quinones have been investigated[81-83]. When triallylborane is allowed to react with 1,4-benzoquinone in 1 : 1 proportions and the resulting organoboron compounds are hydrolysed, the *cis*- and *trans*-isomers of 1,4-diallyl-1,5-dihydroxycyclohexa-2,5-diene (XXIV) are obtained in high yield and are converted on steam distillation in the presence of boric acid into 2,4-diallylphenol (XXV):

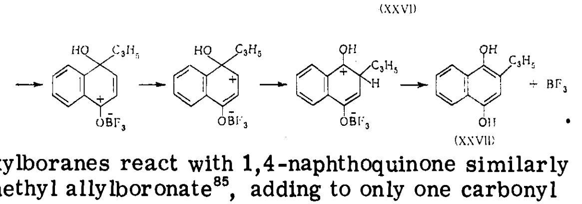


(XXIV) (XXV)

When the reaction ratio is 2 : 1, the main product (61%) is 2-allyl-1,4-hydroquinone together with 2,4-diallylphenol (26%).[83]

The reactions of triallylborane with substituted 1,4-benzoquinones have been investigated[82]. The interaction of equimolar amounts of 2-allyl-1,4-benzoquinone and triallylborane leads to the formation of 2,4,6-triallylphenol while the interaction of the reactants in proportions of 2 : 1 leads to the formation of insignificant amounts of 2,4,6-triallylphenol, the main reaction products being 2,5-diallyl- and 2,6-diallyl-1,4-hydroquinones. 2-Butyl-1,4-benzoquinone reacts with trialkylborane (in 1 : 1 proportions) with formation of 4,6-diallyl-2-butylphenol[83]. The reaction between 9,10-anthraquinone and triallylborane in equimolar proportions leads to 9-allyl-9-hydroxyanthrone and, when two equivalents of triallylborane are used, the main product is *cis*-9,10-diallyl-9,10-dihydroxy-9,10-dihydroanthracene with an admixture of the *trans*-isomer[83].

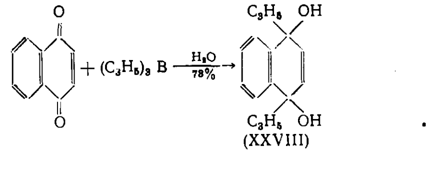
The esters of allylboronic and diallylborinic acids have proved to be extremely reactive in relation to quinones[82]. Dibutyl allylboronate gives a high yield of 2-allyl-1,4-hydroquinone on reaction with 1,4-benzoquinone. The mechanism of the formation of 2-allyl-1,4-hydroquinone was established in a study of the reaction between dimethyl allylboronate and 1,4-naphthoquinone. In this case it is possible to isolate the intermediate (when the reaction is carried out under mild conditions), namely 1-allyl-1-hydroxy-4-oxo-1,4-dihydronaphthalene (XXVI), which is converted into 2-allyl-1,4-dihydroxynaphthalene (XXVII) on heating with boron trifluoride-ether, as happens in the rearrangement of *p*-tolylquinol into 2-methyl-1,4-hydroquinone[84]:



(XXVI)

(XXVII)

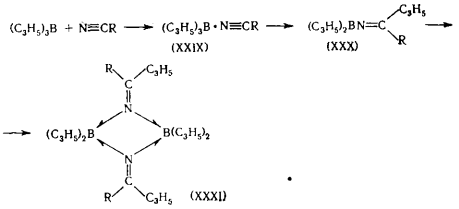
Trialkylboranes react with 1,4-naphthoquinone similarly to dimethyl allylboronate[85], adding to only one carbonyl group, while triallylborane adds readily to two carbonyl groups, forming, after hydrolysis, 1,4-diallyl-1,4-dihydroxy-1,4-dihydronaphthalene (XXVIII):[82]



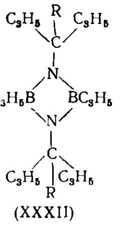
(XXVIII)

The reactions of triallylborane with 1,2-quinones have been investigated[83]. When equimolar amounts of 1,2-naphthoquinone and triallylborane interact, *trans*-1,2-diallyl-1,2-dihydroxy-1,2-dihydronaphthalene is formed after hydrolysis; the same diol is obtained also when 1,2-naphthoquinone is treated with dibutyl allylboronate. 9,10-Phenanthraquinone and acenaphthoquinone react similarly with triallylborane, forming respectively (after hydrolysis) 9,10-diallyl-9,10-dihydroxy-9,10-dihydrophenanthrene and 1,2-diallyl-1,2-dihydroxyacenaphthene (*trans*-configuration).

The first stage of the reaction of triallylborane with nitriles in isopentane between –70° and –50°C involves the formation of complexes (XXIX) which are completely converted, on gradual heating of the reaction mixture to room temperature, into substituted diallyl(but-3-enylidene-amino)boranes (XXX), which dimerise into derivatives of 2,2,4,4-tetra-allyl-1,3-di(but-3-enylidene)cyclodiborazane (XXXI):[86,87]



On heating (100°C), cyclodiborazanes are converted into substituted 2,4-diallyl-1,3-di(hepta-1,6-dien-4-yl)-1,3-diaza-2,4-diboretidines (XXXII), covalent B–N bonds being formed between boron and nitrogen atoms instead of the semicoordinate linkages B ← N, and N=C bonds being converted into single N–C linkages:



(XXXII)

Alcoholysis of diazadiboretidines yields 4-substituted 4-aminohepta-1,6-dienes.

5. Reactions with Compounds Containing an Activated Carbon–Carbon Double Bond

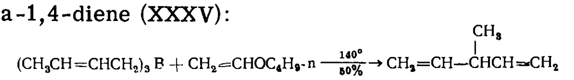
Allylboranes can react with compounds containing an activated double bond—vinyl ethers, 4,5-dihydro-2-methylfuran, and cyclopropene hydrocarbons.

Triallylborane reacts with n-butyl vinyl ether at 110–140°C to form penta-1,4-diene (80% yield)[88,89]. Presumably allylborane initially adds to the double bond with formation of (2-alkoxypent-4-en-1-yl)diallylborane (XXXIII), which is then converted via β-elimination into the diene (XXXIV) and n-butyl diallylboronate:

$$(C_3H_5)_3B + CH_2{=}CHOC_4H_9\text{-}n \rightarrow \underset{\text{(XXXIII)}}{(C_3H_5)_2BCH_2{-}\overset{\overset{\displaystyle OC_4H_9\text{-}n}{|}}{C}HCH_2CH{=}CH_2} \rightarrow$$

$$\rightarrow \underset{\text{(XXXIV)}}{CH_2{=}CHCH_2CH{=}CH_2} + (C_3H_5)_2BOC_4H_9\text{-}n \quad .$$

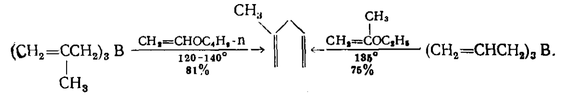
The ether (XXXIII) then reacts with a second molecule of vinyl ether via the same mechanism. The reaction of tricrotylborane with n-butyl vinyl ether yields 3-methylpenta-1,4-diene (XXXV):



$$(CH_3CH{=}CHCH_2)_3B + CH_2{=}CHOC_4H_9\text{-}n \xrightarrow[50\%]{140^\circ} \underset{\text{(XXXV)}}{CH_2{=}CH{-}\overset{\overset{\displaystyle CH_3}{|}}{C}HCH{=}CH_2} \quad .$$

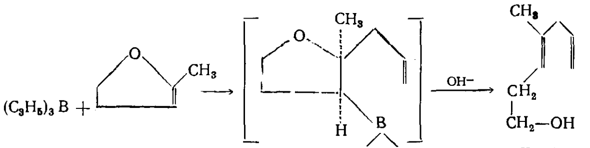
The formation of the diene (XXXV) shows that the addition of tricrotylborane to the carbon–carbon double bond proceeds with allyl rearrangement via a cyclic transition state.

2-Methylpenta-1,4-diene (XXXVI) is obtained from n-butyl vinyl ether and tri-(2-methylallyl)borane and also by the reaction of triallylborane with ethyl isopropenyl ether:



(XXXVI)

The reaction of triallylborane with 4,5-dihydro-2-methylfuran takes place slowly at room temperature and rapidly (in several minutes) at 80–100°C. Alkaline hydrolysis of the addition product leads to 4-methylhepta-1,4-dien-1-ol (XXXVII):

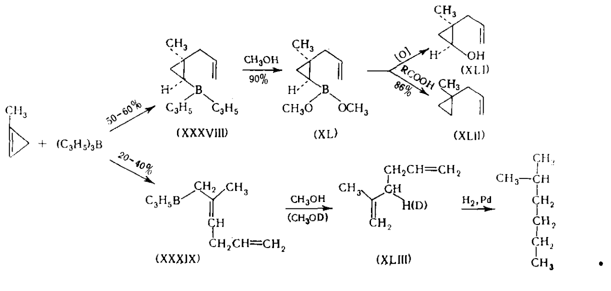


(XXXVII)

Thus reactions of allylboranes with acyclic and cyclic vinyl ethers constitute a convenient preparative method for the synthesis of 1,4-diene hydrocarbons and their derivatives with functional groups, which are otherwise difficult to obtain.

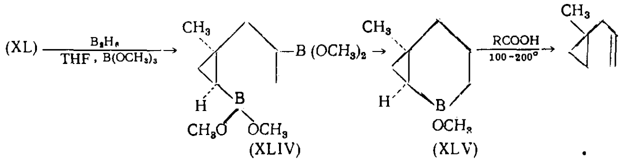
On cooling (to between –70° and 0°C), triallylborane reacts with 1-methylcyclopropene similarly to trialkylboranes[90], namely in two different ways. The preferred pathway involves the *cis*-addition of the organoborane to the double bond of the hydrocarbon with formation of diallyl-(1-allyl-1-methyl-2-cyclopropyl)borane (XXXVIII), but the reaction also takes place partly with rupture of the ring at the $C_{(2)}$–$C_{(3)}$ linkage with formation of diallyl-(2-methylhexa-2,5-dien-1-yl)borane (XXXIX). The methanolysis of compound (XXXVIII) gives rise to (1-allyl-1-methyl-2-cyclopropyl)dimethoxyborane (XL), the oxidation of which leads to 1-allyl-1-methyl-2-cyclopropanol (XLI) and acidolysis yields 1-allyl-1-methylcyclopropane (XLII).

Compound (XXXIX) has not been isolated in a pure state, but its formation has been demonstrated by the isolation of 2-methylhexa-1,5-diene (XLIII) from the products of the methanolysis of the reaction mass:

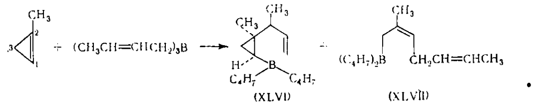


When 1-methyl-2-deuterocyclopropene is treated with triallylborane and the reaction products are subjected to methanolysis, 2-methyl-3-deuterohexa-1,5-diene (30–35%) and (1-allyl-2-deutero-1-methyl-2-cyclopropyl)dimethoxyborane (50–60%) are obtained.

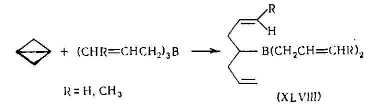
The hydroboration of compound (XL) in tetrahydrofuran (THF) in the presence of methyl borate leads to the diboron compound (XLIV), which is converted on heating (100–200°C) into 5-methoxy-5-methyl-5-borabicyclo[4,1,0]heptane [(5-methoxy-1-methyl-5-boranorcarane)] (XLV) with elimination of methyl borate[92]:



When 1-methylcyclopropene reacts with tricrotylborane, the main product (85–90%) is *cis*-[2-(but-3-en-2-yl)-2-methyl-1-cyclopropyl]di(but-2-enyl)borane (XLVI) together with di(but-2-enyl)-2-methylhepta-2,5-dien-1-ylborane (XLVII) (10–15%) yield); this shows that the addition of the allylborane to the double bond of the three-membered ring takes place with allyl rearrangement, while the insertion in a C–C single bond takes place without such rearrangement[93]:

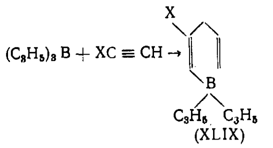


Triallylborane and tricrotylborane react at −70°C with bicyclo[1,1,0]butane to form the unsaturated compounds (XLVIII):[94]



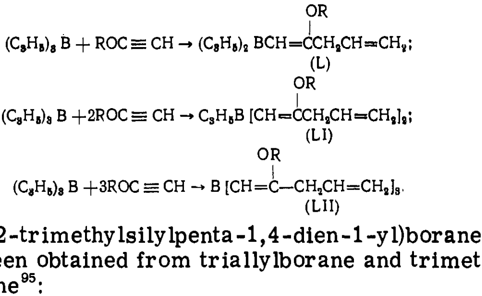
6. Reactions with Acetylenic Compounds

Acetylenic compounds react with triallylborane at room temperature to form 2-substituted diallyl-(2-penta-1,4-dien-1-yl)boranes (XLIX):



(2-Alkylpenta-1,4-dien-1-yl)diallylboranes (X = CH_3 or C_4H_9), obtained by the reaction of triallylborane with methylacetylene or n-butylacetylene[95-98], cannot be isolated in a pure state, since they are unstable and cyclise to 3-allyl-substituted 1,5-diallyl-1-boracyclohex-2-enes, the reaction being slow at room temperature and rapid on vacuum distillation[98].

2-Substituted diallyl(penta-1,4-dien-1-yl)boranes, formed in the first stage of the reaction of triallylborane with trimethylpropargyloxysilane[99], phenylacetylene[100], cyclohexenylacetylene[101], or propargyl chloride[102,103] are altogether unstable. However, alkoxyacetylenes react with triallylborane to form fairly stable addition products, which can be isolated in a pure state. The exothermic reaction of triallylborane with alkoxyacetylenes proceeds between −70° and −50°C and, depending on the reactant ratio, leads to (2-alkoxypenta-1,4-dien-1-yl)diallylboranes (L), di-(2-alkoxypenta-1,4-dien-1-yl)allylboranes (LI), or tri-(2-alkoxypenta-1,4-dien-1-yl)boranes (LII):[84,95]



$$(C_3H_5)_3B + ROC \equiv CH \rightarrow (C_3H_5)_2BCH{=}\overset{\overset{\displaystyle OR}{|}}{C}CH_2CH{=}CH_2; \quad \text{(L)}$$

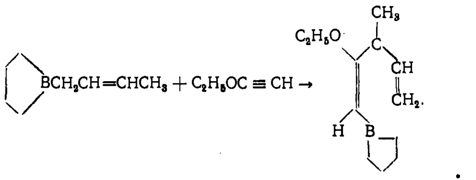
$$(C_3H_5)_3B + 2ROC \equiv CH \rightarrow C_3H_5B[CH{=}\overset{\overset{\displaystyle OR}{|}}{C}CH_2CH{=}CH_2]_2; \quad \text{(LI)}$$

$$(C_3H_5)_3B + 3ROC \equiv CH \rightarrow B[CH{=}\overset{\overset{\displaystyle OR}{|}}{C}{-}CH_2CH{=}CH_2]_3. \quad \text{(LII)}$$

Diallyl-(2-trimethylsilylpenta-1,4-dien-1-yl)borane (LIII) has been obtained from triallylborane and trimethylsilylacetylene[95]:

$$(C_3H_5)_3B + (CH_3)_3SiC \equiv CH \rightarrow (C_3H_5)_2BCH{=}\overset{\overset{\displaystyle Si(CH_3)_3}{|}}{C}CH_2CH{=}CH_2 \quad \text{(LIII)}$$

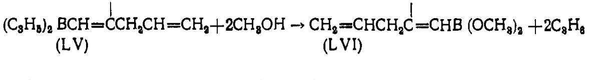
The first condensation stage, leading to compounds (XLIX), involves the *cis*-addition of $(C_3H_5)_2B$ and C_3H_5 fragments to the C≡C bond. The reaction probably proceeds via a six-centre transition state and is accompanied by the allyl rearrangement [as shown in a study of the reaction of 1-crotylboracyclopentane with ethoxyacetylene, which leads to the formation of 1-(2-ethoxy-3-methylpenta-1,4-dien-1-yl)boracyclopentane (LIV) [104,105]



(LIV)

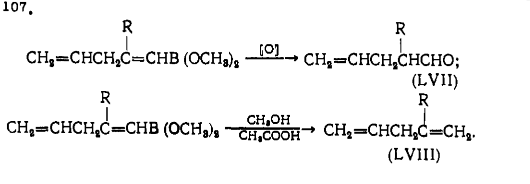
Tri-(2-methylallyl)borane reacts with alkoxyacetylenes like triallylborane. Depending on the reactant ratio, (2-alkoxy-4-methylpenta-1,4-dien-1-yl)di-(2-methylallyl)-boranes, di-(2-alkoxy-4-methylpenta-1,4-dien-1-yl)-2-methylallylboranes, or tri-(2-alkoxy-4-methylpenta-1,4-dien-1-yl)boranes are formed at temperatures between −70° and −20°C.[106]

On treatment with methanol, (2-alkylpenta-1,4-dien-1-yl)diallylboranes (LV) readily exchange their allyl groups for methoxy-groups[95-97,104]. The resulting dimethyl esters of 2-alkylpenta-1,4-dien-1-ylboronic acids (LVI),



$$\underset{\text{(LV)}}{(C_3H_5)_2BCH{=}\overset{\overset{\displaystyle R}{|}}{C}CH_2CH{=}CH_2} + 2CH_3OH \rightarrow \underset{\text{(LVI)}}{CH_2{=}CHCH_2\overset{\overset{\displaystyle R}{|}}{C}{=}CHB(OCH_3)_2} + 2C_3H_6$$

yield 2-alkylpent-4-enals (LVII) on oxidation with hydrogen peroxide and are converted into 2-alkylpenta-1,4-dienes (LVIII) on treatment with a mixture of methanol and acetic acid[96,97,107].

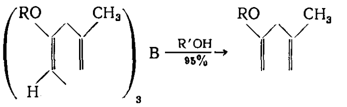


$$CH_2{=}CHCH_2\overset{\overset{\displaystyle R}{|}}{C}{=}CHB(OCH_3)_2 \xrightarrow{[O]} CH_2{=}CHCH_2\overset{\overset{\displaystyle R}{|}}{C}HCHO; \quad \text{(LVII)}$$

$$CH_2{=}CHCH_2\overset{\overset{\displaystyle R}{|}}{C}{=}CHB(OCH_3)_2 \xrightarrow[CH_3COOH]{CH_3OH} CH_2{=}CHCH_2\overset{\overset{\displaystyle R}{|}}{C}{=}CH_2. \quad \text{(LVIII)}$$

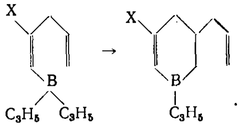
On treatment with alcohols, not only boron–allyl but also boron-vinyl bonds are ruptured in (2-alkoxypenta-1,4-dien-1-yl)diallylboranes and di-(2-alkoxypenta-1,4-dien-1-yl)allylboranes with formation, depending on the reactant ratio and the duration of heating, of 2-alkoxypenta-1,4-dienes or allyl methyl ketone ketals[104,107]. Tri-(2-alkoxypenta-1,4-dien-1-yl)boranes behave similarly with respect to alcohols.

Experiments on the alcoholysis of compounds (L)–(LII) by different alcohols have shown that the boron–vinyl bond dissociates via direct attack on the B–C linkage, which has been confirmed by studies on the reactions of tri-(2-methoxypenta-1,4-dien-1-yl)borane with methyl alcohol containing a labelled carbon atom[108]. The alcoholysis of tri-(2-alkoxy-4-methylpenta-1,4-dien-1-yl)-boranes (LIX) leads to 2-alkoxy-4-methylpenta-1,4-dienes (LX):[106]



(LIX) (LX) .

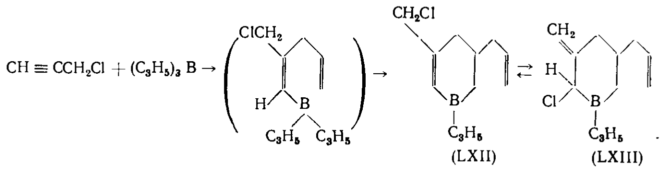
2-Substituted diallyl(penta-1,4-dien-1-yl)boranes (XLIX) can undergo intramolecular cyclisation to 3-substituted 1,5-diallyl-1-boracyclohex-2-enes (LXI):



(XLIX) (LXI) .

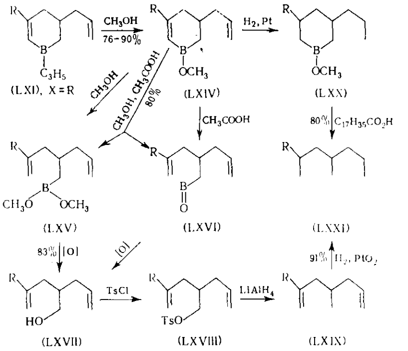
2-Alkyl-substituted compounds (XLIX, X = R) cyclise slowly at room temperature and rapidly on moderate heating (to 40–100°C).[96–98,109,110] 2-Alkoxy-substituted compounds (XLIX, X = OR) are converted into derivatives of type (LXI) at 120–130°C.[109,111] Compounds of type (LXI) are obtained by the reaction of triallylborane with trimethylpropargyloxysilane[99], phenylacetylene[100], and cyclohexylacetylene[101].

Propargyl chloride reacts slowly with triallylborane at room temperature, forming 1,5-diallyl-3-chloromethyl-1-boracyclohex-2-ene (LXII), which isomerises slowly to 1,5-diallyl-2-chloro-3-methylene-1-boracyclohexane (LXIII); after 20 days, the reaction mixture contains approximately 80% of compound (LXII) and 20% of compound (LXIII):[102,103]



(LXII) (LXIII) .

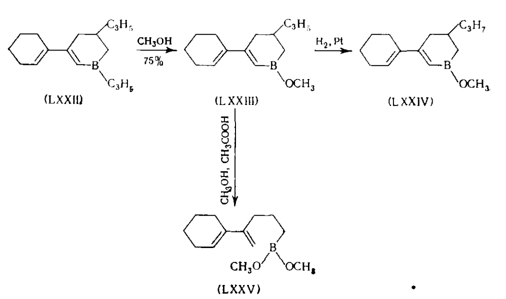
When 3-alkyl-1,5-diallyl-1-boracyclohex-2-enes (LXI) are treated with methanol at 20–30°C, propene is evolved and 3-alkyl-5-allyl-1-methoxy-1-boracyclohex-2-ene (LXIV) is formed[96,97,110]. When compound (LXIV) is refluxed for a long time with an excess of methanol, the B-vinyl bond is cleaved protolytically and (4-alkyl-2-allylpent-4-en-1-yl)dimethoxyborane (LXV) is formed. The ring opening in compound (LXIV) takes place much more rapidly when it is heated (to 80°C) with a mixture of methanol and acetic acid. Under these conditions, the products are the ester (LXV) and the trimer of the anhydride of (4-alkyl-2-allylpent-4-en-1-yl)boronic acid (LXVI) or the trimer (LXVI) alone when the reaction mixture is kept at room temperature for 24 h:



.

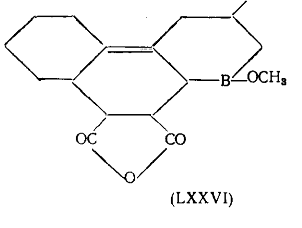
The oxidation of the esters (LXV) or the anhydrides (LXVI) with hydrogen peroxide in an alkaline medium gives an 80–90% yield of 4-alkyl-2-allylpent-4-en-1-ols (LXVII). By reducing the tosylates (LXVIII) with lithium aluminium hydride, it is possible to obtain 2,4-dimethylhepta-1,6-diene (LXIX, R = CH_3) or 2-n-butyl-4-methylhepta-1,6-diene (LXIX, R = n-C_4H_9). Hydrogenation of the methoxy-derivatives (LXIV) over platinum black leads to 3-alkyl-1-methoxy-5-n-propyl-1-boracyclohexenes (LXX). 1-Methoxy-3-methyl-5-n-propyl-1-boracyclohexane can be converted by acidolysis into 2,4-dimethylheptane (LXXI, R = CH_3). 5-Allyl-1-methoxy-3-phenyl-1-boracyclohex-2-ene, obtained by the methanolysis of 1,5-diallyl-3-phenyl-1-boracyclohex-2-ene, is hydrogenated in steps to 1-methoxy-3-phenyl-5-n-propyl-1-boracyclohex-2-ene (over platinum black) and 1-methoxy-3-phenyl-5-n-propyl-1-boracyclohexane (over $Pd/SrCO_3$).[100]

On treatment with methanol, 1,5-diallyl-3-cyclohexenyl-1-boracyclohex-2-ene (LXXII) is converted into 5-allyl-3-cyclohexenyl-1-methoxy-1-boracyclohex-2-ene (LXXIII), which gives rise to 3-cyclohexenyl-1-methoxy-5-n-propyl-1-boracyclohex-2-ene (LXXIV) on hydrogenation over Pt black and (2-allyl-4-cyclohexenylpent-4-en-1-yl)-dimethoxyborane (LXXV) on treatment with a mixture of methanol and acetic acid[101]:



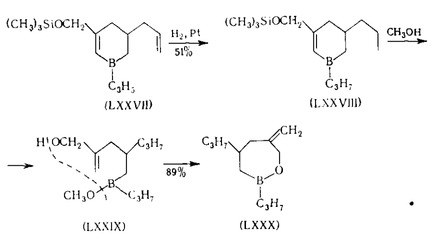
.

Compound (LXXIV) undergoes the diene condensation with maleic anhydride, forming the anhydride of 3-allyl-1-methoxy-1-boradodecahydrophenanthrenedicarboxylic acid (LXXVI):



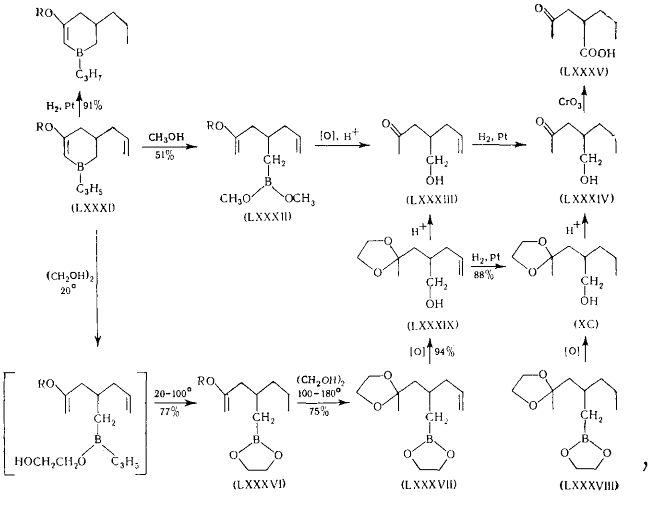
(LXXVI) .

1,5-Diallyl-3-trimethylsiloxymethyl-1-boracyclohex-2-ene (LXXVII) is hydrogenated over the Adams catalyst to 1,5-di-n-propyl-3-trimethylsiloxymethyl-1-boracyclohex-2-ene (LXXVIII), which is smoothly converted on brief heating with methanol [with cleavage of the Si–O– and B–C= bonds and subsequent intramolecular condensation of compound (LXXIX)] into 6-methylene-2,4-di-n-propyl-1-2-oxaborepan (LXXX):[99]



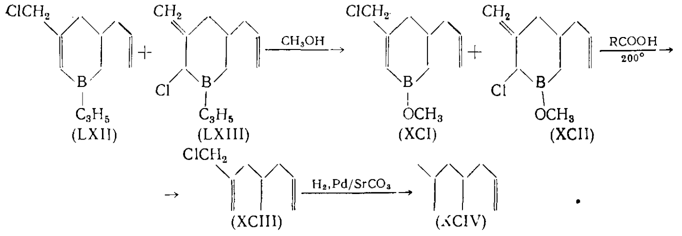
2,4-Dimethylheptane can be obtained from compound (LXXX) by a series of consecutive operations.

On treatment with alcohols, the boron–vinyl ring bond is initially broken in 3-alkoxy-1,5-diallyl-1-boracyclohex-2-ene (LXXXI), as shown by infrared spectroscopy, and the boron–allyl bond then undergoes alcoholysis in the resulting acyclic organoboron complex[111]. The final product of the reaction of compound (LXXXI) with methanol is (4-alkoxy-2-allylpent-4-en-1-yl)dimethoxyborane (LXXXII), from which it is possible to obtain 4-hydroxymethylhept-1-en-6-one (LXXXIII), 4-hydroxymethylheptan-6-one (LXXXIV), and 2-n-propyl-levulinic acid (LXXXV). When compound (LXXXI) is heated with ethylene glycol, the resulting product is 2-(4-alkoxy-2-allylpent-4-en-1-yl)-1,3,2-dioxaborolan (LXXXVI), which yields 2-(2-allyl-4,4-ethylenedioxy-1-pentyl)-1,3,2-dioxaborolan (LXXXVII) on further heating (100–180°C) with ethylene glycol. Catalytic hydrogenation and oxidation with hydrogen peroxide of the last product results in its conversion into 2-(4,4-ethylenedioxy-2-n-propyl-1-pentyl)-1,3,2-dioxaborolan (LXXXVIII), 2-allyl-4,4-ethylenedioxy-pentanol (LXXXIX), and 4,4-ethylenedioxy-2-n-propyl-1-pentanol (XC), from which it is possible to obtain compounds (LXXXIII)–(LXXXV):

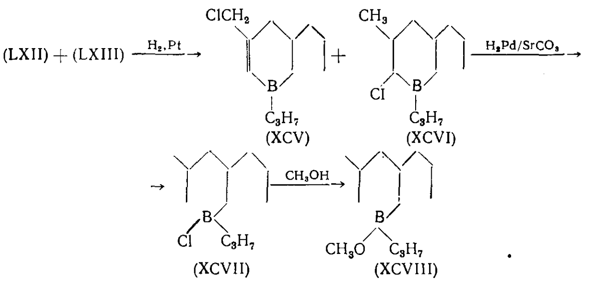


where R = CH_3 or n-C_4H_9.

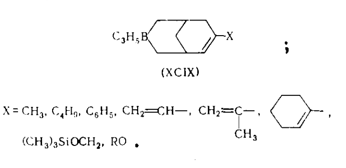
Methanolysis of a mixture of 1,5-diallyl-3-chloromethyl-1-boracyclohex-2-ene (LXII) and 1,5-diallyl-2-chloro-3-methylene-1-boracyclohexane (LXIII) in proportions of 4 : 1 results in a mixture of 5-allyl-3-chloromethyl-1-methoxy-1-boracyclohex-2-ene (XCI) and 5-allyl-1-methoxy-3-methylene-1-boracyclohexane (XCII), which are converted by acidolysis into 2-chloromethyl-4-methylhepta-1,6-diene (XCIII). The last compound is hydrogenated over Pd/$SrCO_3$ to 2,4-dimethylheptane (XCIV):[101]



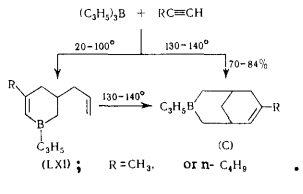
Hydrogenation of a mixture of compounds (LXII) and (LXIII) over platinum yields 3-chloromethyl-1,5-di-n-propyl-1-boracyclohex-2-ene (XCV) and 2-chloro-3-methyl-1-di-n-propyl-1-boracyclohexane (XCVI). On further hydrogenation over Pd/$SrCO_3$, compounds (XCV) and (XCVI) are converted into chloro-n-propyl-(4-methyl-2-n-propyl-1-pentyl)borane (XCVII), which is converted on treatment with methanol into the methyl ester of (4-methyl-2-n-propyl-1-pentyl)-n-propylboronic acid (XCVIII). Acidolysis of the chloride (XCVII) yields 2,4-dimethylheptane (XCIV):



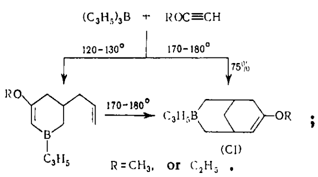
3-Substituted 1,5-diallyl-1-boracyclohex-2-enes (LXI) undergo intramolecular cyclisation on heating (130–180°C) with formation of 7-substituted 3-allyl-3-borabicyclo[3,3,1]non-6-enes (XCIX):



The reaction of triallylborane with acetylene (at 120–130°C) yields directly 3-allyl-3-borabicyclo[3,3,1]non-6-ene (XCIX, X = H).[112,113] The synthesis of 7-alkyl-3-allyl-3-borabicyclo[3,3,1]non-7-enes (C) requires a temperature of 130–140°C:[113,114]

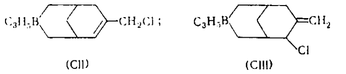


In order to obtain 7-alkoxy-3-allyl-3-borabicyclo[3,3,1]non-6-enes (CI), the reaction must be carried out at 170–180°C:[115]



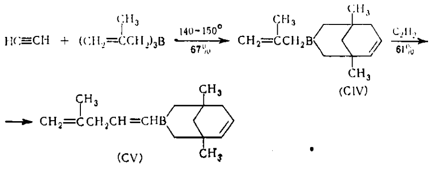
3-Allyl-7-trimethylsiloxymethyl-3-borabicyclo[3,3,1]non-6-ene is formed in 80% yield when triallylborane is heated with trimethylpropargyloxysilane at 140°C;[116] in order to synthesise 3-allyl-7-phenyl-3-borabicyclo[3,3,1]non-6-ene (in 96% yield), a mixture of triallylborane and phenylacetylene is kept for 1 h at 80°C:[100] 3-allyl-7-cyclohexenyl-3-borabicyclo[3,3,1]non-6-ene is formed when 1,5-diallyl-3-cyclohexenyl-1-boracyclohex-1-ene is vacuum-distilled[117].

When propargyl chloride is heated with triallylborane, a mixture of 3-allyl-7-chloromethyl-3-borabicyclo[3,3,1]non-6-ene (CII) and 3-allyl-6-chloro-7-methylene-3-borabicyclo[3,3,1]nonane (CIII) is formed in proportions of 7 : 3:[102,118]



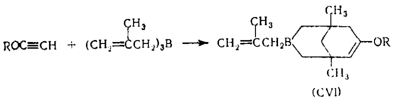
When triallylborane and propargyl bromide are heated, they form a mixture of 3-allyl-7-bromomethyl-3-borabicyclo[3,3,1]non-6-ene and 3-allyl-6-bromo-7-methylene-3-borabicyclo[3,3,1]nonane[119].

When tri-(2-methylallyl)borane is heated in acetylene in an autoclave at 140–150°C, 1,5-dimethyl-3-(2-methylallyl)-3-borabicyclo[3,3,1]non-6-ene (CIV) is formed in 67% yield; it can add to acetylene with formation of compound (CV):[120,121]

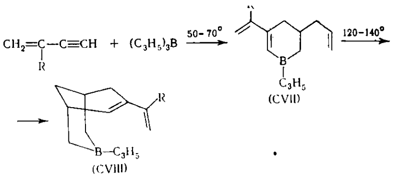


Tri-(2-methylallyl)borane reacts with n-butylacetylene to form 7-n-butyl-1,5-dimethyl-3-(2-methylallyl)-3-borabicyclo[3,3,1]non-6-ene[120].

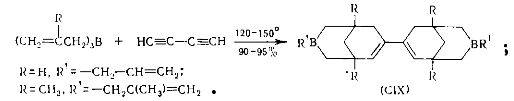
7-Alkoxy-1,5-dimethyl-3-(2-methylallyl)-3-borabicyclo[3,3,1]non-6-enes (CVI) have been obtained by the condensation of tri-(2-methylallyl)borane with alkoxyacetylenes[120,122]:



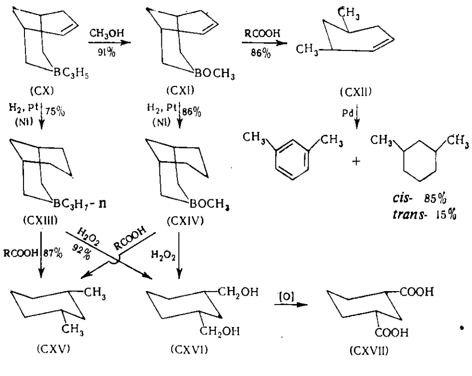
The interaction of triallylborane with vinylacetylene or isopropenylacetylene results in the formation of 1,5-diallyl-3-vinyl-1-boracyclohex-2-ene (CVII, R = H) or 1,5-diallyl-3-isopropenyl-1-boracyclohex-2-ene (CVII, R = CH_3) respectively, which are converted on heating into 3-allyl-7-vinyl-3-borabicyclo[3,3,1]non-6-ene (CVIII, R = H) or 3-allyl-7-isopropenyl-3-borabicyclo[3,3,1]non-6-ene (CVIII, R = CH_3):[123-125]



The reaction of diacetylene with triallylborane or tri-(2-methylallyl)borane at 120–150°C leads to the dibora-compounds (CIX) with a system of conjugated double bonds[126]:

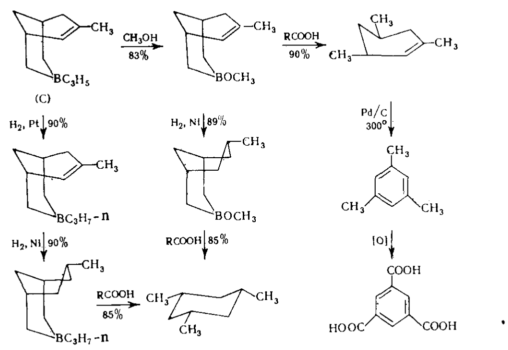


The methanolysis of 3-allyl-3-borabicyclo[3,3,1]non-6-ene (CX) leads to 3-methoxy-3-borabicyclo[3,3,1]non-6-ene (CXI),[113] which is converted into *cis*-3,5-dimethylcyclohexene (CXII) on heating with caproic acid as a result of the cleavage of the B–C bonds. When the THF solution of compound (CXII) is heated with palladium black, a mixture of *m*-xylene and *cis*- and *trans*-1,3-dimethylcyclohexanes is formed. The double bonds in the bicyclic compounds (CX) and (CXI) are readily hydrogenated at 20°C over a platinum catalyst at atmospheric pressure or over Raney nickel in an autoclave, the products being 3-n-propyl-3-borabicyclo[3,3,1]nonane (CXIII) or 3-methoxy-3-borabicyclo[3,3,1]nonane (CXIV) respectively, probably having the chair–chair conformation like bicyclo[3,3,1]nonane. The acidolysis of compounds (CXIII) and (CXIV) leads to *cis*-1,3-dimethylcyclohexane (CXV) with only about 1% of unidentified impurities. The oxidation of compounds (CXIII) and (CXIV) with hydrogen peroxide in an alkaline medium results in the formation of *cis*-1,3-dihydroxymethylcyclohexane (CXVI), which is converted on further oxidation into *cis*-cyclohexane-1,3-dicarboxylic acid (CXVII):



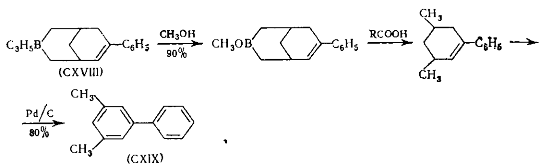
When compound (CX) is heated with n-butylamine, it is converted into 3-n-butylamino-3-borabicyclo[3,3,1]non-6-ene which can be obtained also by the transamination of 3-amino-3-borabicyclo[3,3,1]non-6-ene. The last compound can be obtained by the action of ammonia on 3-n-butylthio-3-borabicyclo[3,3,1]non-6-ene, formed by the reaction of thioborate and 3-methoxy-3-borabicyclo[3,3,1]non-6-ene[127]. The synthesis of 3-alkylthio- and 3-amino-3-borabicyclo[3,3,1]nonanes has been achieved similarly[127].

3-Allyl-7-methyl-3-borabicyclo[3,3,1]non-6-ene (C, R =CH_3) has been subjected to the following reactions[112]:

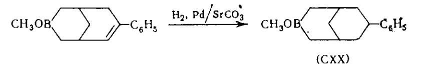


Similar reactions have been achieved with 3-allyl-7-n-butyl-3-borabicyclo[3,3,1]non-6-ene[114].

The structure of 3-allyl-7-phenyl-3-borabicyclo-[3,3,1]non-6-ene (CXVIII) has been demonstrated by converting it into 3,5-dimethylbiphenyl (CXIX):[100]

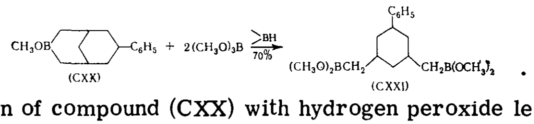


In contrast to 3-methoxy-7-methyl-3-borabicyclo-[3,3,1]non-6-ene, compound (CXVIII) is not hydrogenated in an autoclave over Raney nickel but it can be readily hydrogenated with hydrogen in 7-methoxy-7-phenyl-3-bora-bicyclo[3,3,1]nonane (CXX) in the presence of Pd/$SrCO_3$ at room temperature[100]:

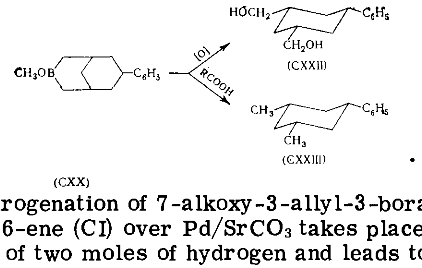


(CXX)

When compound (CXX) is heated with methylborate for a long time in the presence of tetra-n-propyldiborane, the boron-containing ring is cleaved and 1,3-bis(dimethoxy-borylmethyl)-5-phenylcyclohexane (CXXI) is formed:

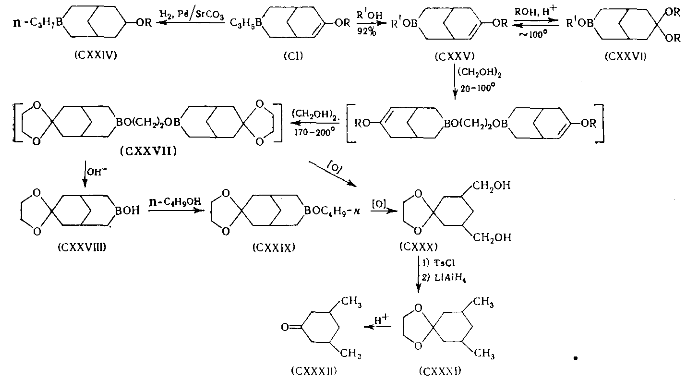


Oxidation of compound (CXX) with hydrogen peroxide leads to the synthesis of 1,3-dihydroxymethyl-5-phenylcyclo-hexane (CXXII) and, when the latter is heated with stearic acid, it is possible to obtain *cis*-1,3-dimethyl-5-phenyl-cyclohexane (CXXIII):

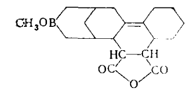


(CXX)

The hydrogenation of 7-alkoxy-3-allyl-3-borabicyclo-[3,3,1]non-6-ene (CI) over Pd/$SrCO_3$ takes place with absorption of two moles of hydrogen and leads to 7-alkoxy-3-n-propyl-3-borabicyclo[3,3,1]nonane (CXXIV).[115] The dialkoxy-derivatives (CXXV) are formed with liberation of propene when compounds (CI) are treated with alcohols. In the presence of acids, the alkoxy-derivative (CXXV), containing the vinyl ether group, readily combines with alcohols to form ketals (CXXVI), which are, however, unstable and split off the alcohol on vacuum distillation (at about 100°C) with reformation of the initial bicyclic compound. Cyclic diboraketals (CXXVII) can be obtained by heating the bicyclic compounds (CI) or (CXXV) with ethylene glycol. The bicyclic acid (CXXVIII) can be obtained by the alkaline hydrolysis of the ethylene ketal (CXXVII) and can be converted by esterification with n-butyl alcohol into 3-n-butoxy-7,7-ethylenedioxy-3-bora-bicyclo[3,3,1]nonane (CXXIX). The oxidation of the cyclic ketal (CXXIX) or the diketal (CXXVII) with hydrogen peroxide in an alkaline medium led to 1,1-ethylenedioxy-*cis*-3,5-dihydroxymethylcyclohexane (CXXX), the reduction of the di-*p*-tosylate of which with lithium aluminium hydride led to the synthesis of 1,1-ethylenedioxy-*cis*-3,5-dimethylcyclohexane (CXXXI). Under the influence of dilute acid, the last compound was converted into *cis*-3,5-dimethylcyclohexanone (CXXXII):

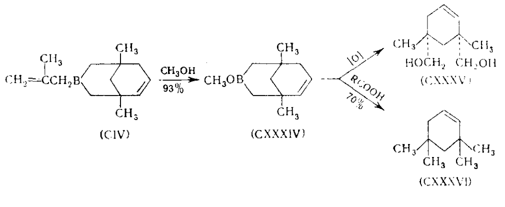


7-Cyclohexenyl-3-methoxy-3-borabicyclo[3,3,1]non-6-ene undergoes the diene condensation with maleic anhydride, forming compound (CXXXIII):[117]

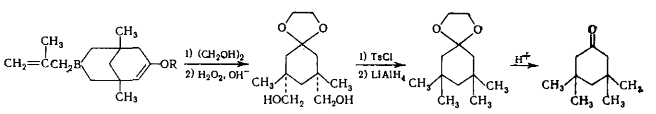


(CXXXIII)

The methanolysis of 1,5-dimethyl-3-(2-methylallyl)-3-borabicyclo[3,3,1]non-6-ene (CIV) leads to 3-methoxy-1,5-dimethyl-3-borabicyclo[3,3,1]non-6-ene (CXXXIV), the oxidation of which with hydrogen peroxide affords *cis*-3,5-di(hydroxymethyl)-3,5-dimethylcyclohex-1-ene (CXXXV) and its acidolysis gives rise to 3,3,5,5-tetra-methylcyclohexene (CXXVI):[120]

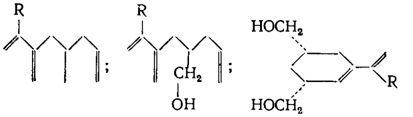


On treatment with ethylene glycol followed by oxidation with hydrogen peroxide in an alkaline medium, 7-alkoxy-1,5-dimethyl-3-(2-methylallyl)-3-borabicyclo[3,3,1]non-6-ene (CVI) can be converted into 1,1-ethylenedioxy-*cis*-3,5-di(hydroxymethyl)-1,3-dimethylcyclohexane (CXXXVII), the reduction of the tosylate of which with lithium aluminium hydride yields 1,1-ethylenedioxy-3,3,5,5-tetramethylcyclohexane (CXXXVIII). The hydrolysis of the last compound results in the formation of 3,3,5,5-tetramethylcyclohexanone (CXXXIX):[120]



(CVI) (CXXXVII) (CXXXVIII) (CXXXIX)

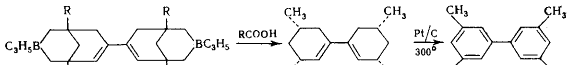
Compounds (CVII) are converted by acidolysis or combined acidolysis and oxidation into the triene hydrocarbons (CXL) or the triene alcohols (CXLI). Oxidation of compounds (CVIII) yields *cis*-di(hydroxymethyl)vinylcyclohexenes (CXLII):[123–125]



(CXL) (CXLI) (CXLII)

R=H,CH_3

Compound (CXLIII) and 3,3′,5′,5′-tetramethylbiphenyl (CXLIV) can be obtained from compound (CIX, R = H) by a series of consecutive chemical reactions[126]:



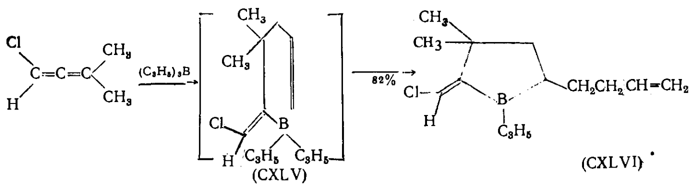
(CIX), R=H (CXLIII) (CXLIV)

Thus a stereospecific method for the synthesis of cyclohexene and cyclohexane derivatives has been developed on the basis of the allylborane–acetylene condensation.

7. Reactions with Allenes

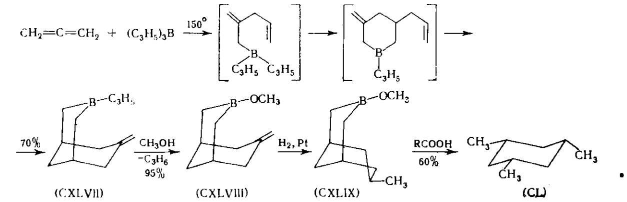
Like acetylenes, allenes can react with allylboranes, forming cyclic compounds, the ease of the reactions and their direction depending on the nature of the allene component.

The reactions of allylboranes with 1-chloro-3-methylbuta-1,2-diene, allene, and 3-methylbuta-1,2-diene have been investigated. It has been found that 1-chloro-3-methylbuta-1,2-diene reacts slowly with triallylborane even at room temperature, forming 1-allyl-2-(but-3-en-1-yl)-5-chloromethylene-4,4-dimethylboracyclopentane (CXLVI).[128,129] By analogy with the allylborane–acetylene condensation, the first reaction stage evidently consists of the addition of triallylborane to the allene system, the diallylboryl group adding to the central carbon atom and the allyl group to the terminal carbon atom joined to two methyl groups. The resulting diallyl-(1-chloromethylene-2,2-dimethylpent-4-en-1-yl)borane (CXLV) undergoes intramolecular cyclisation at room temperature, but the mode of cyclisation is in this case different from that of the pentadienyl derivatives of boron of type (LXIX), i.e. the allyl group adds to the terminal carbon atom of the pentene system and the boron atom adds to a non-terminal atom:



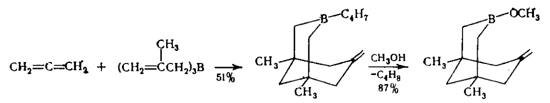
(CXLV) (CXLVI)

Allene, which has less polarised bonds, is more inert with respect to allylboranes than 1-chloro-3-methylbuta-1,2-diene. It reacts slowly with triallylborane on heating (at 150°C) in an autoclave, giving a 60% yield of 3-allyl-7-methylene-3-borabicyclo[3,3,1]nonane (CXLVII), the structure of which has been established by infrared spectroscopy and NMR and also by conversion into known compounds[129–131]. On treatment with methanol, compound (CXLVII) is smoothly converted into 3-methoxy-7-methylene-3-borabicyclo[3,3,1]nonane (CXLVIII), the catalytic hydrogenation of which yields 3-methoxy-7-methyl-3-borabicyclo[3,3,1]nonane (CXLIX). The last compound, which had been obtained previously from methylacetylene and triallylborane[113], is converted on acidolysis into the known *cis*-1,3,5-trimethylcyclohexane (CL):



(CXLVII) (CXLVIII) (CXLIX) (CL)

The reaction of allene with tri-(2-methylallyl)borane proceeds similarly but under more severe conditions[129,131]. When an equimolar mixture of the reactants is heated in an autoclave at 160–170°C, the product is 1,5-dimethyl-7-methylene-3-(2-methylprop-2-en-1-yl)-3-borabicyclo-[3,3,1]nonane (CLI):

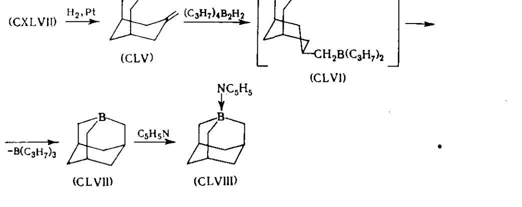


(CLI) (CLII)

8. The Synthesis of 1-Bora-adamantane Derivatives

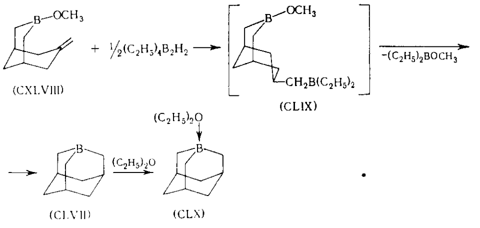
Derivatives of 3-borabicyclo[3,3,1]nonane with a methylene group in the 7-position, obtained by the condensation of allylboranes with allenes, have been used to synthesise 1-bora-adamantanes. Different versions of this synthesis are based on the hydroboration of the 7-methylene group and subsequent intramolecular cyclisation of the resulting dibora-compounds, which had been found previously in a series of acyclic dibora-[132,133],and tri-bora-systems[70].

In the first version, 3-allyl-7-methylene-3-borabicyclo-[3,3,1]nonane (CXLVII) was partly hydrogenated with hydrogen over platinum black to give 7-methylene-3-n-propyl-3-borabicyclo[3,3,1]nonane (CLV), which was then hydroborated by tetra-n-propyldiborane to 3-n-propyl-7-di-n-propylborylmethyl-3-borabicyclo[3,3,1]nonane (CLVI), the latter cyclising to 1-boratricyclo[3,3,1,$1^{3,7}$]-decane (1-bora-adamantane) (CLVII) with elimination of 3-n-propylborane. The bora-adamantane forms a stable adduct [CLVIII] with pyridine[129,131,134,135]:



(CLV) (CLVI) (CLVII) (CLVIII)

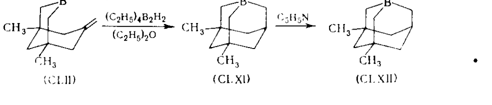
1-Bora-adamantane can be obtained more conveniently by the hydroboration of 3-methoxy-7-methylene-3-borabicyclo[3,3,1]nonane (CXLVIII), since the latter compounds can be synthesised more simply than compound (CLV). Diborane in an ethereal medium or a tetra-alkyldiborane may be used as the hydroborating agent. When compound (CXLVIII) is treated with tetraethyldiborane, the product is 7-diethylborylethyl-3-methoxy-3-borabicyclo[3,3,1]nonane (CLIX), which is converted with elimination of methyl diethylborinate into 1-bora-adamantane and the latter can be isolated by distillation or in the form of the ether adduct (CLX) or the pyridine adduct (CLVIII):



In the hydroboration of compound (CXLVIII) with diborane in an ethereal medium, the ether adduct (CLX) formed can be isolated (after the vacuum distillation of the solvent and methyl borate, which is also produced in the reaction) in the form of a colourless viscous liquid. If compound (CXLVIII) is hydroborated with diborane in THF solution, the product is the tetrahydrofuran complex of 1-bora-adamantane in 72% yield.

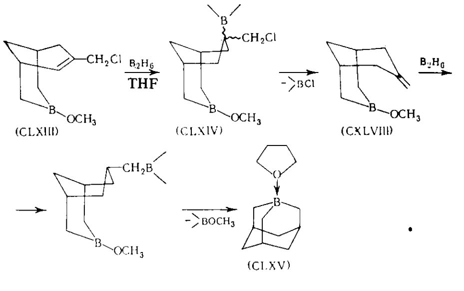
The ether complex of 1-bora-adamantane is comparatively stable, but it partly dissociates into the components even at room temperature. The ether adduct (CLX) has been used to synthesise complexes with other ligands having a more marked electron-donating capacity by simple mixing of the reactants in an inert solvent[129,135]. The thermally stable complex of 1-bora-adamantane with THF and very stable complexes with pyridine and triethylamine, which do not dissociate even at 200°C, have been obtained in this way. A complex of 1-bora-adamantane with ethyl acetate has been synthesised by the interaction of these reactants.

3-Methoxy-1,5-dimethyl-7-methylene-3-borabicyclo-[3,3,1]nonane (CLII) is smoothly converted on treatment with tetraethyldiborane in an ethereal medium into the ether adduct of 3,5-dimethyl-1-bora-adamantane (CLXI). Treatment of compound (CLXI) with pyridine yields the pyridine adduct (CLXII):[129,131]

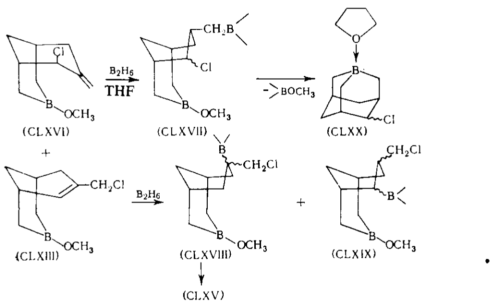


The method of synthesis of the 1-bora-adamantane system described here has been used to obtain 1-bora-adamantane derivatives with functional groups from compounds formed in the allylborane–acetylene condensation.

On treatment with diborane in THF, 7-chloromethyl-3-methoxy-3-borabicyclo[3,3,1]non-6-ene (CLXIII) combines with boron to the extent of 27% in the β-position relative to the CH_2Cl group, forming the borane (CLXIV). The latter eliminates compound (CXLVIII), which is converted as a result of hydroboration and cyclisation into the tetrahydrofuran complex of 1-bora-adamantane (CLXV):[136]



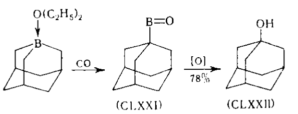
When a 4:1 mixture of compound (CLXIII) and 6-chloro-3-methoxy-7-methylene-3-borabicyclo[3,3,1]nonane (CLXVI) is treated with a tetra-alkyldiborane, a mixture of boranes (CLXVII)–(CLXIX) is formed. The borane (CLXVII) cyclises to 4-chloro-1-bora-adamantane, which can be isolated from the reaction mixture as the adduct (CLXX) with THF. The borane (CLXVIII) is converted by a series of stages into the tetrahydrofuran complex of 1-bora-adamantane (CLXV), which can be isolated from the reaction mixture by vacuum distillation[136]:



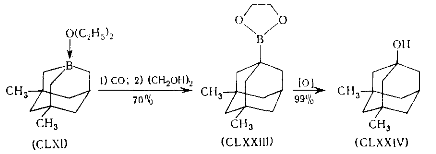
1-Bora-adamantane is a unique compound in which the boron atom is in a tetrahedral state and not in a trigonal valence state as in all the tervalent boron compounds known hitherto. This feature of 1-bora-adamantane is reflected in its chemical properties, in particular in its enhanced tendency towards complex formation. 1-Bora-adamantane forms very stable coordination compounds with pyridine and trimethylamine, which do not dissociate even at 200°C. It also forms complexes with ethyl ether and ethyl acetate, a ^{11}B NMR study of the stability of which made it possible to estimate experimentally the energy of the rearrangement of trialkylborane in its transition during complex formation from the planar to the pyramidal configuration; it proved to be 6–10 kcal mole^{-1}.[129]

9. Synthesis of Adamantanes

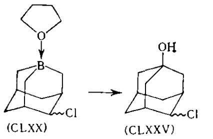
Hillman's studies[137-139] have shown that trialkylboranes are converted into trialkylmethanols on treatment with carbon monoxide and subsequent oxidation of the carbonylation products, 1-Bora-adamantanes undergo similar reactions. The ether adduct of 1-bora-adamantane reacts at room temperature with carbon monoxide, forming the anhydride of 1-adamantylboronic acid (CLXXI). The oxidation of the anhydride of the acid or its ester by an alkaline solution of hydrogen peroxide leads to 1-hydroxyadamantane (CLXXII):[129,131]



The carbonylation of the ether adduct (CLXI) to the anhydride of 3,5-dimethyl-1-adamantylboronic acid proceeds just as smoothly; the oxidation of its ethylene glycol ester (CLXXIII) gives an almost quantitative yield of 1-hydroxy-3,5-dimethyladamantane (CLXXIV):[129,131]



The tetrahydrofuran complex of 4-chloroboraadamantane (CLXX) is converted by carbonylation with carbon monoxide into 4-chloro-1-hydroxyadamantane (CLXXV):[136]



The study of the reactions of allylboranes with acetylenes and allenes has led to the discovery of new methods of synthesising adamantane derivatives, which may be of practical value, since many compounds of the adamantane series possess physiological activity. Compounds with antiviral, antitumour[140], soporific[141], antimalarial[142], insecticidal[143], antidiabetic[144], antibacterial[145], neurotropic[146], curaremimetic[147,148], and other activities have been found in this series.

New Data on Reactions of Organofluorine Compounds

I.L.Knunyants and V.R.Polishchuk

The review surveys data obtained in recent years for chemical reactions of organofluorine compounds. Data for new reactions of these compounds are considered in combination with new concepts concerning the mechanisms of processes known previously separated ionic and radical reactions.
The bibliography includes 280 references.

CONTENTS

Methods for the introduction of fluorine into organic molecules as well as data obtained by physical methods for organofluorine compounds have been considered in an earlier review[1]. The present review surveys the available information about their chemical reactions.

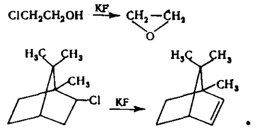
I. ANIONOID REACTIONS

Reactions of this type are most common in the chemistry of organofluorine compounds. A number of reviews have been devoted to their detailed discussion[2-6].

1. Fluorocarbanions Generated with the Aid of Fluoride Ions

The fluoride ion plays an exceptionally important role in the chemistry of organofluorine compounds. Historically the first compound containing the C–F bond (benzoyl fluoride) was obtained by Borodin in 1862 by treating benzoyl chloride with potassium hydrogen fluoride[7].

The high basicity of potassium fluoride, which was already known to Berzelius (quoted after Borodin[7]), began to be used from 1947, when the dehydrochlorination of β-chloroethanol and bornyl chloride was achieved[8]:



Subsequent studies showed that anhydrous salts of hydrofluoric acid are very strong bases. Thus tetraethylammonium fluoride splits off HCl from β-phenylethyl chloride 800 times faster than sodium ethoxide[9]. Strong CH acids (nitro-compounds with pK_a < 7) form salts upon reaction with alkali metal fluorides in an alcoholic medium[10]. On the other hand, in an aprotic medium, the anion is generated even from a CH acid with pK_a = 25 (acetonitrile[11]). Triphenylmethane (pK_a = 28.8) virtually does not form an anion[12].

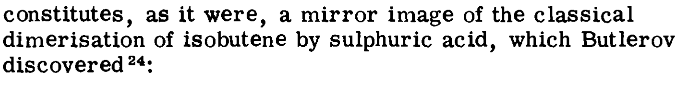
The extremely high energy of the hydrogen bonds formed by the fluoride ion is the cause of certain experimental difficulties associated with the use of thermally unstable tetra-alkylammonium fluorides, from which it is impossible to eliminate completely the water of crystallisation (two H_2O molecules remain[12,13]).

The highest degree of charge delocalisation is acheved when F^- is incorporated in an octahedral cage containing 4 or 6 water molecules. The hydration energies calculated by the CNDO method (128 and 117 kcal mole^{-1} respectively) agree well with the experimental value of 120 kcal mole^{-1}.[14] The high energy of the H–F hydrogen bond is also the cause of acid catalysis in the hydrolysis of, for example, benzyl fluoride[15] (the mechanisms of fluorine-substitution reactions have been reviewed[16]). In the absence of solvation (in the gas phase), the nucleophilic properties of F^- (determined from the kinetics of its reaction with CH_3Cl) are close to those of OH^- and NH_2^- (determined mass-spectrometrically[17]).

Alkali metal fluorides form compounds with hydrogen peroxide[18] just as readily as with water and, like alkalis, with carbon dioxide[19] ($F_2CO_2^{2-}$ is analogous to CO_3^{2-}) and isocyanates[20]:

$$FSO_2NCO + MF \rightarrow FSO_2\bar{N}CO F\overset{+}{M};$$
$$M = Na,\ K,\ Cs.$$

The ability of the fluoride ion to add to the electrophilic double bonds of fluorine-containing olefins[21] and carbonyl compounds[22] is extremely important for organofluorine chemistry. The anions formed are capable of a series of transformations analogous to those of carbonium ions in the chemistry of hydrocarbons. Thus the dimerisation of octafluoroisobutene under the influence of caesium fluoride[23],



$$(CF_3)_2C{=}CF_2 \xrightarrow[(C_2H_5)_2O]{CsF} [(CF_3)_3\bar{C}] \xrightarrow{(CF_3)_2C=CF_2} \rightarrow (CF_3)_3C{-}CF{=}C(CF_3)_2 + (CF_3)_3C{-}CF_2{-}\underset{\displaystyle CF_3}{\underset{|}{C}}{=}CF_2\ ,$$

constitutes, as it were, a mirror image of the classical dimerisation of isobutene by sulphuric acid, which Butlerov discovered[24]:

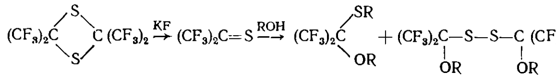
$$(CH_3)_2C{=}CH_2 \xrightarrow{H_2SO_4} [(CH_3)_3\overset{+}{C}] \xrightarrow{(CH_3)_2C=CH_2} \rightarrow (CH_3)_3C{-}CH{=}C(CH_3)_2 + (CH_3)_3C{-}CH_2{-}\underset{\displaystyle CH_3}{\underset{|}{C}}{=}CH_2\ .$$

This example clearly illustrates the role of the fluoride ion as "the proton of organofluorine chemistry". Oligomerisation catalysed by the fluoride ion is also characteristic of other polyfluorinated olefins or carbonyl compounds. It has been shown for hexafluoropropene that this reaction is reversible (when the trimer C_3F_6 is heated with CsF, it is partly converted into the dimer and the monomer[25]). The reversibility of the dimerisation of trifluoroacetyl fluoride is much more marked: in the presence of KF, its dimer ("perfluoroethyl perfluoroacetate") decomposes at −78°C [26]:

$$CF_3C(=O){-}OC_2F_5 \xrightarrow[-78°]{KF} 2\,CF_3CF{=}O \quad .$$

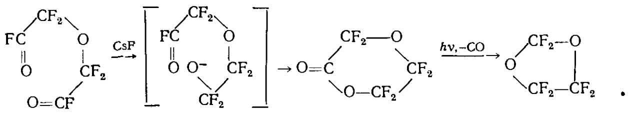
In the absence of fluorine atoms in the *gem*-position relative to the oxygen atom, fully fluorinated esters, for example dodecafluoro-t-butyl acetate, are resistant to the action of CsF even on heating[27].

The dimers of fully fluorinated thioketones also dissociate in the presence of fluoride ions, which makes it possible to generate their monomeric form directly in the reaction medium[28]:



R=CH_3, C_2H_5, C_3H_7.

In contrast to fluoro-olefins, the oligomerisation of which usually stops at the stage involving the formation of trimers or tetramers, hexafluorobut-2-yne forms a polymer on treatment with KF under analogous conditions[29]. An elegant application of "internal dimerisation" in combination with ultraviolet irradiation made it possible to synthesise hexafluoro-1,3-dioxacylopentane[30]:



Not only carbonyl compounds, but also fluoro-oxirans, which rearrange under the influence of the fluoride ion into acyl fluorides, can serve as sources of "perfluoroalkoxides" [31]:

$$\underset{\diagdown O \diagup}{CF_2{-}CF_2} \xrightarrow{KF} [CF_3CF_2O^-] \rightarrow CF_3CF{=}O.$$

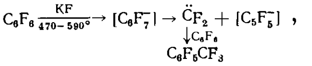
The method of synthesising hexafluoromethyloxiran is based on this reaction:

$$\underset{\diagdown O \diagup}{CF_3CF{-}CF_2} \xrightarrow{KF} [CF_3CF_3CF_2O^\cdot] \xrightarrow{(n-1)\ C_3F_6O} CF_3CF_2CF_2O\,(\underset{CF_3}{CF}{-}CF_2O)_n\underset{CF_3}{CF}COF\ ;$$

n=0—35.

Oligomers in which the terminal acyl fluoride group is replaced by another more inert group are used as lubricating materials and hydraulic liquids[32].

Unusual reactions occur when hexafluorobenzene is treated with potassium fluoride under severe conditions. Together with the formation of fully fluorinated toluene and xylenes, which evidently occurs with participation of difluorocarbene[33],



$$C_6F_6 \xrightarrow[470-590°]{KF} [C_6F_7^-] \rightarrow \underset{\substack{\downarrow C_6F_6 \\ C_6F_5CF_3}}{\ddot{C}F_2} + [C_5F_5^-]\ ,$$

decafluoromethylcyclopentene is also formed in this reaction[34].

The oligomerisation of a fluoro-olefin or a carbonyl compound can be suppressed when the anion is generated in the presence of electrophilic agents capable of reacting with it†. Thus, when octafluoroisobutene is treated with caesium fluoride in the presence of CH_3I, alkylation and not the dimerisation of the olefin takes place[35]:

$$(CF_3)_2C{=}CF_2 + CsF + CH_3I \rightarrow (CF_3)_3C{-}CH_3.$$

In the presence of acrylic acid derivatives, products resulting from the formal addition of $(CF_3)_3CH$ to them are formed after treatment with water[35]:

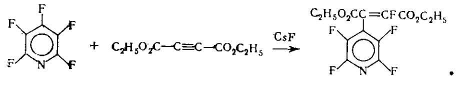
$$(CF_3)_2C{=}CF_2 \xrightarrow{CsF} [(CF_3)_3\overline{C}] \xrightarrow{CH_2=CHX}$$

$$\rightarrow [(CF_3)_3C{-}CH_2{-}\overline{C}HX] \xrightarrow{H_2O} (CF_3)_3C{-}CH_2{-}CH_2{-}CH_2X;$$

$$X{=}CN,\ COOCH_3.$$

The nonafluoro-t-butyl anion substitutes halogen atoms just as readily in unsaturated and aromatic compounds—pentafluoropyridine, cyanuryl chloride, 1-fluoro-2,4-dinitrobenzene, *p*-fluoronitrobenzene [36], and chlorophenylacetylene.[37] From the standpoint of synthetic possibilities in the series of aromatic fluoro-compounds such as octafluorotoluene, pentafluoropyridine, and others, this reaction may be compared with Friedel-Crafts alkylation. The carbanions generated from hexafluoropropene, tetrafluoroethylene, and other fluoro-olefins can also be involved in this reaction[4,5,38].

An anion capable of similar reactions is generated as a result of the addition of F^- to the electrophilic triple bond of the acetylene dicarboxylate ester [39]:



The reaction involving hexafluorobut-2-yne is complicated by polymerisation.

The fluorinated carbanions are capable of adding to cationoid species, forming stable covalent compounds. It has been possible to synthesise in this way mixed azo-compounds[40]:

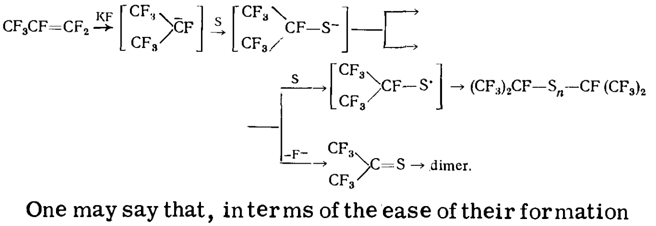
$$R_f^- + C_6H_5N_2^+Cl^- \rightarrow R_fN{=}NC_6H_5;$$

or metal fluoroalkyl derivatives[41-43]:

$$R_f^- + M^+ \rightarrow R_f - M;$$

$$M{=}Ag,\ {}^1/_2\,Hg \quad .$$

When fluorocarbanions are treated with elemental sulphur, the products are mercaptide anions capable of both eliminating the fluoride ion (which leads to thiocarbonyl compounds) and of being oxidised by the excess sulphur with formation of di- and poly-sulphides[44]:



One may say that, in terms of the ease of their formation and the scope of their synthetic applications, "perfluorocarbanions" (actually ionised fluoroalkyl derivatives of alkali metals) can replace to some extent Grignard reagents in fluorine chemistry. In view of the instability of Grignard reagents associated with the ease of elimination of magnesium fluoride, evidently only those fluorine-containing Grignard reagents which contain unsaturated or primary fluoroalkyl residues can be of some preparative value[45].

The attempts at direct detection of fluorocarbanions with with the aid of ^{19}F NMR showed that these species are in a state of rapid exchange. Thus the exchange between the nonafluoro-t-butyl anion and octafluoroisobutene in

---

†See the review of B. L. Dyatkin (deceased), N. I. Delyagina, and S. R. Sterlin "The Perfluoro-t-butyl Anion in the Synthesis of Organofluorine Compounds" in this issue.

1,2-dimethoxyethane cannot be made slow in terms of the NMR time scale even at −100°C [46]:

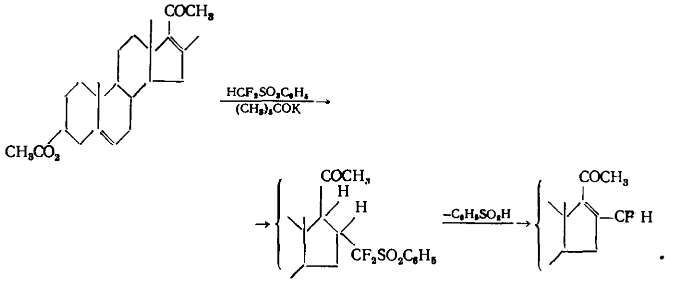
$$(CF_3)_2\bar{C}{-}CF_2{-}F + CF_2{=}C(CF_3)_2 \rightleftharpoons (CF_3)_2C{=}CF_2 + CF_3{-}\bar{C}(CF_3)_2 \,.$$

Comparison of fluoro-olefins and carbonyl compounds in their reactions with the fluoride ion showed that the latter are more reactive: trifluoroacetyl fluoride exchanges with $Cs^{18}F$ seven times faster than hexafluoropropene [47]. Hexafluoroacetone, taken in a minimal excess, causes the complete dissolution of ceasium fluoride in acetonitrile, while one of the most electrophilic fluoro-olefins (octafluoroisobutene) causes only a slight increase of the solubility of CsF in aprotic solvents. By virtue of this feature, hexafluoroacetone is used for the preparation of extremely reactive highly dispersed CsF (by the vacuum evaporation of a solution of "perfluoroalkoxide" [48]).

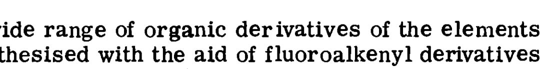
2. Fluorocarbanions Generated by Other Methods

Apart from the methods specific to fluorocarbanions—the addition of the fluoride ion to electrophilic multiple bonds—they can be generated by the general methods of carbanion chemistry. As a result of the high proton mobility of the hydrogen atom at a tertiary carbon atom in polyfluoroalkanes, fluorocarbanions are generated when the alkanes are treated with comparatively weak bases. Thus the reaction of the nonafluoro-t-butylanion with acrylic systems, discussed above, can be achieved also by treating acrylic systems with a mixture of $(CF_3)_3CH$ and triethylamine [49]. Kinetically independent carbanions can probably be in fact involved in processes of this kind. The study of the kinetics of the dehydrohalogenation of compounds having the general formula $C_6H_6CHClCF_3X$, where X = F or Cl, showed that the presence of a chlorine atom in the β-position greatly accelerates the process, probably in consequence of synchronous elimination. If, on the other hand, X = F, a kinetically independent carbanion is evidently formed [50].

Base-catalysed reactions, which ultimately reduce to the insertion of a carbene, can also include a stage involving the formation of a carbanion [51]:



The hydrogen atom at the double bond of a fluoro-olefin can also be sufficiently acidic for the generation of perfluoroalkenyl anions [52]:



$$CF_2{=}CFH \xrightarrow[-100^\circ]{C_4H_9Li} CF_2{=}CFLi \xrightarrow{1)\,(CH_3)_2C{=}O;\ 2)\,H_2O} CF_2{=}CF{-}C(CH_3)_2{-}OH \,.$$

A wide range of organic derivatives of the elements can be synthesised with the aid of fluoroalkenyl derivatives of lithium or magnesium (see the review by Knuyants et al. [53]):

$$CF_2{=}CFMgBr + ECl_3 \rightarrow CF_2{=}CFECl_2;$$
$$E{=}P,\ As,\ Sb,\ Bi \,.$$

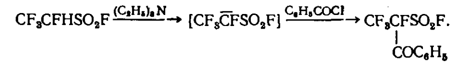
Trifluorovinyl derivatives of sulphur, silicon, germanium, tin, mercury, platinum, and palladium have been obtained similarly.

CH acids are also widely used for synthesising organomercury compounds—the sources of halogenocarbenes. For example [54]:

$$C_6H_5HgCl + CF_3CHFBr \xrightarrow[-35^\circ]{CH_3ONa} C_6H_5HgCFBrCF_3 \,.$$

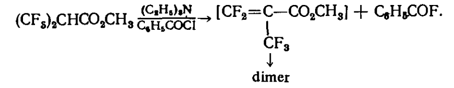
When the product is heated, trifluoromethylfluorocarbene is formed.

The anion generated when 1,2,2,2-tetrafluoroethanesulphonyl fluoride is treated with triethylamine can substitute the chlorine in benzoyl chloride [55]:



$$CF_3CFHSO_2F \xrightarrow{(C_2H_5)_3N} [CF_3\bar{C}FSO_2F] \xrightarrow{C_6H_5COCl} CF_3CF(COC_6H_5)SO_2F.$$

The analogous acylation of polyfluoro-α-hydrocarboxylic acids cannot be achieved; the main reaction pathway involved dehydrofluorination [56]:

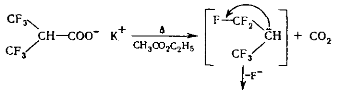


$$(CF_3)_2CHCO_2CH_3 \xrightarrow[C_6H_5COCl]{(C_2H_5)_3N} [CF_2{=}C(CF_3){-}CO_2CH_3] + C_6H_5COF.$$
$$[CF_2{=}C(CF_3){-}CO_2CH_3] \downarrow \text{dimer}$$

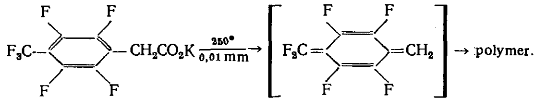
Benzoyl chloride has an electrophilic cooperative effect on dehydrofluorination, making it irreversible in consequence of the binding of the fluoride ion in the form of a covalent compound—benzoyl fluoride. Lewis acids, introduced in the form of complexes with tertiary amines, have a similar effect. The use of these complexes makes it possible to synthesise many interesting unsaturated compounds in preparative yields, for example [57]:

$$(CF_3)_2C{=}CF_2 + CH_2(CO_2C_2H_5)_2 \xrightarrow[-HF]{(C_2H_5)_3N\cdot BF_3} (CF_3)_2C{=}CFCH(CO_2C_2H_5)_2 \xrightarrow[-HF]{(C_2H_5)_3N\cdot BF_3}$$
$$\rightarrow (CF_3)_2C{=}C{=}C(CO_2C_2H_5)_2.$$

The leaving group in the generation of fluorocarbanions may be not only a proton but also CO_2, which makes it possible to use fluorocarboxylate salts in reactions of this kind. Decarboxylation can be used for the synthesis of fluoro-olefins [58]:



The synthesis of fluorine-containing quinonemethides, which form polymers on vacuum condensation on a cold surface, is carried out similarly [59]:



The elimination of CO_2 by fluorocarboxylate salts can be reversible (fluorocarbanions are capable of combining with carbon dioxide [60]). A method for the synthesis of nonafluoro-β-phenoxypropionic acid is based on this fact [61]:

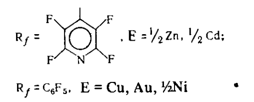
$$C_6F_5OK + C_2F_4 \rightarrow [C_6F_5OCF_2\bar{C}F_2]\,K^+ \xrightarrow{CO_2} C_6F_5OCF_2CF_2COOK.$$

The decarboxylation of heavy metal salts has been used successfully in the synthesis of a wide variety of fluorine-containing organometallic compounds. The mechanism of this process may be more complex, involving a radical generation stage [62–66]:

$$R_f{-}CO_2{-}E \longrightarrow R_f{-}E + CO_2;$$

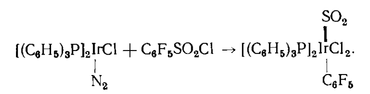
$R_f = (CF_3)_2CH{-}$,

$E = \tfrac{1}{2}\,Hg;$



$R_f = C_6F_5$, E = Cu, Au, ½Ni

SO_2 or SO_3 can also be the leaving groups in reactions of this kind—for example in the synthesis of polyfluoroaryl derivatives of mercury[67],[68] or iron[69]. In the synthesis of σ-pentafluorophenyliridium, SO_2 is combined as the ligand, displacing molecular nitrogen[70]:



$$[(C_6H_5)_3P]_2\underset{\underset{N_2}{|}}{IrCl} + C_6F_5SO_2Cl \rightarrow [(C_6H_5)_3P]_2\overset{\overset{SO_2}{|}}{\underset{\underset{C_6F_5}{|}}{IrCl_2}}.$$

The decarboxylation of silver hexafluoroisobutyrate leads to the formation of hexafluoroisopropylsilver[71]:

$$(CF_3)_2CH—CO_2—Ag \rightarrow (CF_3)_2CH—Ag + CO_2.$$

The basicity of the solvent has a significant influence on the ease of reaction: CO_2 is not evolved in boiling tetrahydrofuran (THF); in acetonitrile, the reaction takes place at 40–50°C and, in pyridine, at room temperature. This demonstrates the important role played in such reactions by the nucleophilic cooperation of solvent molecules. Such cooperation affects just as strongly the reactions of fluoroalkyl derivatives of heavy metals, which can be particularly readily coordinated to bases by virtue of the electron-accepting properties of the fluoroalkyl groups and can also serve as sources of fluorocarbanions. Thus the decomposition of bis(nonafluoro-t-butyl)mercury, which takes place readily in the presence of iodide salts in aprotic solvents, leads to the formation of octafluoroisobutene. The action of KF does not lead to the decomposition of the organomercury compound, but in the presence of KF it reacts much more readily with agents such as sulphur or iodine[72]:

$$[(CF_3)_3C]_2Hg \overset{F^-}{\rightleftarrows} [(CF_3)_3C]_2\overline{H}gF \xrightarrow{I_2} (CF_3)_3CI.$$

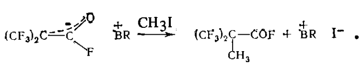
On treatment with triethylamine, hexafluoroisobutyryl fluoride (in contrast to the chloride) does not eliminate the hydrogen halide. The reaction stops at the stage involving the formation of a solid salt-like complex containing a mesomerically stabilised carbanion [73] (see the review of Knunyants et al.[74]):

The extremely high stability of such fluorocarbanions makes it possible to obtain them by a novel method—by treating with bases alkyl polyfluorovinyl ethers, which have been found to be capable of acting as alkylating agents[75-77]:

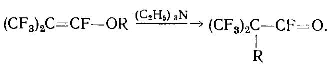
 (1)

R = CH_3, C_2H_5; B = $(C_2H_5)_3N$, $[(CH_3)_2N]_3PO$, C_5H_5N.

In its turn, the mesomeric anion can be also alkylated—for example with methyl iodide[78]:

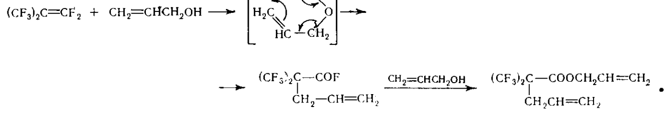


An excess of the initial vinyl ether can also serve as an alkylating agent, so that its heat treatment in the presence of bases leads to a rearrangement[79]:

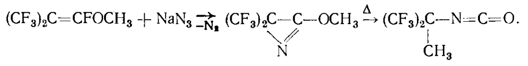


$$(CF_3)_2C=CF—OR \xrightarrow{(C_2H_5)_3N} (CF_3)_2\underset{\underset{R}{|}}{C}—CF=O.$$

The allyl group as the substituent R migrates particularly readily. For this reason, allyl heptafluoroisobutenyl ether cannot be synthesised at all: under the conditions of the reaction of octafluoroisobutene with an alcohol usually employed for this purpose, a rearrangement takes place immediately, so that the final product is allyl α-allylhexafluoroisobutyrate[80]:



Evidently yet another rearrangement is of a related type—the conversion of 2,2-bis(trifluoromethyl)-3-methoxyazirine, obtained by treating heptafluoroisobutenyl methyl ether with sodium azide, into the corresponding isocyanate[81]:



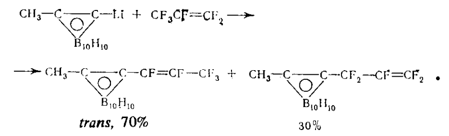
3. Reactions of Fluorine-Containing Unsaturated Compounds with Nucleophilic Agents

It has been shown[82] that the fluorine atom in the vinyl position of a fluoro-olefin is more mobile than the atom in the allyl position. This property is specific to organofluorine compounds and distinguishes them from the majority of substances for which the traditional concept of a greater mobility of the halogen atom in the allyl position is valid.

When a fluoro-olefin is attacked by an anion B^-, the intermediate carbanion may be stabilised either by eliminating the fluoride ion (substitution) or by combining with a cation A^+ (addition):

 (2)

When a fluoro-olefin is attacked by an uncharged nucleophilic species B′ with a lone electron pair, the product is a dipolar species $\rangle\bar{C}-CF_2-\overset{+}{B}'$, which can be stabilised not only by the two pathways indicated above, but also by a third pathway, leading to the formation of cycloaddition products. Studies in recent years make it possible to refine somewhat this general mechanism. Substitution in fluoro-olefins, initially studied in relation to nucleophilic agents ultimately forming in this reaction a substituent with a lone electron pair (HNR_2, RO^-) [82], can be directed to some extent also to the allyl position, provided that it results in the introduction of an electron-accepting substituent[83]:



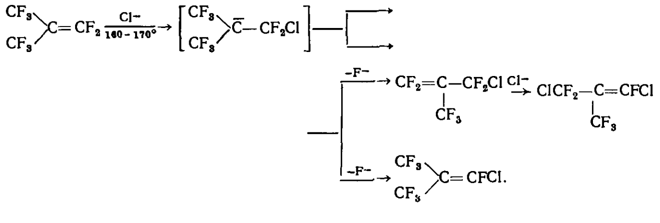
However, the *meta*-carborane analogue, which has a smaller *–I* effect, forms exclusively the vinyl isomer[84].

The interaction of octafluoroisobutene with Grignard reagents also leads to the partial formation of allyl isomers. The ratio of the reaction products depends on the nature of the group introduced[85]:

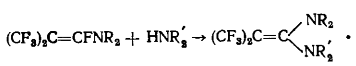
$$(CF_3)_2C{=}CF_2 + RMgBr \rightarrow \underset{(I)}{(CF_3)_2C{=}CFR} + \underset{(II)}{CF_2{=}\underset{\underset{CF_3}{|}}{C}{-}CF_2R};$$

$R{=}(CH_3)_2CH$, (I) : (II)=68 : 32; $R{=}n\text{-}C_4H_9$, (I) : (II) =82 : 18; $R{=}C_6H_5CH_2$, (I): (II)=60:40.

The reaction of octafluoroisobutene with the chloride ion occurring in the presence of phosphoryl chloride, which binds F^-, leads to a mixture of compounds which includes products of both vinyl and allyl substitution[86]:



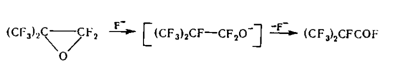
Fluoro-olefins with a non-terminal double bond were previously regarded as relatively unreactive. However, it has been shown recently that they are capable of reversible isomerisation to olefins with a terminal C=C bond on treatment with an attacking nucleophilic agent. As a result of this, it has been possible to introduce into the reaction with amines hexafluoropropene dimers, which constitute a mixture of $(CF_3)_2CFCF{=}CFCF_3$ and $(CF_3)_2C{=}CFCF_2CF_3$.[25] The reaction leads to the formation of $R_2N\underset{\underset{CF_3}{|}}{C}F{=}CFCF_2CF_3$, which may indicate a preliminary isomerisation of the dimers to $CF_2{=}\underset{\underset{CF_3}{|}}{C}(CF_2)_2CF_3$.[87] This result makes possible the extensive application in synthesis of the very readily available fluoro-olefin oligomers. Dialkylaminoheptafluoroisobutenes are also capable of reacting with secondary amines[88]:

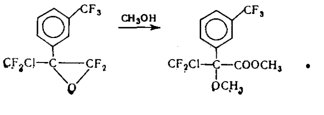


$$(CF_3)_2C{=}CFNR_2 + HNR'_2 \rightarrow (CF_3)_2C{=}C\begin{matrix}NR_2\\NR'_2\end{matrix}.$$

The reaction proceeds readily when R or R′ is a methyl group. When both substituents are a piperidine residue, the reaction proceeds slowly and, when $R = R' = C_2H_5$, it is altogether impossible to achieve selective substitution. Evidently steric hindrance plays a decisive role in this instance.

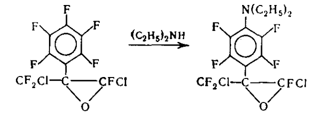
Steric hindrance plays an important role in the reactions of fluoro-oxirans with nucleophilic agents. In the absence of steric hindrance, the attack is directed to the central carbon atom[89,90]:

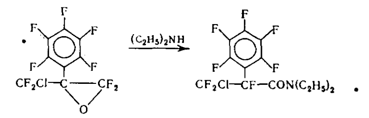




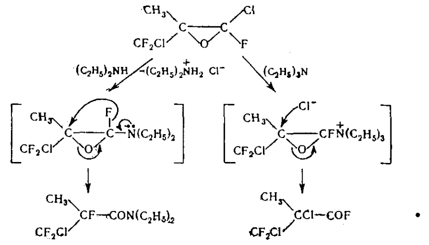
The second reaction takes place fairly readily when the CF_3 group is present in the *meta*- or *para*-position, but does not occur when it occupies the *ortho*-position[90].

The *ortho*-fluorine atoms of the pentafluorophenyl group are evidently also capable of shielding the central carbon atom sufficiently for the attack by the nucleophilic agent to be directed to another centre[90]:

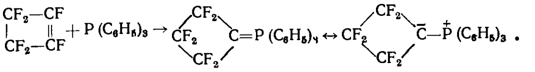




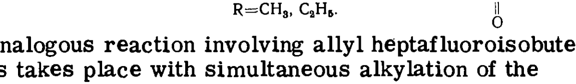
In the second case the reaction is accompanied by a rearrangement, which is of a general type. With its aid, it is possible to synthesise the derivatives of a wide variety of fluorocarboxylic acids. Evidently the driving force of the reaction is the small volume of the halide ions formed in the first stage of the interaction with bulky nucleophilic agents, which are bound to attack the terminal carbon atom[90]:



According to mechanism (2), the primary products of the reactions of fluoro-olefins with uncharged nucleophilic agents are dipolar species. In certain cases, these products can be isolated[91]:



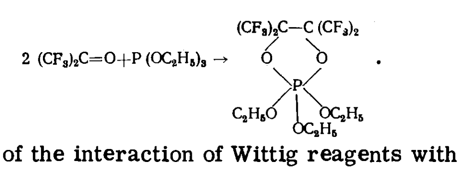
Heptafluoroisobutenylphosphonic acid esters have been obtained by the reaction between octafluoroisobutene and trialkyl phosphites (in which a betaine is an intermediate)[92]:



$$(CF_3)_2C{=}CF_2 + P(OR)_3 \rightarrow [(CF_3)_2\bar{C}{-}CF_2{-}\overset{+}{P}(OR)_3] \rightarrow (CF_3)_2C{=}CF{-}\underset{\underset{O}{\|}}{P}(OR)_2;$$
$$R{=}CH_3,\ C_2H_5.$$

The analogous reaction involving allyl heptafluoroisobutenyl ethers takes place with simultaneous alkylation of the trialkyl phosphite via mechanism (1).[93] The influence of steric hindrance, preventing the attack on the carbon atom of the =CF– group, probably has an effect in this case.

The reaction of triethyl phosphite with hexafluoroacetone is unusual. The addition of two ketone molecules results in the formation of a cyclic phosphorane in which there is a linkage between two carbon atoms previously forming part of the carbonyl groups, i.e. hexafluoroacetone is converted into a "pinacol" derivative[94]:



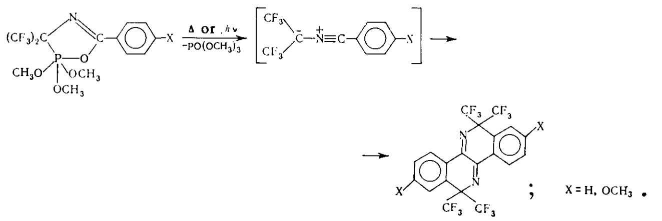
(3)

The study of the interaction of Wittig reagents with unsaturated organofluorine compounds, which was begun in relation to hexafluorobenzene [95], is extremely promising:

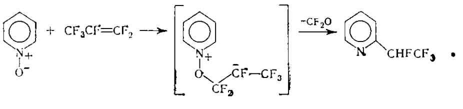
$$(C_6H_5)_3\overset{+}{P}{-}\bar{C}H_2 + C_6F_6 \rightarrow [(C_6H_5)_3\overset{+}{P}{-}CH_2C_6F_5[F^- \xrightarrow{-H^+} (C_6H_5)_3\overset{+}{P}{-}\bar{C}HC_6F_5.$$

The reaction leads to the formation of a new ylid, which is likewise capable of typical reactions of such compounds.

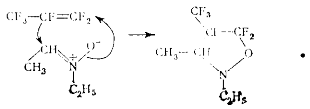
Nitrogen-containing ylids usually cannot be isolated, but the products of their reactions are frequently extremely interesting[96]:



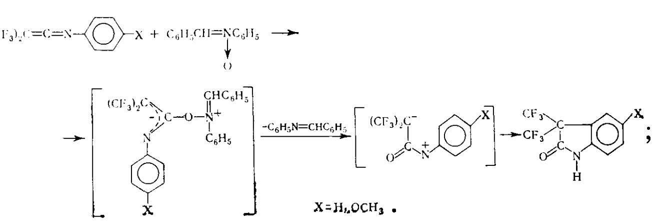
The reaction of the N-oxides of pyridine (and its homologues) with hexafluoropropene makes it possible to introduce the polyfluoroalkyl group under mild conditions into the α-position of the pyridine ring[97]:



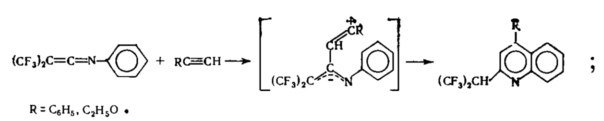
Nitrones also react steadily with hexafluoropropene, but there is no elimination of the COF_2 group[98]:



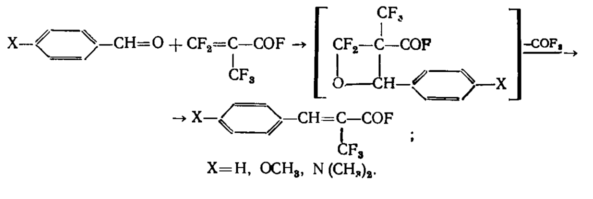
α,N-Diphenyl nitrone behaving as an oxygen donor reacts in an unexpected manner with N-arylbis(trifluoromethyl)ketenimines [99]:



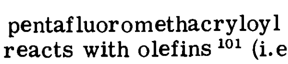
The reaction of a ketenimine with acetylenes probably also includes a stage involving the formation of a dipolar ion, which is stabilised by cyclisation[100]:



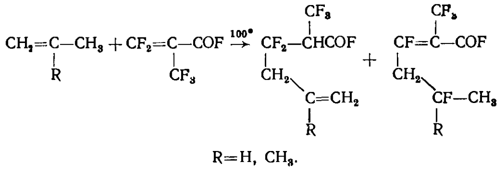
Another pathway to the stabilisation of the dipolar ion, involving the elimination of carbonyl fluoride, which has already been mentioned, occurs in the interaction of aromatic aldehydes with pentafluoromethacryloylfluoride. The intermediate oxetans are unstable[101]:



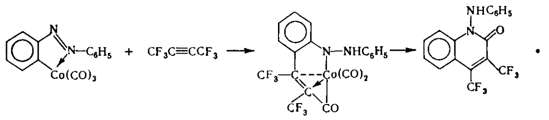
The extreme ease of this reaction, which is formally similar to the Wittig reaction, is not surprising if one bears in mind that both charges in the intermediate dipolar ions are highly delocalised, so that it constitutes a combination of the benzoyl cation with a mesomeric anion:



The C=C bond in pentafluoromethacryloyl fluoride is so electrophilic that it reacts with olefins[101] (i.e., as regards its electrophilic properties, it approaches the C=O bond of fluorinated ketones—see a previous review[1]):



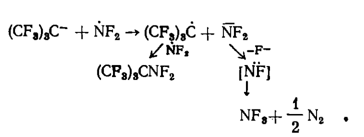
An example illustrating the extremely great promise of the use of transition metal complexes for the synthesis of organofluorine compounds is provided by the incorporation of hexafluorobut-2-yne in the cobalt complex of azobenzene accompanied by carbonylation[102]:



The intermediate complex has been isolated and its structure has been confirmed by X-ray diffraction.

4. New Ideas About the Mechanisms of Anionoid Processes

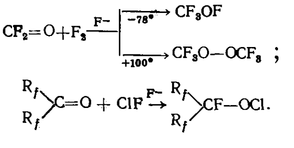
The reactions involving fluorocarbanions cannot always be accounted for within the framework of purely ionic concepts. For example, the interaction of octafluoroisobutene with tetrafluorohydrazine, resulting in the formation of $(CF_3)_3CNF_2$, is catalysed by KF. Since N_2F_4 decomposes on heating with formation of $\dot{N}F_2$ radicals, the decisive stage in the process is probably the oxidation of the carbanion $(CF_3)C^-$ by this radical[103]:



The "ionic" bromination of polyfluoroalkanes[104]:

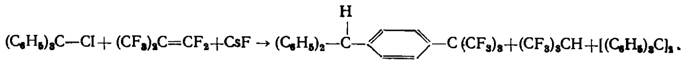
$$(CF_3)_3CH + Br_2 \xrightarrow[C_5H_5N]{} (CF_3)_3CBr$$

and the reactions of "perfluoroalkoxides" with halogens or interhalogen compounds[105,106]:



are just as likely to have oxidative mechanisms.

The ability of the fluorocarbanion to behave under mild conditions as an electron donor was confirmed directly in an ESR study of an unusual reaction between the nonafluoro-t-butyl anion and chlorotriphenylmethane involving the transfer of the reaction centre[107]:

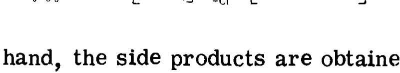


$$(C_6H_5)_3C{-}Cl + (CF_3)_2C{=}CF_2 + CsF \rightarrow (C_6H_5)_2\overset{H}{C}{-}C_6H_4{-}C(CF_3)_3 + (CF_3)_3CH + [(C_6H_5)_3C]_2.$$

At the beginning of the reaction, the concentration of the triphenylmethyl radical increases sharply, and then falls only gradually to the level corresponding to the equilibrium

$$2\,(C_6H_5)_3C^{\cdot} \rightleftarrows [(C_6H_5)_3C]_2 .$$

Thus the main reaction product is obtained as a result of the recombination within a cage of the radical pair formed via electron transfer:



$$(C_6H_5)_3C{-}Cl + [\overset{\odot\cdot}{C}(CF_3)_3]^- \xrightarrow[-Cl^-]{} [(C_6H_5)\dot{C} + \dot{C}(CF_3)_3] .$$

On the other hand, the side products are obtained as a result of the liberation of the radicals from the "cage".

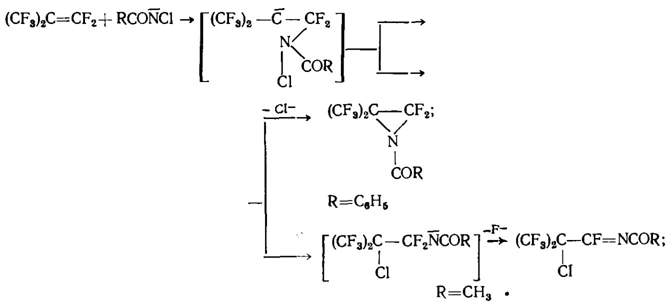
Yet another interesting reaction of carbanions, namely their reaction with nitroso-compounds, takes place with transfer of the reaction centre[108]:

$$(CF_3)_2CF{-}NO + (CF_3)_2C{=}CF_2 \xrightarrow{CsF} (CF_3)_2C{=}NOC(CF_3)_3 .$$

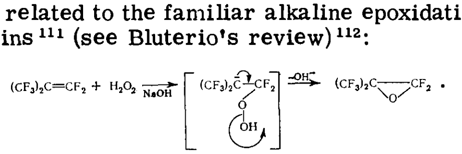
Since it is known that in an aprotic medium fluoroalkylnitroso-compounds behave as one-electron oxidants (demonstrated by polarography in dimethylformamide[109]), this reaction presumably includes an electron transfer stage (otherwise it would be difficult to explain the attack by the carbanion on the oxygen atom rather than on the nitrogen atom):

$$(CF_3)_2\underset{F}{C}{-}N{=}O + [\overset{\odot\cdot}{C}(CF_3)_3]^- \xrightarrow[-F^-]{} [(CF_3)_2{=}N{-}\dot{O} + \dot{C}(CF_3)_3] .$$

The reaction between octafluoroisobutene and *N*-chloramide anions can take place in two ways, depending on the nature of the acyl residue[110]:



The first, which is an example of the fixation of the intermediate of the Hofmann–Lossen rearrangements, is in essence related to the familiar alkaline epoxidation of fluoro-olefins[111] (see Bluterio's review)[112]:



The relation between the two pathways of the reaction with *N*-chloramides is the same as that between the Wurtz reaction and the metal halide exchange:

$$RLi + R'Cl - \begin{cases} \longrightarrow R{-}R' + LiCl \\ \longrightarrow RCl + R'Li \end{cases} .$$

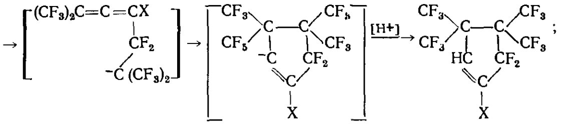
In both cases the key stage involves one-electron transfer[113].

The one-electron transfer stages evidently include also multistep transformations occurring when haloforms are added to a solution of the nonafluoro-t-butyl anion. The initial step is the generation of the trihalogenomethyl anion by virtue of the greater acidity of CX_3H (X = Cl or Br) compared with $(CF_3)_3CH$. The anion formed substitutes the vinyl fluorine atom in octafluoroisobutene:

$$(CF_3)_2C{=}CF_2 + \bar{C}X_3 \xrightarrow[-F^-]{} (CF_3)_2C{=}CFCX_3 \xrightarrow[-F^-]{CX_3^-} (CF_3)_2C{=}C{=}CX_2 + CX_4;$$

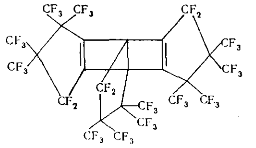
X=Cl, Br.

The dehalogenation of the resulting olefin takes place immediately afterwards, evidently under the influence of the trihalogenomethyl anion, which thus behaves as an electron donor. This leads to the formation of the carbon tetrahalide and an extremely electrophilic allene, which can be detected as an adduct with furan. In the absence of furan, the allene reacts with octafluoroisobutene via the following probable mechanism:



X=Cl, Br.

Thus an unusual conversion of octafluoroisobutene into a pinacol derivative takes place [cf. reaction (3)]. When X = Br, the cyclopentene formed is the final product. On the other hand, when X = Cl, the reaction proceeds further and a trimer is formed via an HCl elimination stage:



It was difficult to predict the formation of such final products on the basis of the structure of the initial reactants[114].

The reaction of bis(trifluoromethyl)thioketen with *NN*-dimethylaniline is accompanied by the formation of red intermediates, while the final product is $C_6H_5\underset{CH_3}{N}CH_2SCH{=}C(CF_3)_2$.[115] Presumably an electron transfer takes place in this case too, since the products of the substitution of the CH_3 group in *NN*-dimethylaniline are in fact usually formed as a result of one-electron oxidation of this amine, which readily gives rise to a radical-cation[116]. It is remarkable that other bases (alcohols, mercaptans, secondary amines) combine with bis(trifluoromethyl)thioketen via the C=C bond and not the C=S bond, i.e. the thioketen behaves as a normal acylating agent[115].

Yet another example of the "nucleophilic" reaction, the result of which is difficult to explain fully on the basis of purely ionic ideas, involves the dimerisation of bis(pentafluorophenyl)methyl bromide on treatment with cyanide ions or triphenylphosphine[117]:

$$2\,(C_6F_5)_2CHBr + CN^- \rightarrow (C_6F_5)_2CH{-}CH(C_6F_5)_2 + BrCN + Br^- .$$

The product of this reaction is probably formed as a result of the recombination of the bis(pentafluorophenyl)methyl radicals.

A similar process is a side reaction in the substitution of pentafluorobenzyl chloride by butyl-lithium; it has been shown by physical methods that the reaction has a one-electron mechanism[118].

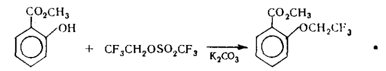
II. CATIONOID REACTIONS

Owing to the presence of electron-accepting substituents in organofluorine compounds, their electrophilic reactions are more difficult than those of the non-fluorinated analogues. For this reason, either severe conditions or the use of very strong acids as the reaction medium are usually required in order to carry out such reactions successfully (see the review of Mochalina et al.[119]). On the other hand, the resistance of organofluorine compounds to severe conditions and strong acids, which cause charring of compounds, such, as for example, non-fluorinated olefins, makes their electrophilic reactions extremely valuable from the synthetic standpoint.

The simplest reaction occurring in strong protic acids is the formation of carbonium ions as a result of the protonation of organic molecules. The interaction of fluoro-olefins with fluorosulphonic acid has proved a convenient method for the synthesis of alkyl fluorosulphonates:

Fluoroethylenes react under extremely mild conditions[120] and tetrafluoroethylene and hexafluoropropene react under severe conditions, the products of their reactions being formed in low yields. α-Chloroperfluoroalkyl sulphonates are readily obtained by the addition of $ClOSO_2F$ to fluoro-olefins[121].

Alkyl fluorosulphonates are the strongest alkylating agents for *O*- and *N*-bases[122]. The reactivity of fluoroalkyl trifluoromethanesulphonates is just as high[123]:



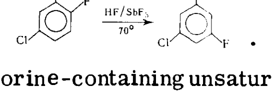
Remarkable prospects arise from the previously unknown ability of fluorosulphonates (other than methyl and ethyl fluorosulphonates) to function as *C*-alkylating agents for aromatic systems[120].

When fluoroethylenes are treated with the HF–SbF_5 mixture, they are hydrofluorinated. The reaction is reversible: the intermediate carbonium ion can be regenerated from the final products[124]:

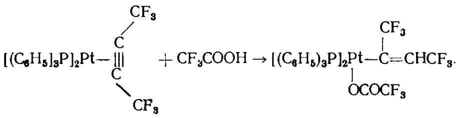
$$CH_2{=}CHF + HF + SbF_5 \rightleftarrows [H_3\text{—}\overset{+}{C}HF] \rightleftarrows CH_3\text{—}CF_2H.$$

Tetrafluoroethylene does not react in this way, which distinguishes it from ethylenes having the general formula $CF_2{=}CFX$, where X = Cl, Br, or I.

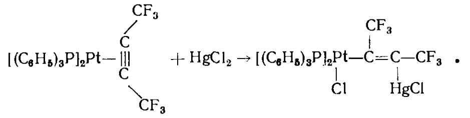
The benzenium ions formed on protonation of fluorobenzenes can be involved in rearrangements associated with the migration of both the proton[125] and the fluorine atom[126]:



The ability of fluorine-containing unsaturated compounds, coordinated to transition metals, to be protonated much more readily than in a free state is an extremely promising property. Thus, hexafluorobut-2-yne forming part of a platinum complex is readily protonated by trifluoroacetic acid[127]:

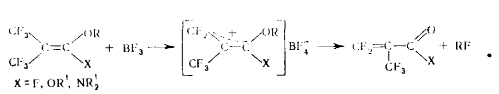


Evidently the range of electrophilic reactions of this kind can be greatly extended. Only the mercuration of this complex by mercury(II) chloride, an extremely mild mercurating agent, has been described so far[127]:



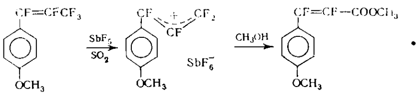
For comparison, one should note that the mercuration of perfluoro-olefins takes place only when the latter are heated with the much more active HgF_2 in HF or AsF_3 (see the review of Mochalina et al.[119]), while fluoro-olefins containing a hydrogen atom or an alkoxy-group at the C=C bond are mercurated by $Hg(NO_3)_2$.[128]

Carbonium ions are also formed when organofluorine compounds are treated with strong Lewis acids. It has been found that the fluorine atoms forming part of the CF_3 group of alkoxypolyfluoroisobutenes are sufficiently mobile for this purpose[129]:



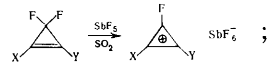
Salt-like intermediate products, containing a mesomerically stabilised cation, can be isolated after the reaction of the aminoacetals of bis(trifluoromethyl)keten (X = NR_2'). The final outcome of the reaction is the formation of derivatives of pentafluoromethacrylic acid and an alkyl fluoride.

On treatment with SbF_5, 4-pentafluoropropenylanisole also gives rise to a stable cation[130]:



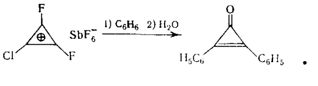
When the cation is treated with methanol, an ester of difluoro-*p*-methoxycinnamic acid is produced.

The salts containing fluorocycloprenyl cations do not decompose until a temperature near 80°C[131]:

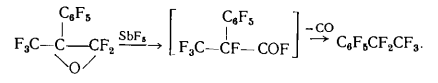


X, Y = F, Cl.

They are capable of alkylating benzene:

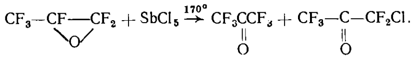


Owing to the ability of the acylium cations generated from carboxylic acid fluorides to eliminate CO, fluoroalkanes can be synthesised from the acids[132]. Oxirans, which are capable of being converted into acid fluorides under the influence of SbF_5, react similarly[90]:



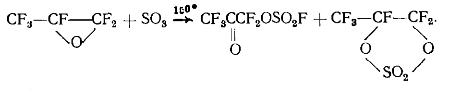
$$\underset{\text{O}}{F_3C\text{—}\overset{C_6F_5}{C}\text{—}CF_2} \xrightarrow{SbF_5} \left[F_3C\text{—}\overset{C_6F_5}{C}F\text{—}COF\right] \xrightarrow{-CO} C_6F_5CF_2CF_3.$$

The reactions of 1-trifluoromethyltrifluoro-oxiran catalysed by Lewis acids take place differently: antimony pentachloride converts it into a mixture of hexafluoro- and chloropentafluoro-acetones[133]:



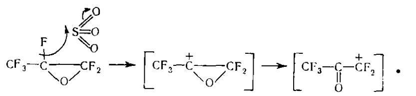
$$\underset{\text{O}}{CF_3\text{—}CF\text{—}CF_2} + SbCl_5 \xrightarrow{170^\circ} CF_3\underset{\|\atop O}{C}CF_3 + CF_3\text{—}\underset{\|\atop O}{C}\text{—}CF_2Cl.$$

Treatment with sulphur trioxide leads to the formation of two main products[133]:



(4)

The hypothesis that Lewis acids can not only attack the oxiran at the oxygen atom, which results in the formation of the second product of reaction (4), but can be also coordinated to the fluorine atom of the CF group constitutes a very attractive explanation of these results:

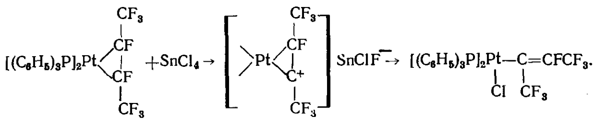


The rearrangement of the carbonium ion with subsequent attack by the anion on the CF_2 group can lead to substituted pentafluoroacetones. The validity of this hypothesis has been confirmed by the isolation of a certain amount of chloropentafluoroacetone in the reaction between 1-trifluoromethyltrifluoro-oxiran with SO_3 in the presence of NaCl. Furthermore, the oxiran is capable of an unexpected rearrangement in the presence of octafluoroisobutene, which is a very weak acid but exhibits a powerful affinity for the fluoride ion[133]:

The conversion of halogenofluoroalkanes into acid halides, catalysed by oleum, is based on the ability of SO_3 to be coordinated to a covalently linked halogen[134]:

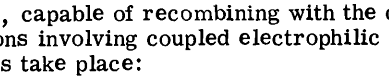
$$CF_2Br{-}CFClBr \xrightarrow[\text{oleum}]{} CF_2Br{-}COF.$$

The stage involving the formation of cations probably occurs also in the reaction of tin(IV) chloride with platinum complexes of fluoro-olefins[135]:



Reaction with the hexafluoropropene complex is accompanied by the exchange of the vinyl fluorine atom for chlorine, as a result of which the final product is $[(C_6H_5)_3P]_2Pt{-}\underset{\substack{|\\ Cl}}{C}Cl{=}CFCF_3$.

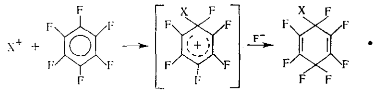
Carbonium ions are generated when a fluoro-olefin is attacked by cationoid species. When the medium contains fluoride ions, capable of recombining with the carbonium ions, reactions involving coupled electrophilic addition to fluoro-olefins take place:



X=NO_2, CH_2OH etc.

These processes, involving anhydrous hydrogen fluoride as a solvent and a source of F^- ions, have been reviewed in detail[136].

Aromatic fluoro-compounds are capable of similar reactions[137]:



Studies of such processes in other strong acids have developed in recent years. Thus, coupled fluorohalogenation of fluoro-olefins takes place readily in IF_5 [138] or BrF_3: [139]

$$CF_2{=}CF_2 + IF_5 + I_2 \rightarrow CF_3{-}CF_2I;$$
$$R_f{-}CF{=}CF_2 + BrF_3 + Br_2 \rightarrow R_f{-}CFBr{-}CF_3.$$

It is noteworthy that the last reaction is also undergone readily by hexafluoropropene dimers, which cannot be introduced into any other electrophilic addition reaction. The reaction involving the addition of chlorofluoroalkanes to fluoro-olefins, catalysed by the $AlCl_3$ (see the relevant reviews[119,140]), is related to these processes.

The results obtained using antimony pentafluoride as the reaction medium are particularly interesting. As already mentioned in a previous review[1], treatment of fluoroethylenes with this reagent leads to ready fluorination of the double bond. Polyfluoropropenes unexpectedly undergo electrophilic dimerisation[141]:

$$2\,CF_3{-}CX{=}CF_2 \xrightarrow{SbF_5} CF_3{-}CX{=}CF{-}CX\,(CF_3)_2;$$
$$X{=}H,\ F.$$

On the other hand, when hexafluoropropene reacts with SbF_3 in the presence of pentafluorobenzene, decafluoro-β-methylstyrene is formed[142]:

$$CF_3{-}CF{=}CF_2 + C_6F_5H \xrightarrow[SbF_5]{} C_6F_5{-}CF{=}CF{-}CF_3.$$

Pentafluorobenzene is alkylated also on treatment with 1,1,2-trichloro-1,2,2-trifluoroethane in SbF_5. The reaction is accompanied by the partial substitution of chlorine by fluorine, so that its main product is β-chlorononafluoroethylbenzene, from which octafluorostyrene can be readily obtained[143]:

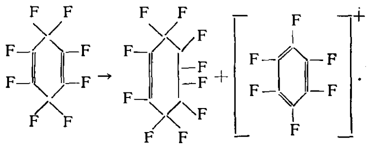
$$C_6F_5H + CF_2Cl{-}CFCl_2 \xrightarrow[SbF_5]{} C_6F_5{-}CF_2{-}CF_2Cl.$$

When vinylidene fluoride was allowed to react with SbF_5, it was possible to isolate an addition product[144]:

$$3\ CF_2{=}CH_2 + SbF_5 \rightarrow (CF_3CH_2)_3SbF_2.$$

The behaviour of fluoro-olefins in SbF_5 is at present difficult to account for unambiguously: possibly the fluorination of the double bond involves a stage where fluoroalkyl derivatives of antimony(V) are formed with subsequent elimination of SbF_5. Presumably the dimerisation of fluoropropenes also includes a stage in which organoantimony compounds are produced. However, the analogous dimerisation of 3,3,3-trifluoropropene occurs when it is acted upon by fluorosulphonic acid and not SbF_5. The intermediate formation of the difluoroallyl cation in this reaction with its subsequent rearrangement to the final dimer has been suggested[145].

However, the dimerisation of hexafluoropropene or its reaction with C_6F_5H can be satisfactorily accounted for by assuming the formation of the vinyl cation $CF_3CF{=}CF^+$. Moreover, one must not fail to take into account the oxidising properties of SbF_5. Thus hexafluorobenzene forms a stable radical-cation in antimony pentafluoride.[146] The same radical-cation has been detected when SbF_5 was allowed to react with octafluorocyclohexa-1,4-diene, which also leads to the formation of decafluorocyclohexene—the disproportionation product[147]:



In principle, one cannot rule out the involvement of one-electron transfer processes also from the above reactions of fluoro-olefins, the study of which is being continued.

The oxidising properties of SbF_5 play a decisive role in the recently developed method for the synthesis of organofluorine derivatives of Group VI elements (sulphur, selenium, and tellurium). The method is based on the ability of these elements to form in SbF_5 the double charged cations E_n^{2+} (n = 4, 8, or 16).[148] When these solutions are allowed to react with fluoro-olefins, disulphides or diselenides are formed[149,150]:

$$CF_3{-}CF{=}CF_2 + E_n^{2+}\cdot 2SbF_6^- \xrightarrow[SbF_5]{} (CF_3)_2CF{-}E{-}E{-}CF(CF_3)_2;\quad E = S, Se.$$

When sulphur reacts with pentafluorobenzene in SbF_5, substitution takes place[151]:

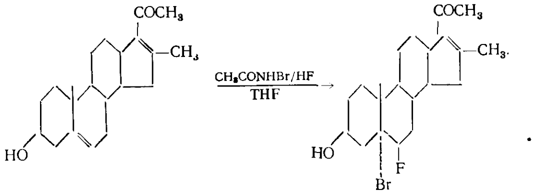
$$C_6F_5H \xrightarrow[SbF_5]{S} (C_6F_5)_2S.$$

Similar results have been obtained when the pure salts $S_8(AsF_6)_2$,[152] $Se_8(AsF_6)_2$,[153] and $Te_4(AsF_6)_2$ [154] were used instead of the solutions. The products of the reactions with tetrafluoroethylene are the corresponding organic derivatives of the elements, hexafluoroethane being formed as a side product.

Antimony pentafluoride in catalytic amounts effectively promotes the addition of arsenic trifluoride to fluoro-olefins[155]:

Sulphur trioxide reacts with fluoro-olefins just as readily as SbF_5, with formation of β-sultones, the chemistry of which has been reviewed[156].

Together with studies on new synthetic possibilities, arising from the application of highly reactive reagents, the development of mild synthetic methods suitable, for example, for physiologically active substances, is important. Thus the use of hydrogen fluoride diluted with tetrahydrofuran as the medium for coupled fluorobromination makes it possible to involve in the reaction only one (more reactive) double bond of 16-methylpregnadiene[157]:



The use of hydrogen fluoride in pyridine as the medium constitutes a significant improvement, permitting reactions involving coupled addition to systems which are unstable in anhydrous hydrogen fluoride[158]. A mild version of fluorohalogenation involves treatment of unsaturated compounds with iodine or bromine in the presence of AgF.[159]

The addition of $(CF_3)_2N{-}X$ (X = Cl, Br, or I) [160] or SF_5Br [161] to fluoro-olefins, the direction of which corresponds to electrophilic addition, should be nevertheless probably classified as a radical process, the direction of which is associated with the pronounced electrophilic properties of the attacking radicals[1]. The stereospecificity of the addition of $(CF_3)_2N{-}X$ (X = Cl or Br) to *cis*- and *trans*-butenes (*trans*-addition[162]) does not constitute exhaustive proof of an ionic process mechanism, since the addition of fluoroalkyl iodides to cyclopentene under the conditions of a radical reaction also leads exclusively to the *trans*-adduct[163].

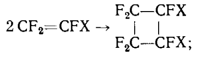
III. RADICAL REACTIONS

Both free-radical processes and reactions to which a latent radical mechanism can be attributed will be considered in this section. Since the latter reactions frequently include thos which have been treated previously as purely "ionic", the assignment of a process to the series of "ionic" or "radical" reactions is in many cases based merely on a traditional classification.

The radical reactions of organofluorine compounds are frequently distinguished by high selectivity, which makes them valuable in syntheses. Thus, using a radical process, it has proved possible to ("liven") activate fluoroalkanes containing the CF_2H group, which were regarded as inert with respect to any influences under mild conditions[164]:

$$n\text{-}C_3F_7H + FSO_2O{-}OSO_2F \xrightarrow[60-70°]{} n\text{-}C_3F_7OSO_2F.$$

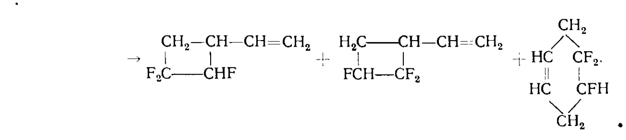
Cycloaddition processes belong to radical reactions of unsaturated organofluorine compounds which are of preparative value. The cyclodimerisation of fluoro-olefins, occurring readily on heating, proceeds very specifically: two molecules of an asymmetrically substituted olefin always combine "head to head":



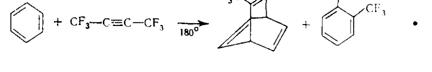
$$2\,CF_2{=}CFX \rightarrow \begin{array}{l} F_2C{-}CFX \\ \;\;|\qquad\;\; | \\ F_2C{-}CFX; \end{array}$$

$X = Cl^{165}$, $C_6H_5^{166}$.

The direction of cycloaddition indicates its "non-concerted mechanism", i.e. the involvement in the reaction of a stage where biradicals are formed, the formation of biradicals of the type $X\dot{C}FCF_2CF_2\dot{C}FX$, with a higher degree of delocalisation of electrons, being preferable[165,167]. The addition of tetrafluoroethylene to ethylene and to *cis*- and *trans*-butenes is also a non-concerted process[168]. However, when trifluoroethylene adds to 1,3-dienes, there is evidence of competition between two process mechanisms—a non-concerted mechanism leading to "2 + 2" addition and a concerted mechanism, which results in "2 + 4" addition[169,170]:

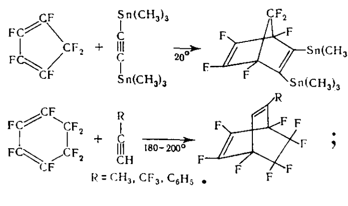


Hexafluorobut-2-yne, which has an extremely electrophilic triple bond, reacts as a dienophile even with aromatic hydrocarbons[171]:



At a higher temperature, bicyclic adducts can not be isolated and poly(fluoroalkyl)benzenes become the main reaction products. The process thus reduces to the substitution of acetylene by hexafluorobut-2-yne. When the same starting materials are irradiated with ultraviolet light in the gas phase, the main reaction product is 1,2-bis(trifluoromethyl)cyclo-octatetraene.[171]

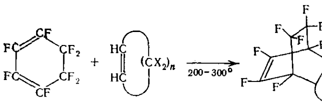
Fully fluorinated cyclic 1,3-dienes are also capable of involvement in diene synthesis[172,173]:



(5)

Pyrolysis of the products of reaction (5) leads to the elimination of C_2F_5 and the formation of substituted 1,2,3,4-tetrafluorobenzenes.[173]

Octafluorocyclohexadiene adds also to cyclo-olefins [174]:



X = H, F; n = 2–4 .

Reactions using fluoroalkyl radicals generated by electrochemical methods are of preparative interest, since readily available carboxylic acids can then be used as the starting compounds. The simplest process occurring in the electrolysis of acids is the Kolbe reaction, for example[175]:

$$2\,(CF_3)_2CH{-}CO_2H \xrightarrow[\text{Pt anode}]{} (CF_3)_2CH{-}CH(CF_3)_2 + 2CO_2.$$

The resulting product is a convenient starting compound for the synthesis of decafluoro-2,3-dimethylbutadiene.

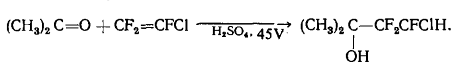
In the presence of agents capable of reacting with a radical, the Kolbe synthesis is suppressed, which leads to many interesting possibilities[176,177]:

$$\begin{gathered} CF_3COOH + Br_2 \xrightarrow[\text{anode}]{} CF_3Br + CO_2; \\ CF_3COOH + H_2O \xrightarrow[\text{anode}]{} CF_3{-}O{-}O{-}CF_3 + CO_2. \end{gathered} \tag{6}$$

It is noteworthy that, under certain electrolysis conditions, an unexpected product of reaction (6) (a peroxide) is obtained in yields up to 80%. Its formation is caused by the fact that the oxidation potential of water is somewhat lower than that of trifluoroacetic acid. Hexafluoroethane, the "normal" reaction product, becomes an impurity (together with trifluoromethyl ether).[177]

Interesting possibilities arise from the "mixed" version of the Kolbe reaction. Thus joint electrolysis of propionic and trifluoroacetic acids gave 3,3,3-trifluoropropene in 23% yield (in a mixture with other products). The authors[178] suggest that the formation of an unsaturated product is caused by the preliminary dehydrogenation of propionic acid, leading ultimately to ethylene, which actually reacts with the $\dot{C}F_3$ radical.

The condensation of acetone with chlorotrifluoroethylene, a cathodic process, is likewise of interest[179]:



$$(CH_3)_2C{=}O + CF_2{=}CFCl \xrightarrow[H_2SO_4,\ 45V]{} (CH_3)_2\underset{\displaystyle OH}{\underset{|}{C}}{-}CF_2CFClH.$$

Evidently the species attacking the C_2F_3Cl molecule is the fairly stable radical $(CH_3)_2\dot{C}OH$, formed as a result of the protonation of the acetone ketyl.

Electrochemical reduction of the CF_3 group linked to an aromatic ring cannot be stopped at the stage involving the formation of the CHF_2 or CH_3F group when there is a methoxycarbonyl group in the *meta*- or *para*-position. Two different mechanisms then operate—a one-electron reversible mechanism for the *meta*-isomer and a two-electron irreversible mechanism for the *para*-isomer (cyclic voltammetry [180]).

The reduction of fluorine atoms linked to the benzene ring is facilitated as they accumulate. Each fluorine atom in pentafluorobenzene is reduced in a one-electron irreversible process via the following mechanism[181]:

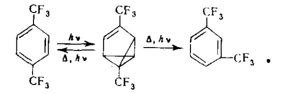
$$ArF \xrightarrow{e} [ArF]^{\cdot} \xrightarrow{H+} [ArFH]^{\cdot} \xrightarrow{e} [ArFH]^{-} \xrightarrow{-F^-} ArH.$$

The first reduction product of pentafluorobenzene is 1,3,4,5-tetrafluorobenzene, i.e. the hydrogen atom is introduced in the *meta*-position relative to that already present and the direction of substitution is similar to that observed in nucleophilic reactions[181]. The reduction of fluorobenzene is difficult, but potassium in liquid ammonia causes it to react with potassium acetonate[182]:

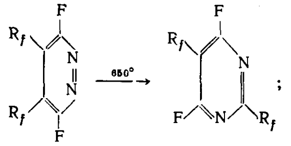
$$C_6H_5F \xrightarrow[K/NH_3,\ -78^{\circ}]{} [C_6\dot{H}_5] \xrightarrow{[CH_3CO\bar{C}H_2]K+} C_6H_5CH_2\underset{\displaystyle OH}{\underset{|}{C}}HCH_3 .$$

Even a Grignard reagent can be synthesised from fluorobenzene with the aid of specially prepared highly reactive magnesium (admittedly in a low yield)[183].

As already mentioned[1], when aromatic fluoro-compounds are irradiated with ultraviolet light, their valence isomers are readily formed. When the aromatic ring contains fluoroalkyl groups, irradiation leads to rearrangements including a benzvalene formation stage[184]:

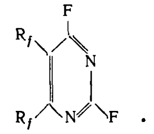


The reaction has a low quantum yield. Similar rearrangements occur also in the series of heterocycles at high temperatures[185]:

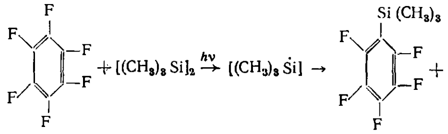


$R_f = (CF_3)_2CF$— .

When $R_f = C_2F_5$, there is no migration of the fluoroalkyl group and the following compound is formed:

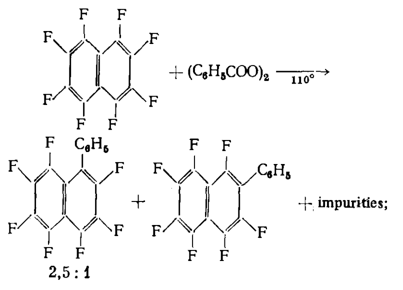


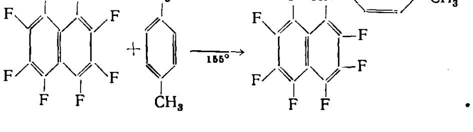
A new type of photochemical reaction of aromatic fluoro-compounds is substitution or addition involving C–F bonds, for example[186]:



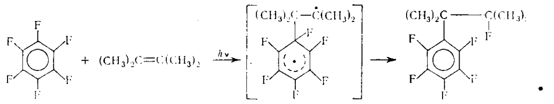
$$+ [(CH_3)_3Si]_2 \xrightarrow{h\nu} [(CH_3)_3\dot{S}i] \rightarrow \ldots + (CH_3)_3SiF + 1.3\text{- и } 1.4\text{-}[(CH_3)_3Si]_2C_6F_4.$$

Similar reactions occur also on thermal generation of radical species[187,188]:

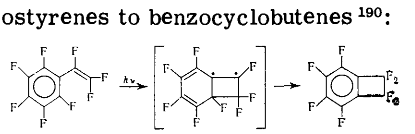




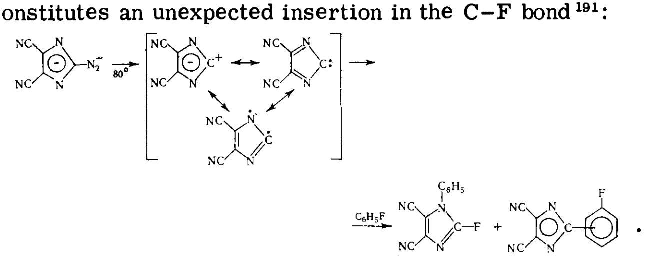
On ultraviolet irradiation, olefins are capable of being "inserted" in the C–F bond[189]:



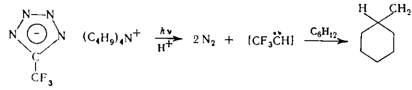
An intramolecular version of this reaction is the cyclisation of polyfluorostyrenes to benzocyclobutenes[190]:



The reaction of fluorobenzene with an extremely interesting carbene having the overall formula C_5N_4 constitutes an unexpected insertion in the C–F bond[191]:



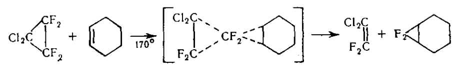
The search for new convenient sources of carbenes is a characteristic feature of research in the chemistry of these species (see Hoffmann's review[192]). Organosilicon ($CHF_2CF_2SiF_3$)[193] or organomercury ($CF_3HgOCOCF_3 + NaI$)[194] compounds are accessible sources of fluorine-containing carbenes. The ready decomposition, promited by iridium complexes, of $CF_2ClCOONa$, which is a traditional source of difluorocarbene, holds out some promise. The only reaction products isolated were iridium compounds, in particular $ClCF_3COO\underset{\underset{CF_2H}{|}}{Ir}(CO)[P(C_6H_5)_3]_2$. Research on its synthetic applications is being continued[195]. Fluorine-containing carbenes are readily generated also with the aid of photochemical reactions[196,197]:



$$CF_2{=}N{-}N{=}CF_2 \xrightarrow{h\nu} CF_2{=}N{-}CF_2{-}N{=}CF_2\ .$$

In the latter case the source of the carbene itself plays the role of a carbene trap[197].

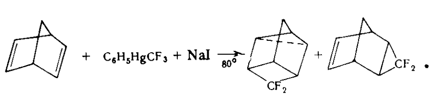
Another source of difluorocarbene employed is 1,1-difluorocyclopropanes—the products of the addition of difluorocarbene to olefins. It is remarkable that the transfer of carbene takes place under milder conditions than the decomposition of the cyclopropane in the absence of the other reactant. This suggests that the transfer proceeds without the formation of a kinetically independent carbene and constitutes "nucleophilic substitution" at the CF_2 group. The reaction takes place with a quantitative yield[198]:



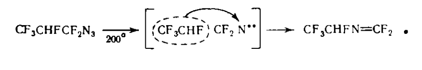
1-Trifluoromethyltrifluoro-oxiran, a widely used source of CF_2, can also be obtained from trifluoroacetyl fluoride—its usual decomposition product[199]:

$$(CF_3)_2PF_2 + CF_3\underset{\underset{O}{\|}}{C}F \xrightarrow[130^\circ]{} CF_3{-}CF{-}CF_2\ (\text{—O— bridge}).$$

Owing to the weak electrophilic properties of difluorocarbene, it has been possible to cause its addition to norbornadiene in an unusual manner[200]:

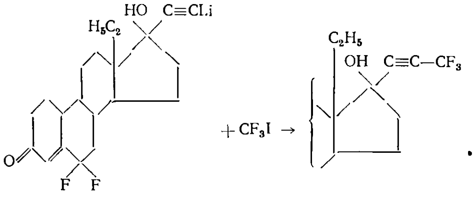


Fluoroalkylnitrenes, formed in the thermolysis of the corresponding azides, undergo a rearrangement analogous to the Curtius rearrangement. This finding illustrates the similarity between the CF_2 and C=O groups[201]:

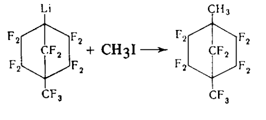


$$CF_3CHFCF_2N_3 \xrightarrow[200^\circ]{} \left[CF_3CHF\,CF_2N^{\cdot\cdot}\right] \longrightarrow CF_3CHFN{=}CF_2\ .$$

Reactions involving the single-stage introduction of a polyfluoroalkyl group into an organic molecule are extremely important from the preparative point of view. Certain examples of such reactions have been examined in previous sections, but they were not general. The simplest method for combining hydrocarbon and fluorocarbon residues, namely the Wurtz reaction, does not occur in many cases: when organomagnesium compounds, for example, interact with fluoroalkyl iodides, there is only metal halide exchange[45], caused by the large difference between the electronegativities of the fluoroalkyl and alkyl groups[113]. However, acetylides are probably capable of substituting iodine in fluoroalkyl iodides[203]:



The reason for this mode of reaction may be the high electronegativity of carbon in the *sp*-hybridised state. Other examples of this reaction are not quoted in the literature. The "opposite" case—the Wurtz reaction between fluoroalkyl derivatives of lithium and methyl iodide—is apparently specific to the bicyclic system involved in it[203]:



An unusual method for the introduction of a fluoroalkyl group into ferrocene has been described in a patent[204]:

$$(C_5H_5FeC_5H_4)_2Hg + C_3F_7I \xrightarrow[100^\circ,\ C_6H_6]{} C_5H_5FeC_5H_4C_3F_7\ .$$

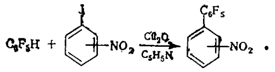
Since the reaction is unknown for other organomercury compounds, presumably the reducing properties of the iron atom forming part of ferrocene play an important role in this case. This hypothesis is supported by the finding that reactions of the type of the Wurtz reaction (RMgBr + R′Br) are effectively promoted by transition metal salts (silver or copper salts) and also (for R = alkenyl) by metallic iron[205].

The recently described synthesis of fluorine-containing ketones is a related process. The reaction is catalysed by a carbonylate anion:

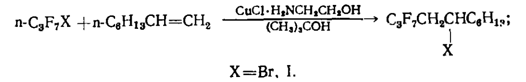
$$n\text{-}C_7H_{15}COCl + Br(CH_2)_6CN \xrightarrow[Na_2Fe(CO)_4]{} C_7F_{15}CO(CH_2)_6CN.$$

Not only acyl chlorides but also fluoroalkyl bromides can be used as the starting compounds. In this case the carbonylate serves as a source of CO.[206]

However, univalent copper is a particularly effective and widely used catalyst. Thus, in the presence of copper(I) oxide, pentafluorobenzene is readily arylated[207]:



Fluoroalkyl halides add to olefins under mild conditions when the reaction is catalysed by a CuCl complex with ethanolamine. The reaction takes place with a high yield and is not accompanied by telomerisation[208]:



$$n\text{-}C_3F_7X + n\text{-}C_6H_{13}CH{=}CH_2 \xrightarrow[(CH_3)_3COH]{CuCl\cdot H_2NCH_2CH_2OH} C_3F_7CH_2\underset{\displaystyle X}{\underset{|}{C}}HC_6H_{13};$$

$X{=}Br, I.$

Copper can be involved in electrophilic cooperation in the substitution of a halogen other than fluorine in the compounds C_6F_5X (X = Br or I). In the absence of copper, only fluorine undergoes nucleophilic substitution by alcohols, amines, or mercaptans, but in its presence the mode of reaction changes completely. Thiourea, which binds copper, restores the usual mode of reaction[209]:

$$C_6F_5Br + C_4H_9SCu \xrightarrow[(CH_3)_2NCHO]{} \begin{cases} \xrightarrow{\qquad} C_6F_5SC_4H_9 \\ \xrightarrow[4(NH_2)_2C=S]{} n\text{-}C_4H_9SC_6F_4Br. \end{cases} \qquad (7)$$

The reaction with secondary amines in the presence of CuBr involves the reduction of the C–Br bond together with the substitution of fluorine[209].

Evidently the catalytic activity of univalent copper is due to its ability to be oxidised by transferring an electron to the C–Br or C–I bond. Copper forming part of fluoroalkyl derivatives, which are fairly resistant to heat and hydrolysis, probably retains this ability (see Normant's review[210]). These compounds are readily obtained by the general method for the synthesis of many organometallic derivatives—the reaction between the metal and the halide. In the series of organofluorine derivatives, the reaction is used for a particularly wide range of elements[211-213]:

$$R_fI + M \to R_fM + MI;$$
$$R_f{=}n\text{-}C_3F_7,\ n\text{-}C_7F_{15},\ M{=}Cu;$$
$$R_f = C_6F_5,\quad M = \frac{1}{2}Zn,\ Cd.$$

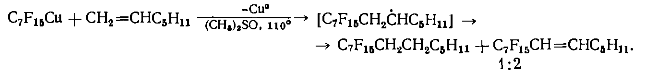
Other examples are quoted in a previous review[1].

Fluoroalkyl derivatives of copper are capable of adding to olefins, which results in the formation of a mixture of alkanes and alkenes[214]:

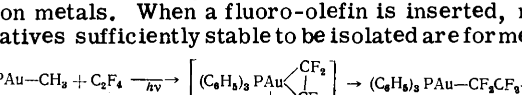
$$C_7F_{15}Cu + CH_2{=}CHC_5H_{11} \xrightarrow[(CH_3)_2SO,\ 110°]{-Cu^0} [C_7F_{15}CH_2\dot{C}HC_5H_{11}] \to$$
$$\to C_7F_{15}CH_2CH_2C_5H_{11} + C_7F_{15}CH{=}CHC_5H_{11}.$$

1:2

This reaction probably includes a "*cis*-insertion" stage, which is common to many reactions of σ-derivatives of transition metals. When a fluoro-olefin is inserted, new σ-derivatives sufficiently stable to be isolated are formed[215]:



A similar stage may be involved also in the fluoroalkylation of halogeno-olefins by copper compounds[214]:



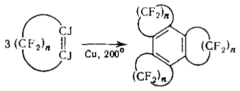
$R_f{=}C_3F_7,\ C_7F_{15}.$

Another explanation is that copper is merely involved in electrophilic cooperation in the substitution of a halogen by the R_f anion, as in reaction (7).[216]

All these processes closely resemble the classical Ullmann reaction, whose "mixed" version can be very successfully achieved using fluoroalkyl derivatives of copper:

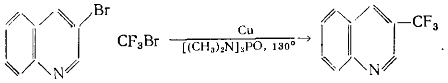
$$R_fHal + RHal \to R_f{-}R.$$

Since RHal is added to a previously prepared solution of R_fCu, the formation of $R_f{-}R_f$ or R–R is ruled out[217,218]. A novel method for the synthesis of an aromatic system has been described in a patent[219]:



$n = 2, 3$.

A particularly valuable feature is that the Ullmann reaction makes it possible to introduce a fluoroalkyl group into heterocyclic compounds and it has been found that fluoroalkyl bromides, which are much cheaper than the iodides, can be used as a source of such groups[220]:



Under more severe conditions, a fluoroalkyl group can be introduced into the benzene ring, substituting a hydrogen atom, with the aid of fluoroalkyl derivatives of copper. The reaction evidently has a free-radical mechanism[221].

ADDENDUM

During the preparation of the review for the press, a number of new publications of significant interest appeared. Among these, mention should be made of a two-volume edition[222], which is a valuable compilation of studies in organofluorine chemistry published during 1969–1972. Another publication is a book entitled "Ftorpolimery" (Fluoro-Polymers)[223], which includes, among others, an extensive chapter devoted to the synthesis and properties of fluorine-containing monomers. In addition, data concerning the thermal stabilities[224] of fluoro-polymers and their resistance to benzene and oils[225] have also been reviewed. Among other new reviews, mention should be made of a paper[226] devoted to fluorine-containing medicinal preparations, a compilation of data[227] concerning the applications of fluorocarbon emulsions as blood substitutes, a review[228] of the valence isomers of aromatic poly(fluoroalkyl) compounds, and a paper[229] containing data on the silylation reactions of certain organofluorine compounds. A paper by Liebman[230], containing an extensive compilation of data on nucleophilic substitution reactions directed to the fluorine atom, is also of interest.

New data concerning the influence of the CF_3 group on the benzene ring to which it is linked have been obtained[231] by photoelectronic spectroscopy. The wide scope of this research technique in the study of organofluorine compounds has been demonstrated by an investigation[232] in which the structure of the hexafluorocyclobutene trimer has been proved with its aid and also in a study[233] where the method has been used to investigate thin layers of fluoro-polymers obtained photochemically on supports.

A number of new studies of the properties of the fluoride ion have been published. Thus a new version of the synthesis of alkyl fluorides has been proposed: by treating alkyl trifluoromethylsulphinates with caesium fluoride[234]. A method suggested[235] for increasing the reactivity of KF and also its solubility in aprotic solvents (acetonitrile, benzene) with the aid of a macrocyclic complex-forming agent (18-crown-6) also apparently gives rise to important possibilities. The geometry of the hydrogen fluoride ion has been studied[236]. A paper[237] is devoted to the anodic oxidation of *para*-disubstituted benzenes in the presence of the fluoride ion.

Reactions involving the elimination of the fluoride ion from organic molecules have been investigated[238,239]. The first study is devoted to the unusual reaction of polyfluorinated aldehydes with hydrazines, leading to the formation of alkazones. In the second study, an extremely convenient agent is proposed for the dehydrofluorination of polyfluorinated hydrocarbons—the complex $(C_2H_5)_3N.BF_3$. Derivatives of pentafluoromethacrylic acid can be readily synthesised with its aid[239]. The reactions of these derivatives with amines[240], isonitriles[241], and trialkyl phosphites[242] have also been investigated. The last reaction constitutes an unusual version of the substitution of vinyl fluorine atoms by alkoxy-groups. Among other studies in the chemistry of highly electrophilic organofluorine compounds, mention should be made of an investigation[243] of the synthesis and properties of 6,6-bis(trifluoromethyl)fulvene. A paper[244] deals in detail with the reaction of octafluoroisobutene with haloforms in the presence of CsF. New electrophilic olefins (perfluoromethylenecyclopropane[245]) and also ethylenes containing the CF_3SO_2 group[246] have been investigated.

A study has been made of the synthesis and properties of acetylene containing the same substituent[247].

The reactions of fluoro-olefins with nucleophilic agents have been the subject of a study[248] in which the erroneous results of studies by earlier workers, who investigated the reactions of fluoro-olefins with sodiomalonic ester have been revised, a study dealing with the addition-elimination mechanism in nucleophilic reactions[249], and also a study[250] where the radical and ionic pathways in the reactions between fluoro-olefins and phosphines are considered. The characteristics of nucleophilic substitution in perfluoromesitylene are discussed by Markov et al.[251]

A number of studies have been devoted to fluorine-containing organometallic compounds: that of Nefedov et al.[252], who investigated the mechanism of the elimination of LiF by the *o*-fluorophenyl-lithium ether adduct, a study by Fedorov et al.[253] of the stoichiometry of the solvation of fluoroalkyl derivatives of mercury (by NMR), and a study[254] where an unusual type of thermal decomposition of 1,6-di(bromomagnesio)dodecafluorohexane, leading to high yields of decafluorocyclohexene, has been demonstrated. The syntheses of a number of fluorine-containing β-diketones—analogues of thenoyltrifluoroacetone which are promising complex-forming agents—have been described[255].

New reactions of fluorine-containing oxirans have been investigated—their synthesis form α-substituted difluoroacrylic acids[256] and the interaction of oxirans with azides[257] and lithium aluminium hydride[258]. In addition the mode of the opening of the oxiran ring has been studied as a function of the catalyst employed and the reaction conditions[259].

Among investigations devoted to electrophilic reactions of fluoro-olefins, mention should be made of those concerned with the reactions of metastable enols of polyfluoroacetones[260] (see Bekker et al. for the synthesis of the enols[261]). The behaviour of polyfluorinated 1,3-dienes under the conditions of ionic halogenation has been studied[262]. It is remarkable that the authors demonstrated the tendency of these compounds towards 1,4-addition. The alkenylation of aromatic polyfluoro-compounds by hexafluoropropene[263] and by polyfluorinated arenonium ions[264] (the generation of these ions has been described[265]) has been studied in detail. The remarkable ability of the SO_2–SbF_5 mixture (usually employed merely as a catalyst of electrophilic processes) to serve as an agent for introducing the SO_2 group into organic molecules has been discovered[266].

New radical reactions involving the addition of CF_3–O–O–Cl[267] and CF_3–S–S–Cl[268] to fluoro-olefins under mild conditions have been described[268]. The directions and rates of reaction have been studied in relation to the addition of CBr_4 and $CHBr_3$.[269] The high-temperature reaction between trifluoroiodoethylene and sulphur leads to a dimeric product: tetrafluorodithiosuccinyl fluoride[270]. It has been established that the free radicals $C_2F_5^{\cdot}$ react with hexafluorobenzene, forming a mixture of isomers of 4,4′-diethylperfluorotetrahydrobiphenyl.[271] A novel method for the generation of CF_3 radicals by the action of a glow discharge on hexafluoroethane enabled Lagow et al.[272] to synthesise in high yields derivatives of mercury, tellurium, tin, and germanium fully substituted by CF_3 groups. The photochemical generation of the CF_3 group from CF_3I permitted the synthesis of α-fluoroalkyl ketones from enamines[273]. The photolysis of CF_3I in the presence of benzene derivatives leads to substituted trifluoromethylbenzenes; the direction of substitution has been studied[274]. Among other photochemical reactions, mention should be made of an elegant synthesis of tetrakis(trifluoromethyl)cyclobutadiene dimer from the ozonide of hexakis(trifluoromethyl)benzvalene[275]. The selectivity and kinetics of the addition of difluorocarbene to substituted styrenes have been investigated[276].

The research on a very promising method for the introduction of fluoroalkyl groups into organic molecules with the aid of organocopper compounds by a reaction of the Ullmann type (a new review of this reaction has been published[277]) is being continued. Methods for the synthesis of acids and alcohols[278] and alkynes[279] containing fluoroalkyl groups have been developed on the basis of products obtained by the substitution of bromine in bromoalkenes. Interesting results have been obtained in a study of the reactions of fluoroalkylcopper compounds with 1-bromo-1-fluoroalkylethylenes[280]. Unexpectedly, this results in the formation of 1,2-bis(fluoroalkyl)ethylenes, i.e. the substitution of bromine takes place with transfer of the reaction centre, which suggests the involvement of the copper *d* electrons in the intermediate stages of the process.

Derivatives of Perfluoromethacrylic Acid

E.M.Rokhlin, Ë.G.Abduganiev, and U.Utebaev

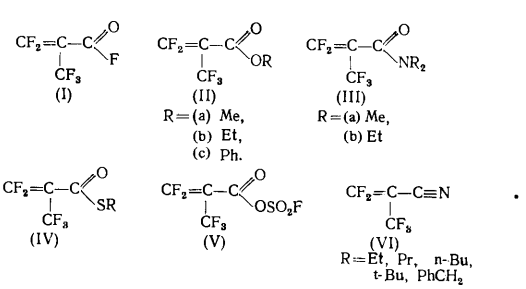
Methods for the synthesis and the chemical properties of perfluoromethacrylic acid derivatives are examined. The most characteristic reactions of these compounds are those with nucleophiles, including very weak nucleophiles; cycloaddition reactions are very common, and some perfluoromethacrylic acid derivatives polymerise and copolymerise with various unsaturated compounds.
The bibliography includes 83 references.

CONTENTS

I. INTRODUCTION

The comparatively ready availability and high reactivity of derivatives of $\alpha\beta$-unsaturated fluorine-containing carboxylic acids are responsible for the understandable interest shown in these compounds by investigators working in the fields of both pure and applied chemistry of organofluorine compounds. Derivatives of perfluoromethacrylic acid (**PFMA**) proved to be particularly reactive. Vigorous studies on compounds belonging to this class did not begin until very recent years, but during this short period it has proved possible to demonstrate the wide variety of their reactions and their synthetic possibilities. One cannot rule out the possibility that some **PFMA** derivatives may be used as monomers.

PFMA itself and its salts have not so far been obtained. It is quite likely that these compounds (particularly the salts) are altogether incapable of existence, since their molecules would contain simultaneously a nucleophilic centre (the COOH or COO^- group) and the highly electrophilic group $CF_2{=}C(CF_3)$. However, PFMA derivatives have been described in the literature: the acid fluoride (**I**), esters (**II**), dialkylamides (**III**), esters of the corresponding thiolo-acid (**IV**), the mixed anhydride of **PFMA** and fluorosulphonic acid (**V**), and perfluoromethacrylonitrile (**VI**).



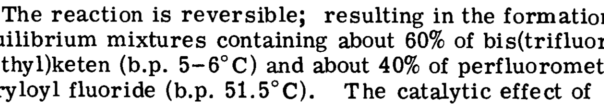
This review describes methods for the synthesis of these derivatives and their chemical reactions.

II. METHODS OF SYNTHESIS

The high reactivity of **PFMA** derivatives as a rule precludes the use for their synthesis of the usual synthetic methods for perfluoro-olefins or perfluorocarboxylic acid derivatives. In most cases it has been necessary to develop special methods (or special procedures) in order to obtain these compounds.

1. The Isomerisation of Bis(trifluoromethyl)keten

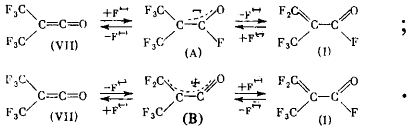
The first **PFMA** derivative, the acid fluoride (**I**), was obtained by the isomerisation of the comparatively readily available bis(trifluoromethyl)keten (**VII**):[1]



$$(CF_3)_2C{=}CF_2 \xrightarrow{H_2O} (CF_3)_2CHCOOH \xrightarrow{P_2O_5} \underset{(VII)}{(CF_3)_2C{=}C{=}O} \xrightarrow[\text{catalyst}]{t^\circ} \to \underset{\displaystyle CF_3}{\underset{|}{CF_2{=}C}}{-}COF \quad (I) \quad .$$

This reaction takes place when gaseous bis(trifluoromethyl)keten is passed over NaF at 200–300°C[2-5] or through a hollow glass tube at 400°C[6] and also on heating under pressure with glass wool[1], with a catalytic amount of $Et_2O.BF_3$,[7] or with butylether (preferably in the presence of $ZnCl_2$).[1]

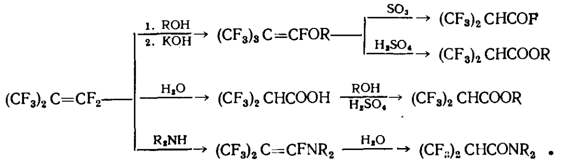
The reaction is reversible; resulting in the formation of equilibrium mixtures containing about 60% of bis(trifluoromethyl)keten (b.p. 5–6°C) and about 40% of perfluoromethacryloyl fluoride (b.p. 51.5°C). The catalytic effect of NaF indicates the intermediate formation of a mesomeric fluorine-containing carbanion (A); in the absence of NaF, small amounts of F^- ions are obtained, probably as a result of the etching of the glass[6]. On the other hand, in the isomerisation under the influence of Lewis acids ($ZnCl_2$ and BF_3), the elimination of the F^- anion with intermediate formation of a mesomeric carbonium ion (B) is postulated[7]:



The isomerisation of bis(trifluoromethyl)keten is the most convenient method for the preparation of perfluoromethacryloyl fluoride. However, unfortunately other PFMA derivatives cannot usually be obtained directly from the acid fluoride, since attack by nucleophiles is directed primarily to the β-carbon atom of the "acrylic" system and not to the carbonyl group (see Section **III**). The formation of **PFMA** derivatives from the fluoride (**I**) therefore requires protection of the reactive $CF_2{=}C<$ group (for example by halogenation) followed by reaction with a nucleophile (e.g. an alcohol), and the removal of the protecting group[8]†. Incidentally, in most cases it is more convenient to use other methods for the synthesis of PFMA derivatives—dehydrofluorination of derivatives of α-hydrohexafluoroisobutyric acid and electrophilic elimination of alkyl fluorides from alkoxypolyfluoroisobutenes.

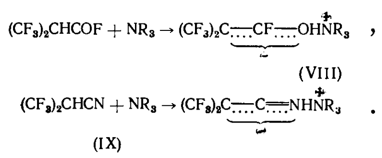
2. Dehydrofluorination of α-Hydrohexafluoroisobutyric Acid Derivatives

Derivatives of α-hydrohexafluoroisobutyric acid (HFIBA) are fairly readily available; they are obtained from perfluoroisobutene (see, for example, Refs. 9–11):



These derivatives contain in the α-position a labile hydrogen atom and in principle should be readily dehydrofluorinated in the presence of bases. However, the usual methods for the preparation of perfluoro-olefins—dehydrofluorination of fluoroalkanes by alkalis[12–14]—is inapplicable in this instance, since PFMA derivatives very readily undergo further attack by the nucleophiles[7] (see Section III).

When the acid fluoride of HFIBA is acted upon by triethylamine, only the first dehydrofluorination stage is achieved—the elimination of the proton—and the stable salt (VIII), containing the mesomeric perfluoroisobutenoxide anion, is formed[1]. The nitrile of HFIBA (IX) reacts similarly[15]:



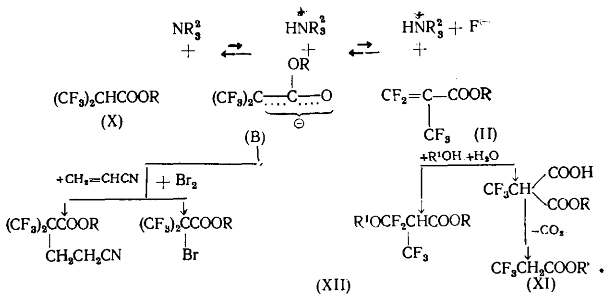
$$(CF_3)_2CHCOF + NR_3 \rightarrow (CF_3)_2C\underbrace{\cdots CF\cdots}_{-}O\overset{+}{H}NR_3 \text{ ,}$$

(VIII)

$$(CF_3)_2CHCN + NR_3 \rightarrow (CF_3)_2C\underbrace{\cdots C\cdots}_{-}N\overset{+}{H}NR_3 \text{ .}$$

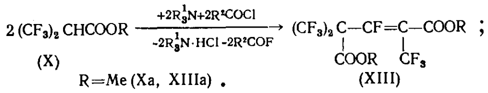
(IX)

HFIBA esters (X) in which the hydrogen atom is less mobile, form on treatment with a tertiary amine equilibrium mixtures containing mainly the initial ester together with small amounts of the mesomeric carbanion (C) and PFMA esters (II). The addition of a third component, which reacts either with the carbanion or with the PFMA ester, displaces the equilibrium towards the formation of the final products[6,14]. Indeed, in the presence of triethylamine or pyridine, HFIBA esters are readily brominated[16,17] and cyanoethylated[18] and, on treatment with water and alcohols, give respectively the esters of βββ-trifluoropropionic acid (XI)[19] and those of α-hydro-β-alkoxypentafluoroisobutyric acids (XII)[20]:



(1)

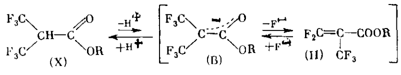
The removal of the F⁻ anion from the equilibrium (for example on treatment with an acyl chloride) should lead to the formation of the PFMA ester. It is known that, when nonafluoroisobutane $(CF_3)_3CH$ reacts with triethylamine and benzoyl chloride it is dehydrofluorinated, yielding perfluoroisobutene $(CF_3)_2C{=}CF_2$.[20] However, the analogous reaction with the HFIBA ester leads only to the "dimer" (XIIIa):[21,22]



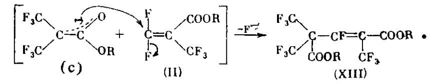
$$2(CF_3)_2CHCOOR \xrightarrow[-2R_3^1N\cdot HCl-2R^2COF]{+2R_3^1N+2R^2COCl} (CF_3)_2\underset{COOR}{C}{-}CF{=}\underset{CF_3}{C}{-}COOR \text{ ;}$$

(X) R=Me (Xa, XIIIa) . (XIII)

Evidently this involves the intermediate formation of the PFMA ester (II), but the exceptional reactivity of this compound precludes its isolation, since it reacts immediately with the fluoro-carbanion (C); substitution of the vinyl fluorine atom yields the "dimer" (XIII):



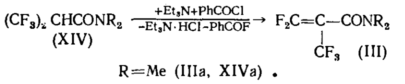
(2)



(3)

The analogous interaction of triethylammonium perfluoroisobutenoxide (VIII) with an acyl chloride leads to "δ-lactone-dimers"[6,23] [cf. Eqn. (10)].

The dimethylamide of PFMA, which is less reactive than its fluoride and esters, can be obtained from the saturated amide (XIVa) on treatment with triethylamine and benzoyl chloride[7]:

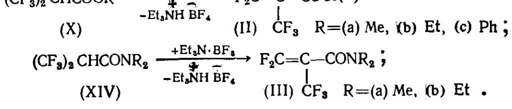


$$(CF_3)_2CHCONR_2 \xrightarrow[-Et_3N\cdot HCl-PhCOF]{+Et_3N+PhCOCl} F_2C{=}\underset{CF_3}{C}{-}CONR_2 \text{ ;}$$

(XIV) (III)

R=Me (IIIa, XIVa) .

A very convenient dehydrofluorinating agent for the synthesis of PFMA derivatives from the corresponding HFIBA derivatives proved to be the adduct of triethylamine with boron trifluoride $Et_3N.BF_3$. On treatment with this adduct, the esters and dialkylamides of HFIBA are converted into the PFMA derivatives (II) and (III) in high yields[7,10,24]:



$$(CF_3)_2CHCOOR \xrightarrow[-Et_3\overset{+}{N}H\,\overset{-}{B}F_4]{+Et_3N\cdot BF_3} F_2C{=}\underset{CF_3}{C}{-}COOR \text{ ;}$$

(X) (II) R=(a) Me, (b) Et, (c) Ph ;

$$(CF_3)_2CHCONR_2 \xrightarrow[-Et_3\overset{+}{N}H\,\overset{-}{B}F_4]{+Et_3N\cdot BF_3} F_2C{=}\underset{CF_3}{C}{-}CONR_2 \text{ ;}$$

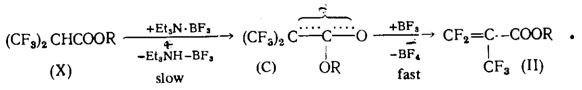
(XIV) (III) R=(a) Me, (b) Et .

---

† The method for the preparation of methyl perfluoromethacrylate from the acid fluoride via perfluoromethacryloyl fluorosulphonate (V) is described at the end of Section II.

‡ The ester of difluoromethylenemalonic acid $F_2C{=}C(COOMe)_2$ has been obtained similarly from the ester of trifluoromethylmalonic acid[25].

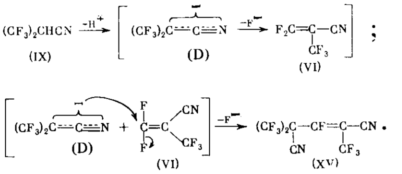
There are no "dimers" in the reaction products even when HFIBA esters are dehydrofluorinated. Evidently the nucleophilic properties of the adduct $Et_3N.BF_3$ are reduced so much that the carbanion (C) is formed slowly compared with the next stage—the elimination of the F^- anion from the carbanion:



$$\underset{(X)}{(CF_3)_2CHCOOR} \xrightarrow[\substack{-Et_3\overset{+}{N}H-BF_3 \\ \text{slow}}]{+Et_3N\cdot BF_3} \underset{(C)}{(CF_3)_2C\cdots\underset{OR}{C}\cdots O^-} \xrightarrow[\substack{-\overset{-}{BF_4} \\ \text{fast}}]{+BF_3} \underset{CF_3\ (II)}{CF_2{=}C{-}COOR} \ .$$

The carbanion (C) does not accumulate in the mixture and there is not sufficient time for its reaction with the PFMA ester, which would lead to the "dimer" (XIII). The dehydrofluorination of the dimethylamide of PFMA is accelerated in the presence of triethylamine and retarded in the presence of $Et_2O.BF_3$. This apparently confirms that the slowest stage determining the rate of the entire dehydrofluorination process is heterolysis of the C–H bond[10].

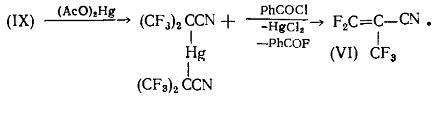
When an attempt was made to synthesise perfluoromethacrylonitrile by this procedure from the nitrile of HFIBA, only the "dimer" (XV) was obtained. The equilibrium in the heterolysis of the C–H bond of a strong CH acid such as the nitrile (IX) is displaced to the right[15], so that sufficient carbanion (D) is obtained for it to be able to react with perfluoromethacrylonitrile, forming the dinitrile (XV)[10]:



(4)

When the less basic adduct of pyridine and boron trifluoride was used, only the "dimer" was again obtained[10].

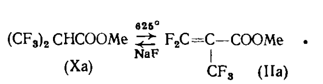
Perfluoromethacrylonitrile can be synthesised from the saturated nitrile (IX) by an indirect procedure—via an organomercury derivative[26]:



$$(IX) \xrightarrow{(AcO)_2Hg} \underset{\substack{| \\ Hg \\ | \\ (CF_3)_2CCN}}{(CF_3)_2CCN} + \xrightarrow[\substack{-HgCl_2 \\ -PhCOF}]{PhCOCl} \underset{(VI)\ CF_3}{F_2C{=}C{-}CN} \ . \qquad (5)$$

Yet another method for the synthesis of PFMA derivatives from the corresponding HFIBA derivatives involves thermal dehydrofluorination in the vapour phase over a catalyst. In the dehydrofluorination of the fluoride of HFIBA, the reaction is complicated by isomerisation and dimerisation. Thus, when the vapour of the HFIBA fluoride was passed over NaF, a mixture of perfluoromethacryloyl fluoride and bis(trifluoromethyl)keten was obtained[9]. Under other conditions, treatment with KF leads to the formation of "δ-lactone-dimers" [cf. Eqn. (10)] and at 400°C over glass wool one obtains a mixture containing 1,1,3,3,3-pentafluoropropene and other products in addition to perfluoromethacryloyl fluoride and bis(trifluoromethyl)keten[8].

Methyl perfluoromethacrylate is obtained by the dehydrofluorination of the methyl ester of HFIBA over sodium chloride[9,27]:

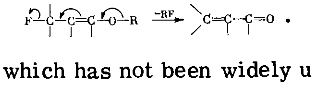


$$\underset{(Xa)}{(CF_3)_2CHCOOMe} \underset{NaF}{\overset{625^\circ}{\rightleftarrows}} \underset{CF_3\quad (IIa)}{F_2C{=}C{-}COOMe} \ . \qquad (6)$$

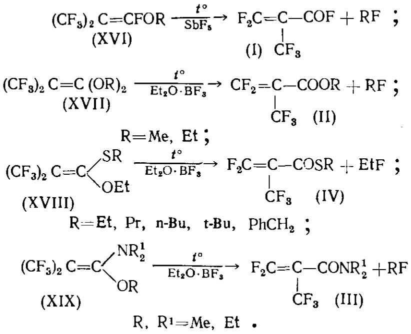
This results in the formation of an equilibrium mixture containing almost equal amounts of the dehydrofluorination products and of the initial saturated ester; the separation of the mixture by distillation is difficult owing to the similar boiling points of these two compounds. It has been stated (without experimental evidence) that it is useful to employ NaF together with quartz in this reaction[27] §.

3. Electrophilic Elimination of Alkyl Fluorides from Alkoxypolyfluoroisobutenes

One of the possible ways of forming a fluorine-containing conjugated αβ-unsaturated carbonyl system involves the elimination of an alkyl fluoride from an alkoxyfluoroolefin[29–31]:



This method, which has not been widely used in other instances, has been successfully employed to synthesise PFMA derivatives from the relatively readily available alkoxypolyfluoroisobutenes[7,32–34]. Thus, when alkyl perfluoroisobutenyl ethers (XVI) are heated in the presence of catalytic amounts of SbF_5 or $Et_2O.BF_3$ with simultaneous distillation of the product, perfluoromethacryloyl fluoride is formed[33]. On heating dialkylacetals of bis(trifluoromethyl)keten (XVII), dialkylthioacetals (XVIII), or *ONN*-trialkylaminoacetals (XIX) with a catalytic amount of $Et_2O.BF_3$, the corresponding esters[33], thiolo-esters[34], or dialkylamides of PFMA are formed[33]¶.



$$\underset{(XVI)}{(CF_3)_2C{=}CFOR} \xrightarrow[SbF_5]{t^\circ} \underset{(I)\ CF_3}{F_2C{=}C{-}COF} + RF \ ;$$

$$\underset{(XVII)}{(CF_3)_2C{=}C(OR)_2} \xrightarrow[Et_2O\cdot BF_3]{t^\circ} \underset{CF_3\quad (II)}{CF_2{=}C{-}COOR} + RF \ ;$$

R=Me, Et ;

$$\underset{(XVIII)}{(CF_3)_2C{=}C\begin{matrix} SR \\ OEt \end{matrix}} \xrightarrow[Et_2O\cdot BF_3]{t^\circ} \underset{CF_3\quad (IV)}{F_2C{=}C{-}COSR} + EtF \ ;$$

R=Et, Pr, n-Bu, t-Bu, $PhCH_2$;

$$\underset{(XIX)}{(CF_3)_2C{=}C\begin{matrix} NR^1_2 \\ OR \end{matrix}} \xrightarrow[Et_2O\cdot BF_3]{t^\circ} \underset{CF_3\quad (III)}{F_2C{=}C{-}CONR^1_2} + RF \ ;$$

R, R^1=Me, Et .

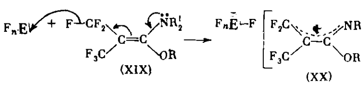
These reactions are carried out at approximately 100–140°C. Ethyl fluoride is usually split off under somewhat milder conditions than methyl fluoride[7,33]. On heating to 200°C, the aminoacetal (XIX, R = R^1 = Me) is cleaved even in the absence of a catalyst. The role of the Lewis acid evidently involves the elimination of the allyl fluorine atom from the alkoxyolefin, which leads to the formation of a mesomeric carbonium ion. Stable salts (XX) containing

---

§ In the dehydrofluorination of 2,3,3,3-tetrafluoropropionyl fluoride, the use of NaF and quartz makes it possible to obtain perfluoroacryloyl fluoride in a high yield. The tube is packed alternately with these two catalysts, which are arranged in layers[28].

¶ Perfluoroacryloyl fluoride has been obtained similarly from the esters $CF_3CF{=}CFOR$[7,33], and the esters of difluoromethylenemalonic acid $CF_2{=}C(COOR)COOR^1$ have been synthesised from the acetals of alkoxycarbonyltrifluoromethylketens[35].

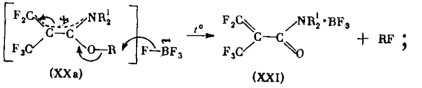
such cations have been obtained from the aminoacetals (XIX)[7,33]:



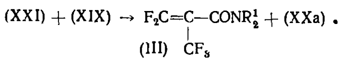
$F_nE = BF_3$ (a), SbF_5 .

The cleavage of aminoacetals on heating with catalytic amounts of a Lewis acid is carried out in accordance with the following scheme (each stage has been confirmed experimentally): the formation of a salt (XXa) [Eqn. (7)]; the cleavage of this salt on heating owing to the alkylation of the complex anion BF_4^- by the mesomeric carbonium ion [Eqn. (8)]; the exchange reaction between the adduct of the dialkylamide of PFMA with boron trifluoride (XXI), on the one hand, and the next aminoacetal molecule, on the other, which results in the formation of the final product—the dialkylamide of PFMA (III)—and the regeneration of the salt (XXa) [Eqn. (9)]; the salt is again cleaved and this is continued until almost the entire aminoacetal is converted into the alkyl fluoride and the dialkylamide of PFMA[7,33]:

$$(XIX) + Et_2O \cdot BF_3 \rightarrow (XXa) + Et_2O \ ; \qquad (7)$$



(8)

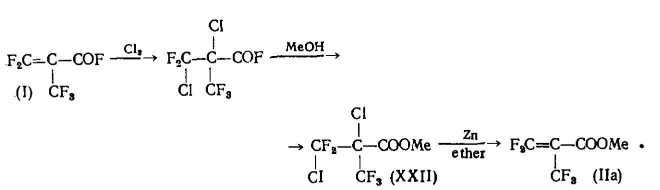


$$(XXI) + (XIX) \rightarrow \underset{(III)}{F_2C{=}\underset{CF_3}{C}{-}CONR'_2} + (XXa) \ . \qquad (9)$$

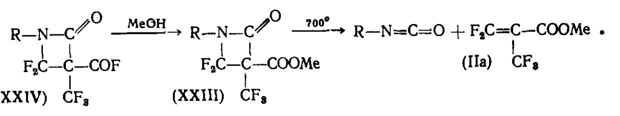
The mechanism of the cleavage of the esters (XVI), the acetals (XVII), and the thioacetals (XVIII) probably differs in detail from the above scheme, but the role of the Lewis acid as an agent for the elimination of the F⁻ ion remains[7].

4. Other Methods for the Synthesis of PFMA Derivatives

A PFMA ester was obtained for the first time by the dechlorination of an ester of $\alpha\beta$-dichloropentafluoroisobutyric acid (XXII)[8]:

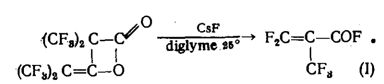


The same ester is formed in a low yield on thermal cleavage of 2-oxoacetidine-3-carboxylic acid ester (XXIII) obtained from the 1,2-cycloadduct of perfluoromethacryloyl fluoride with alkyl isocyanate (XXIV)[5,36] (see subsection 7 in this Section):



A new method for synthesising a PFMA ester, involving the interaction of perfluoromethacryloyl fluorosulphonate (V) with methyl ether[37] [see Eqn. (15)], has been proposed recently. A disadvantage of this method is the difficulty of separating the mixture containing the PFMA ester and FSO_3Me. The mixed anhydride (V) was obtained by treating perfluoromethacryloyl fluoride with SO_3 [see Eqn. (22)].

Perfluoromethacryloyl fluoride is formed in a low yield together with other products when the "β-lactone-dimer of bis(trifluoromethyl)keten" is treated with CsF[3]:

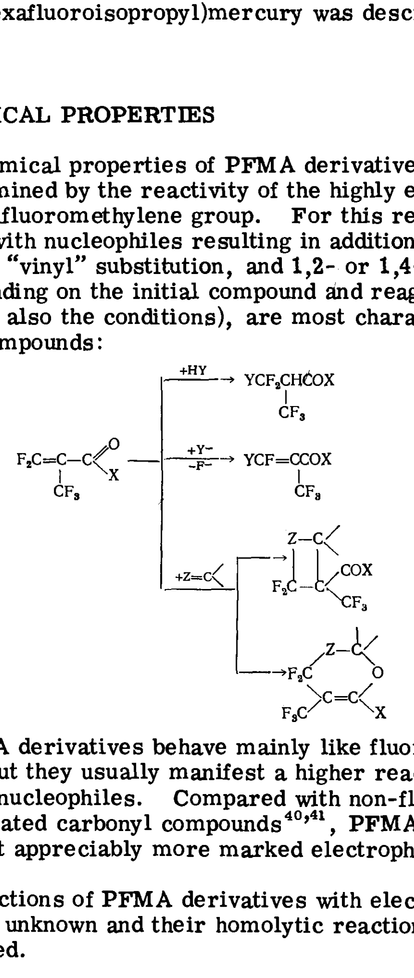


The mechanism of this reaction is obscure. Possibly the dimer decomposes at least partially with formation of bis(trifluoromethyl)keten, which isomerises to perfluoromethacryloyl fluoride.

The formation of perfluoromethacrylonitrile from bis(α-cyanohexafluoroisopropyl)mercury was described above [Eqn. (5)].

III. CHEMICAL PROPERTIES

The chemical properties of PFMA derivatives are as a rule determined by the reactivity of the highly electrophilic terminal difluoromethylene group. For this reason, reactions with nucleophiles resulting in addition to the C=C bond, "vinyl" substitution, and 1,2- or 1,4-cycloaddition, depending on the initial compound and reagents (and sometimes also the conditions), are most characteristic of these compounds:

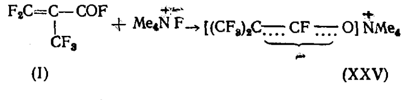


Thus PFMA derivatives behave mainly like fluoro-olefins[38,39], but they usually manifest a higher reactivity with respect to nucleophiles. Compared with non-fluorinated $\alpha\beta$-unsaturated carbonyl compounds[40,41], PFMA derivatives also exhibit appreciably more marked electrophilic properties.

The reactions of PFMA derivatives with electrophiles are almost unknown and their homolytic reactions have been little studied.

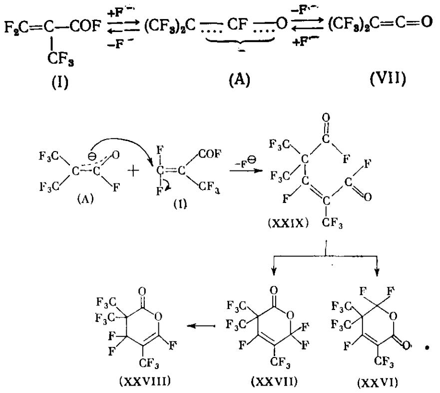
1. Reactions with Halide Anions

Perfluoromethacryloyl fluoride reacts readily with the F⁻ anion, forming a mesomeric fluoro-carbanion—the perfluoroisobutenoxide anion (A).[6] Depending on the reaction conditions, the subsequent fate of this carbanion may be various. Thus, when perfluoromethacryloyl fluoride reacts with tetramethylammonium fluoride in acetonitrile, the tetramethylammonium salt (XXV) is formed[42]:



On heating at 300°C over NaF, perfluoromethacryloyl fluoride reversibly isomerises to bis(trifluoromethyl)keten[2-5] (see subsection 1 of Section II).

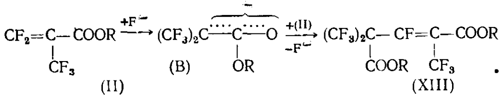
When perfluoromethacryloyl fluoride or the isomeric bis(trifluoromethyl)keten are acted upon by alkali metal fluorides or triethylamine, the "δ-lactone-dimers" (XXVI), (XXVII), and (XXVIII) are formed[3,21,43]. Evidently, the initial product is the mesomeric carbanion (A), which reacts with perfluoromethacryloyl fluoride, substituting the vinyl fluorine atoms, and the resulting dicarboxylic acid fluoride (XXIX) cyclises to the "δ-lactone-dimers" (XXVI) and (XXVII); the isomerisation of compound (XXVII) leads to compound (XXVIII):[6]



(10)

The dimerisation to "δ-lactone-dimers" also occurs in the presence of tetraethylammonium chloride[3,44] or zinc chloride[45].

PFMA esters dimerise very readily in the presence of the F^- ion, forming the dicarboxylic acid esters (XIII)[10,46,47]† [see also Eqns. (3), (14), and (21)]:



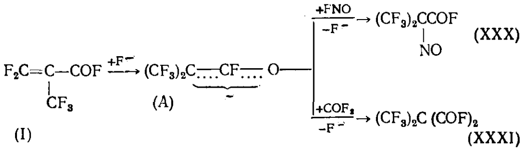
$$\underset{\text{(II)}}{\mathrm{CF_2{=}\underset{\displaystyle CF_3}{C}{-}COOR}} \xrightarrow{+F^-} \underset{\text{(B)}}{\mathrm{(CF_3)_2C\overset{\cdots}{-}\underset{\displaystyle OR}{C}\overset{\cdots}{-}O^-}} \xrightarrow[-F^-]{+(II)} \underset{\text{(XIII)}}{\mathrm{(CF_3)_2\underset{\displaystyle COOR}{C}{-}CF{=}\underset{\displaystyle CF_3}{C}{-}COOR}} .$$

Perfluoromethacrylonitrile dimerises even more readily and cannot be obtained even in the presence of the adduct $R_3N.BF_3$ [10] [see Eqn. (4)]. The less reactive dialkyl amides of PFMA show no tendency towards dimerisation[7,46].

The perfluoro-t-butyl anion $(CF_3)_3C^-$, formed when the F^- ion adds to perfluoroisobutene, reacts with a wide variety of electrophiles, yielding the compounds $(CF_3)_3CR$. [49-52] The mesomeric carbanions obtained from PFMA derivatives and the F^- anion are also capable of combining with electrophiles, although such reactions have been studied much less than in the case of perfluoroisobutene.

The addition of a proton results in the formation of HFIBA derivatives. Thus methyl perfluoromethacrylate combines with hydrogen fluoride in the presence of NaF, the reaction being reversible[9,27]‡ [Eqn. (6)]. Like perfluoroisobutene[53,54], PFMA esters can play the role of dehydrofluorinating agents in the presence of tertiary amines [Eqn. (19)]. The dimethylamide of PFMA reacts with hydrogen fluoride evolved when the vinyl fluorine atom is substituted on treatment with phenols or mercaptans [Eqns. (13) and (18)].

The interaction of nitrosyl fluoride with perfluoromethacryloyl fluoride, leading to the fluoride of the α-nitrosocarboxylic acid (XXX), probably also begins with the addition of the F^- anion to the C=C bond[55] (cf. Ref. 38). On treatment with carbonyl difluoride in the presence of KF, perfluoromethacryloyl fluoride is converted into the difluoride of bis(trifluoromethyl)malonic acid (XXXI):[56]§

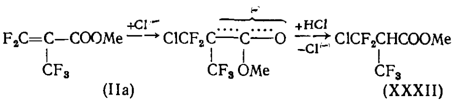


$$\underset{\text{(I)}}{\mathrm{F_2C{=}\underset{\displaystyle CF_3}{C}{-}COF}} \xrightarrow{+F^-} \underset{(A)}{\mathrm{(CF_3)_2C\overset{\cdots}{-}CF\overset{\cdots}{-}O^-}} \xrightarrow[-F^-]{+FNO} \underset{\text{(XXX)}}{\mathrm{(CF_3)_2\underset{\displaystyle NO}{C}COF}}$$

$$\mathrm{(CF_3)_2C\overset{\cdots}{-}CF\overset{\cdots}{-}O^-} \xrightarrow[-F^-]{+COF_2} \underset{\text{(XXXI)}}{\mathrm{(CF_3)_2C(COF)_2}} .$$

(11)

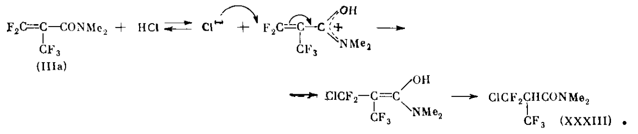
Methyl perfluoromethacrylate does not react with hydrogen chloride at room temperature in the absence of a catalyst, but, in the presence of a catalytic amount of pyridinium chloride, it readily gives rise to the chloropentafluoroisobutyrate ester (XXXII)[57]¶:



$$\underset{\text{(IIa)}}{\mathrm{F_2C{=}\underset{\displaystyle CF_3}{C}{-}COOMe}} \xrightarrow{+Cl^-} \mathrm{ClCF_2\underset{\displaystyle CF_3}{C}\overset{\cdots}{-}\underset{\displaystyle OMe}{C}\overset{\cdots}{-}O^-} \xrightarrow[-Cl^-]{+HCl} \underset{\text{(XXXII)}}{\mathrm{ClCF_2\underset{\displaystyle CF_3}{C}HCOOMe}} .$$

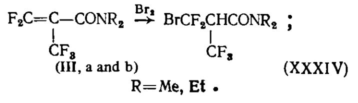
In the absence of a catalyst, perfluoromethacrylonitrile does not react with hydrogen chloride and bromide even at 150°C.[26]

In contrast to the ester and the nitrile, the dimethylamide of PFMA readily combines with hydrogen chloride in a non-polar solvent in the absence of a catalyst, forming the amide of the chloro-substituted acid (XXXIII).[57] Evidently we are dealing here with "intramolecular base catalysis". The protonation of the amide group leads, on the one hand, to the activation of the PFMA dialkylamide molecule, and, on the other, to the appearance in the mixture of the fairly nucleophilic anion Cl^-, which is capable of attacking the β-carbon atom[46,57]:



$$\mathrm{F_2C{=}\underset{\displaystyle CF_3}{C}{-}CONMe_2} + \mathrm{HCl} \rightleftarrows \mathrm{Cl^-} + \mathrm{F_2C{=}\underset{\displaystyle CF_3}{C}{-}C(OH)(NMe_2)^+} \longrightarrow \mathrm{ClCF_2{-}\underset{\displaystyle CF_3}{C}{=}C(OH)(NMe_2)} \longrightarrow \mathrm{ClCF_2\underset{\displaystyle CF_3}{C}HCONMe_2} .$$

The hydrogen bromide addition products (XXXIV) have been obtained in low yields in attempts to brominate PFMA dialkylamides[7]:



$$\underset{\text{(III, a and b)}}{\mathrm{F_2C{=}\underset{\displaystyle CF_3}{C}{-}CONR_2}} \xrightarrow{Br_2} \underset{\text{(XXXIV)}}{\mathrm{BrCF_2\underset{\displaystyle CF_3}{C}HCONR_2}} ;$$

$$\mathrm{R{=}Me, Et} .$$

(12)

[†] The esters of difluoromethylenemalonic acid dimerise just as readily[21,35]. The analogous dimerisation of perfluoroisobutene[48] and the perfluoroacrylate ester[9] has also been described.

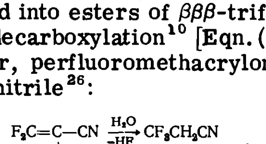
[‡] Perfluoroacryloyl fluoride also combines with HF in the presence of NaF.[9]

[§] Perfluoroacryloyl fluoride gives rise similarly to the difluoride of α-fluoro-α-trifluoromethylmalonic acid[56]. The analogous reaction with a perfluoromethacrylate ester is described in subsection 7 of the present Section.

[¶] Perfluoroisobutene also combines with hydrogen halides in the presence of bases[58].

2. Reactions with *O*-Nucleophiles

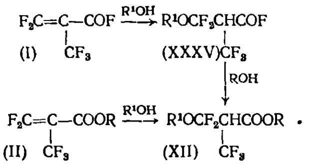
Perfluoromethacryloyl fluoride reacts readily with water, being converted into trifluoromethylmalonic acid $CF_3CH(COOH)_2$.[7] When HFIBA esters react with water in the presence of triethylamine, the intermediate PFMA esters are converted into esters of $\beta\beta\beta$-trifluoropropionic acid as a result of decarboxylation[10] [Eqn. (1)]. On treatment with water, perfluoromethacrylonitrile yields $\beta\beta\beta$-trifluoropropionitrile[26]:



$$\underset{CF_3}{F_2C{=}\overset{}{C}{-}CN} \xrightarrow[-HF,\ -CO_2]{H_2O} CF_3CH_2CN \ .$$

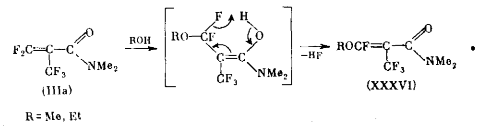
(VI)

The C=C double bond in perfluoromethacryloyl fluoride is so electrophilic that it reacts with hydroxy-compounds faster than the acid fluoride group. On treatment with equimolar amounts of alcohols ($MeOH$, $CH_2{=}CHCH_2OH$, $HOCH_2COOMe$) under mild conditions, perfluoromethacryloyl fluoride is converted into the corresponding addition products (XXXV)[9,27] [see also Eqn. (17)]†. The COF group also reacts with an excess of the alcohol, forming esters of α-hydro-β-alkoxypentafluoroisobutyric acids (XII)[4,8,21,59]. PFMA esters likewise combine readily with alcohols, forming the adducts (XII)[8,59]‡:



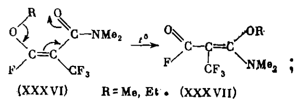
$$\begin{array}{ccc} \underset{(I)\quad CF_3}{F_2C{=}C{-}COF} & \xrightarrow{R^1OH} & \underset{(XXXV)\,CF_3}{R^1OCF_2CHCOF} \\ & & \downarrow{\scriptstyle ROH} \\ \underset{(II)\quad CF_3}{F_2C{=}C{-}COOR} & \xrightarrow{R^1OH} & \underset{(XII)\quad CF_3}{R^1OCF_2CHCOOR} \ . \end{array}$$

In contrast to the acid fluoride and esters, the dimethylamide of PFMA reacts with alcohols to form only products arising from the substitution of the vinyl fluorine atom—the dimethylamides of β-alkoxy-β-fluoro-α-trifluoromethylacrylic acids (XXXVI) (in the form of a mixture of *cis*- and *trans*-isomers)[59]§. This difference can probably be accounted for by the appreciable basicity of the $CONMe_2$ group, which can bind the proton and can prevent its addition to the carbanionic centre[7,46,59]:

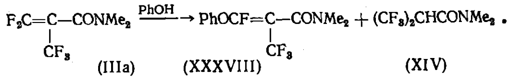


Perfluoroisobutene is known to react readily with alcohol, forming mainly addition products together with small amounts of substitution products[61,62]. It has been shown by the method of competition kinetics that methyl perfluoromethacrylate reacts with alcohol much faster than perfluoroisobutene or PFMA dimethylamide[46].

The β-alkoxyamides (XXXVI) have proved to be relatively unstable. They rearrange on heating to the acid fluorides (XXXVII) as a result of the 1,5-migration of the alkyl group from the "enolic" oxygen atom to the carbonyl oxygen atom of the alkoxyvinylcarbonyl system[59]:

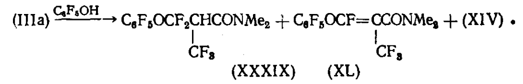


In contrast to the reaction with alcohols, in the reaction with phenols the PFMA ester is less reactive than PFMA dimethylamide. Methyl perfluoromethacrylate does not react with phenol and pentafluorophenol at room temperature¶, while PFMA dimethylamide does react under these conditions, although more slowly than in the analogous reaction with alcohols[57]. The reaction with unsubstituted phenol yields the "vinyl" substitution product (XXXVIII) (the *cis*- and *trans*-isomers); the hydrogen fluoride evolved adds to the initial amide (IIIa), forming the dimethylamide of HFIBA (XIV):



$$\underset{(IIIa)}{\underset{CF_3}{F_2C{=}C{-}CONMe_2}} \xrightarrow{PhOH} \underset{(XXXVIII)}{\underset{CF_3}{PhOCF{=}C{-}CONMe_2}} + \underset{(XIV)}{(CF_3)_2CHCONMe_2} \ . \qquad (13)$$

Pentafluorophenol forms mainly the addition product (XXXIX) and only small amounts of the substitution product (XL) (the *cis*- and *trans*-isomers):



$$(IIIa) \xrightarrow{C_6F_5OH} \underset{(XXXIX)}{\underset{CF_3}{C_6F_5OCF_2CHCONMe_2}} + \underset{(XL)}{\underset{CF_3}{C_6F_5OCF{=}CCONMe_2}} + (XIV) \ .$$

Comparison of the reactivities of various *O*- and *S*-nucleophiles in reactions with PFMA dimethylamide showed that the rate of reaction decreases in a sequence which is quite different from the sequence of the corresponding acidities: AlkOH ($pK_a \simeq 18$) > RCOOH† ($pK_a = 0.23$–4.75) > PhSH‡ ($pK_a = 8.0$) > C_6F_5OH ($pK_a = 5.5$) > $PhCH_2SH$‡ ($pK_a \simeq 12$) > PhOH ($pK_a = 9.9$) ≫ $(CF_3)_2CHOH$ ($pK_a = 9.3$). Evidently, when the nature of the nucleophile (acidity, nucleophilic properties of the reaction centre) changes appreciably, there is also a change in reaction mechanism, the influence of the basic properties of the amide group having an effect to different extents[46,57]. The $+M$ effect of the substituent X, which promotes the dissociation of the C−F bond, probably plays a significant role in the formation of the "vinyl" substitution products:

If this effect is insignificant, the addition product is formed in a larger amount as a result of the attack by the proton on the central carbon atom.

Little information is available about the interaction of PFMA derivatives with alkoxides and phenoxides. The reaction of perfluoromethacryloyl fluoride with sodium methoxide followed by hydrolysis yields the ester of trifluoromethylmalonic acid (XLI).[9] This probably involves

---

†The analogous reaction of perfluoroacryloyl fluoride with methanol takes place in the presence of NaF and leads to a mixture containing $MeOCF_2CHFCOOMe$ and $MeOCF_2CHFCOF$ as well as traces of $F_2C{=}CFCOOMe$ and $CF_3CHFCOOMe$.[9]

‡It has been stated[26] that perfluoromethacrylonitrile reacts very readily with alcohols, but the structure of the resulting products has not been given. Ethyl perfluoroacrylate reacts with alcohols under somewhat more severe conditions[60].

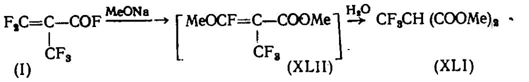
§Hexafluoroisopropyl alcohol $(CF_3)_2CHOH$ does not react with PFMA dimethylamide at room temperature[57].

¶ Perfluoromethacryloyl fluoride reacts with phenol at 100°C to form the adduct $PhOCF_2CH(CF_3)COF$.[9]

†See Eqn. (16).

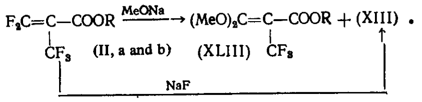
‡See Eqn. (18).

the initial formation of the "vinyl" substitution product (**XLII**):



$$\underset{(I)}{F_2C{=}\underset{CF_3}{\underset{|}{C}}{-}COF} \xrightarrow{MeONa} \left[MeOCF{=}\underset{CF_3}{\underset{|}{C}}{-}COOMe\right]_{(XLII)} \xrightarrow{H_2O} \underset{(XLI)}{CF_3CH(COOMe)_2}$$

Treatment of **PFMA** esters with sodium methoxide leads to the formation of acetals of the substituted ketens (**XLIII**) together with the "dimers" (**XIII**):[47]



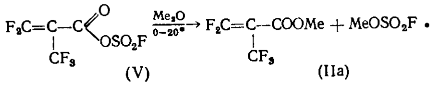
$$F_2C{=}\underset{CF_3}{\underset{|}{C}}{-}COOR \xrightarrow{MeONa} (MeO)_2C{=}\underset{CF_3}{\underset{|}{C}}{-}COOR + (XIII)$$

(II, a and b) (XLIII) NaF

(14)

The "vinyl" substitution product (**XXXVIII**) has been obtained from PFMA dimethylamide and sodium phenoxide[57].

The mixed anhydride of **PFMA** and fluorosulphonic acid (**V**) readily reacts with methyl ether. In contrast to other reactions of **PFMA** derivatives with nucleophiles, the β-carbon atom is not involved in this process and one **PFMA** derivative is thus converted into another; this results in the formation of a **PFMA** ester and methyl fluorosulphonate[37]:



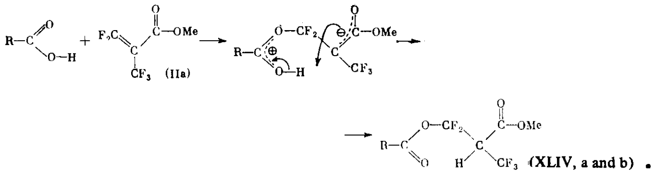
(V) (IIa) (15)

PFMA derivatives are able to combine even with very slightly nucleophilic carboxylic acids in the absence of basic catalysts. Methyl perfluoromethacrylate reacts readily with acetic or trifluoroacetic acid, forming the addition products (**XLIV**, a and b). The analogous reactions of **PFMA** dimethylamide led to the β-acyloxyamides (**XLIV**, c, d, and e):[57]

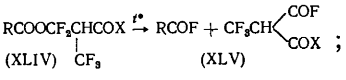
$$\underset{(IIa),\ (IIIa)}{F_2C{=}\underset{CF_3}{\underset{|}{C}}{-}COX} + RCOOH \rightarrow \underset{(XLIV)}{RCOOCF_2\underset{CF_3}{\underset{|}{C}}HCOX} \qquad (16)$$

(a) $X{=}OMe,\ R{=}Me;$
(b) $X{=}OMe,\ R{=}CF_3;$
(c) $X{=}NMe_2,\ R{=}Me;$
(d) $X{=}NMe_2,\ R{=}CF_3;$
(e) $X{=}NMe_2,\ R{=}Ph.$

Whereas "intramolecular base catalysis" can be suggested for the reactions with **PFMA** dimethylamide, this is much less likely for the **PFMA** ester (see subsection 1 in this Section); possibly the carboxylic acid, even trifluoroacetic acid, behaves as a nucleophile in the reaction with the **PFMA** ester[57]. The addition probably takes place via a six-membered cyclic transition state, which facilitates the reaction[46]:

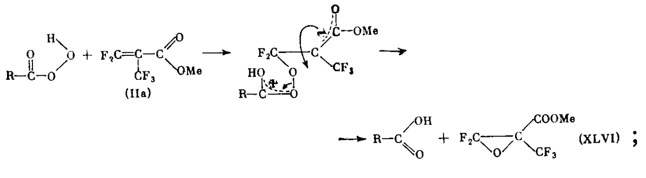


The addition of carboxylic acids is not characteristic of the usual $\alpha\beta$-unsaturated carbonyl compounds[41]. This can also be said of electrophilic perfluoro-olefins. Only in the presence of a base (triethylamine) does perfluoroisobutene react with acetic acid, but the resulting adduct immediately decomposes into acetyl fluoride and the fluoride of HFIBA.[23] The analogous cleavage of the adduct (**XLIV**) takes place on heating and leads to derivatives of trifluoromethylmalonic acid (**XLV**) containing one acyl fluoride group[57]:



$R{=}Me,\ CF_3;\ X{=}OMe,\ NMe_2.$

Peracids are probably more powerful nucleophiles than carboxylic acids[63]. It is therefore not surprising that peracids react still faster with the **PFMA** ester. However, they give rise to an epoxide [the fluorine-containing glycidyl ether (**XLVI**)] in this reaction and not to addition products[46,64]:

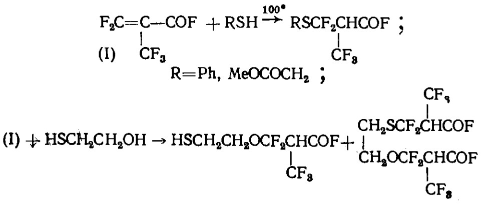


$R = Ph,\ p\text{-}O_2NC_6H_4,\ m\text{-}ClC_6H_4.$

In the usual epoxidation of ethylenic compounds by peracids (the Prilezhaev reaction), the latter are known to behave as electrophiles and the introduction of electron-withdrawing substituents into the molecule of the unsaturated compound hinders its epoxidation[63]. However, it has been found that the **PFMA** ester is epoxidised more readily than perfluoroisobutene or methyl acrylate[64]. Evidently the epoxidation of the highly electrophilic **PFMA** ester involves an unusual inversion of the mechanism of the Prilezhaev reaction, the peracid behaving as a nucleophile. O-Nucleophiles capable of reacting with **PFMA** derivatives include also certain carbonyl compounds. Reactions with these compounds, leading to cycloadducts or their conversion products, are examined in a separate subsection (subsection 7).

3. Reactions with *S*-Nucleophiles

The reactions of **PFMA** derivatives with mercapto-compounds have been little investigated. Perfluoromethacryloyl fluoride gives rise to products formed by addition to the C=C bond on interaction with thiophenol and the mercaptoacetate ester[9]; in contrast to the reaction with alcohols, this process takes place only on heating. 2-Mercaptoethyl alcohol adds to perfluoromethacryloyl fluoride, forming 1 : 1 and 1 : 2 adducts[9]:



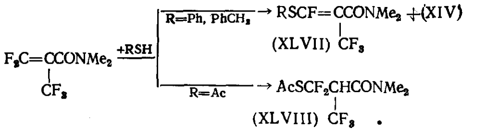
$$\underset{(I)}{F_2C{=}\underset{CF_3}{\underset{|}{C}}{-}COF} + RSH \xrightarrow{100^\circ} RSCF_2\underset{CF_3}{\underset{|}{C}}HCOF;$$

$R{=}Ph,\ MeOCOCH_2;$

$$(I) + HSCH_2CH_2OH \rightarrow HSCH_2CH_2OCF_2\underset{CF_3}{\underset{|}{C}}HCOF + \begin{array}{l} CH_2SCF_2\overset{CF_3}{\overset{|}{C}}HCOF \\ | \\ CH_2OCF_2\underset{CF_3}{\underset{|}{C}}HCOF \end{array} \qquad (17)$$

The "hard" hydroxy-group is apparently somewhat more reactive with respect to the carbon atom of the $CF_2{=}$ group than the "soft" mercapto-group.

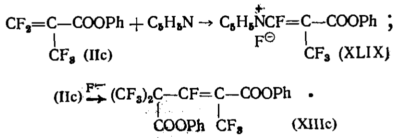
The reaction of **PFMA** dimethylamide with thiophenol or phenylmethanethiol gives the "vinyl" substitution product (**XLVII**) (the *cis*- and *trans*-isomers) together with the HFIBA dimethylamide (**XIV**) (the rate of this reaction is discussed in subsection 2 of this Section). Thioacetic acid reacts readily with **PFMA** dimethylamide, but it gives rise to a mixture of products from which only the thioloacetyl derivative (XLVIII) could be isolated in a low yield[57]:



$$\underset{\displaystyle CF_3}{F_2C{=}CCONMe_2} \xrightarrow{+RSH} \begin{cases} \xrightarrow{R=Ph,\ PhCH_2} \underset{(XLVII)\ CF_3}{RSCF{=}CCONMe_2} + (XIV) \\ \xrightarrow[R=Ac]{} \underset{(XLVIII)\ CF_3}{AcSCF_2CHCONMe_2}\ . \end{cases} \qquad (18)$$

4. Reactions with *N*-Nucleophiles

When PFMA derivatives are acted upon by tertiary amines, they usually dimerise readily (subsection 1 of this Section). For example, phenyl perfluoromethacrylate (IIc) is converted into the dicarboxylate ester (XIIIc) in the presence of a catalytic amount of pyridine at room temperature[10]. Possibly the reaction begins with the substitution of the vinyl fluorine atom by the pyridinium residue and the F^- anion split off then catalyses the dimerisation reaction:

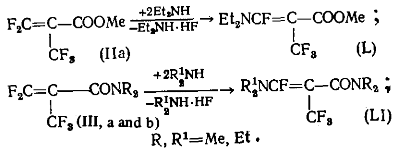


$$\underset{CF_3\ (IIc)}{CF_2{=}C{-}COOPh} + C_5H_5N \rightarrow \underset{F^{\ominus}}{C_5H_5\overset{+}{N}}CF{=}\underset{CF_3\ (XLIX)}{C{-}COOPh}\ ;$$

$$(IIc) \xrightarrow{F^-} (CF_3)_2\underset{COOPh}{C}{-}CF{=}\underset{CF_3}{C}{-}COOPh\ . \quad (XIIIc)$$

However, this mechanism remains purely speculative, since there is no direct evidence for the formation of compounds of type (XLIX). Like tertiary amines, certain carboxylic acid dialkylamides also catalyse the dimerisation of PFMA esters (see subsection 7 of this Section).

The reactions with secondary amines usually lead to the formation of the "vinyl" substitution products (L) and (LI)[59,65]§:

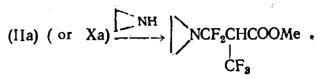


$$\underset{CF_3\ \ (IIa)}{F_2C{=}C{-}COOMe} \xrightarrow[-Et_2NH\cdot HF]{+2Et_2NH} Et_2NCF{=}\underset{CF_3\ \ (L)}{C{-}COOMe}\ ;$$

$$\underset{CF_3\ (III,\ a\ and\ b)}{F_2C{=}C{-}CONR_2} \xrightarrow[-R^1_2NH\cdot HF]{+2R^1_2NH} R^1_2NCF{=}\underset{CF_3\ \ (LI)}{C{-}CONR_2}\ ;$$

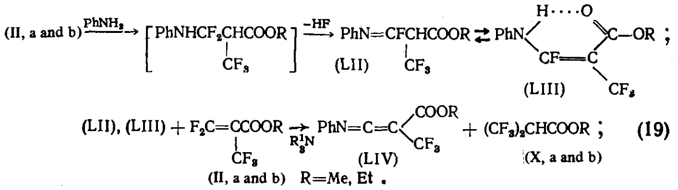
$$R, R^1{=}Me, Et\ .$$

In contrast to dimethyl- and diethyl-amines, aziridine forms an addition product on reaction with the perfluoromethacrylate ester. The same product has been obtained from the HFIBA ester[67]:



Here the PFMA ester behaves like perfluoroisobutene, which reacts with dialkylamines to form substitution products and with aziridine to form addition products[67].

The reaction of perfluoroisobutene with arylamines in the presence of tertiary amines leads to imidoyl fluorides and ketenimines[53]. PFMA esters react with aniline via a similar mechanism, forming imidoyl fluorides (LII) [in the form of tautomeric mixtures with enamines (LIII)] and ketenimines (LIV)[68]:



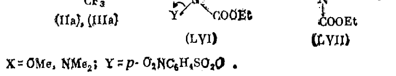
(19)

An excess of the PFMA ester acts in this reaction like a dehydrofluorinating agent. The enamines (LIII) are comparatively stable owing to the hydrogen bond between the NH and COOR groups.

The anion (LV), formed from *p*-nitrobenzenesulphonyloxyurethane on treatment with triethylamine, is an active *N*-nucleophile. Like perfluoroisobutene, methyl perfluoromethacrylate and PFMA dimethylamide readily react with this anion; the resulting carbanions (LVI) are stabilised by cyclisation with elimination of the *p*-nitrobenzenesulphonyloxy-group, readily removed in the form of the anion, and not by the elimination of an F^- anion (as in "vinyl" substitution) or by the capture of a proton (as in an addition reaction). Nucleophilic elimination of PFMA derivatives is thus achieved with formation of substituted aziridines (LVII)[64]:

$$EtOCONHY + R_3N \rightleftarrows EtOCO\overset{-}{N}Y + R_3\overset{+}{N}H\ ;$$

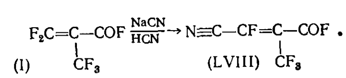
(LV)



The reactions involving the cycloaddition of *N*-nucleophiles such as nitriles and isocyanates to perfluoromethacryloyl fluoride are discussed below in subsection 7.

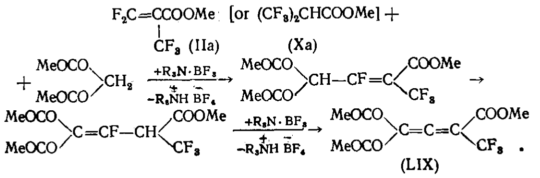
5. Reactions with *C*-Nucleophiles

The "vinyl" substitution product (LVIII) has been obtained in a low yield by the reaction of perfluoromethacryloyl fluoride with the cyanide anion[36]:



$$\underset{(I)\quad CF_3}{F_2C{=}C{-}COF} \xrightarrow[HCN]{NaCN} N{\equiv}C{-}CF{=}\underset{(LVIII)\ CF_3}{C{-}COF}\ .$$

When the malonic ester reacts with the PFMA ester in the presence of the adduct $Et_3N.BF_3$, a "vinyl" substitution product is also formed; isomerisation and subsequent dehydrofluorination lead to 1-trifluoromethyl-1,3,3-tri(methoxycarbonyl)allene (LIX). The same product was obtained also from the HFIBA ester, which is converted into a PFMA ester under the reaction conditions[25]:



As in many other reactions, the PFMA ester behaves here like perfluoroisobutene[69].

Another type of reactions of PFMA derivatives with *C*-nucleophiles involves dimerisation, the vinylfluorine

---

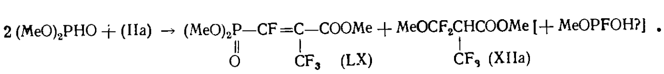
[§] The reaction of perfluoromethacrylonitrile with diethylamine followed by hydrolysis yields the amidonitrile $Et_2NCOCH(CF_3)CN$.[26] On treatment with secondary amines, methyl perfluoroacrylate forms unstable addition products, which undergo further transformations[66].

atom being substituted on treatment with a mesomeric carbanion of type (A), (C), or (D) [Eqns. (2), (4), and (10)].

Certain *C*-nucleophiles are involved in cycloaddition reactions with perfluoromethacryloyl fluoride (see sub-section 7 below).

6. Reactions with *P*-Nucleophiles

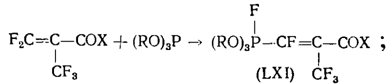
Methyl perfluoromethacrylate reacts with dimethyl phosphite at room temperature, forming the "vinyl" substitution product (LX) together with the methanol addition product (XIIa)[47]:



$$2\,(MeO)_2PHO + (IIa) \rightarrow \underset{\underset{O}{\|}}{(MeO)_2P}-CF=\underset{\underset{CF_3}{|}}{C}-COOMe\ (LX) + MeOCF_2\underset{\underset{CF_3}{|}}{C}HCOOMe\ (XIIa)\ [+ MeOPFOH?]\ .$$

The mechanism of this reaction is obscure.

PFMA esters and dialkylamides react very readily with trialkyl phosphites, forming substituted perfluoroalkenyltrialkoxyfluorophosphoranes (LXI)[47,70]¶:



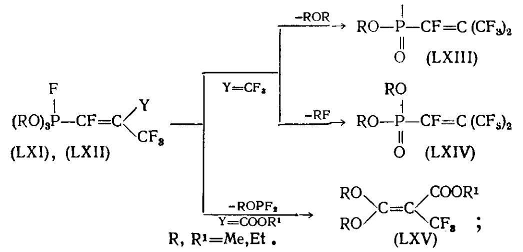
$$F_2C=\underset{\underset{CF_3}{|}}{C}-COX + (RO)_3P \rightarrow (RO)_3\overset{\overset{F}{|}}{P}-CF=\underset{\underset{CF_3}{|}}{C}-COX\ ;\quad (LXI)$$

(II), (III) X=OMe, OEt, NMe$_2$; R=Me, Et .

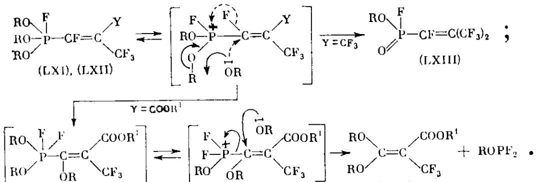
An analogous reaction is known for perfluoroisobutene, which interacts with triethyl phosphite to form a stable intermediate of the Arbuzov rearrangement, namely $(EtO)_3PFCF=C(CF_3)_2$ (LXII).[71] As in the reactions with other nucleophiles, methyl perfluoromethacrylate proved to be more reactive than perfluoroisobutene in the reaction with trimethyl phosphite[46].

The structures of the adducts of trialkyl phosphites with PFMA derivatives [compounds (LXI)] and with perfluoroisobutene [compounds (LXII)] have been confirmed by NMR. The covalent character of the P–F bond leads to spin–spin coupling between the ^{31}P and ^{19}F nuclei (J = 820 Hz).[47,70] The formation of these adducts constitutes a rare instance of the isolation of pentacovalent (and not tetracovalent quasiphosphonium) intermediates of the Arbuzov rearrangement[72].

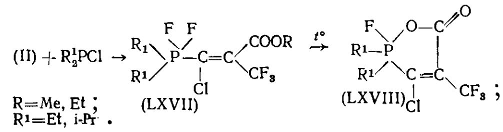
The adducts of perfluoroisobutene with trialkyl phosphite decompose in two ways on heating, forming the products of the Arbuzov rearrangement—the fluoride of the acid ester of perfluoroisobutenylphosphonic acid (LXIII) (as a result of the elimination of an ether)—and the diester (LXIV) (as a result of the elimination of an alkyl fluoride)[47,71]. In contrast to this, the adducts of PFMA esters with trialkyl phosphites are cleaved in an unusual way on heating, forming phosphorus(III) compounds (alkyl phosphorodifluoridites) and acetals of substituted ketens (LXV)[47,70]†:



This sharp difference in behaviour can probably be accounted for by the much more marked electrophilic properties of the carbon atom in the CF= group in the phosphoranes obtained from PFMA esters, compared with the phosphoranes derived from perfluoroisobutene. It is suggested that the first stage in the cleavage of the phosphoranes (LXI) and (LXII) is their reversible dissociation into an anion (RO^- or F^-) and a quasiphosphonium cation. Further reactions depend on which electrophilic centre is attacked by the anion. In the adducts formed from perfluoroisobutene, the carbon atom of the alkyl group R functions as the electrophilic centre, while in adducts obtained from PFMA esters the electrophilic centre is the β-carbon atom of the "acrylic" system. The new phosphorane (LXVI) formed in the latter case dissociates into an anion RO^- and a quasiphosphonium cation; the repeated attack by the alkoxide anion on the β-carbon atom cleaves the molecule into an acetal (LXV) and an alkyl phosphorodifluoridite[46,47]‡:



Thus, owing to the enhanced electrophilic properties of the β-carbon atom, in the decomposition of the adducts of PFMA esters with trialkyl phosphites the substituents at the phosphorus and carbon atoms change places. A similar exchange occurs also in the interaction of PFMA esters with dialkylchlorophosphines, which leads to the phosphoranes (LXVII), containing the PF_2 and CCl= groups [when these phosphoranes are heated, an alkyl fluoride is split off and cyclisation products are obtained—substituted oxaphospholens (LXVIII)][47]:



In contrast to this, the products obtained from chlorodiethylphosphine and perfluoroisobutene retain the CF= group and only bis(dialkylamino)chlorophosphines react with perfluoroisobutene to form compounds $(R_2N)_2PF_2.CCl=C(CF_3)_2$ containing the CCl= group[73].

7. Cycloaddition

The appreciably electrophilic properties of PFMA derivatives are responsible for the ease with which they undergo cycloaddition reactions on treatment with various unsaturated compounds having fairly pronounced nucleophilic properties. PFMA derivatives containing the $>C=\underset{|}{C}-\underset{|}{C}=O$ bond system can be involved in 1,2- or 1,4-cycloaddition reactions, only the C=C bond, and not the

---

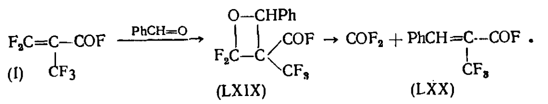
¶The esters of difluoromethylenemalonic acid react similarly[35].

†The adduct of the difluoromethylenemalonic ester with $(MeO)_3P$ is cleaved similarly to $MeOPF_2$ and $(MeO)_2C=C(COOMe)_2$.[35]

‡In the process represented in the above scheme, the nucleophilic participation of the carbonyl group, leading to the intermediate formation of 1,2-oxaphospholen structures, may also play an important role.

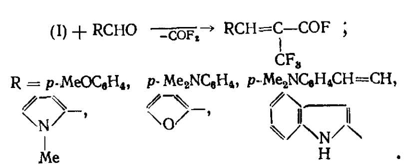
C=O bond, reacting in the former case. Cycloaddition results in the formation of three-, four-, five-, and six-membered rings; it is sometimes possible to isolate only the products of the further reactions of these compounds. The oxygen, nitrogen, and carbon atoms in the reactant can function as the nucleophilic centre.

When perfluoromethacryloyl fluoride reacts with benzaldehyde, a substituted oxetan (LXIX) is formed[9,27,36]. It is relatively unstable, decomposing on heating into carbonyl difluoride and α-trifluoromethylcinnamoyl fluoride (LXX) (a mixture of the *cis*- and *trans*-isomers):



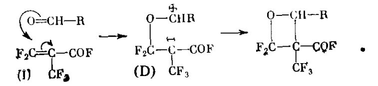
This reaction constitutes a method for the introduction of the substituted methylene group $=C(CF_3)COF$ in place of the oxygen atom of the carbonyl group and, in terms of its final result, it thus resembles the Wittig reaction.

A number of unsaturated acid fluorides have been obtained similarly but without the isolation of the intermediate oxetans[9,74]:



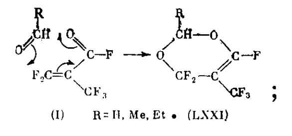
2,6-Dimethyl-γ-pyrone enters into a similar reaction[9].

The mechanism of the 1,2-cycloaddition of carbonyl compounds to perfluoromethacryloyl fluoride probably involves the formation of a dipolar ion (D)[36]:

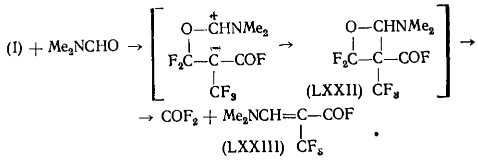


(20)

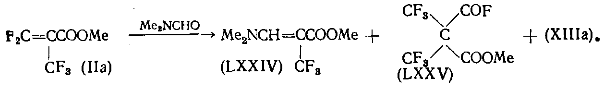
The negative charge in this dipolar ion is stabilised by the electron-withdrawing fluorine-containing groups and the positive charge by the electron-donating mesomeric effect of the group R. On the other hand, if the group R is incapable of stabilising the positive charge on the neighbouring carbon atom, the formation of the dipolar ion becomes unfavourable and synchronous (or almost synchronous) 1,4-cycloaddition takes place instead of the 1,2-cycloaddition. Thus, aliphatic aldehydes add to perfluoromethacryloyl fluoride, giving rise to substituted *m*-dioxins (LXXI)[9,27]:



The presence of the dimethylamino-group, which exhibits a considerable +*M* effect, stabilises the dipolar ion; for this reason, the reaction of perfluoromethacryloyl fluoride with dimethylformamide involves 1,2-cycloaddition with formation of the oxetan (LXXII), which, however, cannot be isolated, since it is immediately cleaved to difluorophosgene and the acid fluoride (LXXIII)[9,74]§:



Methyl perfluoromethacrylate reacts more slowly with dimethylformamide than the acid fluoride. Together with the ester (LXXIV), the reaction also leads to the formation of the acid fluoride (LXXV) and of insignificant amounts of the "dimer" (XIIIa)[46]:

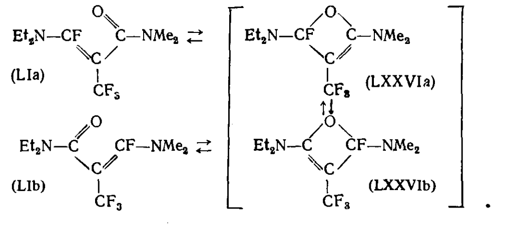


(21)

Evidently the carbonyl difluoride produced adds to the PFMA ester [see Eqn. (11)]. The analogous reaction of dimethylformamide with perfluoroisobutene leads to the enamine $Me_2NCH{=}C(CF_3)_2$ and the acid fluoride $(CF_3)_3COF$.[75] Perfluoroisobutene reacts with dimethylformamide somewhat more slowly than does the PFMA ester[46].

In contrast to dimethylformamide, dimethylacetamide and tetramethylurea do not undergo cycloaddition to methyl perfluoromethacrylate. In the latter case, the initial ester is wholly converted into the "dimer" (XIIIa). PFMA dimethylamide does not react with dimethylformamide[46].

An interesting intramolecular reaction, analogous to the formation of oxetans from PFMA derivatives and dimethylformamide, has been discovered recently. It was found that the dialkylamides of β-dialkylamino-β-fluoro-α-trifluoromethylacrylic acids (LI), containing various alkyl groups at the "amine" and "amide" nitrogen atoms, form on heating to 140°C (or to 100°C in the presence of $Et_3O.BF_3$) an equilibrium mixture containing the isomeric amides (LIa) and (LIb) in proportions of 1 : 1. This evidently involves the intermediate cyclisation of the $\alpha\beta$-unsaturated amides to the substituted oxetens (LXXVI, a and b) (or their adducts with BF_3), the allyl rearrangement with a shift of the F^- ion, and the reverse ring opening reaction[65]:

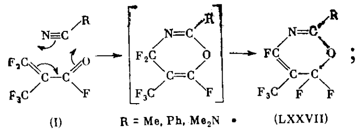


Methyl β-diethylamino-β-fluoro-α-trifluoromethylacrylate (L) and the dimethylamide of β-fluoro-α-trifluoromethyl-β-phenoxyacrylic acid (XXXVIII) do not undergo this type of isomerisation. Evidently the rearrangement requires both sufficiently pronounced electrophilic properties of the carbonyl oxygen atom attacking the β-carbon atom and sufficient mobility of the fluorine atom, determined by the mesomeric effects of the substituent[65].

---

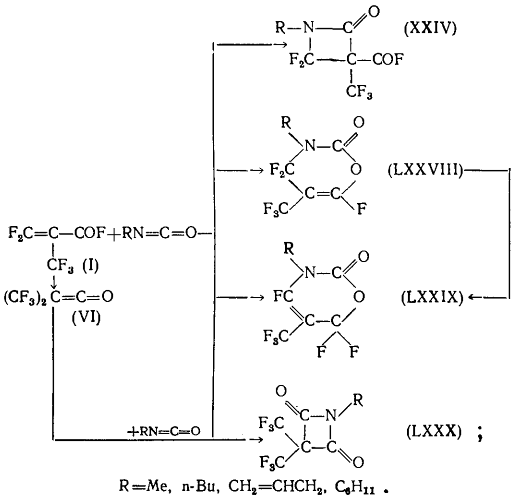
§ A similar reaction of $CF_2{=}CFCOF$ requires somewhat more severe conditions[9].

In contrast to carbonyl compounds, nitriles are involved in 1,4-cycloaddition on interaction with perfluoromethacryloyl fluoride; the subsequent rearrangement leads to substituted 1,3-oxazines (LXXVII)[27,36]:



The reaction with dimethylcyanamide takes place much more readily than those with acetonitrile and benzonitrile.

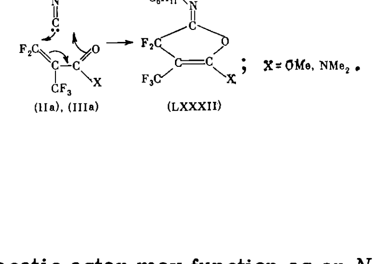
On reaction with perfluoromethacryloyl fluoride, isocyanates form the 1,2-cycloaddition products (XXIV), the 1,4-cycloaddition products (LXXVIII), the allyl rearrangement products (LXXIX), and the products of their cycloaddition to bis(trifluoromethyl)keten (LXXX)[5,27,36]:



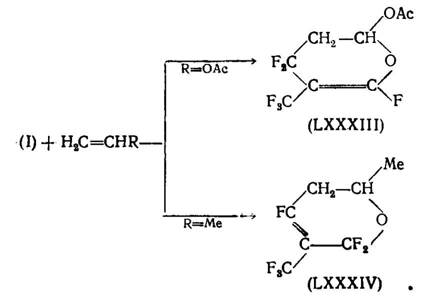
An increase in the polarity of the medium favours 1,2-cycloaddition (via a dipolar ion)[5,27,36].

The diazoacetic ester¶, isonitriles, olefins, phenylacetylene and ketens are *C*-nucleophiles capable of being involved in cycloaddition reactions.

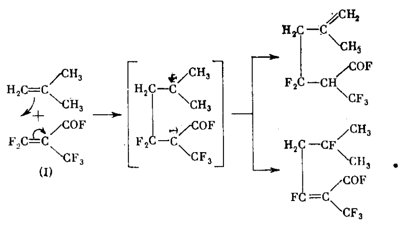
The diazoacetic ester reacts with perfluoromethacryloyl fluoride under mild conditions, giving a substituted cyclopropane (LXXXI) (the *erythro*- and *threo*-isomers)[9]. When cyclohexyl isocyanide reacts with PFMA derivatives, substituted iminodihydrofurans (LXXXII) are formed via 1,4-cycloaddition to the system $\rangle C=\underset{|}{C}-\underset{|}{C}=O$:[77]



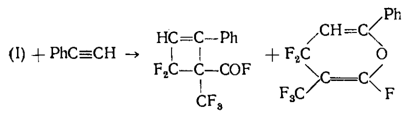
The reaction of perfluoromethacryloyl fluoride with certain olefins leads to six-membered rings via 1,4-cycloaddition; under these conditions, subsequent allyl rearrangement (1,3-migration of the fluorine atom) is frequently observed. The reaction with vinyl acetate leads to the formation of the 1,4-cycloadduct (LXXXIII) and the reaction with propene (and with norbornene) gives the allyl rearrangement product (LXXXIV)[27,36,78]:



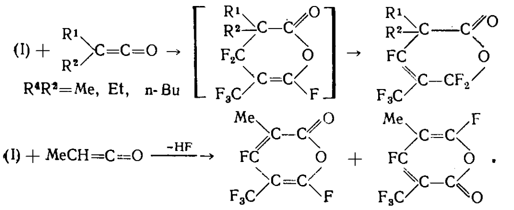
In the reaction with propene, a further two linear products were isolated: $CH_3CHFCH_2CF=C(CF_3)COF$ and $CH_3CH=CHCF=C(CF_3)COF$. Only linear products were obtained after the reaction with isobutene. It may be that, as in the reaction with aromatic aldehydes [Eqn. (20)], a dipolar ion (with the positive charge stabilised by the action of two methyl groups) is formed here as an intermediate, but it does not cyclise to cyclobutane, isomerising with migration of the H⁺ or F⁻ ion[27,36]:



Phenylacetylene adds to perfluoromethacryloyl fluoride, forming 1,2- and 1,4-cycloaddition products[79]:



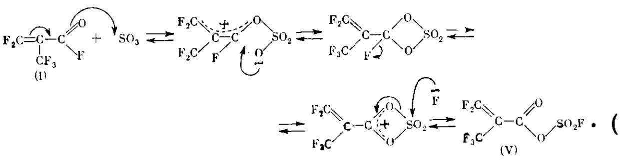
When perfluoromethacryloyl fluoride reacts with dialkylketens, 1,4-cycloaddition to the C=C bond of the keten takes place with subsequent 1,3-migration of the fluorine[27,36]. In the reaction with methylketen, the corresponding dehydrofluorination products were isolated[36]:



¶The diazoacetic ester may function as an *N*-nucleophile (cf. Gambaryan et al.[76]).

8. Other Reactions of PFMA Derivatives

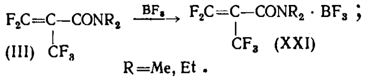
Reactions with electrophilic compounds are completely uncharacteristic of PFMA derivatives. Only sulphur trioxide, a powerful electrophile, is capable of reacting with perfluoromethacryloyl fluoride. In contrast to reactions with nucleophiles, in this case the acyl fluoride group is the most reactive, the product being the mixed anhydride (V). It may be that the reaction begins with attack by the electrophilic SO_3 species on the carbonyl oxygen atom[37]:



(22)

The reaction is reversible—on heating to 125–140° C, the anhydride (V) is cleaved to the initial compounds.

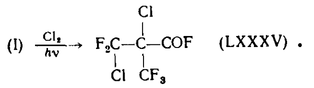
When dialkylamides of PFMA are acted upon by BF_3, the adducts (XXI) are formed [cf. Eqn. (8)][7,33]:



$$\underset{\text{(III)}}{F_2C{=}\underset{\substack{|\\CF_3}}{C}{-}CONR_2} \xrightarrow{BF_3} \underset{\text{(XXI)}}{F_2C{=}\underset{\substack{|\\CF_3}}{C}{-}CONR_2\cdot BF_3}\ ;\quad R{=}Me, Et\,.$$

The attempts to brominate the dialkylamides were unsuccessful—only the HBr addition products were obtained [Eqn. (12)][7].

On chlorination, perfluoromethacryloyl fluoride gives rise to $\alpha\beta$-dichloropentafluoroisobutyryl fluoride (LXXXV)[8]:



$$\text{(I)} \xrightarrow[h\nu]{Cl_2} F_2\underset{\substack{|\\Cl}}{C}{-}\overset{\substack{Cl\\|}}{\underset{\substack{|\\CF_3}}{C}}{-}COF \quad \text{(LXXXV)}\,.$$

This reaction is initiated by ultraviolet irradiation and evidently proceeds via a radical mechanism. The use of chlorination for the protection of the reactive $CF_2{=}C{<}$ group is discussed in subsections 1 and 4 of Section II.

In the presence of a radical reaction initiator, cyclohexane readily adds to the C=C bond of perfluoromethacryloyl fluoride[9,37]:

There is little information available about the polymerisation of PFMA derivatives†. Perfluoromethacryloyl fluoride does not apparently polymerise by itself, but it does undergo copolymerisation with other monomers[9,82,83]. The rubber-like copolymer of perfluoromethacryloyl and ethylene, obtained on heating under pressure in the presence of t-butyl peroxide, is soluble in carbon tetrachloride; on treatment with ethylenediamine, a cross-linked polymer, insoluble in carbon tetrachloride, is formed[9,82]. A patent[82] also indicates the possibility of obtaining copolymers from perfluoromethacryloyl fluoride and monomers such as methyl methacrylate, acrylonitrile, tetrafluoroethylene, vinyl fluoride, and vinylidene fluoride. After cross-linking the copolymers can be used for the preparation of films and various coatings, for the impregnation or coating of porous materials, etc. The copolymers of perfluoromethacryloyl fluoride and $CH_2{=}CF_2$, obtained by radiation-induced copolymerisation, are readily cross-linked by bifunctional compounds; they have high thermal stabilities and readily adhere to metals[83].

Ethyl perfluoromethacrylate (IIb) and the diethylamide of PFMA (IIIb) do not polymerise on heating in the presence of benzoyl peroxide, while the dimethylamide (IIIa) forms under these conditions a brittle solid polymer, soluble in acetone and insoluble in carbon tetrachloride. Similar polymers have been obtained from the dimethyl- and diethylamides of PFMA (III, a and b) on γ-irradiation[7].

Examination of the chemical properties of PFMA derivatives reveals distinct electrophilic properties of these compounds. The reactions with very weak nucleophiles, for example with carboxylic acids, which do not require base catalysis, are particularly instructive in this respect. Such reactions are completely uncharacteristic of either perfluoro-olefins or perfluoro-derivatives of $\alpha\beta$-unsaturated carbonyl compounds. Evidently the electrophilic properties of fluoro-olefins and $\alpha\beta$-unsaturated carbonyl compounds are "added together" in the case of PFMA derivatives.

The Perfluoro-t-butyl Anion in the Synthesis of Organofluorine Compounds

B.L.Dyatkin (deceased), N.I.Delyagina, and S.R.Sterlin

Methods for the generation and reactions of the perfluoro-t-butyl anion—a convenient model for the investigation of the chemistry of perfluoroalkyl carbanions, are examined. Syntheses based on this anion lead to the formation of a wide variety of compounds containing the $(CF_3)_3C$ group.

The bibliography includes 76 references.

CONTENTS

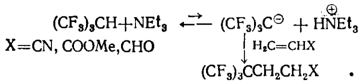
I. INTRODUCTION

Reactions involving perfluoroalkyl carbanions have been acquiring increasing importance in the chemistry of organofluorine compounds, because of the comparatively high thermodynamic stability of such carbanions due to the stabilising effect of the fluorine atoms [1,2]†. The perfluoro-t-butyl anion is particularly stable. Vigorous studies on methods for the preparation of this carbanion and its reactions have led during the last 10 years to the synthesis of a wide variety of compounds containing the $(CF_3)_3C$ group. The two main pathways to the synthesis of the $(CF_3)_3C^-$ anion are heterolysis of the C–H bond in nonafluoroisobutane and the addition of the F^- anion to perfluoroisobutene. Furthermore, it is possible to employ for synthetic purposes di(perfluoro-t-butyl)mercury under the conditions of nucleophilic catalysis.

II. REACTIONS OF NONAFLUOROISOBUTANE IN THE PRESENCE OF TERTIARY AMINES

Nonafluoroisobutane $(CF_3)_3CH$ is a comparatively strong CH acid. (According to various estimates, the pK_a values are approximately 11,[1] approximately 7,[5] or approximately 20.[6]) It is normally unstable when acted upon by bases, readily eliminating fluorine atoms in the form of ions [1]. However, when nonafluoroisobutane is mixed with triethylamine, fluorine atoms are not converted into an inorganic form. It has been observed by ^1H NMR that this entails the formation of a comparatively strong hydrogen bond between the molecules of nonafluoroisobutane and triethylamine with participation of the hydrogen atom of the methine group (the chemical shift due to the hydrogen bond amounts to 1.95 p.p.m.)[7].

Although a signal due to the $(CF_3)_3C^-$ carbanion cannot be detected in the ^1H NMR spectrum, its presence in the mixture can be demonstrated by reactions with various electrophiles [8]. Thus nonafluoroisobutane can be made to take part in the Michael reaction. In the presence of triethylamine, it readily adds to the C=C bonds of acrylic systems—acrylonitrile, methyl acrylate, and acrolein[9,10]:



$$\begin{tikzcd}(CF_3)_3CH + NEt_3 \arrow[r, shift left] & (CF_3)_3C^{\ominus} + H\overset{\oplus}{N}Et_3 \arrow[l, shift left] \arrow[d, "H_2C=CHX"] \\ X=CN, COOMe, CHO & (CF_3)_3CCH_2CH_2X \end{tikzcd}$$

(I)

Further reactions of products (I) led to the formation of various compounds containing the $(CF_3)_3C$ group, such as

$(CF_3)_3CCH_2CH_2COOH$, $(CF_3)_3CCH_2CH_2CH_2OH$, $(CF_3)_3CCH_2CH_2CH_2SH$, $(CF_3)_3CCH_2CH_2CH_2NH_2$ etc. (Ref.10).

The addition to the activated triple bond C≡C of benzoylaetylene or the acetylenedicarboxylate ester takes place just as readily [11]:

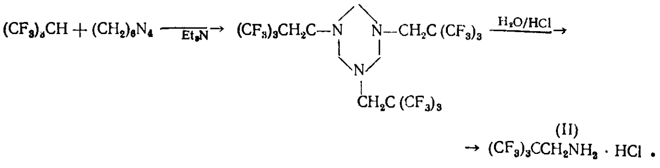
$$(CF_3)_3CH + HC\equiv CCOPh \xrightarrow[Et_3N]{} (CF_3)_3CCH=CHCOPh\ ;$$

$$(CF_3)_3CH + H_3COCOC\equiv CCOOCH_3 \xrightarrow[Et_3N]{} (CF_3)_3C\overset{\displaystyle COOCH_3}{\overset{|}{C}}=CHCOOCH_3\ .$$

Nonafluoroisobutane is involved in hydroxymethylation and aminomethylation reactions [8,12]. When it was heated with paraformaldehyde in the presence of triethylamine, a low yield of perfluoro-t-butylmethanol was obtained:

$$(CF_3)_3CH + (CH_2O)_n \xrightarrow[Et_3N]{} (CF_3)_3CCH_2OH\ .$$

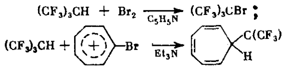
Its reaction with urotropine gave a substituted triazine (II) whose hydrolysis led to the hydrochloride of perfluoro-t-butylmethylamine:



(II)

Ionic halogenation [13] and tropylation [14] of nonafluoroisobutane have also been achieved:

$$(CF_3)_3CH + Br_2 \xrightarrow[C_5H_5N]{} (CF_3)_3CBr\ ;$$



The attempt to alkylate nonafluoroisobutane by ethyl iodide in the presence of triethylamine was unsuccessful, probably because of the formation of tetraethylammonium iodide, which is incapable of alkylating monohydroperfluoroalkanes under the reaction conditions [8].

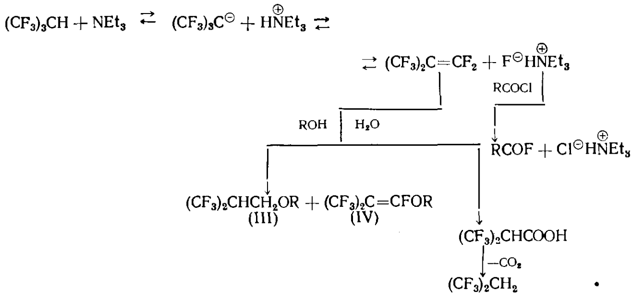
---

†For a discussion of the possible role of the "negative hyperconjugation" in the stabilisation of fluoro-carbanions, see Refs. 1, 3, and 4.

The benzoylation of nonafluoroisobutane could not be achieved either. On treatment with benzoyl chloride in the presence of triethylamine, it is dehydrofluorinated, yielding perfluoroisobutane[15]:

$$(CF_3)_3CH + PhCOCl + Et_3N \rightarrow (CF_3)_2C{=}CF_2 + PhCOF + Et_3\overset{\oplus}{N}HCl^{\ominus} .$$

Evidently, when nonafluoroisobutane is mixed with triethylamine, it is dehydrofluorinated, but the reaction is reversible, the equilibrium being almost completely displaced towards the starting materials (see above). Benzoyl chloride can participate in a reversible exchange reaction with triethylamine hydrofluoride, which shifts the equilibrium towards the formation of perfluoroisobutene[8,15]. A similar shift of the equilibrium can be achieved by removing perfluoroisobutene from the reaction instead of triethylamine hydrofluoride. Thus when nonafluoroisobutane reacts with methanol in the presence of triethylamine, the products are the stable ethers (III) and (IV).[15] If water is used instead of methanol, one obtains 1,1,1,3,3,3-hexafluoropropane as a result of the decarboxylation of 2,2,2-trifluoro-2-trifluoromethylpropionic acid (α-hydrohexafluoroisobutyric acid)[16]:

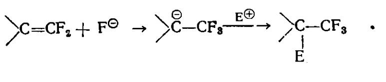


All these reactions take place with the intermediate formation of the perfluoro-t-butyl anion.

Thus the use of the carbanion $(CF_3)_3C^-$ generated from nonafluoroisobutane gives rise to fairly considerable synthetic possibilities. However, another method for the preparation of this carbanion—by the addition of the fluoride anion to perfluoroisobutene—is much more important for the synthesis of organofluorine compounds.

III. REACTIONS OF PERFLUOROISOBUTENE IN THE PRESENCE OF ALKALI METAL FLUORIDES

Perfluoro-olefins occupy an especially important place in the chemistry of organofluorine compounds. Owing to the electron-accepting effect of the fluorine atoms, they exhibit very marked electrophilic properties[17]. One of the most interesting reactions of perfluoro-olefins, which is being very vigorously investigated at the present time, is that with various electrophiles in the presence of fluoride ions in aprotic polar solvents. According to current ideas, the first step in this process is nucleophilic addition of the fluoride ion to the double bonds of the perfluoro-olefin with formation of a perfluoroalkyl carbanion, which then reacts with the electrophile[18]:

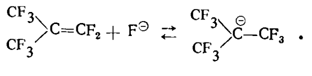


$$>C{=}CF_2 + F^{\ominus} \rightarrow >\overset{\ominus}{C}{-}CF_3 \xrightarrow{E^{\oplus}} >\underset{\displaystyle E}{\underset{|}{C}}{-}CF_3 .$$

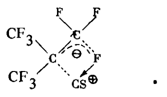
The perfluoro-olefin–alkali metal fluoride system can be regarded as a perfluoroalkyl derivative of the alkali metal. Such systems are involved in a wide range of reactions, the synthetic value of which not only largely compensates the limited applicability of perfluoroalkyl Grignard reagents, but also gives rise to additional possibilities, associated, in particular, with the use of processes such as the Wurtz reaction.

Reactions of this kind were investigated previously mainly in relation to fluorine-containing ethylenes and perfluoropropene. However, the perfluoro-t-butyl anion, obtained from perfluoroisobutene, is a more convenient model for the investigation of the reactions of perfluoroalkyl carbanions. Its advantages are due to a series of factors, including the low tendency of perfluoroisobutene towards dimerisation and oligomerisation‡ and its pronounced electrophilic properties, which ensure the ease of addition of the fluoride ion. In contrast to other perfluoroalkyl carbanions, the generation of the perfluoro-t-butyl anions can be observed directly with the aid of ^{19}F NMR spectra[22].

Two characteristic multiplets, corresponding to the CF_3 and CF_2 groups (−18 and 20 p.p.m. relative to CF_3COOH), in the perfluoroisobutene spectrum are converted after the addition of caesium fluoride into a broadened singlet displaced downfield (−27 p.p.m.) relative to the CF_3COOH signal. This reaction constitutes a rapid exchange, since the above spectral change is caused by much less than the equivalent amount of caesium fluoride:



The downfield signal shift can be accounted for by a reverse redistribution of electron density via fluorine atoms to the vacant inner orbitals of the metal atom:



The perfluoro-t-butyl anion generated from perfluoroisobutene readily combines with a proton. Thus the reaction of perfluoroisobutene with hydrogen fluoride in the presence of catalytic amounts of ammonium fluoride[23] or triethylamine[15] leads to the formation of nonafluoroisobutene:

$$(CF_3)_2C{=}CF_2 \xrightarrow{+F^{\ominus}} (CF_3)_3C^{\ominus} \xrightarrow[-F^{\ominus}]{+HF} (CF_3)_3CH .$$

This reaction makes it possible to use perfluoroisobutene as a dehydrofluorinating agent[24,25].

The nucleophilic fluoroiodination of perfluoroisobutene leads to iodoperfluoroisobutane[26]:

$$(CF_3)_2C{=}CF_2 \xrightarrow{+F^{\ominus}} (CF_3)_3C^{\ominus} \xrightarrow[-I^{\ominus}]{+I_2} (CF_3)_3CI .$$

The same compound has been obtained by the reaction of perfluoroisobutene with iodine monofluoride[27].

The alkylation of the perfluoro-t-butyl anion by various alkyl halides gives rise to considerable possibilities for the synthesis of various organic compounds containing the perfluoro-t-butyl group[22,28]:

$$(CF_3)_2C{=}CF_2 + RX \xrightarrow{CsF} (CF_3)_3C{-}R ;$$

$$R{=}CH_3,\ C_4H_9,\ CH_2{=}CHCH_2;$$

$$C_6H_5CH_2,\ n\text{-}FC_6H_4CH_2,\ (C_6H_5)_2CH;$$

$$X{=}Cl,\ Br,\ I .$$

---

‡It is claimed, incidentally, that perfluoroisobutene is dimerised on treatment with CsF in ether or diglyme.[19-21]

3-Bromocyclohexene reacts similarly[22].

It is readily seen that the results of these reactions are similar to those of the Wurtz reaction; at the same time the lower reactivity of the anion $(CF_3)_3C^-$ compared with hydrocarbon carbanions makes it possible to substitute the halogen in compounds containing other reaction centres, for example in β-bromopropionitrile[28], ethylbromoacetate[29], and β-bromoethyl acetate[30]. The reaction with 1,2-dibromoethane under mild conditions leads to the formation of the product resulting from the substitution of one bromine atom by the $(CF_3)_3C$ group[30]:

$$(CF_3)_3C^{\ominus} + BrCH_2X \xrightarrow[-Br^{\ominus}]{} (CF_3)_3CCH_2X\ ;$$

$$X{=}CH_2CN,\ CH_2COOEt,\ CH_2OAc,\ CH_2Br\ .$$

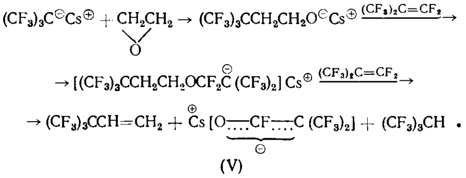
Perfluoro-t-butylacetic acid $(CF_3)_3CCH_2COOH$ was obtained by the hydrolysis of the corresponding ester. The dissociation constant of the acid has been determined and the Taft constant σ* for the $(CF_3)_3C$ group (1.48) has been calculated[31]. This value proved to be much smaller than the additive constant ($\sigma^*_{(CF_3)_3C} = 3\sigma^*_{CF_3} \times 0.357 = 2.79$).

Perfluoro-t-butylethylene has been obtained by the dehydrobromination of 2-(perfluoro-t-butyl)ethyl bromide with solid alkali or by the pyrolysis of 2-(perfluoro-t-butyl)ethyl acetate[30]:

$$(CF_3)_3CCH_2CH_2Y \xrightarrow[-HY]{} (CF_3)_3CCH{=}CH_2\ ;$$

$$Y{=}Br,\ OAc\ .$$

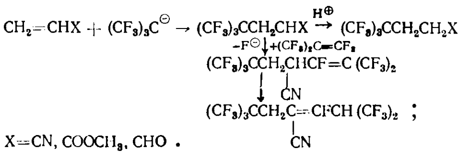
The same olefin is formed together with nonafluoroisobutane and the salt (V), containing a mesomeric anion, is formed when perfluoroisobutene reacts with oxiran in the presence of caesium fluoride[32]:



(V)

Here perfluoroisobutene behaves not only as a dehydrofluorinating agent but also as a kind of dehydrating agent. Under other conditions, perfluoro-t-butylethanol $(CF_3)_3CCH_2CH_2OH$ was isolated from the reaction mixture (after acidification).

Derivatives of perfluoro-t-butylpropionic acid have been obtained by the reaction of the perfluoro-t-butyl anion with derivatives of acrylic acid; in the case of acrylonitrile, the product of further interaction of the intermediate carbanion with a molecule of perfluoroisobutene is also formed[28]:



$$CH_2{=}CHX + (CF_3)_3C^{\ominus} \rightarrow (CF_3)_3CCH_2\overset{\ominus}{C}HX \xrightarrow{H^{\oplus}} (CF_3)_3CCH_2CH_2X$$

$$(CF_3)_3CCH_2\overset{\ominus}{C}HX \xrightarrow[-F^{\ominus}]{+(CF_3)_2C=CF_2} (CF_3)_3CCH_2\underset{\substack{|\\CN}}{C}HCF{=}C(CF_3)_2 \rightarrow (CF_3)_3CCH_2\underset{\substack{|\\CN}}{C}{=}CFCH(CF_3)_2\ ;$$

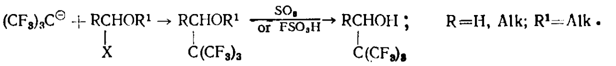
$$X{=}CN,\ COOCH_3,\ CHO\ .$$

Perfluoropropene and tetrafluoroethylene react with carbon dioxide in the presence of caesium fluoride to form perfluoroisobutyric and perfluoropropionic acids respectively. The attempt to synthesise perfluoropivalic acid by carboxylating the perfluoro-t-butyl anion was unsuccessful[19]. Perfluoropivaloyl fluoride $(CF_3)_3CCOF$ is formed together with the enamine (VI) when perfluoroisobutene reacts with dimethylformamide, evidently as a result of the addition of carbonyl difluoride to perfluoroisobutene[33]:

$$(CF_3)_2C{=}CF_2 + OCHN(CH_3)_2 \rightarrow \underset{(VI)}{(CF_3)_2C{=}CHN(CH_3)_2} + (CF_3)_3CCOF\ ;$$

$$(CF_3)_2C{=}CF_2 \xrightarrow{+F^{\ominus}} (CF_3)_3C^{\ominus} \xrightarrow[-F^{\ominus}]{+COF_2} (CF_3)_3COF\ .$$

Carbonyl difluoride adds to perfluoro-olefins in the presence of CsF or KF.[34-36] The perfluoroethyl and perfluoroisopropyl anions interact with carbonyl compounds, forming fluorinated alcohols[37-39]. The corresponding alcohols containing the $(CF_3)_3C$ group have been obtained by an indirect procedure—via α-halogenoethers[40]:



$$(CF_3)_3C^{\ominus} + \underset{\substack{|\\X}}{RCHOR^1} \rightarrow \underset{\substack{|\\C(CF_3)_3}}{RCHOR^1} \xrightarrow[\text{or } FSO_3H]{SO_3} \underset{\substack{|\\C(CF_3)_3}}{RCHOH}\ ; \quad R{=}H,\ Alk;\ R^1{=}Alk\ .$$

The acylation of the perfluoro-t-butyl anion has not been described (if one disregards the synthesis of perfluoropivaloyl fluoride from perfluoroisobutene and dimethylformamide; see above). However, the anion $(CF_3)_3C^-$ reacts readily with aromatic imidoyl halides:

$$(CF_3)_3C^{\ominus} + PhN{=}\underset{\substack{|\\Cl}}{C}Ar \rightarrow PhN{=}\underset{\substack{|\\C(CF_3)_3}}{C}Ar\ .$$

The attempts to obtain ketones by the hydrolysis of the products of this reaction proved unsuccessful[40].

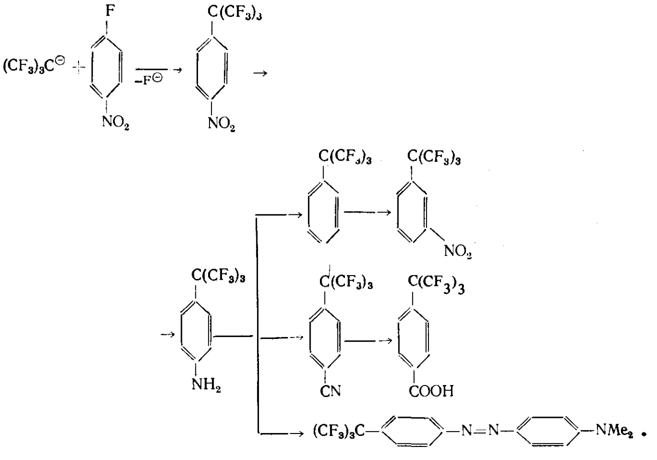
The perfluoro-t-butyl anion can substitute the chlorine atom in 1-chloroacetylenes containing a fairly electronegative substituent in the 2-position[41]. Thus 1-chloro-3,3,3-trifluoropropyne reacts with the ion $(CF_3)_3C^-$ in diglyme at room temperature and chloro(phenyl)acetylene reacts at 120°C:

$$(CF_3)_3C^{\ominus} + ClC{\equiv}CR \rightarrow (CF_3)_3CC{\equiv}CR\ ;$$

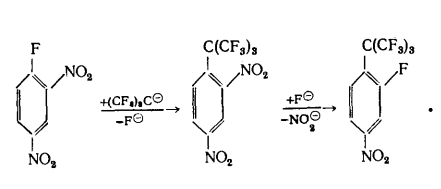
$$R{=}CF_3,\ Ph\ .$$

On the other hand 1-chlorohex-1-yne and 1-chloro-2-methoxyethyne do not react with perfluoroisobutene and caesium fluoride even under severe conditions. The perfluoroisopropyl anion does not react with either 1-chloro-3,3,3-trifluoropropyne or 1-chloro-2-phenylethyne.

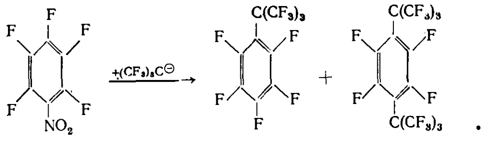
The introduction of the perfluoro-t-butyl group into an aromatic or heterocyclic ring is of definite theoretical interest in connection with the electronic and steric features of the structure of this group. The interaction of the anion $(CF_3)_3C^-$ with various aromatic and heterocyclic compounds containing a mobile halogen atom leads to the corresponding perfluoro-t-butyl substituted derivatives[42]. Thus *p*-nitro(perfluoro-t-butyl)benzene has been obtained from *p*-fluoronitrobenzene and has been used to synthesise various substituted benzenes containing the $(CF_3)_3C$ group[31]:



When the 1-fluoro-2,4-dinitrobenzene is acted upon by the perfluoro-t-butyl anion, the fluorine atom is initially substituted by the $(CF_3)_3C$ group and then the *ortho*-nitro-group, displaced from coplanarity with the benzene ring, is substituted by fluorine on being acted upon by the fluoride ion:

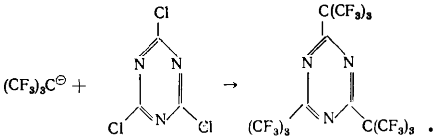


The substitution products (VII) and (VIII) have been isolated in the reaction with pentafluoronitrobenzene:

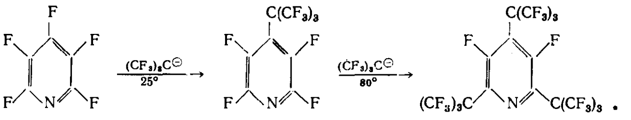


(VII) (VIII)

All three chlorine atoms are substituted in cyanuric acid chloride:



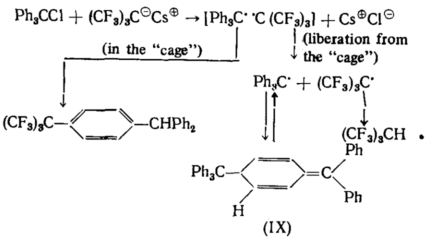
Depending on the conditions, the reaction with perfluoropyridine yields products obtained by the substitution of one or three fluorine atoms:



The interaction of the perfluoro-t-butyl anion with triarylmethyl halides constitutes a special case[42,43]. The reaction with chlorotriphenylmethane proceeds very readily, the chlorine atom being substituted by the perfluoro-t-butyl group. However, this is not direct substitution: the perfluoroalkyl group enters the *para*-position of one of the benzene rings:

An ESR study of this reaction (in diglyme) showed that free triphenylmethyl radicals are formed. In the presence of triphenylmethyl chloride, the concentration of the free radicals passes through a maximum and then approaches the value determined by the constant for the equilibrium between the radical and its diamagnetic dimer [Gomberg's "hexaphenylethane" (IX)].

The one-electron transfer stage constitutes a general problem for nucleophilic substitution reactions[44]. The reaction of triphenylmethyl chloride with the perfluoro-t-butyl anion is the first example of proven electron transfer from a perfluoroalkyl anion. The main reaction product is formed within the cage; the triphenylmethyl radicals emerging from the cage are detected by ESR. The perfluoro-t-butyl radicals leaving the cage abstract hydrogen atoms from the solvent and form nonafluoroisobutane. The overall reaction mechanism can be represented as follows:



(IX)

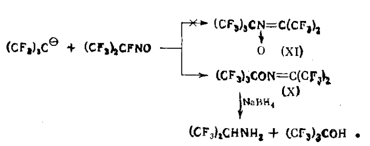
Electron transfer is also observed in the interaction with tri-(p-nitrophenyl)methyl bromide, which results in the formation of the radicals $(p\text{-}O_2NC_6H_4)_3\dot{C}$ and $(CF_3)_3\dot{C}$. Since the tri-(p-nitrophenyl)methyl radical is incapable of dimerisation or recombination, both radicals emerge from the cage. The only organofluorine reaction product is nonafluoroisobutane; the substituted triphenylmethyl radical is stable in the absence of air[43].

There are many other reactions for which one-electron transfer has not so far been demonstrated but is extremely probable§. Evidently the mechanism of the reaction of the perfluoro-t-butyl anion with nitrosoperfluoroalkanes can be treated from the same standpoint. It appeared strange that, in the reaction of perfluoroalkyl carbanions with nitrosyl fluoride[45,46] or nitrosyl chloride[47], further interaction of the perfluoroalkyl carbanions with the nitrosoperfluoro-compounds formed is not observed:

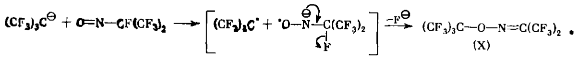
$$>C=CF< + XNO \xrightarrow{KF} R_FNO;$$

$R_F=C(CF_3)_3$, $CF(CF_3)_2$, cyclo-C_4F_7.

Subsequent studies showed that only the perfluoro-t-butyl anion is capable of involvement in the reaction with nitrosoperfluoroalkanes and only when the nitroso-group in the nitrosoperfluoro-compound is attached to a primary or secondary carbon atom[48,49]. The study of the chemical properties of the product of the reaction of the perfluoro-t-butyl anion with 2-nitrosoperfluoropropane, in particular its reduction with sodium tetrahydroborate, established that it has the structure of the N-perfluoro-t-butyl derivative of hexafluoroacetone oxime (X)[48] and not the perfluoronitrone (XI), as suggested previously[49]:



This unusual course of the reaction (attack by the carbanion directed to the negatively charged oxygen atom and not to the positively charged nitrogen atom, as might have been expected) can be explained if it is assumed that the first stage in this reaction is one-electron transfer from the perfluoroalkyl carbanion to the nitroso-group; the final product is then formed as a result of the elimination of the fluoride ion from the α-position relative to the nitrogen atom:



---

§For a discussion of the reactions of perfluoroisobutene with haloforms in the presence of the F^- ion, see the review by I. L. Knunyants and V. R. Polishchuk in this issue.

Nitrosoperfluoroisobutane without a fluorine atom in the α-position does not react with a perfluoroalkyl carbanion under comparable conditions. In the synthesis of 2-nitrosoperfluoropropane from perfluoropropene and a nitrosyl halide, the subsequent reaction of the anion $(CF_3)_2CF^-$ with nitroso-compounds is apparently unable to compete with the dimerisation and oligomerisation reactions of perfluoropropene.

The formation of difluoro(perfluoro-t-butyl)amine in the reaction of perfluoroisobutene with tetrafluorohydrazine in the presence of potassium fluoride can also be treated as a one-electron transfer[50]:

$$(CF_3)_2C{=}CF_2 + N_2F_4 \xrightarrow[150^\circ]{KF} (CF_3)_3C{-}NF_2 + N_2 + NF_3\,.$$

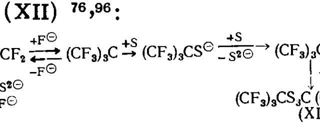
In this case, the perfluoro-t-butyl anion is oxidised by the difluoroamino-radical:

$$(CF_3)_3C^{\ominus} \xrightarrow[\overset{\ominus}{-NF_2}]{+\dot{N}F_2} (CF_3)_3C^{\cdot} \xrightarrow{+\dot{N}F_2} (CF_3)_3C{-}NF_2\,.$$

The range of reactions for which a one electron transfer mechanism is extremely probable¶ can be supplemented by the interaction of perfluoroalkyl carbanions with diazonium salts leading to arylazoperfluoroalkanes[52,53]:

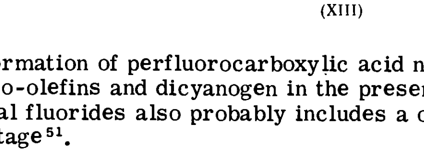
$$R_F^{\ominus} + N{\equiv}\overset{\oplus}{N}{-}C_6H_5 \rightarrow R_F{-}N{=}N{-}C_6H_5 + Cl^{\ominus}\,;$$
$$Cl^{\ominus}$$
$$R_F{=}(CF_3)_3C,\ (CF_3)_2CF,\ \text{cyclo-}C_4H_7\,.$$

Like other perfluoroalkyl anions, the perfluoro-t-butyl anion reacts with elemental sulphur under relatively mild conditions. Generally speaking, the reactions of perfluoroalkyl carbanions with sulphur proceed in different ways, leading to a wide variety of sulphur derivatives, the formation of which may be accounted for by the reactions of the perfluoroalkylmercaptide anions formed initially[54-57,76]. Depending on the structure of the initial olefin and the reaction conditions, these species can undergo the following transformations: (a) they can eliminate a fluoride anion from the α-position relative to the sulphur atom, forming a perfluorothiocarbonyl compound; (b) they can be oxidised by sulphur to a perfluoroalkanethiyl radical and can give rise to di(perfluoroalkyl) di- and poly-sulphides; (c) they can react with the fluoro-olefin via the vinyl substitution mechanism, forming an alkenyl perfluoroalkyl sulphide:



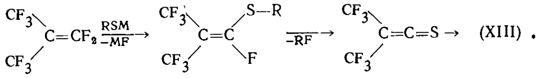
$$R_F^{\ominus} + S \rightarrow R_FS^{\ominus}\,;$$
$$\text{(a)}\ {-}\underset{F}{\overset{|}{\underset{|}{C}}}{-}S^{\ominus} \xrightarrow[-F^{\ominus}]{} {>}C{=}S\,;$$
$$\text{(b)}\ R_FS^{\ominus} \xrightarrow[-S^{2\ominus}]{+S} R_FS^{\cdot} \rightarrow R_FS_nR_F\,;$$
$$\text{(c)}\ R_FS^{\ominus} + CF_2{=}C{<} \xrightarrow[-F^{\ominus}]{} R_FSCF{=}C{<}\,.$$

In the case of perfluoroisobutene, the possibility of the elimination of a fluoride ion from the α-position is ruled out. The perfluoro-t-butylmercaptide anion is oxidised to the corresponding radical, which is converted into the trisulphide (XII); the sulphide ion formed interacts with perfluoroisobutene, forming the dimer of bis(trifluoromethyl)thioketen (XII)[76,96]:



(XIII)

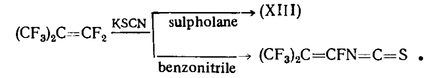
The reaction of perfluoroisobutene with potassium sulphide[57] or with salts of thiolic acids constitutes a preparative method for the synthesis of the thioketen dimer (XIII)[58,59]:



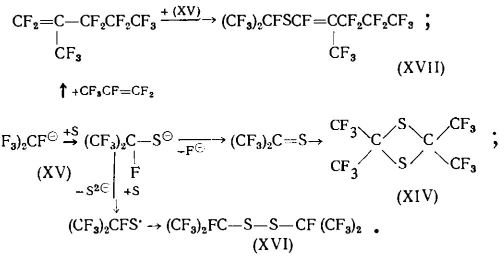
The best result was obtained with potassium diethyl phosphorodithioate[58]:

(XIII)

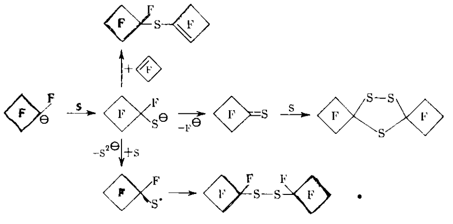
It is interesting to note, that, when this reaction is carried out with potassium thiocyanate, the thiocyanate ion exhibits the properties of an ambident nucleophile[60]:



In the presence of catalytic amounts of potassium fluoride, perfluoropropene gives a satisfactory yield of virtually only one sulphur-containing product—the dimer of perfluorothioacetone (XIV), which is formed as a result of the elimination of the F^- ion from the perfluoroisopropylmercaptide ion (XV); in the presence of large amounts of potassium fluoride, there is a significant increase of the yield of the disulphide (XVI) and of the unsaturated sulphide (XVII)[76]:



The reaction of perfluorocyclobutene with sulphur and KF leads to a similar result, but in this instance the elimination of the fluoride ion from the perfluorocyclobutylmercaptide anion is somewhat difficult, because the formation of perfluorothiocyclobutanone (XVIII)—a compound with a semicyclic double bond—is energetically less favourable; accordingly there is an increase in the yield of compounds containing the perfluorocyclobutylthio-group, i.e. the unsaturated sulphide (XIX) and the disulphide (XX)[56,76]:



(XIX)

(XX)

The reactions of perfluoroalkyl carbanions give rise to considerable possibilities for the preparation of fluorine-containing organomercury compounds[61-63]. In contrast to the electrophilic mercuration reaction known previously[54,64-66], such reactions may be called "nucleophilic mercuration of fluoro-olefins". Depending on the nature of the reagent and the reactions conditions, they make it possible to obtain fully substituted or mixed

---

¶The formation of perfluorocarboxylic acid nitriles from fluoro-olefins and dicyanogen in the presence of alkali metal fluorides also probably includes a one-electron transfer stage[51].

perfluoroalkyl derivatives of mercury. Thus perfluoroisobutene reacts with mercury trifluoroacetate in the presence of KF, giving a high yield of di(perfluoro-t-butyl)-mercury and the reaction with trifluoromethylmercury trifluoroacetate leads to trifluoromethyl(perfluoro-t-butyl)mercury [63]:

$$(CF_3)_2C{=}CF_2 + KF \longrightarrow \left| \begin{array}{l} \xrightarrow{Hg(OCOCF_3)_2} [(CF_3)_3C]_2Hg \\ \xrightarrow{CF_3HgOCOCF_3} (CF_3)_3C{-}Hg{-}CF_3\,. \end{array} \right.$$

It is noteworthy that fluorides—HgF_2 and phenylmercury fluoride—add to perfluoroisobutene in the absence of a catalyst [62], behaving themselves as sources of the fluoride ion; one cannot, however, rule cut the possibility that the addition can proceed in this case also via a cyclic four-centre mechanism.

The reaction of perfluoroisobutene with mercury(II) chloride in the presence of KF proceeds less vigorously and stops at the stage involving the formation of perfluoro-t-butylmercury chloride [62]:

$$(CF_3)_2C{=}CF_2 + HgCl + KF \xrightarrow[DMF]{} (CF_3)_3CHgCl \not\longrightarrow \left[(CF_3)_3C\right]_2Hg\,.$$

Evidently the more covalent character of the Hg–Cl bond compared with the Hg–F and Hg–$OCOCF_3$ bonds is manifested here.

In contrast to perfluoroisobutene, perfluoropropene acted upon by potassium fluoride and mercury(II) chloride can form, depending on the reaction conditions, both fully substituted and mixed derivatives of mercury: the reaction in dimethylformamide leads to di(perfluoroisopropyl)-mercury and that in the less polar dimethoxyethane yields perfluoroisopropylmercury chloride [62]:

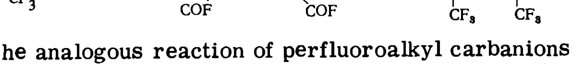
$$CF_3CF{=}CF_2 + HgCl_2 + KF \longrightarrow \left| \begin{array}{l} \xrightarrow{DMF} [(CF_3)_2CF]_2Hg \\ \xrightarrow{DME} (CF_3)_2CFHgCl\,. \end{array} \right.$$

The formation of the symmetrical compound indicates a higher reactivity of the perfluoroisopropyl anion compared with the perfluoro-t-butyl anion. This is confirmed directly by the displacement of perfluoroisobutene from perfluoro-t-butylmercury chloride on treatment with perfluoropropene in the presence of KF [62]:

$$\begin{array}{l} CF_3CF{=}CF_2 + (CF_3)_3CHgCl \xrightarrow{F^{\ominus}} [(CF_3)_2CF]_2Hg + Cl^{\ominus} + (CF_3)_3C^{\ominus} \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \downarrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (CF_3)_2C{=}CF_2 + F^{\ominus}\,. \end{array}$$

Fluoro-olefins containing not only a terminal double bond but also an inner double bond can be involved in the nucleophilic mercuration reaction. Thus perfluorocyclobutene, the mercuration of which could not be achieved under the conditions of the electrophilic reaction [65], in the presence of KF interacts with mercury(II) fluoride and chloride, forming respectively di(perfluorocyclobutyl)-mercury and perfluorocyclobutyl mercury chloride [62]:

Bis(trifluoromethyl)keten, a powerful electrophile, combines with mercury(II) fluoride in the absence of a catalyst [67]. Treatment of the adduct with potassium carbonate leads to the formation of di(perfluoroprop-2-enyl) mercury:



$$(CF_3)_2C{=}C{=}O \xrightarrow{HgF_2} (CF_3)_2(COF)C{-}Hg{-}C(CF_3)_2(COF) \xrightarrow[-COF_2]{K_2CO_3} CF_2{=}C(CF_3){-}Hg{-}C(CF_3){=}CF_2\,.$$

The analogous reaction of perfluoroalkyl carbanions with silver salts can be used to synthesise various perfluoroalkyl derivatives of silver. These compounds were obtained for the first time by the addition of silver fluoride to fluoro-olefins [68-71]; the fluoro-olefin–fluoride ion–$AgOCOCF_3$ system is, however, much more effective. Together with perfluoroisobutene, perfluoropropene, and perfluorocyclobutene, it proved possible to introduce into this reaction chlorotrifluoroethylene [72],[73]:

$$\left.\begin{array}{r} (CF_3)_2C{=}CF_2 \\ CF_3CF{=}CF_2 \\ cyclo\text{-}C_4F_6 \\ CF_2{=}CFCl \end{array}\right\} + MF + AgOCOCF_3 \rightarrow \left\{\begin{array}{l} (CF_3)_3CAg \\ (CF_3)_2CFAg \\ cyclo\text{-}C_4H_7Ag \\ CF_3CFClAg \end{array}\right. ;$$

$$M{=}K,\, Cs\,.$$

On the other hand, the attempt to add silver fluoride as such to chlorotrifluoroethylene was unsuccessful [68], Evidently, silver fluoride, which is a fairly covalent compound, adds via a four-centre mechanism, while in the case of a perfluoroalkyl carbanion only an ionic reaction takes place.

A ^{19}F NMR study of compounds R_FAg showed that exchange reactions involving perfluoroisopropylsilver are much slower than those involving perfluoro-t-butylsilver [73]. This difference can be explained by the coordination of the lone electron pairs of the fluorine atoms in the α-position of perfluoroisopropylsilver to the vacant electronic orbitals of the silver atoms.

The "steric" interaction of the geminal halogen atoms and the metal is also indicated by data obtained from the ^{19}F NMR spectra of perfluoroalkyl derivatives of mercury in solvents with different solvating capacities [74]. It has been shown that the constant for the spin–spin interaction between the mercury atom and the β-fluorine atom increases with increase of the solvating capacity of the solvent and that the opposite behaviour obtains for the fluorine atom in α-position. Evidently the donor solvent molecule competes with the α-fluorine atom in the interaction with the unfilled orbitals of the mercury atom, which leads to a decrease of the steric contribution to the quantity

$$J_{^{199}Hg-C-^{19}F}\,.$$

IV. SYNTHESES BASED ON DI(PERFLUORO-t-BUTYL)-MERCURY

It is well known that, in contrast to their non-fluorinated analogues, perfluoroalkylmercury compounds are extremely stable in relation to electrophiles. Their reactions with such reagents either proceed with difficulty or not at all [65]. This is shown, in particular, by the finding that the best method for their purification is distillation from concentrated sulphuric acid [62]. However, under the conditions of nucleophilic catalysis, the reactivity of perfluoroalkyl mercury compounds in reactions with electrophiles increases significantly, the most convenient catalysts being alkali metal fluorides [75],[76].

Evidently the fluoride ion is coordinated via its lone electron pairs to the mercury atom, but, in contrast to other halides, this coordination does not lead to the complete displacement of the perfluoroalkyl carbanion (and the decomposition of perfluoroalkylmercury), increasing merely the carbanionic character of the carbon atom linked to mercury; as a result, the complex formed in the process

$$F^{\ominus} + R_F{-}Hg{-}R_F \rightleftarrows [R_F{\cdots}Hg(F){-}R_F]^{\ominus}$$

enters into the reaction and not the free carbanion.

Thus reactions of di(perfluoroalkyl)mercury with various electrophiles become possible. For example, di(perfluoro-t-butyl)mercury and di(perfluoroisopropyl)mercury become desymmetrised by mercury(II) chloride in the presence of potassium fluoride:

$$(R_F)_2Hg + HgCl_2 \xrightarrow{KF} R_FHgCl\ ;$$
$$R_F = (CF_3)_3C,\ (CF_3)_2CF\ .$$

Potassium fluoride also catalyses the reactions of these mercury perfluoroalkyls with iodine:

$$(R_F)_2Hg + I_2 \xrightarrow{KF} R_FI + HgI_2\ ;$$
$$R_F = (CF_3)_3C,\ (CF_3)_2CF\ .$$

It is noteworthy that di(perfluoro-t-butyl)mercury reacts with iodine in dimethylformamide also in the absence of a catalyst, probably due to the readily polarisability of iodine in a polar solvent; however, this reaction is much slower than in the presence of the fluoride ion.

When di(perfluoro-t-butyl)mercury and di(perfluoroisopropyl) mercury are heated with sulphur in dimethylformamide in the presence of potassium fluoride, mercury di(perfluoroalkyl)mercaptides are formed:

$$(R_F)_2Hg + S \xrightarrow{KF} (R_FS)_2Hg\ ;$$
$$R_F = (CF_3)_3C,\ (CF_3)_2CF\ .$$

The interaction of di(perfluoroalkyl)mercury with sulphur, catalysed by potassium fluoride, is remarkable in that it proceeds quite unambiguously—mercury perfluoroalkylmercaptides are the only reaction products. This finding suggests that the reaction with electrophiles proceeds within the limits of the complex $(R_F)_2Hg.KF$ without the involvement of the free carbanion:

Otherwise products of the oxidation of the perfluoroalkylmercaptide anion (di- and poly-sulphides) would have appeared in the reaction medium. Thus one may say that perfluoroalkylmercury compounds serve as a store of perfluoroalkylcarbanions and the experimental results obtained using the above method for their generation can differ from the results obtained in a fluoro-olefin–fluoride ion system.

In all the reactions enumerated above, di(perfluoro-t-butyl)mercury is much more reactive than di(perfluoroisopropyl)mercury. If one assumes that the catalytic activity of the fluoride ion is determined by its coordination to the mercury atom, the lower reactivity of perfluoroisopropylmercury can be accounted for not only by the destabilising effect of the fluorine atom in the α-position relative to the carbanionic centre but also by the competing intramolecular coordination of the mercury atom to the geminal fluorine atom.

Radical-cation Mechanism of the Anodic Fluorination of Organic Compounds

I.N.Rozhkov

The current state of the problem of the electrochemical fluorination of organic compounds is surveyed, and the mechanism of the substitution of hydrogen by fluorine during anodic oxidation in anhydrous hydrogen fluoride and in aprotic organic solvents is discussed. Formation of a carbon-fluorine bond during oxidation at platinum in the latter solvents is shown to be due to reaction of an organic radical-cation with a fluoride anion present in the electrolyte. Arguments are given in support of a mechanism of electrochemical fluorination in hydrogen fluoride not involving oxidation of the fluoride anion. A list of 160 references is included.

CONTENTS

I. INTRODUCTION

Electrochemical fluorination in anhydrous hydrogen fluoride is an important industrial method for obtaining perfluorinated organic compounds. This interesting process, devised by Simons more than twenty-five years ago[1,2], consists in the electrolysis at nickel electrodes of solution of organic compounds in anhydrous hydrogen fluoride. It is used to obtain completely fluorinated alkanes, carboxylic acids and their derivatives, ethers, tertiary amines, alkanesulphonyl fluorides, and other groups of organic compounds. The electrochemical production of organofluorine compounds possesses several advantages over other methods of fluorination. Firstly, it is a most economic and a comparatively safe process. Another attractive feature of the Simons method is that it yields perfluorinated products retaining the functional group of the original compound.

Although electrochemical fluorination is at first glance a simple and convenient method of preparation, it possesses many substantial disadvantages. This process usually results only in exhaustive fluorination of the organic molecule, and incompletely fluorinated products cannot be obtained. Electrochemical fluorination is accompanied by less degradation of the initial carbon framework of the molecule than in other methods, but this is still considerable. The yield of products retaining the original structure does not normally exceed 30%.

Since 1950 numerous attempts have been made to improve and modernise the Simons process. However, although more than 250 publications have appeared, the mechanism and the principal laws of electrochemical fluorination have remained until recently almost uninvestigated, owing to the extreme difficulty of working in anhydrous hydrogen fluoride[3-7]. In Dresdner's apt phrase[8] electrochemical fluorination is "... an art in many respects. The conditions of operation... ... are based on highly empirical considerations"

However, results have recently been obtained in Knunyants' laboratory that have drawn slightly aside the "curtain of secrecy" hiding the mechanism of this complicated reaction. The present Review will examine facts in support of a mechanism of anodic fluorination involving initial oxidation of the organic compounds.

II. FUNDAMENTAL IDEAS ON THE MECHANISM OF ELECTROCHEMICAL FLUORINATION IN ANHYDROUS HYDROGEN FLUORIDE

Several hypothetical mechanisms—(1) radical, (2) fluorination by higher fluorides of nickel, and (3) fluorination by complex nickel fluorides—have been suggested for electrochemical fluorination in hydrogen fluoride. The present Section is mainly confined to experimental results inconsistent with these hypothetical mechanisms, suggesting that anodic fluorination is quite different in character.

1. Radical Mechanism

According to this mechanism, suggested by Simons as early as 1950,[1] the first step is oxidation of a fluoride anion at the anode to the radical. The formation of perfluorinated organic compounds results from subsequent homolytic substitution of hydrogen atoms:

$$F^- \xrightarrow[\text{Ni}]{-e} F^\cdot \xrightarrow[-\text{HF}]{\text{RH}} R^\cdot \xrightarrow{F^\cdot} R{-}F\ .$$

Nagase[5] assumes that electrochemical fluorination is "an anodic reaction very definitely of free-radical type". Chang and Watanabe[9] consider that the molecular fluorine evolved is adsorbed on the nickel anode covered with a film of the difluoride. Fluorination takes place directly in hydrogen-fluoride solution at or below 20°C. The reason why only perfluorinated compounds are formed is that slightly fluorinated products are soluble in hydrogen fluoride, and therefore continue to be involved in the process. Completely fluorinated organic compounds, however, lose their basicity and become almost insoluble.

This is why only perfluorinated compounds are removed from the electrolyte, either as gaseous products or as heavy liquids separating out at the bottom of the cell.

The radical mechanism represented the first attempt—which proved to be greatly oversimplified—at explaining the results. A striking feature is the marked difference between the products obtained by electrochemical fluorination and those resulting from the action of elementary fluorine on organic compounds. It is incomprehensible, for example, why attempts to fluorinate molecular chlorine to the pentafluoride ClF_5 by the action of fluorine dissolved in hydrogen fluoride have been unsuccessful, whereas anodic fluorination gives a high yield of this product[10,11]. Such a radical mechanism leaves completely obscure also problems associated with the effect of the electrode material on the process: (i) nickel has proved the only suitable material for the anode[12]; (ii) even the brand of nickel and its crystalline structure influence the relative proportions of products of the fluorination of tertiary amines[13,14]; (iii) when new nickel electrodes are used, a peculiar, fairly long induction period is observed, during which perfluorinated products are not formed on passage of a current[4,13,14]; and (iv) fluorination is affected also by the material of the cathode, the use of soft iron instead of nickel lowering the yield of perfluorinated amines by two-thirds[15].

2. Fluorination by Higher Fluorides of Nickel

The fluorinating agents in this hypothetical mechanism are higher fluorides of nickel—NiF_3 and NiF_4—whose formation follows initial formation of nickel difluoride when nickel electrodes undergo anodic polarisation in hydrogen fluoride[16-19]. This is the reason for the induction period. An organic molecule present in solution then reacts with the modified surface of the anode. Such heterophase fluorination results in the appearance of perfluorinated compounds:

$$\begin{gathered}\mathrm{Ni-2e+2F^- \rightarrow NiF_2}\\ \mathrm{NiF_2-}n\mathrm{e}+n\mathrm{F^- \rightarrow NiF_{\mathit{n}+2}}\quad (n=1,\ 2)\\ \mathrm{RH+NiF_{\mathit{n}+2} \rightarrow R{-}F+HF+NiF_2}\quad .\end{gathered}$$

The formation of nickel difluoride in absolute hydrogen fluoride leads to very high ohmic polarisation[19]. Addition to the solvent of water (up to 2%) produces a marked decrease in the resistance of the cell, since the anodic coating becomes semiconducting. Water was regarded as necessary for stabilising species—NiOF and $NiOF_2$—containing the nickel atom in a higher state of oxidation. This concept was even used as basis for a tentative estimate[9] of the content of higher fluorides in the coating: their formation accounts for 0.1–1% of the current.

Nor does a mechanism of heterophase anodic fluorination of organic compounds by higher fluorides of nickel provide an acceptable explanation of many facts. Firstly, fluorination should be promoted by the introduction of additives such as cobalt into the nickel, since higher fluorides of cobalt are known[20] to be good fluorinating agents. However, such additions produce a marked deterioration in the electrochemical process, with increase in degradation and decrease in yield[21]. Furthermore, qualitative differences exist between the products of electrolysis and of fluorination by higher metal fluorides[3-5]. In particular, the electrochemical process is distinguished by preservation of the functional group of the initial compound, whereas fluorination by cobalt(III) fluoride involves detachment of functional groups from the organic molecule.

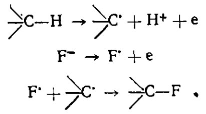
3. Fluorination by Complex Nickel Fluorides

In this mechanism, first suggested in 1960 by Burdon and Tatlow[4], highly conducting complexes of the organic compound with nickel fluorides—$(RH)_3NiF_6$ and $(RH)_2NiF_6$—are formed at the nickel electrode during electrolysis in hydrogen fluoride. Direct fluorination, i.e. replacement of hydrogen atoms in the organic molecule by fluorine atoms, occurs on decomposition of these complexes. Indirect evidence for this scheme was discovered later: (i) coloured anions—$[Ni^{3+}F_6]^{3-}$ and $[Ni^{4+}F_6]^{2-}$—were detected[22] in the anode layer during electrolysis of a solution of potassium fluoride in hydrogen fluoride; and (ii) potassium hexafluoronickelate, in anhydrous hydrogen fluoride at 0°C, reacts with xenon to form its difluoride[23].

Voitovich and Kazakov[24] regard this scheme as dubious, since the fluorinating effect of complex fluorides should be similar to the action of cobalt(III) fluoride. Electrochemical processes should not yield perfluorinated products with a retained functional group. In their opinion the primary act of the electrochemical process must be formation of nickel difluoride, which, in the presence of fluoride ions and e.g. a protonated tertiary amine, is oxidised electrochemically to a complex of type (I), sparingly soluble in hydrogen fluoride:

$$\begin{gathered}\mathrm{R_3N+HF \rightarrow R_3NH^+ + F^-}\\ n\mathrm{(R_3NH)^+ + NiF_2 + 2F^- \rightarrow (R_3NH)_{\mathit{n}}\,NiF_{\mathit{n}+4} + 2e}\quad .\\ \text{(I)}\end{gathered}$$

The compound R_3N, having entered the complex, is then oxidised electrochemically at carbon–hydrogen bonds to form radicals, able to recombine with fluorine radicals appearing at the anode from the discharge of fluoride anions:

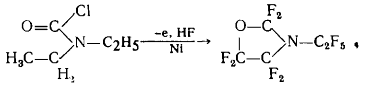


The completely (or almost completely) fluorinated amine loses its basicity, with the result that the complex breaks down:

$$\begin{gathered}\mathrm{[(R_F)_3\,NH]_{\mathit{n}}\,NiF_{\mathit{n}+4} \rightarrow \mathit{n}\,(R_F)_3\,N + \mathit{n}\,HF + NiF_4}\\ \mathrm{NiF_4 \rightarrow NiF_2 + 2F^{\cdot}}\quad .\end{gathered}$$

The main direction of electrochemical fluorination—substitution of hydrogen in the organic molecule by fluorine—is attributed to adsorption of the organic compound on the anode during formation of the complex, with a resultant weakening of carbon–hydrogen bonds. As a consequence, these bonds are preferentially attacked by the fluorine radical, while the carbon–carbon bonds are considerably less affected. In the case of substances that possess no basicity, fluorination takes place on the surface of complex inorganic fluorides such as K_2NiF_6. On such a surface electrochemical oxidation of carbon–carbon bonds predominates, which leads to considerable degradation of the initial molecule.

In spite of the great attractiveness of this mechanism, however, it cannot explain several facts. Firstly, if a complex is formed, why a large excess of the organic compound should favour the formation of incompletely fluorinated products is obscure[25,26]. Secondly, if anodic fluorination is a radical process, the introduction of acceptor substituents into the initial organic molecule should hinder radical fluorination and yield only partly fluorinated compounds; yet perfluorinated products exclusively were isolated from the electrochemical fluorination of sulphones[27,28] and nitroalkanes[29] in hydrogen fluoride. Thirdly, it is incomprehensible with such a reaction scheme why fragmentation of the organic molecule increases when the current density is lowered[8,30]. Finally, it is difficult to explain the cyclisations[31,32] and isomerisations[33,34] typical of electrochemical fluorination at nickel in hydrogen fluoride:

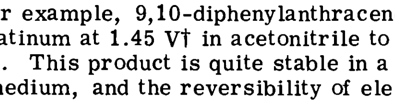


Replacement of hydrogen by fluorine atoms in the anodic fluorination of *N*-alkylpiperidines is accompanied by a peculiar isomerisation of the carbon skeleton. Fluorination of the isopropyl, isobutyl, and isopentyl derivatives gives mixtures of perfluoroalkylpiperidines having branched and unbranched alkyl chains. The content of the straight-chain isomer increases with chain length, to reach 75–90% with the isopentyl compound. Formation of perfluorinated products having an iso-structure is not observed on the fluorination of amines containing n-alkyl substituents[34].

III. *ECE* MECHANISM OF ANODIC FLUORINATION IN APROTIC SOLVENTS

A characteristic feature of the above hypothetical mechanisms of electrochemical fluorination in hydrogen fluoride is a homolytic reaction involving the fluorine radical. It was supposed[7] that "the only anions present in solution are fluoride ions, which excludes the possible occurrence of processes other than discharge of the fluoride anion". The radical type of fluorination can obviously take place at an anode potential adequate for oxidation of the fluoride ion, i.e. above 2.85 V.[35–39].

Many classes of organic compounds, however, are oxidised at considerably lower anodic potentials[40]. This difference in oxidation potentials has revealed a possible new route for the introduction of fluorine into an organic molecule in an electrochemical process. In 1970 Knunyants et al.[41–43] found that anodic oxidation can be used to generate at a platinum anode an organic cation that will then react with a fluoride anion in solution to form a carbon–fluorine bond. This process is applicable to the anodic fluorination of many classes of organic compounds having oxidation potentials below 2.85 V: e.g.



This mthod for the anodic fluorination of organic compounds opened up wide possibilities for studying the mechanism, since it enabled anhydrous hydrogen fluoride and nickel to be dispensed with as solvent and as the only suitable material for the anode. Anodic substitution of hydrogen by fluorine in an organic molecule occurred smoothly on platinum in solutions of fluorides in aprotic solvents. For example, 9,10-diphenylanthracene is oxidised on platinum at 1.45 V† in acetonitrile to form a radical-cation. This product is quite stable in a non-nucleophilic medium, and the reversibility of electron transfer could be demonstrated by cyclic voltammetry with a triangular pulse[44–46]. An oscillopolarogram obtained during anodic polarisation exhibits a peak representing the oxidation of diphenylanthracene to a radical-cation (Fig. 1*a*, curve *BA*$_1$*M*), which on reverse cathodic scanning acquires an electron and is reduced to the original compound (curve *MC*$_1$*D*). Anodic and cathodic peaks *A*$_1$ and *C*$_1$ have the same height[44].

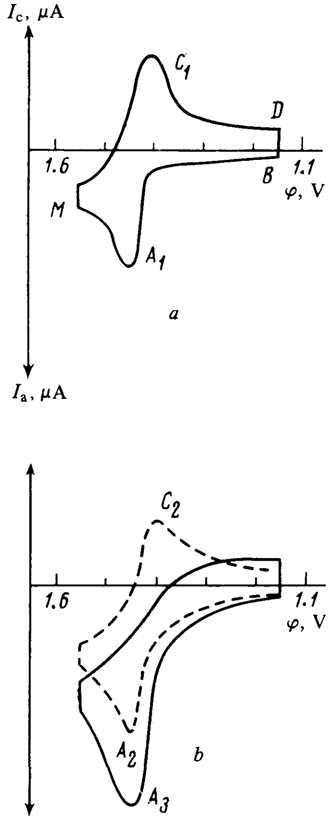


Figure 1. Cyclic voltammetry of 9,10-diphenylanthracene: *a*) non-nucleophilic medium (CH_3CN, $(C_2H_5)_4NClO_4$); *b*) as (*a*) in presence of the fluoride anion—$(C_2H_5)_4NF$.

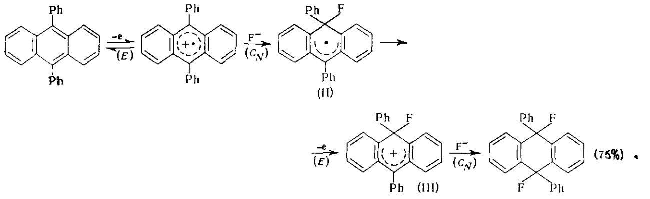
Extremely significant changes are observed when tetraethylammonium fluoride is added to this solution[47–49] (Fig. 1*b*): the anodic peak *A*$_3$ expands at the same potential and now corresponds to a two-electron oxidation; and the transfer of electrons to the anode becomes irreversible, with no cathodic peak present on reverse scanning. Reaction of the radical-cation with the fluoride anion has a large rate constant, but lowering the temperature to −30°C and increasing a hundredfold the rate of scanning nevertheless enables a cathodic peak *C*$_2$ to be registered.

The picture obtained agrees excellently with the theory of the so called *ECE* mechanism (where *C* and *E* denote chemical and electrochemical stages respectively)[50–53]. It had been shown with 9,10-diphenylanthracene as example[54–56] that the addition of pyridine converted the

---

† Potentials in this Review are given relative to the normal hydrogen electrode.

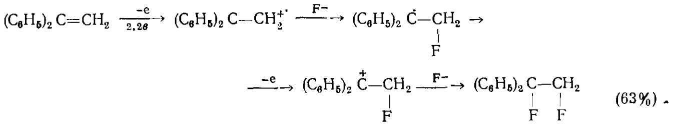
original one-electron mechanism of oxidation into a two-electron mechanism. Similarly in the oxidation of 9-phenylanthracene[57] the anodic peak in the oscillopolarogram increased greatly in the presence of water. The preparative electrolysis of 9,10-diphenylanthracene in the presence of the fluoride ion (tetraethylammonium fluoride in acetonitrile at 1.45 V) gives a 75% yield of 9,10-difluorodihydro-9,10-diphenylanthracene[58]. The same results are obtained when diphenylanthracene is electrolysed at 1.90 V [59] (corresponding to the formation potential of the bication[46]) in a solution of $(CH_3)_4NH_2F_3$ in acetonitrile. Thus in this case an EC_NEC_N mechanism operates (where C_N denotes a stage of nucleophilic chemical reaction)[56,60–62]:



A condition for such a mechanism is that the potential for oxidation of the intermediate radical (II) to the cation (III) should be lower than or equal to the oxidation potential of the initial molecule, a condition that is satisfied by aromatic compounds[63].

The main conclusion that follows from the experiment with 9,10-diphenylanthracene is that formation of a carbon–fluorine bond takes place at potentials considerably below the oxidation potential of the fluoride anion.

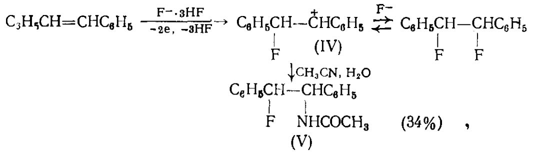
An EC_NEC_N mechanism probably operates also in the anodic oxidation of alkenes[64,65]. In the presence of the fluoride anion their oxidation at platinum leads in several cases to addition of two fluorine atoms at the double bond:



$$(C_6H_5)_2C{=}CH_2 \xrightarrow[2,26]{-e} (C_6H_5)_2C{-}CH_2^{+\cdot} \xrightarrow{F^-} (C_6H_5)_2\dot{C}{-}\underset{\displaystyle F}{\underset{|}{CH_2}} \rightarrow$$

$$\xrightarrow{-e} (C_6H_5)_2\underset{\displaystyle F}{\underset{|}{\overset{+}{C}}}{-}CH_2 \xrightarrow{F^-} (C_6H_5)_2\underset{\displaystyle F}{\underset{|}{C}}{-}\underset{\displaystyle F}{\underset{|}{CH_2}} \quad (63\%) .$$

With stilbene use as electrolyte of a solution of tetraethylammonium fluoride–3-(hydrogen fluoride) in acetonitrile results in fluoroacetamidation, which is explained by the great mobility of the benzyl fluorine atom in acid medium:



$$C_3H_5CH{=}CHC_6H_5 \xrightarrow[-2e,\ -3HF]{F^-\cdot 3HF} \underset{\displaystyle F}{\underset{|}{C_6H_5CH}}{-}\overset{+}{C}HC_6H_5 \overset{F^-}{\rightleftarrows} \underset{\displaystyle F}{\underset{|}{C_6H_5CH}}{-}\underset{\displaystyle F}{\underset{|}{CHC_6H_5}}$$

$$(IV)$$

$$\downarrow CH_3CN,\ H_2O$$

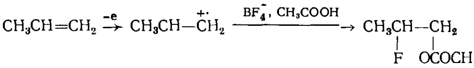
$$\underset{\displaystyle F}{\underset{|}{C_6H_5CH}}{-}\underset{\displaystyle NHCOCH_3}{\underset{|}{CHC_6H_5}} \quad (34\%) ,$$

$$(V)$$

Addition of a fluoride anion to the cation (IV) in acid medium is reversible, so that (IV) undergoes an irreversible Ritter reaction with acetonitrile. Further substitution of the fluorine atom in (V) by an acetamido-group does not occur owing to its insolubility in acetonitrile. Schmidt[67,68] had earlier reported the addition of two fluorine atoms in the anodic oxidation of stilbene and cyclohexene in an acetonitrile solution of silver fluoride. However, these results could not be reproduced[66], since such solutions are non-conducting.

Acetamidation takes place in the anodic oxidation not only of alkenes but also of alkanes and alkylbenzenes[69]. To avoid this reaction other solvents, in particular dichloromethane, are usually employed in the electrolysis[70,71].

It has recently been found that the tetrafluoroborate anion may also be a source of the fluoride anion in the anodic fluorination of alkenes. Thus fluorinated acetates are formed in the anodic oxidation of alkenes in acetic acid with ammonium tetrafluoroborate as supporting electrolyte[72]:



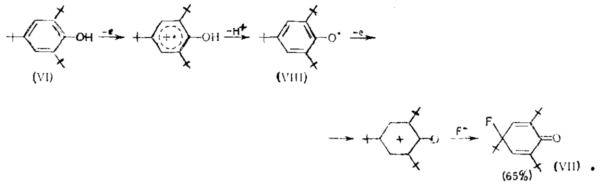
$$CH_3CH{=}CH_2 \xrightarrow{-e} CH_3CH{-}\overset{+\cdot}{C}H_2 \xrightarrow{BF_4^-,\ CH_3COOH} \underset{\displaystyle F}{\underset{|}{CH_3CH}}{-}\underset{\displaystyle OCOCH_3}{\underset{|}{CH_2}} .$$

Substitution of hydrogen by fluorine (also at potentials considerably below the oxidation potential of the fluoride anion) is also possible in the anodic oxidation of organic compounds at platinum in the presence of the fluoride anion in acetonitrile. This process has been observed with aromatic compounds (below) even in cases[73,75] in which the intermediate radical-cation of the organic molecule is capable of rapid elimination of a proton under the influence of a base. For example, the oxidation of triphenylmethane, obviously by an EC_bEC_N mechanism, gives a high yield of triphenylmethyl fluoride[73]:

$$(C_6H_5)_3CH \underset{(E)}{\xrightarrow[1.8\ V]{-e}} (C_6H_5)_3\overset{+\cdot}{C}H \underset{(C_b)}{\xrightarrow[-3HF]{F^-}} (C_6H_5)_3\dot{C} \xrightarrow[(E)]{-e}$$

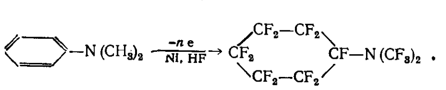
$$\rightarrow (C_6H_5)_3\overset{+}{C} \xrightarrow[(C_N)]{F^-} (C_6H_5)_3C{-}F \quad (80\%) .$$

Such rapid elimination of a proton (stage C_b) is extremely characteristic of radical-cations not only of alkylbenzenes but also of phenols[40,74]. The oxidation of tri-t-butylphenol (VI) by the above mechanism yields the "quinofluoride" (VII).[75] The corresponding formation of a chlorocyclohexadienone had previously been observed in the oxidation of (VI) in the presence of the chloride anion[76,77]. The light blue stable radical (VIII) was recorded[78] in the anodic oxidation:



A distinguishing feature of the anodic oxidation of aromatic compounds in the presence of the fluoride anion is the partial replacement of hydrogen by fluorine while the aromatic structure is preserved, which involves an EC_NEC_b mechanism of fluorination. In the oxidation of benzene at platinum in acetonitrile, for example, fluorobenzene is obtained in 40% yield[79]:

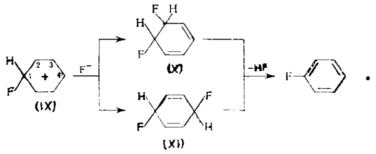
Yet the Simons method of fluorinating aromatic compounds (at nickel in anhydrous hydrogen fluoride) usually occurs exhaustively to give derivatives of perfluorocyclohexane[5–7] and in some cases resinous products[2,80,81]:



Oxidation by cyclic voltammetry at platinum[82] shows that at 2.63 V benzene forms a radical-cation, which rapidly eliminates a proton, after which polymerisation takes place and a polyphenylene film appears on the anode:

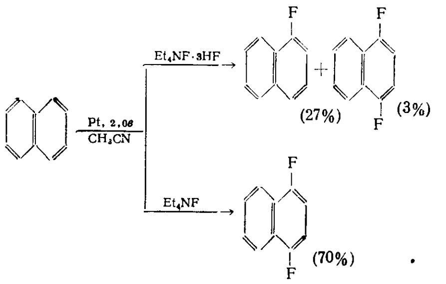
$$C_6H_6 \xrightarrow{-e} C_6H_6^{+\cdot} \xrightarrow{-H^+} C_6H_5^{\cdot} \rightarrow \text{Biphenyl + Polyphenylenes} .$$

In the presence of the fluoride anion the radical-cation is stabilised by nucleophilic attack. The above EC_NEC_b scheme of formation of fluorobenzene may be rather more complicated: the arenonium ion (IX) may add a second fluoride anion; this nucleophilic attack on (IX) should follow at the 2- and 4-carbon atoms with formation of the difluorocyclohexadienes (X) and (XI):

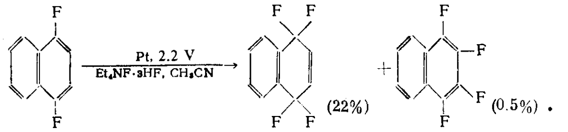


Calculations by the INDO method[83] using a TOREAMOR programme[84,85] show that the greatest positive charge is concentrated on these carbon atoms in the cation (IX): values for $C_{(1)}$–$C_{(4)}$ are respectively +0.254, +0.140, −0.012, and +0.275.

The anodic fluorination of naphthalene on platinum yields 1-fluoronaphthalene and 1,4-difluoronaphthalene depending on the conditions[41,42]:

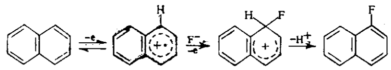


Prolonged electrolysis results in further fluorination to 1,1,4,4-tetrafluorodihydronaphthalene and traces of 1,2,3,4-tetrafluoronaphthalene:

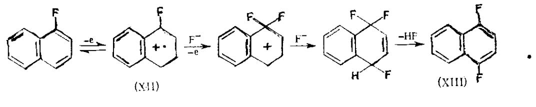


A striking feature is the sharp orientation of the substitution of hydrogen by fluorine: initially only 1-fluoronaphthalene is formed, after which 1,4-difluoronaphthalene appears. Yet anodic cyanation[86] and acetoxylation[87–89] yield mixtures of the 1- and 2-substituted naphthalenes. It must be emphasised that, in the anodic fluorination of naphthalene, a carbon–fluorine bond can be formed only by reaction with a fluoride anion. Radical fluorination by F· is excluded, for the anodic potential is only 2.0 V. Cyanation and acetoxylation, however, may be radical processes, since the oxidation potentials are 0.73 and 1.83 V for the cyanide[86] and acetate[90] ions respectively. Occurrence of a radical process in anodic acetoxylation is confirmed by the formation of methylnaphthalenes[88], which indicates that the acetate anion is oxidised to a radical, subsequently decarboxylated with formation of a methyl radical.

In the anodic fluorination of naphthalene (when homolytic substitution is exluded) it may be supposed that the orientation of nucleophilic attack by the fluoride anion will be determined by the distribution of positive charge in the radical-cation[42]. Inspection of Table 1 shows that, when anodic fluorination occurs on platinum, replacement of hydrogen by fluorine takes place at the carbon atom bearing the highest total positive charge in the radical-cation. Thus the initial nucleophilic attack



is governed by the distribution of positive charge density. The positive charges at positions 1 and 4 in the radical-cation of 1-fluoronaphthalene are respectively 0.392 and 0.120. Nucleophilic attack is therefore extremely probable at position 1, with subsequent stabilisation of the cation by addition of a second fluoride anion and detachment of hydrogen fluoride:



This direction of attack on the radical-cation (XII) is confirmed indirectly by the formation of tetrafluorodihydronaphthalene on the anodic fluorination of (XIII).

Table 1. Distribution of charge in the radical-cation.

All the above *ECE* schemes of anodic fluorination on platinum consist in the successive transfer of two electrons separated by an intermediate chemical stage (reaction with a nucleophile or elimination of a proton). In some cases anodic fluorination may involve the transfer of only one electron to the anode. An example is the anodic oxidation of tetra-alkylsilanes, which in the presence of fluoride ions leads to replacement of an alkyl group by fluorine[92]:

$$R_4Si \xrightarrow[F^-]{-e} R_4SiF^\cdot \xrightarrow{-R^\cdot} R_3Si{-}F \quad (50\text{–}80\%) \ .$$

In concluding this Section we must examine a recent paper by Eberson[93], who concludes, on the basis of certain experimental results[94–96] and a theoretical survey, that the interaction of an aromatic radical-cation with a halide anion X^- involves merely the transfer of an electron. In his opinion nucleophilic attack by halide anions is forbidden by the Dewar–Zimmerman rules[97]. Assuming that attack by a nucleophile takes place along the normal to the plane of the ring passing through the middle of a carbon–carbon bond, Eberson distinguishes between suprafacial and antarafacial attack (in which the nucleophile orbital interacting with the π-system of the ring is respectively symmetric and antisymmetric—(*a*) and (*b*) in Fig. 2). The transition state of the seven-membered ring corresponds respectively to Hückel and anti-Hückel systems. With eight electrons (systems having an odd number of electrons are treated as containing a fictitious extra electron) the second transition state is aromatic and corresponds to an allowed process, whereas the first is antiaromatic and hence forbidden by the Dewar–Zimmerman rules. A vulnerable point in Eberson's argument is[58] the choice of nucleophile orbital interacting with the radical-cation. He considers only the p_z orbital of halogens. Nevertheless, estimates of the overlap integrals for fluoride and chloride ions indicate close similarity of interaction of the p_z and p_x orbitals of the halogen with the p_z orbitals of carbon atoms[58]. Thus, although suprafacial interaction (Fig. 2*a*) is indeed prohibited by the Dewar–Zimmerman rules, nucleophilic attack on aromatic radical-cations by halide anions may result from the antarafacial interaction, disregarded by Eberson, of a lone pair of the halide ions located in a p_x orbital (Fig. 2*b*).

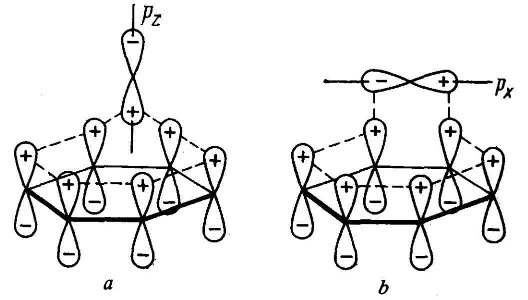

Figure 2. Arrangement of orbitals of transition state in nucleophilic attack on the radical-cation of an aromatic compound: *a*) suprafacial attack; *b*) antarafacial attack.

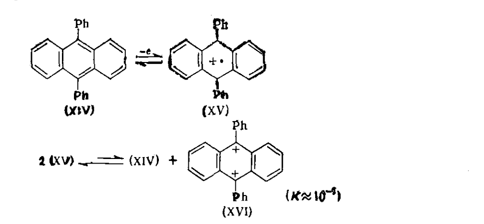
Nucleophilic attack by halide anions on aromatic radical-cations is supported by several experimental facts. (1) Millington[98] showed that high yields of 1-bromonaphthalene are formed by the anodic oxidation of naphthalene in the presence of bromide ions. (2) The radical-cation of diphenylanthracene reacts with the chloride anion to form chlorinated products of undetermined structure[99]. (3) In the presence of the chloride ion the chemical oxidation of anisole and naphthalene[100,101] by sodium peroxodisulphate to the radical-cations yields the corresponding monochlorinated aromatic compounds. (4) Nucleophilic attack on aromatic radical-cations by the fluoride anion probably occurs under the influence of xenon difluoride in hydrogen fluoride[102,103]. (5) Burdon[91] gives several forcible arguments for nucleophilic attack by the fluoride ion on aromatic radical-cations during fluorination with cobalt(III) fluoride. (6) In many cases the anodic oxidation of aromatic compounds in the presence of fluoride anions yields compounds containing fluorine.

Nucleophilic reaction between the fluoride ion and a radical-cation is convincingly confirmed by the kinetics of the cyclic voltammetry of diphenylanthracene (XIV) in the presence of the fluoride anion[58]:



$$(XVI) + F^- \rightarrow \text{Products} \quad .$$

Other possible reaction paths are rejected. Thus disproportionation of the radical-cation[104-106] is unreal, since extraordinarily high rate constants must then be assumed for reaction of the fluoride ion with the bication (XVI). Furthermore, the kinetics of the reaction of (XV) with pyridine shows a first order with respect to diphenylanthracene, which excludes disproportionation of (XV).[107,108] The high oxidation potential of the fluoride ion excludes another possible path, which would have "avoided" nucleophilic attack by the ion on the radical-cation (XV)

$$(XIV) \underset{}{\overset{-e}{\rightleftharpoons}} (XV)$$

$$(XV) + F^- \not\rightarrow (XIV) + F^\bullet$$

$$(XIV) + F^\bullet \longrightarrow \text{Products} \quad .$$

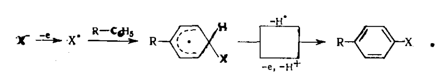
IV. ORIENTATION OF NUCLEOPHILIC ATTACK IN RADICAL-CATIONS OF AROMATIC COMPOUNDS

Results obtained during recent years showed convincingly that the electrochemical oxidation of aromatic compounds in non-nucleophilic media usually involves the transfer of a single electron to the anode with formation of a radical-cation[109]. In a nucleophilic medium the oxidation becomes a two-electron process: an *ECE* mechanism of anodic substitution operates (acetoxylation, cyanation, methoxylation)[110,111]. The exceptional character of anodic fluorination by an *ECE* mechanism lies in the impossibility of a parallel homolytic process (the anodic potential is insufficient for formation of the fluorine radical). Acetoxylation, cyanation, and methoxylation, however, occur at anode potentials sufficient for oxidation of the corresponding anions to radicals.

The formation of substitution products in an anodic process can be regarded as the result of reactions occurring by the following mechanisms.

(*a*) *ECE* Mechanism. It is assumed in this case that the orientation of nucleophilic attack and hence the relative proportions of isomers are determined by the distribution of positive charge density in the radical-cation of the aromatic compound[40,42,47,94,112].

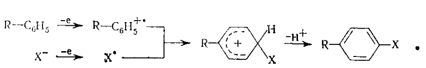
(*b*) Radical mechanism. An analogy with homolytic aromatic substitution should be observed:



The same products will result from initial oxidation of the aromatic substrate followed by a redox reaction of the radical-cation with the anion X⁻:

$$R-H \overset{-e}{\rightleftharpoons} R-H^{+\bullet} \xrightarrow{X^-} R-H + X^\bullet \quad .$$

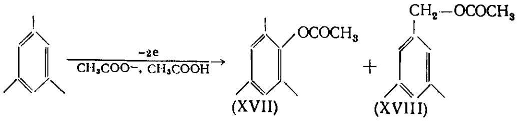
(*c*) Parallel oxidation. The aromatic molecule is oxidised to the radical-cation and the anion X^- is oxidised simultaneously. The orientation of substitution would then be determined by the distribution of density of the lone electron in the radical-cation:



It is evident that processes by all three mechanisms (*a*)-(*c*) involve the transfer of two electrons to the anode. Thus microcoulometry is uninformative in these cases. Several authors adduce the results of polarisation measurements, which register the anodic depolarisation effect on addition of an aromatic compound, as the main argument in support of an *ECE* mechanism for cyanation or acetoxylation. The weakness of such arguments has recently been pointed out by Mirkind[111].

In the Reviewer's opinion anodic acetoxylation and cyanation can take place by *ECE* and radical mechanisms simultaneously, the relative importance of the latter depending on the conditions[23]. The distribution of reaction products is greatly affected by the state of the anode surface and by adsorption. Very significant results have been obtained for the effect of adsorption in the acetoxylation of anisole on platinum[113]: whereas in the absence of any additive the ratio of the *o*- and *p*-methoxyphenyl acetates formed is 2.2, the addition of small quantities of napththalene to the electrolyte produces a sharp decrease in the proportion of the *ortho*-isomer, and the ratio falls to unity. Acetoxylation probably occurs mainly by a radical mechanism in the absence of additives: the ratio of the products agrees well with the orientation of attack in the homolytic substitution of hydrogen in anisole. Addition of naphthalene, which is strongly adsorbed on platinum, blocks the anode surface, which hinders oxidation of the acetate anion. Only strong electron donors such as anisole can compete with naphthalene for a place on the surface of the platinum anode. In this case anisole is oxidised to the radical-cation, its acetoxylation takes place mainly by an *ECE* mechanism, and the *ortho/para* ratio agrees well with the results of anodic fluorination.

The influence of the anode material on the relative proportions of products of the acetoxylation of mesitylene



is also extremely significant[114]. The ratio of products of acetoxylation in the ring and in the side-chain (XVII)/(XVIII) has the values 4.4 and 23 on platinum and on graphite respectively. Adsorption of the acetate on platinum is large, and it undergoes oxidation with subsequent radical reaction in the side-chain. On graphite, however, the adsorption of acetate is small[7], so that the main process is the adsorption of mesitylene, its oxidation to the radical-cation, and subsequent reaction with the acetate ion. In this case acetoxylation occurs almost exclusively in the ring. The composition of the electrolyte also influences the ratio of the products of the acetoxylation of mesitylene[115].

We shall now consider the orientation of the substitution of hydrogen by fluorine in the anodic fluorination of aromatic compounds.

1. Donor Substituents

The special feature of the anodic fluorination of aromatic compounds by the *ECEC* mechanism—the impossibility of parallel homolytic reactions—is clearly revealed by a comparison with other anodic aromatic substitutions. Table 2 summarises data on the effect of substituents on the orientation of anodic substitution in aromatic compounds. It includes results for certain homolytic reactions and "oxidative" substitutions in the aromatic ring, to which is attributed a mechanism with intermediate formation of radical-cations and subsequent nucleophilic attack. Analysis of all these results leads to the following conclusions.

Table 2. Proportions of products in the substitutions $R.C_6H_5 \rightarrow R.C_6H_4.X + X.C_6H_5$.

*Solvents: A = acetonitrile; M = methanol; Y = acetic acid.

** Electrolysis in the presence of naphthalene.

*** Isomers detected in the electrolysis products.

1. In no case of the anodic fluorination of an aromatic compound containing a donor substituent has the formation of a *m*-fluoro-isomer been recorded (Table 2, No. 1, 12, 14, 18, 30, 31, 36, and 43). In contrast, anodic acetoxylation and cyanation lead in most cases to a considerable

quantity of the *meta*-isomer among the reaction products (No. 2–4, 10, 11, 13, 15, 17, 21, 32, 37, and 44). "Oxidative" substitutions also yield the *meta*-isomer (No. 6, 7, 27, 33, 40, and 41). The *meta*-isomer is formed in all cases of homolytic substitution (No. 8, 9, 17, 29, 35, 42, and 45).

2. The anodic fluorination of aromatic compounds containing donor substituents (t-butyl, methoxyl, ethoxyl, chlorine, bromine) usually yields mainly the *para*-isomer, whose ratio to the *ortho*-isomer lies in the range 2–3. With methyl and isopropyl substituents the ratio is unity. Nevertheless, the *ortho*-isomer usually predominates in other anodic substitutions and in "oxidative" substitutions (Table 2, No. 2, 6, 7, 11, 13, 19–21, 24, 27, and 28). This isomer predominates also in homolytic substitutions (No. 8, 9, 17, 29, 35, 42, and 45).

3. A distinguishing feature of anodic fluorination is *ipso*-attack, leading to the replacement of isopropyl, t-butyl, and methoxyl groups, as well as chlorine and bromine atoms (Table 2, No. 12, 14, 18, 36, and 43).

4. Fluorobenzene exhibits a marked difference in orientation of substitution, with exclusive formation of the *para*-isomer.

We shall now compare the data in Table 2 with calculated positive charge densities (Tables 3 and 4) and spin densities (Table 5) for the radical-cations of aromatic compounds. This leads to the following detailed conclusions on the mechanism of anodic fluorination and the orientation of nucleophilic attack in such radical-cations.

(1) Nucleophilic attack by a fluoride anion is governed by the density distribution of positive charge in the radical-cation. Only the π-component of the charge does not determine the position of attack. In the radical-cations of anisole and chlorobenzene, for example, the π-component of the charge at position 1 is respectively 0.047 and –0.135. Yet the corresponding total charges at this position are +0.185 and +0.110. Attack at position 1 occurs both in anisole and in chlorobenzene, since the product was fluorobenzene, resulting from replacement of the methoxy-group and the chlorine atom.

(2) The density distribution of the unpaired electron usually correlates well with the positive charge distribution in the radical-cation (the atom bearing the highest positive charge possesses also the greatest spin density). Nevertheless, the density distribution of the unpaired electron has no effect on the orientation of attack in anodic fluorination. For example, the distribution of spin density cannot explain the *ipso*-attack and simultaneous absence of the *meta*-isomer in the case of anisole.

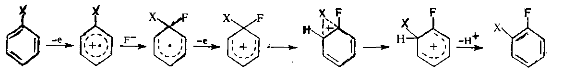
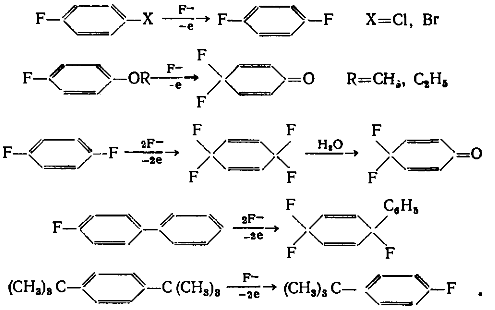
(3) Nucleophilic attack by the fluoride anion takes place at positions 1 and 4 according to the highest positive charge in radical-cations of aromatic compounds containing donor substituents. The *ortho*-isomer is probably formed as a result of *ipso*-attack followed by oxidation and isomerisation of the arenonium ion[131]:



Direct confirmation of *ipso*-attack in anodic fluorination is provided by the substitution of chlorine, bromine, methoxyl, isopropyl, and t-butyl by fluorine to give fluorobenzene:

$X{=}Cl,\ Br,\ OCH_3,\ i\text{-}C_3H_7,\ t\text{-}C_4H_9$.

Furthermore, *ipso*-attack is clearly evident also in the anodic fluorination of *para*-disubstituted benzene derivatives[86,127,132]:



(4) Absence of direct *ortho*-attack is assumed because the positive charges at the *ortho*- and *meta*- positions are very similar in the radical-cations of toluene and t-butylbenzene, and in those of anisole and chlorobenzene the *meta*-charge even exceeds the charge in the *ortho*-position. Nevertheless, a considerable quantity of the *ortho*-isomer is formed in all these cases, whereas the *meta*-isomer has not been detected. Fluorobenzene provides an especially clear example, being the only case in which the *ortho*-isomer is not formed, although the general pattern of positive charge distribution in the radical-cation is qualitatively the same as with other donor substituents. This fact is readily explained in terms of *ipso*-attack (migration of fluorine is impossible in the corresponding arenonium ion):

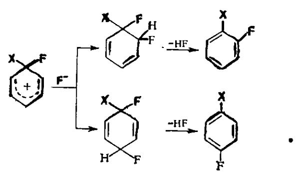
*Methods of calculation: 1) INDO; 2) CNDO/2.[91]

(5) *ipso*-Attack by the fluoride anion may result also in formation of the *para*-isomer:



A similar process may, perhaps, supplement the above *ECE* mechanism:

(6) The arenonium ion formed after *ipso*-attack can be stabilised only at *ortho*- and *para*-positions, as follows from the calculated positive charge distributions in these cations (Table 6).

(7) In conclusion it must again be emphasised that aromatic compounds containing donor substituents undergo anodic oxidation in the presence of the fluoride anion at potentials considerably lower than 2.87 V. Under these conditions oxidation of the fluoride anion to the radical is impossible, so that homolytic processes are excluded. For this reason we can speak of "pure" cases of the orientation of nucleophilic attack on aromatic radical-cations during anodic fluorination. The differences between orientation on anodic fluorination and on acetoxylation, cyanation, and methoxylation can evidently be regarded as contributions by the homolytic process in acetoxylation and cyanation.

2. Acceptor Substituents

Anodic processes involving aromatic compounds containing acceptor substituents (C_6H_5–A) have been very little studied: one paper was published in 1971, on the anodic fluorination of trifluoromethylbenzene[136], and in 1975 three communications appeared on anodic trifluoroacetoxylation[133–135]. The scarcity of publications in this field is due to the very high anodic potential (2.5–3.5 V) required for the oxidation of compounds of type C_6H_5–A. At such high potentials oxidation of the substrate is accompanied by many secondary processes—oxidation of the solvent, other components of the electrolyte, and, of course, the traces of water always present as impurity even in carefully dried aprotic solvents.

Introduction into an aromatic ring of an acceptor instead of a donor substituent leads to substantial changes in the proportions of products of anodic fluorination at platinum in acetonitrile. Knunyants et al. have shown that, when compounds containing such substituents as acetyl, methoxycarbonyl, fluoroformyl, cyano, and trichloromethyl are fluorinated[122], all three possible fluorinated isomers are formed in the relative proportions *ortho* > *meta* > *para* (Table 7). Unexpectedly, the pattern of distribution of fluorinated isomers from acetophenone, methyl benzoate, and benzonitrile was remarkably similar to the distribution obtained on the trifluoroacetoxylation of these compounds[134]. Exceptions were trifluoromethylbenzene (anodic fluorination yields exclusively the *meta*-isomer) and nitrobenzene (equal quantities of *ortho*- and *meta*-isomers formed).

Certain conclusions arise from an analysis of results for the anodic fluorination of aromatic compounds containing acceptor substituents and their comparison with the calculated distributions of positive charge and spin density in the radical-cations.

1. The orientation of substituents is not determined by the density distribution of positive charge in the radical-cation (Tables 8 and 9). In some cases (trifluoromethyl, nitro) the orientation of the substitution of hydrogen by fluorine is even opposite to the charge distribution. Yet the orientation of trifluoroacetoxylation correlates well[134] with the distribution of charge in the radical-cations of

methyl benzoate, acetophenone, benzonitrile, trifluoromethylbenzene, and nitrobenzene. It was mentioned[134] that the calculations were made by the INDO method, but no specific results were given.

2. The density of the unpaired electron is distributed very characteristically in aromatic radical-cations containing acceptor substituents (Table 10). The orbitals of the ring carbon atom have a very small spin density, with almost the whole density of the unpaired electron concentrated on substituent atoms. Furthermore, the difference in spin density between *o*-, *m*-, and *p*-carbon atoms is negligible, e.g. 0.001 and 0.009 in the radical-cations of acetophenone and nitrobenzene respectively. Such differences are quite unable to determine the orientation in substitutions.

Thus the rules of orientation in the substitution of hydrogen by fluorine in the anodic fluorination of aromatic compounds containing acceptor substituents are no longer unambiguously consistent with an *ECE* scheme (as occurs with donor substituents). It must be emphasised that the anodic fluorination of compounds of type C_6H_5-A has been conducted at potentials above 2.87 V, i.e. under conditions such that oxidation of the fluoride anion and hence radical fluorination are possible. However, a purely homolytic mechanism for these reactions would be an oversimplification. Indeed, the type of adsorption and the behaviour of organic compounds on platinum at such high potentials are completely uninvestigated. Yet the formation of surface oxides or higher fluorides produces a marked change in the adsorption and catalytic properties of the anode surface. The high energy of adsorption in these regions may prevent surface mobility of the oxidisable species, in particular of aromatic radical-cations.

Therefore, as Mirkind has recently remarked[111], investigation of the mechanism of such reactions must first take into account the influence of heterogeneous factors on the rate and the direction of the electrode processes.

V. RADICAL-CATION PATH OF ELECTROCHEMICAL FLUORINATION IN HYDROGEN FLUORIDE

Right up to potentials of 2.8 V the oxidation of an aromatic compound at platinum in an aprotic medium involves the transfer of a single electron to the anode with formation of a radical-cation. It is therefore reasonable to suppose that the half-wave oxidation potential will be correlated with the energy of the highest occupied orbital and with the ionisation potential. Such a relation has been detected, and several workers have shown a linear correlation at platinum in acetonitrile with ionisation potentials[129,137–140] and with energies of highest occupied orbitals calculated by self-consistent field methods[141]. The linear dependence can be understood from a detailed examination of the energetic factors[139] governing the half-wave potential for the reaction Red → Ox + e:

$$E_{1/2}=\alpha IP+\Delta E_{\text{solvn.}}-\beta EA-\frac{T\cdot\Delta S^0}{\mathrm{F}}-\frac{RT}{F}\ln\frac{f_0D_R}{f_RD_0}+C,$$

where IP is the ionisation potential, α a coefficient representing the effect of adsorption on the electrode in the presence of the solvent, ΔE_{solvn} the difference in energy of solvation between Red and Ox, β a coefficient representing the effect of the adsorbed substance and the solvent on transfer of the electron, f an activity coefficient, F Faraday's constant, D the diffusion coefficient, EA the electron affinity of the metal (anode), and C a constant depending on the reference electrode.

When the same metal (platinum), solvent (acetonitrile), and supporting electrolyte are used, many terms in this equation will obviously be the same. When compounds of similar structure are oxidised, furthermore, the differences in ΔS^0 and activity coefficients may be expected to be small in comparison with the changes in ionisation potentials. The observed linear correlations can be represented by the equations

$$E_{1/2}=0.678IP-3.72^{138};$$
$$E_{1/2}=0.827IP-4.87^{139};$$
$$E_{\mathrm{p}/2}=0.75IP-4.55^{142}\ (E_{\mathrm{p}}-\text{peak potential})\ .$$

A correlation between ionisation potentials and oxidation half-wave potentials (at platinum in acetonitrile) has been observed not only with aromatic compounds but also with alkenes and alkanes[143].

However, this clear picture changes on passing to systems in other solvents (Table 11). Thus alkanes undergo anodic oxidation in acetonitrile at potentials above 3.9 V.[143] But on the addition of a strong acid, trifluoroacetic, the oxidation potential of these compounds drops sharply (by about 0.5 V), and corresponding oxidation peaks can be recorded by cyclic voltammetry[144]. Further considerable fall in oxidation potentials is observed in a strongly acid medium—fluorosulphuric acid—in the absence of acetonitrile[145]. An analogous pattern is evident with anhydrous hydrogen fluoride[147], in which the half-wave potentials are more than 1.0 V lower. It must be stressed that reversible processes, similar to those in acetonitrile, are observed in the oxidation of aromatic compounds at platinum both in fluorosulphuric and in hydrofluoric acids. Thus long-lived radical-cations are formed by the oxidation of perfluorinated aromatic compounds in fluorosulphuric acid[146]; the oxidation of perylene in hydrogen fluoride involves formation of a radical-cation at +0.12 V and irreversible transfer of a second electron with formation of a bication at +0.69 V.[147] Irreversible transfer of two electrons to the anode has been recorded in the oxidation of alkanes. Thus replacement of acetonitrile by fluorosulphuric or hydrofluoric acid results merely in a sharp quantitative fall in the oxidation potentials of organic compounds on platinum: the qualitative character of the oxidation processes themselves remains unchanged, since the same products are formed and the same dependence of half-wave potential on ionisation potential is maintained.

Quite different changes in electrochemical processes are evident on passing from organic solvents to water. For example, the rate of oxidation on platinum falls with increase in chain-length of the hydrocarbon and decrease in its ionisation potential[148]: i.e. an antiparallel dependence is observed. The reason is the completely different character of the process: considerable degradative chemisorption of the organic molecule occurs, accompanied by dehydrogenation and cracking[137,149,150].

* Potentials given relative to the normal hydrogen electrode.

Thus the anodic oxidation of aromatic compounds at platinum in hydrofluoric and chlorosulphuric acids and in aprotic organic solvents (acetonitrile) involves the transfer of one electron to the anode with formation of a radical-cation. In the absence of a nucleophile[82] the phenyl radical-cation rapidly eliminates a proton with subsequent recombination of radicals to give biphenyl or polyphenylenes:

$$C_6H_6\xrightarrow{-e}C_6H_6^{+\cdot}\xrightarrow{-H+}C_6H_5^{\cdot}\ .$$

Nyberg considers[151–154] that the mechanism of the formation of biphenyls consists in direct recombination of radical-cations with subsequent elimination of two protons[151]. In a later investigation of cross dimerisation he concluded[115] that the formation of dimeric products was the result of electrophilic attack on the radical-cation of the unoxidised aromatic molecule diffusing towards the electrode.

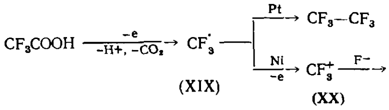
The anodic oxidation of benzene at platinum in hydrogen fluoride is very similar[158] to these processes: an electrically conducting polyphenylene film is formed, resembling soft graphite in its behaviour towards X-rays. The voltage in the cell does not exceed 1.1 V:

$$C_6H_6\xrightarrow[\text{HF}]{\text{Pt; 1.1 V}}(C_6H_{6-x})_n\ .$$

Polymer films of the same type have been obtained from naphthalene and toluene at low voltages[158]. The probable explanation of these results is that smooth platinum in hydrogen fluoride is an example of a "purified" electrode. Indeed, adsorption of the fluoride anion is probably the lowest for any anion at potentials up to 1.5 V.[155] Adsorption of fluoride ions on platinum begins only at higher potentials, which is explained by their entry into the oxide film[156]. Thus platinum at 1.0 V in hydrogen fluoride contains no adsorbed species, and under these conditions benzene and its homologues undergo the above "mild" oxidation. Comparison with oxidation results in acetonitrile[82,137–139] suggests that, in the limiting stage of the oxidation of aromatic compounds, charge is transferred to platinum through a layer of adsorbed acetonitrile molecules, which requires a considerable consumption of energy. A significant gain in energy ΔE_{solvn}, leading to a decrease in half-wave potential, is obtained also from the strong solvation of radical-cations in hydrogen fluoride.

Similar results have been obtained also at a nickel anode[158]. When benzene and toluene are oxidised at voltages up to 1.5 V in hydrogen fluoride, electrically conducting graphitic electrode coatings are formed, having the same elementary composition and structure as on a platinum anode. The yield of such "graphite" is quantitative. Polymerisation in attempts at the electrochemical fluorination of toluene had earlier been noted by Simons[2]. Similarly, an attempt at the electrochemical fluorination of anisole on nickel in hydrogen fluoride failed because of a rapid fall in conductivity and the separation of a black polymer[80]. Products of the polymerisation of benzene in this solvent were obtained also by Kokhanov[81].

Thus the products obtained at low potentials in hydrogen fluoride suggest that similar anodic processes occur on platinum and on nickel. As the anodic potential rises, however, considerable differences in behaviour appear between these anodes, owing to the different character of the adsorption of organic compounds on them. Electrolysis of a solution of hydrogen fluoride in trifluoroacetic acid at platinum, for example, yields mainly the Kolbe reaction product, hexafluoroethane, with a 2% yield of tetrafluoromethane[157] ($CF_4 : C_2F_6 = 2:100$), whereas at a nickel anode the latter is the main product (5 : 3). The probable reason for such a change in product composition is a difference in the energy of bonding of the adsorbed radical (XIX) with the anode surface, for on platinum this bonding is weak, the radical is mobile in the surface, and dimerisation occurs readily, whereas on nickel (more precisely on its difluoride) the adsorbed radical is firmly retained, dimerisation is difficult, and therefore oxidation to the cation (XX) is followed by the formation of carbon tetrafluoride:



$$CF_3COOH \xrightarrow[-H+,\ -CO_2]{-e} \underset{(XIX)}{CF_3^{\cdot}} \begin{cases} \xrightarrow{Pt} CF_3{-}CF_3 \\ \xrightarrow[-e]{Ni} \underset{(XX)}{CF_3^+} \xrightarrow{F^-} CF_4 \end{cases}$$

Still more significant differences are observed in the chemisorption of the methyl radical. Electrolysis of an acetic-acid solution of potassium fluoride at platinum yields ethane, as would be expected. At nickel the main product is tetrafluoromethane (44%) accompanied by fluoroform (7%), while the yield of the dimer of the methyl radical (ethane) is only 2%. In the Reviewer's opinion the formation of fluorinated products does not involve oxidation of the fluoride anion but consists in intermediate generation of organic radical-cations at the anode followed by "ionic fluorination". The organic radical-cation eliminates a proton with formation of a radical, which is rapidly oxidised to the cation and stabilised by addition of a fluoride anion. Thus the anodic fluorination of alkanes on nickel (just as on platinum) can be represented by an EC_bEC_N scheme:

$$CH_3COO^- \rightarrow CH_3COO^-\ (ads) \xrightarrow{-e} CH_3COO^{\cdot}\ (ads) \xrightarrow{-CO_2} CH_3^{\cdot}\ (ads) \xrightarrow{-e}$$
$$\rightarrow CH_3^+\ (ads) \xrightarrow{F^-} CH_3F\ (ads) \xrightarrow[(E)]{-e} CH_3F^{+\cdot}\ (ads) \xrightarrow[C_b]{-H+}$$
$$\rightarrow CH_2F^{\cdot}\ (ads) \xrightarrow[(E)]{-e} CH_2F^+\ (ads) \xrightarrow[(C_N)]{F^-}$$
$$\rightarrow CH_2F_2\ (ads) \xrightarrow[-H+]{-2e} CHF_2^+\ (ads) \xrightarrow{F^-} CHF_3\ (ads) \xrightarrow[-H+]{-2e} CF_3^+\ (ads) \xrightarrow{F^-} CF_4\ .$$

The energy of adsorption of alkanes on nickel (difluoride) is very large, and they are firmly retained on the anode. As fluorination proceeds, the bonding of alkanes to the surface becomes weaker, and polyfluoroalkanes can now be described from the anode. This difference in adsorption energy between alkanes and perfluoroalkanes is the reason for the predominant formation of only completely fluorinated compounds.

The present scheme has recently been confirmed[158] by a modified method of pulse polarography. Fluorination can be interrupted at any stage, depending on the duration of the anodic current pulse, with predominant formation of either methyl fluoride, difluoromethane, or fluoroform. This is explained by the possibility of desorption of incompletely fluorinated compounds when anodic polarisation of the electrode is switched off.

Pivalic acid behaves similarly to acetic acid. On oxidation at nickel in the presence of the fluoride anion the main product is perfluorobutane, with very little rupture of carbon–carbon bonds:

$$(CH_3)_3CCOOH \xrightarrow[-CO_2]{-e,\ -H+} (CH_3)_3C^{\cdot}\ (ads) \xrightarrow[-e,\ HF]{F^-,Ni} \underset{10}{C_4F_{10}} + \underset{:\ 1}{C_3F_8} + \underset{:\ 2}{C_2F_6} + \underset{:\ 1}{CF_4}\ .$$

Thus the fluorination of acetic and pivalic acids exemplifies the close analogy between these reactions and Simons electrochemical fluorination. Significantly, this analogy extends even to such "details" as the effect of the purity of the nickel anode and the material of the cathode on the yield of perfluorinated products[157, 158].

It is noteworthy that the formation of fluorinated products in the electrolysis of an acetic-acid solution of potassium fluoride at a nickel electrode is observed at a potential of 2.6 V, which corresponds to the only inflexion on the polarisation curve. This inflexion is undoubtedly due to oxidation of the acetate ion[157]. It has recently been shown[159] by a galvanostatic pulse method that on nickel the oxidation of acetic acid in anhydrous hydrogen fluoride precedes the start of oxidation of the fluoride anion. Other workers have found[160] that 2-chloroethanol is oxidised at a rotating nickel disc electrode in hydrofluoric acid also before the fluoride ion is oxidised.

---o0o---

Thus the above account can be summarised by a general scheme of anodic fluorination of organic compounds in which the first step is adsorption of the organic molecule on the electrode and its oxidation to the corresponding radical-cation, whose subsequent fate is governed both by the structure of the initial organic compound and by the character of its adsorption on the electrode. When oxidised on platinum, the radical-cations of aromatic compounds and alkenes react directly with the fluoride anion present in the electrolyte; those of saturated compounds usually eliminate a proton. The organic radicals formed in both cases are rapidly oxidised on the anode to the corresponding cations, whose stabilisation is effected by elimination of a proton or addition of a fluoride anion. During oxidation on nickel the organic compounds and their radical-cations are firmly adsorbed on the electrode surface. Only polyfluorinated organic molecules can be desorbed from the surface of the nickel anode, which is the probable reason for the predominant formation of perfluorinated products.

The anodic fluorination of organic compounds does not usually involve oxidation of the fluoride anion to the radical (with subsequent homolytic reaction): carbon–fluorine bond formation results from ionic fluorination.

Fluorinated Ketenimines

N.P.Gambaryan

Methods of obtaining imines of fluorinated ketens are surveyed, together with their dimerisation and nucleophilic addition. Cycloaddition at the carbon-nitrogen bond and 1,4-dipolar cycloaddition involving the aromatic ring are most characteristic of fluorine-containing *N*-arylketenimines. A two-stage mechanism is suggested, involving intermediate formation of small rings. The Review concludes with 92 references.

CONTENTS

I. INTRODUCTION

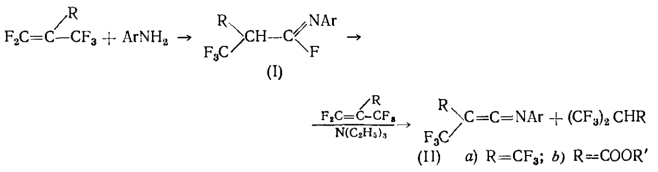
Imines of ketens were first obtained by Staudinger[1] in 1920, but their chemical properties have been studied only during recent years. Trialkylketenimines are unstable, so that the diaryl and mainly the triaryl derivatives have been investigated. Replacement of alkyl by trifluoromethyl groups greatly improves the stability both of ketens and of their imines, and hence imines of bistrifluoromethylketen provide a convenient model for studying the properties of aliphatic ketenimines.

Imines of ketens are of interest as dehydrating agents in peptide synthesis, as coreagents in oxidations with dimethyl sulphoxide, and especially as substrates in numerous cycloadditions with nucleophilic multiple bonds and dipolar compounds. The great variety of reactions involving cycloaddition is due to the fact that triarylketenimines react not only at the C=C and C=N bonds of the cumulative system but also at carbon or nitrogen with involvement of the aromatic rings, behaving in the latter reactions formally as dienes or nitrogen heterodienes. As a result, diverse carbocyclic and heterocyclic compounds are made available.

Reviews[2,3] have appeared during recent years, covering methods of preparation and reactions of ketenimines, but they contain hardly any information on fluorine-containing ketenimines. Nevertheless, fluoroketens and their imines exhibited a characteristic general feature of organofluorine compounds: the electron-accepting character of trifluoromethyl groups increases the electrophilic activity of bistrifluoromethylketen and its imines, which become capable of many reactions quite uncharacteristic of their unfluorinated analogues. Fluoroketens have been surveyed in Ref. 4. The present Review is concerned mainly with imines of bistrifluoromethylketen as the most readily available and thoroughly studied fluorinated ketenimines. Special attention is paid to *N*-aryl derivatives, since they reveal the effects of electron-donating and electron-accepting substituents on the activity of the cumulative bond system. Furthermore, the reactions of *N*-arylketenimines involving the aromatic ring are most interesting.

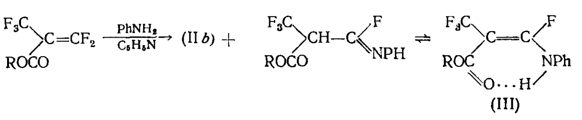
II. METHODS OF PREPARATION

A broad study of ketenimines became possible only after a simple general method of preparation was developed in 1973.[5,6] The latter was based on the reaction of perfluoroalkenes with primary amines, the result of which was determined by the ratio of the reactants. With perfluoroisobutene and perfluoromethacrylic esters excess of the amine gives difficultly separable mixtures of products. With excess of the alkene in the presence of catalytic quantities of triethylamine, on the other hand, excellent yields of the corresponding *N*-arylketenimines (II) are obtained in a single stage:



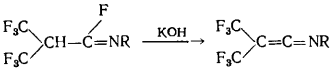
Thus a mixture of a fluoroalkene and triethylamine is a mild dehydrofluorinating agent, in which triethylamine acts as a carrier of hydrogen fluoride from the imidoyl fluoride (I) to the fluoroalkene. When pyridine is used instead of triethylamine, the reaction ceases at the stage of the imidoyl fluoride (I).

It is interesting that perfluoromethacrylic esters yield not only the imidoyl fluorides (I) but also the isomeric enamines (III):



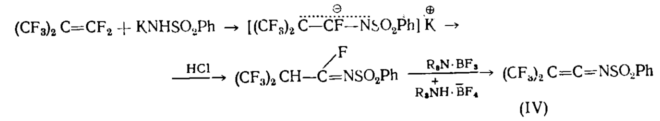
The comparative stability of the latter (III) is obviously due to the presence of an intramolecular hydrogen bond between the amino-group and the alkoxycarbonyl group. This is confirmed by the fact that the ratio of the latter to the former isomer increases with decrease in the ability of the solvent to form a hydrogen bond[6,7].

A second general method for preparing fluorinated ketenimines is the dehydrofluorination of imidoyl fluorides with powdered caustic potash in ether, which has been used to obtain the most diverse *N*-aryl-, *N*-alkyl-†, and *N*-cycloalkyl-ketenimines[5]‡:



(II *a*)

Such weak nucleophiles as benzenesulphonamide do not react with perfluoroisobutene. *N*-Benzenesulphonylbistrifluoromethylketenimine can be obtained as a stable adduct with potassium fluoride by treating perfluoroisobutene with the potassium salt of benzenesulphonamide; the free ketenimine (IV) is obtained by the action on the imidoyl fluoride of a mild dehydrofluorinating agent, such as the complex of triethylamine with boron trifluoride[9,10]:

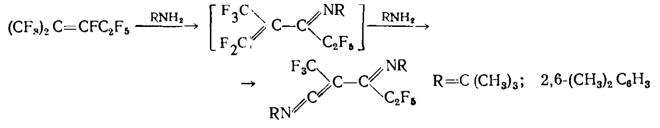


$$(CF_3)_2C{=}CF_2 + KNHSO_2Ph \rightarrow [(CF_3)_2\overset{\ominus}{C}{-}CF{-}NSO_2Ph]\overset{\oplus}{K} \rightarrow \xrightarrow{HCl} (CF_3)_2CH{-}CF{=}NSO_2Ph \xrightarrow[R_3\overset{+}{N}H\cdot\bar{B}F_4]{R_3N\cdot BF_3} (CF_3)_2C{=}C{=}NSO_2Ph$$

(IV)

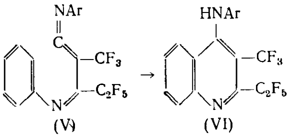
N-*p*-Nitrophenylbistrifluoromethylketenimine can be prepared similarly from the imidoyl fluoride only by means of this complex[11].

The reaction of fluoroalkenes with primary amines extends even to perfluoroisohexene[12]:



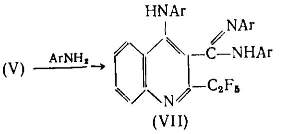
$R{=}C(CH_3)_3$; $2,6\text{-}(CH_3)_2C_6H_3$

N-Arylketenimines (V) in which an *ortho*-position is unsubstituted, especially when the ring contains electron-donor substituents, are cyclised under the reaction conditions to fluorinated quinolines (VI):



(V) (VI)

In the presence of a large excess of an aromatic amine the ketenimine (V) undergoes further reaction, ultimately with formation of the quinoline (VII)[13]:



(VII)

A less general method for preparing bistrifluoromethylketenimines is Staudinger's reaction[14]:

$$(CF_3)_2C{=}C{=}O + Ph_3P{=}NR \xrightarrow[-Ph_3PO]{} (CF_3)_2C{=}C{=}NR$$

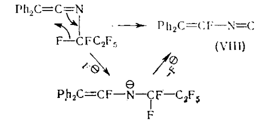
Bistrifluoromethylketen can be replaced by perfluoroisobutene, which reacts with tetraphenylphosphine imide, replacing two fluorine atoms by a phenylimino-group §[15]:

$$(CF_3)_2C{=}CF_2 + Ph_3P{=}NPh \xrightarrow[-Ph_3PF_2]{} (CF_3)_2C{=}C{=}NPh$$

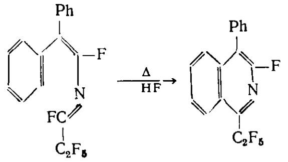
The Staudinger reaction can be used also to obtain ketenimines having an *N*-perfluoroalkyl group[18]:

$$(CF_3)_3CN{=}C{=}O + Ph_3P{=}CPh_2 \rightarrow (CF_3)_3CN{=}C{=}CPh_2$$

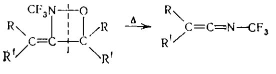
In contrast to perfluoro-t-butyl isocyanate, perfluoropropyl isocyanate, which contains mobile α-fluorine atoms, reacted with the yields to give the azabutadiene (VIII), obviously as a result of isomerisation of the intermediate ketenimine with migration of fluorine[18]:



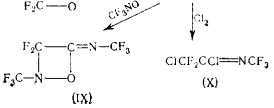
This rearrangement of a heterocumulene into a heterodiene can occur via a four-membered cyclic transition state or as a result of attack by a fluoride ion on the central carbon atom. An analogous isomerisation is found with bistrifluoromethylketen[19]. When heated, the azabutadiene (VIII) undergoes dehydrofluorination with ring closure, which provides a simple method for preparing a fluorinated isoquinoline[18]:



Ketenimines in which a trifluoromethyl group is attached to the nitrogen atom are formed also by pyrolysis of products of the cycloaddition of trifluoronitrosomethane to allenes[20]:



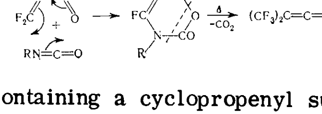
Ketenimines having fluorine atoms adjacent to the multiple bond, like the corresponding ketens, are unstable, and their formation in such a reaction can be judged from isolation of the cycloadduct (IX) or the chlorinated product (X)[21]:



Iminosulphuranes are analogous to iminophosphoranes in reacting with bistrifluoromethylthioketen to form *N*-alkyl- and *N*-phenyl-bistrifluoromethylketenimines[22]:

$$(CF_3)_2C{=}C{=}S \xrightarrow{RN{=}S{=}NR} (CF_3)_2C{=}C{=}NR$$

The remaining preparations of ketenimines having perfluoroalkyl groups attached to carbon are more specific in character. Thus *N*-alkylbistrifluoromethylketenimines are formed in the pyrolysis of a cycloaddition product of an isocyanate and perfluoromethacryloyl fluoride[23]:



Ketenimines containing a cyclopropenyl substituent are obtained by the interaction of perfluorobutyne with isonitriles in inert solvents; in the presence of an alcohol the

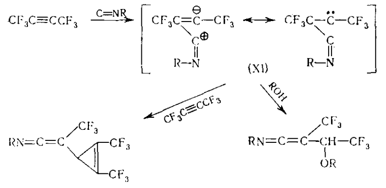
---

† Hexafluoroisobutyronitrile reacts with triethylamine to form a stable adduct[8], which can be regarded as a salt of the unsubstituted imine of bistrifluoromethylketen $(CF_3)_2C:C:NH.NH_3$.

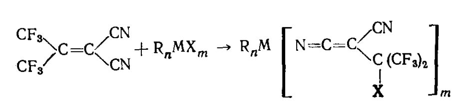
‡ The dehydrohalogenation of imidoyl halides is a general method for preparing unfluorinated ketenimines[2].

§ This reaction illustrates the analogy between the carbonyl and difluoromethylene groups[4,16,17].

intermediate equimolecular adduct (XI) reacts, not with another hexafluorobutyne molecule, but with the alcohol[24,25]:

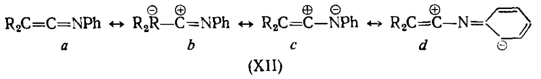


Finally, ketenimines containing *N*-organometallic groups are formed by the 1,4-addition of organo-silicon, -germanium, -tin, and -boron compounds to bistrifluoromethylmethylenemalononitrile[26,27]:



III. CHEMICAL PROPERTIES

Ketenimines are iso-π-electronic with allenes and ketens, and can be represented by the resonance structures[28,29]



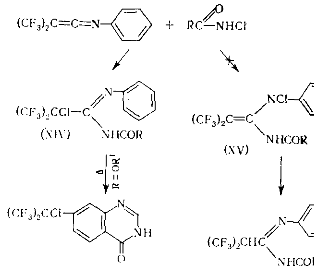
(XII)

As the ketens, the electrophilic character of the central atom can be strengthened by attaching electron-donor substituents to the carbon atom. Furthermore, the structural features of ketenimines permit the reactivity of the heterocumulative bond system to be changed by attaching electron-donor or electron-acceptor substituents also to the nitrogen atom, the latter enhancing the electrophilic character. The most active electron acceptors exert in principle the same influence on the reactivity of ketenimines as does electrophilic catalysis, bringing their activity close to that for ketenimmonium salts[30]. Furthermore, the structure (XII*d*) indicates the possibility of reactions involving the aromatic ring of *N*-arylketenimines, in which the latter behave formally as 1,4-heterodienes— cf. (XXVII).

In conformity with the above, bistrifluoromethylketenimines react far more readily than unfluorinated ketenimines with water, alcohols, and amines to give the corresponding derivatives of hexafluoro-α-hydroisobutyric acid (XIII)[31]:

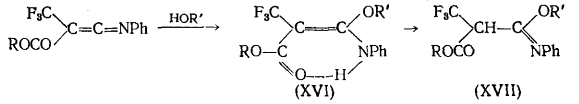
X=OH, OR, NR$_2$ (XIII)

This reaction does not answer the question—important for the chemistry of heterocumulenes—at which of the cumulative bonds the nucleophiles add on, since products of addition at the C=N bond, not stabilised by a hydrogen bond (Section II), would have immediately isomerised into the more stable end-products (XIII) ¶. However, the formation of the α-chlorohexafluoroisobutyramidines (XIV)[44] when the anil of bistrifluoromethylketen is treated with *N*-chloro amides indicates addition at the ethylenic bond in the ketenimine, since the product (XV) of addition at the C=N bond would have isomerised with migration of chlorine into the aromatic ring[33]:

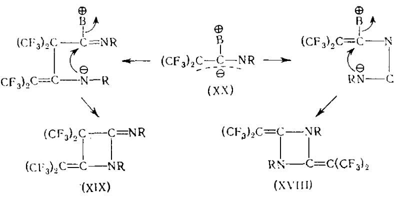


Cyclisation of the amidines (XIV) on being heated is a good method for the preparation of quinazolines.

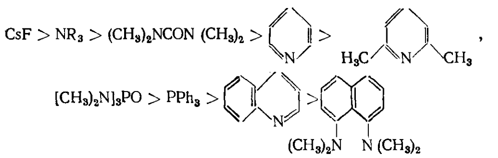
It is interesting that products formed by addition at the C=N bond in ketenimines — aminoacetals (XVI) — can be detected in the reactions of the anil of an alkyl trifluoro-β-*N*-phenyliminomethacrylate with alcohols; they rearrange comparatively slowly to imidic esters (XVII), a process which is irreversible[6], in contrast to the isomerisation of enamines into imidoyl fluorides (Section II):



In contrast to trialkylketenimines, *N*-alkyl- and especially *N*-aryl-bistrifluoromethylketenimines are stable, remaining unchanged even on prolonged heating †, However even such weak bases‡ as oxiran, dimethylformamide, benzylidenaniline, triethyl phosphate, pyridine, etc. cause rapid dimerisation of *N*-arylketenimines into symmetrical (XVIII) or unsymmetrical (XIX) dimers[11,31]:



Dimerising agents form the reactivity sequence



in which only the nitrogen heterocycles give rise to the symmetrical dimer (XVIII).[11] Comparison shows that the activity of a dimerising agent is determined mainly by its nucleophilicity, not its basicity. For example, such a strong base but weak nucleophile as naphthalene-1,8-bisdimethylamine[34] dimerises ketenimines more slowly than does the considerably less basic but more nucleophilic Hexametapol, triphenylphosphine, and tetramethylurea. Similarly,

---

¶ Results on the addition of dialkyl phosphites at the C=N bond in the anil of bistrifluoromethylketen[32] are unreliable.

† *N*-t-Butylimines of fluorinated ketens on being heated decompose into isobutene and the corresponding nitrile[14].

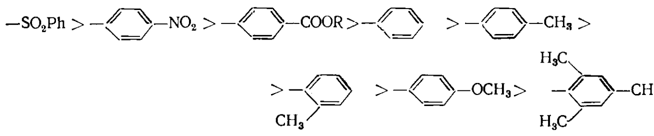
‡ The poorer stability of unfluorinated ketenimines may be due to autocatalysis, since they themselves are quite strong bases. The basicity of imines of fluorinated ketens is depressed by the electron-accepting action of the trifluoromethyl groups.

lutidine dimerises ketenimines more slowly than does pyridine[11]. The greater importance of the nucleophilicity of dimerising agents is consistent with the hypothesis that dimerisation begins with nucleophilic attack on the central carbon atom of the ketenimine to form the zwitterion (XX).

Unsymmetrical dimers are thermodynamically more stable than the symmetrical compounds, in accordance with which the latter rearrange into the former even under the influence of such weak bases as Hexametapol, tetramethylurea, pyridine, lutidine, and quinoline[11] §:

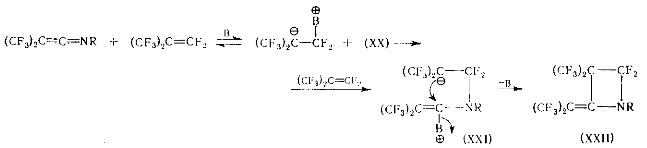
It is interesting that *para*-substituents in the aromatic ring have the same effect on the rate of rearrangement of symmetrical into unsymmetrical dimers as on the activity of the ketenimines.

The relative activities of fluorinated ketenimines have been studied in nucleophilic addition, dimerisation, and cycloaddition involving the aromatic ring. The anils of alkyl trifluoro-β-*N*-phenyliminomethacrylates are more active than the anil of bistrifluoromethylketen[6], since alkoxycarbonyl groups are stronger electron acceptors than is the trifluoromethyl group[37]. As already stated with regard to the effect of *N*-substituents, increasing the electron density on the nitrogen should diminish the electrophilic activity of the central carbon atom of the cumulative system. Indeed, the activities of *N*-substituted bistrifluoromethylketenimines are antiparallel to the basicities of the nitrogen in them[11]:



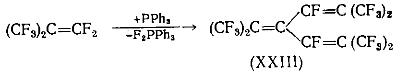
where the *N*-benzenesulphonyl derivative is the most active, and the *N*-alkyl compounds are the least active. The activity of imines of fluorinated ketens depends not only on the basicity of the nitrogen atom but also on the bulk of the reactant and of the substituent, especially in cycloadditions. Thus *N*-phenylbistrifluoromethylketenimine adds methanol and ethanol in 1–2 h, whereas with t-butyl alcohol the reaction is not complete after 6 months[44]; *N*-mesitylbistrifluoromethylketenimine adds alcohol considerably more slowly than does *N*-phenylketenimine, and is dimerised with immeasurably greater difficulty than any other ketenimine[11]; and *N*-*o*-tolybistrifluoromethylketenimine dimerises more slowly than does the *para*-isomer.

It is interesting that the presence of perfluoroisobutene slows down by more than 99% the dimerisation of imines of fluorinated ketens under the influence of tertiary amines. Perfluoroisobutene not only tends to inhibit dimerisation but also recaptures the mesomeric anion (XX); the resulting carbanion (XXI) undergoes cyclisation to the azetidine (XXII) with regeneration of the tertiary amine. Thus the extremely electrophilic character of perfluoroisobutene enables it to compete successfully with ketenimines both in bonding the amine and in recapturing the betaine (XX). Dimerisation is suppressed, and the main reaction product is the corresponding azetidine (XXII)[38]:



The same result is obtained in the presence of alkali-metal fluorides. Such mixed dimerisation of ketenimines with perfluoroisobutene provides an excellent method for preparing fluorinated azetidines.

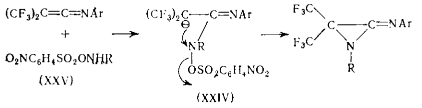
Triphenylphosphine is more active than tertiary amines in catalysing the dimerisation of activated alkenes and the Michael reaction[39,40]. However, it cannot be used to catalyse the cycloaddition of perfluoroisobutene to ketenimines: perfluoroisobutene reacts not only in preference to the ketenimine but also irreversibly, being converted ultimately into the conjugated triene (XXIII) ¶:



$$(CF_3)_2C{=}CF_2 \xrightarrow[-F_2PPh_3]{+PPh_3} (CF_3)_2C{=}C(CF{=}C(CF_3)_2)_2$$

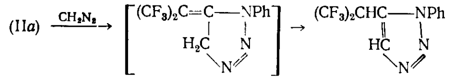
(XXIII)

In the synthesis of azetidines the carbanion (XXI) is stabilised by intramolecular nucleophilic substitution of the group B with closure of the four-membered ring. Nucleophilic elimination of imines of fluorinated ketens is accomplished similarly but at the ethylenic bond of the ketenimine. The carbanion (XXIV) is then obtained by the action of substituted amides (XXV) on the fluorinated ketenimines.

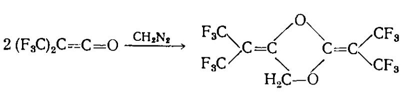


It is interesting that the direction of the reaction is predetermined by the nature of the leaving group: whereas chlorine migrates to the anionic centre of the molecule—cf. (XV)—the sulphonyloxy-group is readily detached with closure of the three-membered ring.

Nucleophilic elimination and formation of the unsymmetrical dimer (XIX) are among the few examples of cycloaddition at the ethylenic bond in imines of fluorinated ketens. Almost all cycloadditions involving unfluorinated ketenimines, on the other hand, take place at the ethylenic bond in the heterocumulene[2] †. An exception is the reaction of triarylketenimines with diazomethane[43]. Imines of fluorinated ketens also react with diazomethane at their C=N bond[44].



Bistrifluoromethylketen gives with diazomethane a cyclic trimer as a result of the reaction of both keten molecules at the carbonyl group[45]:



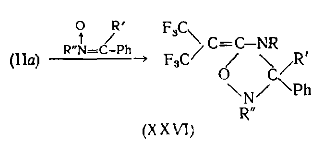
---

§ Symmetrical dimers of ketens (cyclobutanediones) isomerise into the unsymmetrical dimers in the presence of aluminium chloride; the reverse rearrangement takes place in the presence of bases[35]. Symmetrical dimers of unfluorinated ketenimines have not been described; for the only examples of unsymmetrical dimers see Ref. 36.

¶ Perfluorocyclobutene and butadiene give a 1 : 1 adduct with triphenylphosphine[41,42].

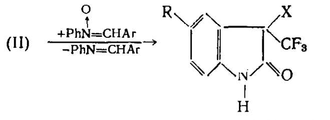
† Since hardly any information is available on aliphatic ketenimines[2], imines of bistrifluoromethylketen must be compared with those of aromatic ketens.

With nitrones unfluorinated ketenimines give products resulting from addition at the ethylenic bonds[46]. Imines of fluorinated ketens, on the other hand, form with triphenyl and *N*-methyl-*α*-phenyl nitrones cyclic adducts at the C=N bond — oxa-2,4-diazolidines (XXVI)[47]:

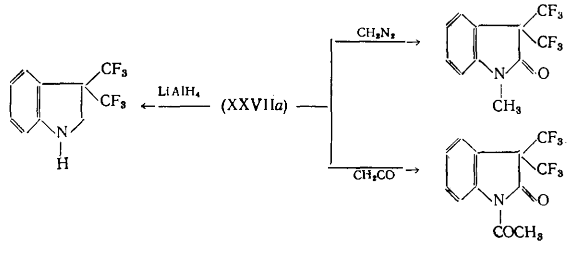


(XXVI)

In the cycloadditions discussed hitherto the fluorinated ketenimines have behaved as 1,2-dipolar compounds. As already mentioned — cf. (XII) and (XV) — however, with *N*-arylketenimines reactions involving the aromatic ring are also possible, in which these derivatives behave formally as 1,4-dipolar compounds. An example of this type is the unusual reaction undergone by imines of fluorinated ketens with *α*-aryl *N*-phenyl nitrones, in which fluorinated oxindoles (XXVII) have already formed on cooling[48], instead of cycloaddition products:

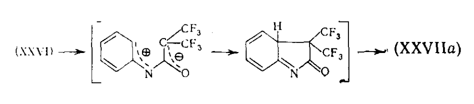


(XXVII) *a*) $X=CF_3$ *b*) $X=CO_2R'$



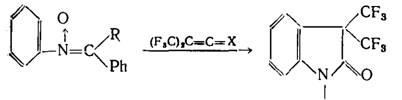
The structure of (XXVII*a*) is confirmed by cross synthesis, as well as by its chemical reactions. The oxindole (XXVII*a*) is formed also from oxadiazolidines (XXVI: R = C_6H_5). On standing for a long time or on being heated in a solvent, the latter compounds break down into the oxindole (XXVII*a*) and the corresponding Schiff bases. Isolation of products of the 1,3-cycloaddition of triphenyl and *N*-methyl *α*-phenyl nitrones to *N*-arylbistrifluoromethylketenimines and their conversion into the oxindole (XXVII*a*) suggest that reaction with the latter nitrones may involve the formation of unstable oxadiazolidines, which decompose so easily into an oxindole and an imine that they cannot be detected even by spectroscopic methods.

Thus nitrones are ultimately donors of oxygen in their reactions with *N*-arylbistrifluoromethylketenimines, which is unusual for nitrones. The mechanism of this peculiar reaction of oxygen transfer can be represented[47]:



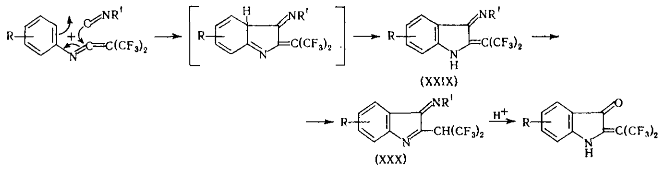
The betaine is stabilised by cyclisation at an *ortho*-position in the aromatic ring.

Substituted oxindoles (XXVII) are formed eventually also by the reaction of *N*-benzenesulphonylbistrifluoromethylketenimine and bistrifluoromethylketen[47] with *N*-phenyl nitrones, which, in contrast to the above reactions, involves the phenyl group of the nitrone:



(XXVIII) X=O, NSO_2Ph; Y=$OCOCH(CF_3)_2$, $NHSO_2Ph$

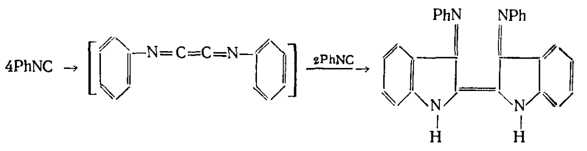
Indole derivatives are obtained also by reaction between *N*-arylbistrifluoromethylketenimines and isocyanides[49]. The indogenimines (XXIX) formed by 1,4-dipolar addition under very mild conditions then isomerise into iminoindolenines (XXX), whose hydrolysis involves migration of hydrogen back to the nitrogen[49]:



Reactions with isocyanides, similarly to nucleophilic addition and cyclodimerisation, are accelerated by electron-acceptor substituents in the aromatic ring of bistrifluoromethylketenimines, but restrained by electron-donor substituents. Whether in the imino-group or in the benzene ring, substituents have the opposite effect on the rate of isomerisation of indogenides into indolenines: indogenimines obtained from methoxyketenimine and alkyl isocyanides are the least stable. The reactivities of isocyanides with *N*-arylbistrifluoromethylketenimines fall in the sequence[50]

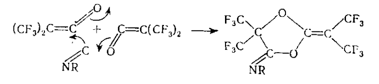
It is interesting that the reactivity sequence of isocyanides with nucleophilic acetylenic bonds is just the reverse[51]. This clearly indicates a difference in reaction mechanisms: whereas isocyanides react as nucleophiles with extremely electrophilic organofluorine compounds‡, they react as electrophiles with nucleophilic alkynes.

Unfluorinated triarylketenimines react with isocyanides only on irradiation, when heated, or in the presence of a catalyst. The reaction may involve the aromatic ring, the nitrogen atom, or a carbon atom, its direction being governed by the substituents in the aryl rings[53,54]. Only the tetramerisation of phenyl isocyanide



is accomplished at room temperature and without external assistance[49,54,55].

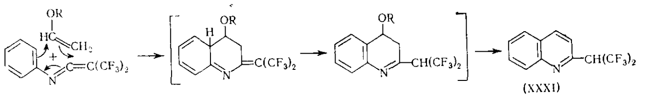
Bistrifluoromethylketen gives with isocyanides, as with diazomethane, a cyclic trimer in which both keten molecules have reacted at the carbonyl group[45], whereas unfluorinated ketens react at the ethylenic bond[52]:



---

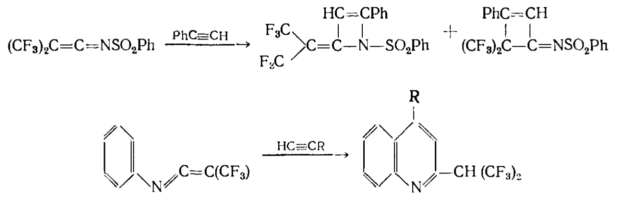
‡ The nucleophilicity of the carbene carbon atom is less in aryl than in alkyl isocyanides[52], and decreases on the introduction of electron-accepting substituents into the aromatic ring.

Ordinary alkenes are insufficiently nucleophilic and do not react with imines of fluorinated ketens. With especially nucleophilic vinyl ethers, however, *N*-arylbistrifluoromethylketenimines react even at room temperature, yet again by 1,4-cycloaddition with the ultimate formation of a fluorinated quinoline (XXXI)[56]:



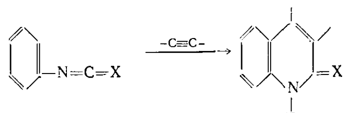
(XXXI)

Imines of fluorinated ketens react similarly with ethoxy- and phenyl-acetylenes (only the especially active *N*-*p*-nitrophenyl- and *N*-benzenesulphonyl-ketenimines react with the latter without heating). *N*-Benzenesulphonylbistrifluoromethylketenimine, which does not contain a conjugated bond system, gives a mixture of cyclic adducts formed at the C=N and C=C bonds, whereas *N*-arylketenimines react as nitrogen heterodienes with involvement of the aromatic ring[31,56]:



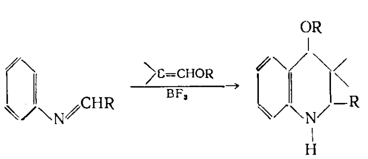
Various reactions of *N*-arylbistrifluoromethylketenimines involving the aromatic ring can be accomplished with good yields, usually with cooling or at room temperature, and provide a convenient method for preparing fluorinated heterocycles. The Reviewer considers reactions of this type most interesting, and will therefore discuss them in somewhat greater detail.

Apart from the processes discussed above, several other reactions have been discovered during recent years, usually achieved also under mild conditions, in which the cumulative or the azomethine bond with an attached aromatic ring behaves as a nitrogen heterodiene. Examples are the reactions of phenyl isocyanate[57–59] and of *N*-arylketenimines[60,61] with nucleophilic alkynes:

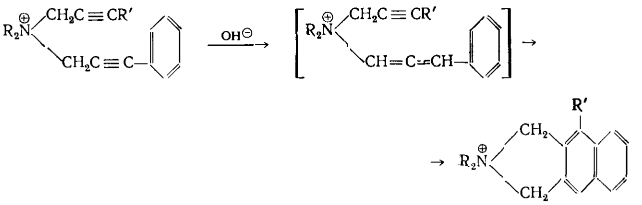


$X = O, CPh_2$

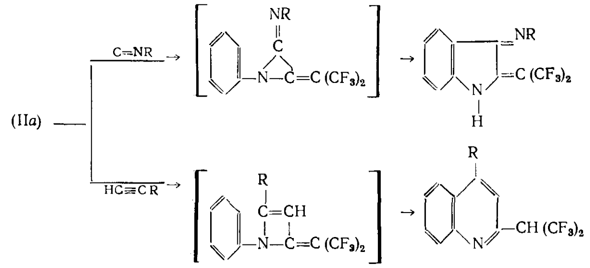
Formation of a quinoline ring by the reaction of vinyl ethers § with Schiff bases (in the presence of boron trifluoride)[62–64]

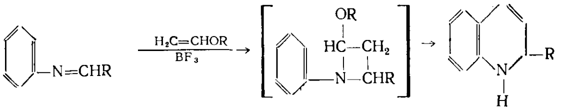


or with ammonium salts[65,66] has been widely studied. An ethylenic bond to which an aromatic ring is attached can also react as a diene under mild conditions[67,68]. Examples are the reaction of styrene with perfluorothioacetone[69] and the intramolecular cyclisation of amines and ammonium salts containing an *N*-arylprop-2-ynyl group[70,71]:



All these reactions are structurally similar to Diels–Alder reactions. Their mechanism has not been established, yet they have usually been regarded, in view of the isolation of final products to be expected from a mechanism of diene synthesis, as fresh examples of the Diels–Alder reaction¶. This approach seems unsound. Indeed, it is improbable that, under such mild conditions, an aromatic ring would react as a double bond of a diene. Typical Diels–Alder reactions represent concerted ($\pi 4_s + \pi 2_s$) addition, requiring very specific orientation of the reactants. They are therefore characterised by high negative entropies of activation: the pre-exponential factors in the rate constants are smaller by factors of 10^5–10^6 than would follow from collision theory[73,74]. Compensation for these rigorous demands on mutual reactant orientation is usually provided by a favourable energy balance in the reaction, with the disappearance of two double bonds and the formation of two σ-bonds. Such compensation is absent from reactions involving an aromatic ring, since they entail loss of the aromatic stabilisation energy. Yet they are usually accomplished under far milder conditions than are typical Diels–Alder reactions, which casts still greater doubt on the identification of these two types of processes. A two-stage rather than a synchronous mechanism is more probable for such reactions, involving intermediate formation of small rings subsequently stabilised by reaction with the aromatic ring†: e.g.





The best proof of a two-stage mechanism for reactions involving the aromatic ring would be isolation of compounds containing small rings and their conversion into the final heterocycles. However, this is not the simplest of tasks,

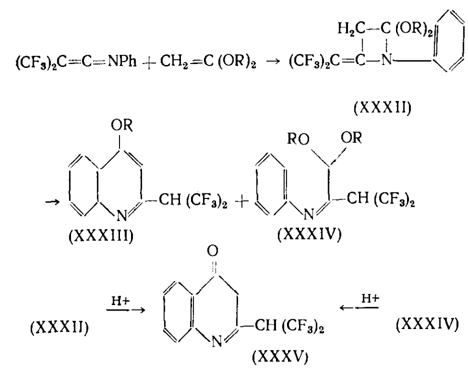
---

§ Isocyanides also react like alkenes with Schiff bases[72].

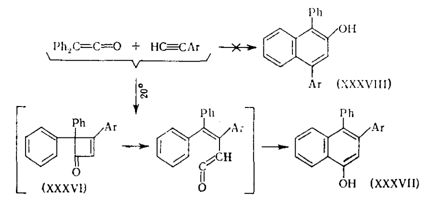
¶ An alternative mechanism with intermediate formation of cyclobutanone followed by isomerisation to a six-membered ring has been discussed[75].

† Such changes are well known with three-membered[76–79] and four-membered[80–85] rings.

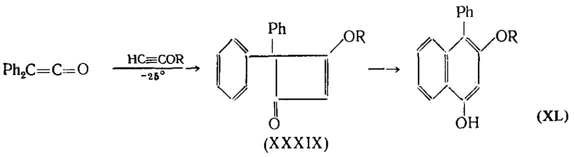
since small rings are very reactive[86,87]. Indeed, few data are available on the isolation of small rings in reactions of this type. Despite numerous attempts in the case of imines of fluorinated ketens, for example, only in a reaction with a keten acetal could a fairly stable product of cycloaddition at the C=N bond — the azetidine (XXXII) — be isolated. On prolonged storage at room temperature this azetidine is converted into the ethoxyquinoline (XXXIII) and the linear anil (XXXIV). Concentrated sulphuric acid converts both (XXXII) and its linear isomer into hexafluoroisopropyl-4-quinolone (XXXV)[56]:



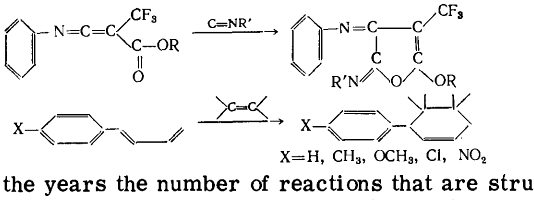
In the reaction of diphenylketen with arylacetylenes the intermediate product—cyclobutene (XXXVI)—could not be isolated, but the final formation of the 1-naphthol (XXXVII) instead of the 2-naphthol (XXXVIII) provided a forcible argument in support of a two-stage process[88]:



With the more reactive ethoxyacetylene, indeed, the cyclobutenone (XXXIX) could be isolated and converted into the 1-naphthol (XL)[84]:



Indirect support for a two-stage mechanism of "diene synthesis" involving an aromatic ring is that, when another conjugated multiple bond is present as well as the ring, this bond, of course, reacts[50,68,89]: e.g.



Over the years the number of reactions that are structurally similar to Diels–Alder reactions has so increased and their variety is so great that it would be naive to suppose that they all have the same mechanism. Both concerted and two-stage mechanisms have many variations. Formation of the two bonds may not be altogether simultaneous in a concerted mechanism[73,90]. Initial formation of charge-transfer molecular complexes is possible[91,92]. The first stage of two-stage reactions may produce betaines, perhaps in equilibrium with small rings. However, a covalent structure is more probable for the intermediate products, since substituents of the first and second kinds in the aromatic ring would have had a far greater effect in the case of betaines than is observed[73] ‡.

---o0o---

Thus both in nucleophilic addition and in cycloaddition not only are imines of fluorinated ketens more reactive than unfluorinated ketenimines but they also undergo reactions that are unknown with the latter compounds. Another distinguishing feature of the fluorinated imines is that most cycloadditions involve the methine bond, not the ethylenic bond as with the unfluorinated analogues (perhaps because of steric factors, which are especially important in cycloaddition). Because the methine bond is less polar than the carbonyl bond, imines of bistrifluoromethylketen are less reactive than bistrifluoromethylketen itself. Reactions involving the aromatic ring, which are structurally similar to the Diels–Alder reaction but obviously occur by a completely different mechanism, extend significantly the synthetic possibilities of ketenimines.

Four- and Five-membered Cyclic Disulphides

T.P.Vasil'eva, M.G.Lin'kova, and O.V.Kil'disheva

The principal methods for synthesising 1,2-dithiolans are surveyed, together with their advantages and disadvantages. Information is given on the geometry of the 1,2-dithiolan ring. The polarography, photolysis, and spectra of 1,2-dithiolans are discussed, and results are given for their polymerisation, reduction, oxidation, and chlorolysis, as well as the removal of a sulphur atom. Data are presented on the biological importance and application of 1,2-dithiolans. The major part of the review is devoted to the chemistry of unsaturated five-membered cyclic disulphides—the 3-thiones, 3-ones, 3-imines, and 3-ylidenes of 1,2-dithiolens—with methods of preparation and both chemical and physical properties. A detailed examination is made of their reactions with electrophilic and nucleophilic reagents, as well as condensations. Fields of practical application of 1,2-dithiolens are surveyed. The review concludes with 233 references.

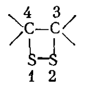
CONTENTS

I. INTRODUCTION

The chemistry of saturated and unsaturated four- and five-membered cyclic disulphides forms a new field, widely developed during the past decade. Saturated and unsaturated five-membered disulphides (1,2-dithiolans and 1,2-dithiolens) are present as fragments in certain antibiotics (gliotoxin, thiolutin, holomycin) and naturally occurring physiologically active compounds (α-lipoic and asparagusic acids, nereistoxin, brugine, etc.). Certain compounds find application as insecticides, antioxidants, and colorants.

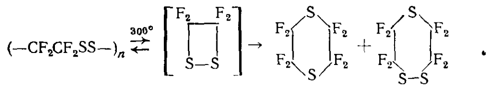
II. 1,2-DITHIETANS AND 1,2-DITHIETENS

Four-membered cyclic disulphides, 1,2-dithietans (I)



(I)

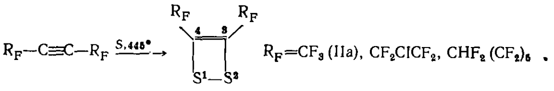
have not yet been obtained. It is known only that, when the pressure is lowered in the pyrolysis of polymeric perfluoroethylene disulphide, dithian and trithiepan are obtained. The mass spectra suggest the intermediate formation of tetrafluoro-1,2-dithietan (Ia), which at low temperatures is reconverted into the initial polymer[1]:



(Ia)

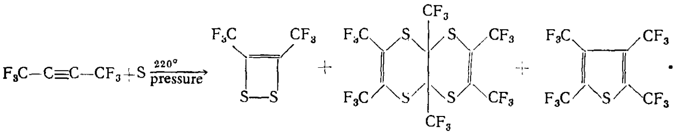
The instability of the almost planar 1,2-dithietan ring (I) is attributed to strong repulsion of the *p*,π electrons of the neighbouring sulphur atoms[1]. However, unsaturated four-membered cyclic disulphides, 1,2-dithietens (II), are more stable than the saturated analogues (I) because of the presence in the ring of an "aromatic" sextet of electrons[2].

Perfluorinated 1,2-dithietens (II) were first obtained by Krespan[3] by the action of sulphur on polyfluorinated alkynes[3,4]:



(II)

A yield of 80% of bistrifluoromethyl-1,2-dithieten (IIa) was prepared in this way[3]. At lower temperatures the yield does not exceed 26% owing to the formation of secondary condensation products[4]:

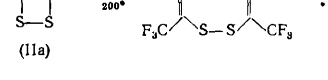


(IIa) 26% 29% 11%

However, 1,2-dithietens (II) cannot be obtained from acetylene and dimethyl acetylenedicarboxylate[4]. The first report that benzo-1,2-dithieten had been obtained[5] has proved to be erroneous[4].

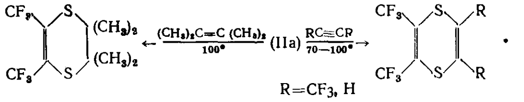
The 1,2-dithieten ring exhibits characteristic ultraviolet absorption in two ranges—at 231–243 and 334–340 nm[4].

The chemical properties of 1,2-dithietens are determined by the labile disulphide bond. Thus (IIa) dimerises slowly at 25°C, rapidly in the presence of weakly basic catalysts (triethylamine, ethanol); (IIa) is reformed when the dimer is heated to 200°C: [3,4]

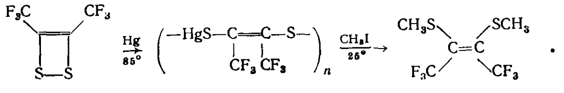


(IIa)

Cycloaddition at the disulphide bond occurs readily with alkenes and alkynes[3,4,6]:

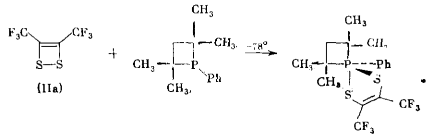


The presence of electron-donor substituents in the unsaturated hydrocarbons facilitates cycloaddition[6]. The action of mercury converts (IIa) into a polymer, which with iodomethane forms 2,3-bismethylthioperfluorobut-2-ene[6]:

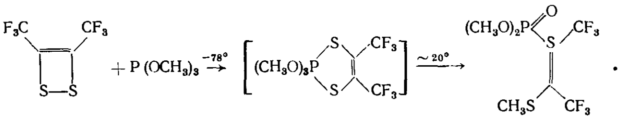


(IIa)

With phosphines and phosphites (IIa) yields sulphur-containing phosphorans[7]:



Methyl *o*-phenylene hydrogen, ethyl methyl hydrogen, and trimethyl phosphites react similarly. In the latter two cases the adducts are unstable, and undergo the Arbuzov rearrangement even at 20°C:[7]

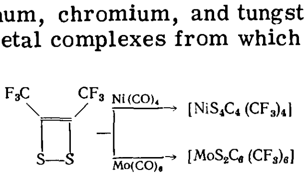


(IIa)

With transition-metal carbonyls (IIa) form complexes also with cleavage of the cyclic disulphide bond. Thus it gives a trimeric complex with octacarbonyldicobalt[8]:

$$Co_2(CO)_8 + (IIa) \rightarrow [(CF_3)_2C_2S_2Co(CO)]_3 \ .$$

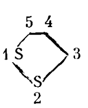
Nickel, molybdenum, chromium, and tungsten carbonyls form with (IIa) metal complexes from which the carbonyl group is absent[9]:



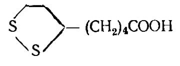
(IIa)

III. 1,2-DITHIOLANS

This survey of the literature on 1,2-dithiolans (III) mainly covers the period after 1963, for earlier investigations were summarised in a monograph[10]. Because of the great biological importance of α-lipoic (thioctic) acid (IIIa)



(III)



(IIIa)

results for this compound have been segregated as an independent topic[10], and will not be considered in detail here.

1. Methods of Preparation

(*a*) Oxidation of 1,3-dithiols

The most general method for obtaining 1,2-dithiolans is the intramolecular oxidation of 1,3-dithiols (Table 1).[10–23] Thus a substituted 1,2-dithiolan was first obtained by Reissert in 1906, by oxidising the dianilide of dithiomalonic acid[10]:

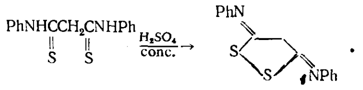


Table 1. 1,2-Dithiolans obtained by the oxidation of 1,3-dithiols.

1,2-Dithiolan	Oxidant (temp., °C)	Yield, %	Ref.
 (III)	H_2O_2—KI (25°)	35*	12

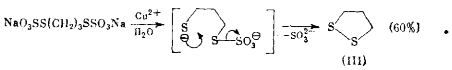
*Yield determined from concentration in solution (by ultraviolet spectrometry).

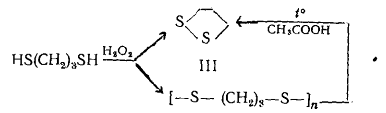
**Here and below the numeral indicates the position of the substituent in the ring (III).

***Yield of crude product.

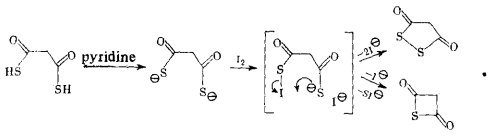
The early attempts at synthesising unsubstituted (III) usually yielded solid polymers or dimers, and only in 1950 did Affleck obtain (III)—in benzene solution—by the action of copper(II) chloride on trimethylene bisthiosulphate[11]:



A disadvantage of this method is secondary intermolecular oxidation to poly-1,2-dithiolans; on prolonged heating in acetic acid these are converted into (III):[12]

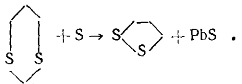


Intermediate formation of a monosulphenyl iodide is postulated in the oxidation of 1,3-dithiols (or 1,3-bisthiolic acids) to 1,2-dithiolans: e.g.[17]



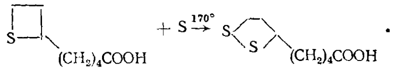
The intermediate undergoes either conversion into the cyclic disulphide or, with elimination of an SI⁻ ion, cyclisation to a four-membered sulphide[17].

High yields of various derivatives of 1,2-dithiolan (III) are obtained by the action of sulphur on the corresponding lead dithiolates[24]:



(III)

It is noteworthy that α-lipoic acid (IIIa) and its methyl ester can be prepared by introducing a second sulphur atom into the corresponding thietan derivatives[25]:



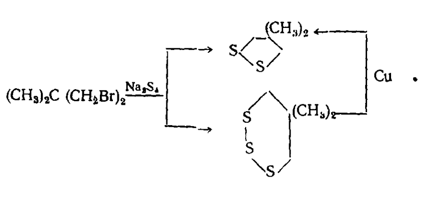
(III a)

(*b*) Condensation of 1,3-dihalogeno-derivatives with alkali-metal polysulphides

The lower yields are responsible for the less frequent use made of the cyclisation of 1,3-dihalides (or bisarenesulphonic esters of 1,3-glycols) by means of alkali-metal polysulphides (Table 2):[26-28]

(III)

Higher yields of (III) are obtained with Na_2S_4 than with Na_2S_2. Use of the latter yields thietans as byproducts[10], whereas Na_2S_4 gives cyclic trisulphides, which are converted into disulphides (III) by boiling with copper powder[27]:



(*c*) Intramolecular cyclisation of β-mercaptothio-carboxylic acids

The most general method for obtaining 1,2-dithiolan-3-ones is intramolecular acylation of β-thiothiols (or their acetyl derivatives) containing an activated carboxyl:

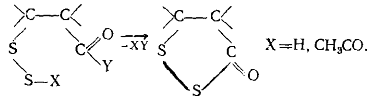


Table 2.

1,2-Dithiolan (III)	Initial compound	Reagent	Yield, %	Ref.
Unsubstituted	$Br(CH_2)_3Br$	Na_2S_2	9	
4-$(CH_3)_2$	$(CH_3)_2C(CH_2Br)_2$	K_2S_2	55	10
3,5-$(COOH)_2$	$CH_2[CH(Br)COONa]_2$	Na_2S_2	22	
Ditto	$CH_2[CH(Br)COOH]_2$	Na_2S_2	11	26
4-$(CH_2)_5$		Na_2S_4	47	27
4-$(CH_2OH)_2$	$(HOCH_2)_2C(CH_2Br)_2$	Na_2S_4 Na_2S_2	94 57	10
3-$(CH_2)_4CONH_2$	$Cl(CH_2)_2CH(Cl)(CH_2)_4CONH_2$	Na_2S_2	83	10
3,3,5,5-$(CH_3)_4$-4-(=O)	$O{=}C[C(CH_3)_2Br]_2$	Na_2S_2	35	28

The disulphides to be cyclised are readily formed and are used without isolation in pure form, by the action of hydrogen sulphide on β-chlorosulphenyl-carboxylic acids, when cyclisation occurs sometimes spontaneously[29], and sometimes in the presence of an organic base[30]:

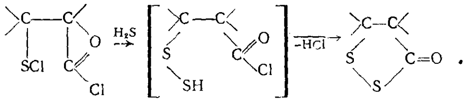

Table 3. Cyclisation of β-acetyldithio-carbonyl chlorides by zinc chloride[32].

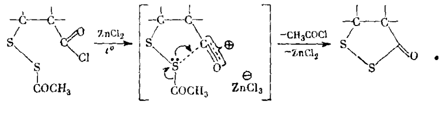
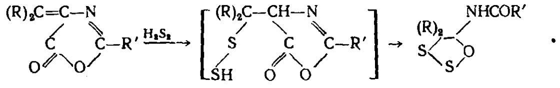
1,2-Dithiolan-3-one	Unsubstituted	5-C_6H_5-	4-CH_3-	5-CH_3-	4-Cl-	4-Cl-4-CH_3
Yield, %	50	70	67	71	89	86

1,2-Dithiolan-3-ones are formed especially readily by intramolecular transacylation of the chlorides of β-acetyldithio-carboxylic acids (Table 3) catalysed by zinc chloride, with removal of acetyl chloride from the reaction zone[31,32]:



An example is the intramolecular transacylation of a 4-mercaptothiomethyl-1,3-oxazolin-5-one:[33]



2. Physical Properties

Crystallographic examination of the structure of 1,2-dithiolan-4-carboxylic acid has shown[10] that the molecule is non-planar and unsymmetrical. The angle between the $C_{(5)}-S_{(1)}-S_{(2)}$ and the $S_{(1)}-S_{(2)}-C_{(3)}$ planes is 26.6°—not the 90° found in open-chain disulphides[34]—which leads to repulsion of the unshared *p*-electrons of the sulphur atom and instability of the 1,2-dithiolan ring[35]. The angle at a sulphur atom is also smaller (92° instead of the 107° in linear disulphides)[36], so that the S−S bond is longer in 1,2-dithiolans than in open-chain disulphides (2.1 instead of 2.044 Å)[10].

	11	crystallographic structure analysis	10,38
	16—30	conformational analysis	10,38

*The stress in 1,2-dithian determined by the same method was 0.5 kcal $mole^{-1}$.[38]

** $HS(CH_2)_3SH \xrightarrow{I_2} (III)$.

*** 
$HS(CH_2)_2CH(CH_2)_4CO_2H \rightarrow (IIIa)$ (SH on CH).

The stress in the 1,2-dithiolan ring has been determined by many workers using various methods (Table 4). Strongly divergent values have been obtained. The underestimates given by chemical methods may be due either to the presence of a polymer in the specimens or to the fact that the comparable reactions were conducted in solution, not in the vapour phase[10,37,38].

In conformity with the negative inductive effect of the disulphide group the measured dipole moments and the acidity of 1,2-dithiolan-4-carboxylic acids exceed those of cyclopentanecarboxylic acids (Table 4a)[39].

Table 4a.

	μ, D	pK_a

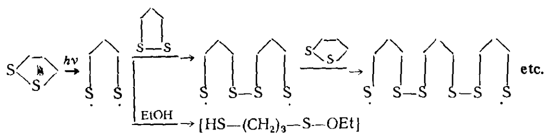
	3.15	3.82

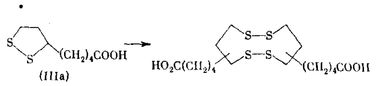
1,2-Dithiolans are reduced polarographically (mostly at pH ~ 2.2) by a two-electron mechanism via intermediate mercury complexes to dithiols[10,40,41]:

The half-wave potential $E_{1/2}$ is higher for 1,2-dithiolans than for linear and more macrocyclic disulphides[40,41].

On photolysis 1,2-dithiolans readily polymerise[42], and in alcohol they react with the solvent[35]:



Exposure of aqueous α-lipoic acid (IIIa) leads to rapid dimerisation[43]:

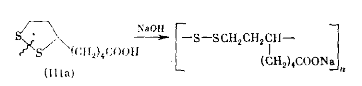


The ultraviolet spectra of 1,2-dithiolans have been studied ($\lambda_{max} \simeq 310-350$ nm).[36] In contrast to cyclic disulphides, polymeric linear disulphides absorb at 230 to 250 nm.[22] 1,2-Dithiolancarboxylic acids are exceptions, absorbing at 250−280 nm, with only weak absorption at 330 nm.[10] 1,2-Dithiolan-3-ones exhibit carbonyl absorption in the infrared (at 1710−1720 cm^{-1}).[32]

3. Chemical Properties

(*a*) Polymerisation

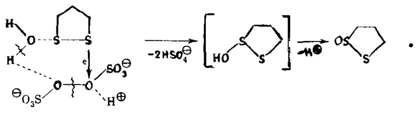
The most characteristic property of 1,2-dithiolans is their ease of polymerisation to linear disulphides, especially when heated or in the absence of a solvent, the activation energy of polymerisation being very low (8.6 kcal $mole^{-1}$).[36] All monosubstituted 1,2-dithiolans—the 4-amine[22], 3-carboxylic acid[44,45], methyl 3-carboxylate[41], 3-one[32], 4-one[24], and 4-hydroxymethyl derivative[46]—tend to polymerise, as well as certain disubstituted derivatives, 3,3-dimethyldithiolan[37] and the 4-methyl-3-valeric acid[23]. 3,3,5,5-Tetramethyl-1,2-dithiolan polymerises only in the presence of a catalyst (H^+, RS^-, OH^-, $AlCl_3$).[37] On addition of an aqueous alkali the compound (IIIa) also forms a polymer[47]:



(*b*) Reduction and oxidation

In the presence of zinc in hydrochloric acid[21], zinc in aqueous ammonia, sodium in liquid ammonia, and sodium tetrahydroborate[44,45], 1,2-dithiolans are readily reduced at the disulphide bond to 1,3-dithiols (Table 5).[10]

1,2-Dithiolans are more easily oxidised than are linear or macrocyclic disulphides[41]. Under controlled conditions both cyclic thiosulphinates (1-oxides) and thiosultones (1,1-dioxides) can be obtained (Table 6). Thiosultones are most stable compounds[41]. Oxidation with hydrogen peroxide more often gives 1-oxides, but 1,1-dioxides are formed when the ring contains electron-donor substituents or in the presence of a catalyst (Table 6). The oxidation of 1,2-dithiolans (e.g. by a persulphate) proceeds by a mechanism of one-electron transfer[20,36]:



The primary oxidation products of 1,2-dithiolans are thiosulphinates, which can then be oxidised further to 1,1-dioxides (Table 7).[20,49]

Table 5. Reduction of 1,2-dithiolans.

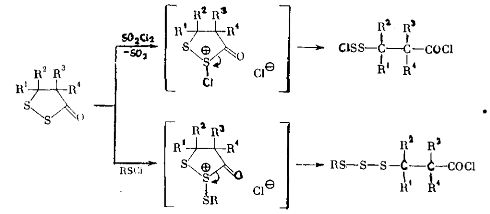
The oxidation of 4,4-bishydroxymethyl-1,2-dithiolan by hydrogen peroxide to the 1,1,2,2-tetroxide is usually accompanied by ring cleavage to give disulphonic acids[10]. Better yields of the latter are obtained from alkylated 1,2-dithiolans by the prolonged action of excess of potassium permanganate[41] or hydrogen peroxide[10]:

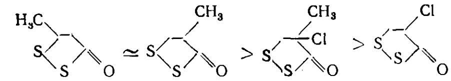
$(CH_3)_2C(CH_2SO_3H)_2$ (53%) .

(*c*) Reactions with electrophilic reagents

It has recently been shown that the chlorolysis of 1,2-dithiolan-3-ones by sulphuryl or sulphenyl chlorides involves selective cleavage of only the CO—S bond (Table 8)[50,51]:



These dithiolanones form the sequence



according to ease of rupture of the CO–S bond.

(*d*) Removal of a sulphur atom

A novel reaction of 1,2-dithiolans is the removal of a sulphur atom by trisdiethylaminophosphine[13,52] or triphenylphosphine[17,53] with the formation of four-membered heterocycles—thietans, β-thiolactones, and thietan-2,4-diones (Table 9). The process is a second-order reaction accompanied by inversion (S_N2), with intermediate formation of an internal phosphonium salt[13,52]:

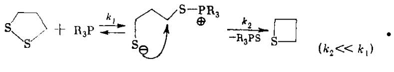


Table 9. Thietans from 1,2-dithiolans.

(*e*) Reactions with metal alkyl sulphides and with inorganic salts

Thiols cleave 1,2-dithiolans very slowly:

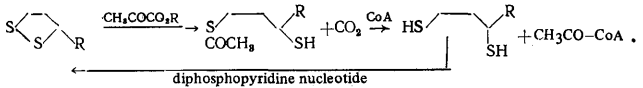
(III)

The rate of reaction increases in the presence of a weak base (the acetate ion)[10,54]. The rate of cleavage of the disulphide bond by sodium cyanide depends on the structure of (III). Thus unsubstituted (III) is cleaved rapidly and completely, the 3,3-dimethyl derivative slowly, and 3,3,5,5-tetramethyl-1,3-dithiolan does not react with sodium cyanide[10,37].

The antibiotic gliotoxin (IIIb), which contains a 1,2-dithiolan ring, is cleaved at the disulphide bond when heated with potassium sulphide[33]. With mercury(II) chloride and bromide substituted 1,2-dithiolans form crystalline adducts, but their nature is still obscure[10,55,56].

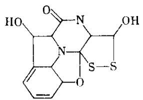
4. Biological Importance and Application

Of all the compounds containing a cyclic disulphide bond α-lipoic acid (IIIa) is the most important: it is a growth factor, and is involved in the oxidation of pyruvate and in photosynthesis[57]. In the organism reductive cleavage of (IIIa) gives a dithiol[58]:

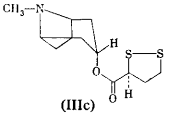


diphosphopyridine nucleotide
$R = (CH_2)_4COOH$ (III a)

Gliotoxin (IIIb)—an antibiotic in which nitrogen atoms are attached to positions 3 and 4 of a 1,2-dithiolan ring—has an antitubercular and bacteriostatic action. 4-Acylamino-1,2-dithiolan-3-ones also possess tuberculostatic and cytotoxic activity[33]. 4-Amino-1,2-dithiolans are insecticidal[59]. 4-Dimethylamino-1,2-dithiolan—nereistoxin, isolated from marine worms—exerts a selective toxic action on harmful insects[60]. Intensive research is being conducted on its synthesis[22,61–63].



(IIIb)



(IIIc)

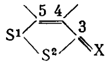
(IIId)

Bruguine—the tropinyl 1,2-dithiolan-3-carboxylate (IIIc) isolated from Cinchona—is an antitumour alkaloid[64,65]. 4-Hydroxy-1,2-dithiolan *trans*- and *cis*-1-oxides (brugierol and isobrugierol)[66], 1,2-dithiolan-3-carboxylic acid[67], and the 4-carboxylic (asparagusic) acid and its sulphoxide (IIId) also occur in plants; they inhibit the growth of lettuce, rice, radish, etc.[46,48]

All functionally substituted 1,2-dithiolans are potential protective agents against radiation[16].

IV. 1,2-DITHIOLENS

Unsubstituted 1,2-dithiolen and its 3,3-disubstituted analogues are known. The 3-thiones (trithiones) (IVa), 3-ones (IVb), 3-imines (IVc), and 3-ylidenes (IVd) are discussed below.



(IV)

a) X=S c) X=NR
b) X=O d) $X=CR_2$

(V)

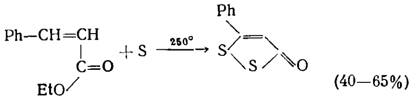
Several reviews have appeared on the chemistry of 1,2-dithiolium (V) salts[10,69,70], which therefore will not be considered in detail here. The literature on 1,2-dithiolens (IV) up to 1963 was examined in Breslow's monograph[10].

1. Methods of Preparation

(*a*) Sulphurisation of various types of organic compounds (with sulphur, phosphorus pentasulphide, and carbon disulphide)

4,5-Dimethyltrithione was first obtained in 1884 by Barbagliya by the action of sulphur on isovaleraldehyde[10]:

Although the corresponding reaction with ethyl cinnamate gives 5-phenyl-1,2-dithiolen-3-one[71]



the *α*-methyl and *α*-ethyl-cinnamates yield the alkyl trithione-4-carboxylates or thiophens[10]. Sulphurisation of carbonyl (or thiocarbonyl) derivatives with sulphur and (or) phosphorus pentasulphide has so far remained the most general method for obtaining the 3-thiones (IVa), 3-ones (IVb), and 3-ylidenes (IVd) of 1,2-dithiolens (Table 10)[72-90]. The yields of trithiones from the reactions of hydrocarbons and halogenated hydrocarbons with sulphur (Table 11)[91-100] improve in the presence of basic catalysts (diphenylguanidine, mercury acetamide)[95].

Table 10. 1,2-Dithiolens by the sulphurisation of carbonyl and thiocarbonyl derivatives.

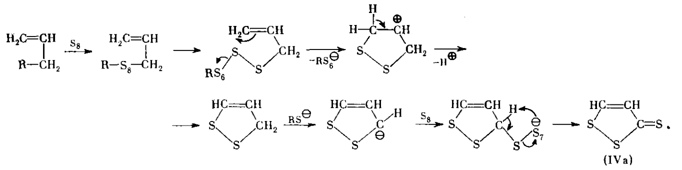
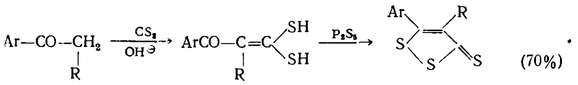
*Z represents a secondary product not containing 1,2-dithiolen.

The mechanism of the formation of trithiones (IVa) from alkenes[101] is



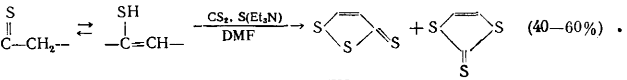
The use of phosphorus pentasulphide enables the temperature of this reaction to be lowered from 500° to 200°C.[91,92,101]

Sulphurisation of saturated and unsaturated hydrocarbons often produces difficultly separable mixtures of thiols, disulphides, thiophens, etc., so that the yields of (IV), especially from aliphatic compounds, rarely exceed 20% (Table 11). 5-Aryltrithiones are formed in higher yields, especially by the action of phosphorus pentasulphide on products of the condensation of aryl ketones with carbon disulphide (Table 10):[10,101]



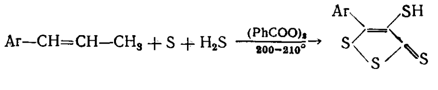
The action of sulphur and carbon disulphide in dimethylformamide on nitrogen-containing derivatives of hydrocarbons—ketimines, enamines, nitriles—also yields trithiones, together with isothiazolines (Table 12).[76,102-106]

With aliphatic thioketones (enethiols) carbon disulphide and sulphur give mixtures of isomeric 1,2-dithiolen-3-thiones (IVa) and 1,3-dithiolen-2-thiones[107]:

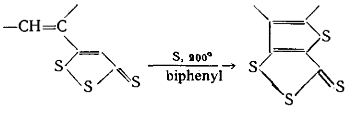


(IV a)

The sulphurisation of propenylbenzene in an atmosphere of hydrogen sulphide produces 4-mercaptotrithiones[10]:



In the presence of basic catalysts 5-alkenyltrithiones react with sulphur to form bicyclic thienotrithiones[108,109]:



(*b*) Cyclisation of derivatives of *β*-acetyldithio-carboxylic acids

Good yields of arylated and poor yields of alkylated 1,2-dithiolen-3-ones are obtained by the action of hydrogen chloride on *β*-acetyldithio-acrylic esters (in boiling methanol)[110].

When *β*-acetyldithio-*β*-chloro-carboxylic acids are heated in the presence of a zinc chloride catalyst without a solvent, high yields of alkylated and of halogenated

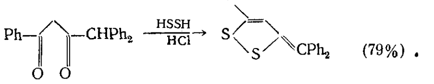
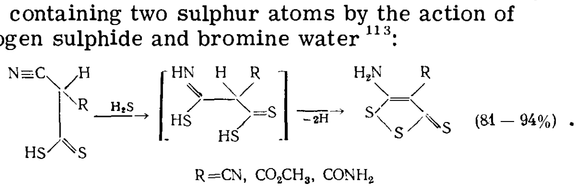
The reaction of disulphane with arylated 1,3-diketones yields 1,2-dithiolylidene compounds[112]:



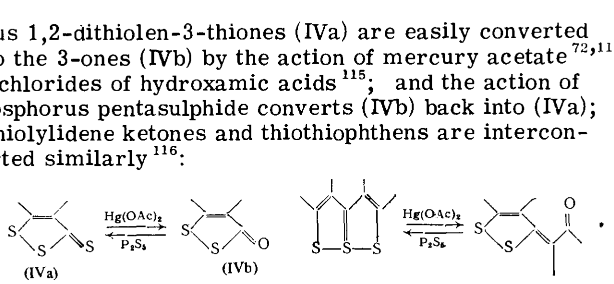
5-Aminotrithiones are formed from α-cyano-carboxylic acids containing two sulphur atoms by the action of hydrogen sulphide and bromine water[113]:



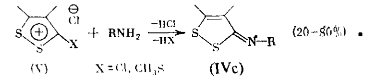
R=CN, CO_2CH_3, $CONH_2$

(*d*) Interconversion of 1,2-dithiolen derivatives

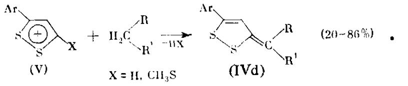
1,2-Dithiolens themselves are often the starting materials for obtaining other compounds of this type. Thus 1,2-dithiolen-3-thiones (IVa) are easily converted into the 3-ones (IVb) by the action of mercury acetate[72,114] or chlorides of hydroxamic acids[115]; and the action of phosphorus pentasulphide converts (IVb) back into (IVa); dithiolylidene ketones and thiothiophthens are interconverted similarly[116]:



1,2-Dithiolen-3-imines (IVc) are obtained by the reaction of 3-chloro- or 3-methylthio-1,2-dithiolium salts (V) with amines[117-120] or with *NN*-dichlorobenzamides[121], the yield of (IVc) depending on the basicity of the amine:

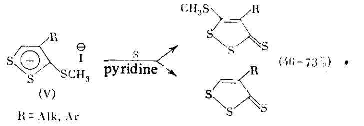


1,2-Dithiolylidenes (IVd) are usually obtained by condensing 1,2-dithiolium salts (V) with compounds containing active methylene groups[122-124]:



However, the reaction of a 4-phenyl-1,2-dithiolium salt with acetone gives a stable 3-monosubstituted 1,2-dithiolen, which forms a dithiolylidene ketone (IVd) only in the presence of chloranil[125,126]:

Sulphur acts on 1,2-dithiolium salts under mild conditions to form trithiones; in the case of 3-methylthio-1,2-dithiolium salts (V) this reaction gives a mixture of the expected 5-methylthiotrithione and a trithione formed by demethylation of the initial compound (V):[127-129,159]

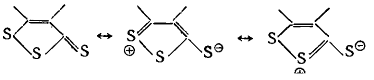


More nucleophilic bases convert 3-chloro-1,2-dithiolium salts into trithiones, and the less nucleophilic bases yield 1,2-dithiolen-3-ones[74,130]:

2. Physical Properties

1,2-Dithiolens have a planar *cis*-configuration of the disulphide bond, which would appear to be energetically less favourable than in 1,2-dithiolans, and still less than in open-chain disulphides (dihedral angle between the planes of the valencies of the sulphur atoms respectively 0°, 27°, and 90°). Actually, however, unsaturated five-membered cyclic disulphides are far more stable than the saturated rings, because the energy of repulsion of the unshared *p* electrons of the sulphur atoms is balanced by the conjugation energy of *p* and π electrons[34].

The structures of trithione[131] and 4-methyltrithione[132] have been established by means of X-rays. The molecules are planar[10], with carbon–carbon and carbon–sulphur bond lengths closely similar to those in benzene and in thiophen, but the sulphur–sulphur bond length in trithiones (2.04 Å) is identical with that in S_8 and R_2S_2 molecules. The structure of trithiones is therefore a hybrid of the resonance structures



in the proportions 5 : 4 : 1.[133]

According to LCAO-MO calculations, trithione and its 4- and 5-phenyl analogues have a low π-order of the S–S bond (0.07–0.08,[133] 0.242 [34]) and a higher order of the $C_{(4)}-C_{(5)}$ π-bond (~0.8).[134] In contrast to the $C_{(3)}$ and $C_{(5)}$ atoms the $C_{(4)}$ atom of trithiones bears a fractional negative charge (about −0.06).[133,134] The considerable negative charge on the exocyclic sulphur atom (about −0.28) is explained by the tendency of trithione to acquire an aromatic configuration by repelling the "spare" π-electron[133].

1,2-Dithiolen-3-ones and -thiones are analogues of the non-alternant tropone and tropothione systems. A clear comparison of the aromaticities of the various types of 1,2-dithiolens (IVa–c) and (V) can be obtained from their energies calculated by the LCAO-MO method (Table 14).[134] According to their *DE/n* values these compounds form the sequence of diminishing aromaticity

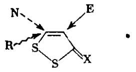
(V) (IVc) (IVa) (IVb)

Table 14. Energies of 1,2-dithiolens (in β-units)*.

No.	System	*n*	*DE*	*W*	*DE/n*
(IVb)	1,2-Dithiolen-3-one	8	1.063	12.527	0.133
(IVc)	1,2-Dithiolen-3-imine	8	1.096	10.332	0.137
(IVa)	1,2-Dithiolen-3-thione	8	1.057	9.425	0.132
(V)	1,2-Dithiolium ion	6	1.57÷2.05	7.57÷8.13	0.198÷0.342

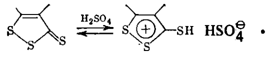
**DE* = delocalisation energy; *n* = number of π-electrons; *W* = total π-electron energy.

From the molecular diagrams for (IVa–c) it is predicted that centres of electrophilic, nucleophilic, and radical reactivity—*E*, *N*, and *R*—will have the locations[134]

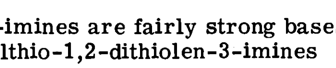


(IVa–c) (X = S, O, NR)

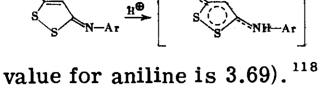
Because of the high electron density on the thiocarbonyl sulphur atom (1.576,[135] 1.433 [134]) trithiones exhibit basic properties and dissolve readily in acids[135]:



Protonation of the less basic 1,2-dithiolen-3-ones leads to a greater proportion of the oxonium form than of the 1,2-dithiolium structure (according to ^{1}H-n.m.r. data)[70,136]:

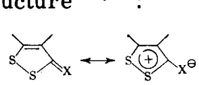


1,2-Dithiolen-3-imines are fairly strong bases. Thus for *N*-aryl-5-methylthio-1,2-dithiolen-3-imines



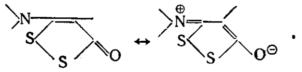
pK_b = 2.57 (the value for aniline is 3.69).[118]

Both trithiones and 1,2-dithiolen-3-ones have considerable dipole moments, although higher for similarly substituted trithiones because of the greater importance of the limiting polar structure[137,138]:



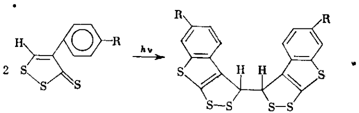
X = S, O .

Thus the measured dipole moments of the two groups lie in the ranges 3.3–5.5 and 2.8–4.9 D. The measured "apparent" conductivities are also higher for the former than for the latter group ($10^{15}\kappa$ is respectively 8.3–52 and 2.6 to 30 ohm^{-1} cm^{-1}).[137] The calculated dipole moment of unsubstituted trithione is 5.25 D.[133] 4-Halogeno- and 5-aryl-1,2-dithiolens have higher dipole moments than the corresponding 5-halogenated and 4-arylated compounds[138]. 1,2-Dithiolen-3-ones containing a tertiary amino-group at position 5 have extremely high dipole moments (4.74 to 6.73 D):[137,138]



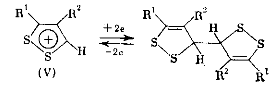
The surprisingly high melting points of trithiones[10] may be due to their high polarity.

The photochemical behaviour of 1,2-dithiolens is influenced by the position of the substituent. Whereas 5-phenyltrithione is photochemically stable[139], 4-*p*-tolyl- and 4-phenyl-trithiones undergo photochemical reactions at the C=S bond[140]:



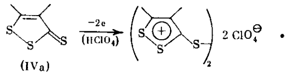
R = H (40%); CH_3 (44%)

1,2-Dithiolium ions (V) and bi-1,2-dithiolen-3-yls are interconverted electrochemically at a platinum electrode in acetonitrile[141]:



(V)

The preparative anodic oxidation of trithiones (IVa) yields bis-1,2-dithiolium disulphide[142]:



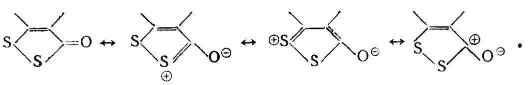
(IVa)

Trithiones are oxidised at potentials of ~0.8–1.32 V, and 1,2-dithiolium salts are reduced between about +0.32 and −0.06 V. Substituents in the ring affect both oxidation and reduction potentials: monosubstituted derivatives are oxidised and reduced far more easily than are disubstituted derivatives[142]. Polarographic reduction of trithiones gives a cathodic wave having a half-wave potential of −0.9 V.[101]

Ultraviolet and visible spectra. Trithiones exhibit strong absorption bands at 225, 250, 280, 335, and 417 nm,[101] which are somewhat displaced in the arylated compounds[10].

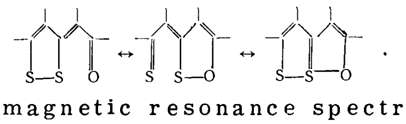
Infrared spectra. The 1,2-dithiolen framework shows characteristic absorption bands at 504–561 and 1508–1567 cm^{-1} (sulphur–sulphur and carbon–carbon vibrations of the ring)[143]. Later results reveal characteristic infrared lines at 405–420 and 430–450 cm^{-1} (planar deformation vibrations of the ring) and at 1305 to 1350 and 1490–1565 cm^{-1} (stretching vibrations of the ring). Sulphur–sulphur stretching vibrations of 1,2-dithiolens[144] appear at 480–525 cm^{-1}.

1,2-Dithiolens-3-ones exhibit a low carbonyl frequency (1610–1685 cm^{-1}),[32,115] like their analogue tropone (1638 cm^{-1}), as a consequence of the electron displacement[138,144]



(IVb)

Therefore (IVb) with a tertiary amino-group at position 5 have the lowest carbonyl frequency (1610–1635 cm^{-1}).[138] The thiocarbonyl group in trithiones[115] absorbs at 1110 to 1190 cm^{-1}. The carbonyl frequency of α-1,2-dithiol-3-ylidene ketones is located in a very low range (1550–1600 cm^{-1}), owing to interaction of the carbonyl oxygen with a cyclic sulphur atom[145,146]:



Proton magnetic resonance spectra. The signals of the ring protons, especially the fragment =CH–S, in 1,2-dithiolen-3-ones and -thiones are situated down-field (δ ≃ 6.3–8.4 p.p.m.) from those for cycloalkenes (for cyclopentene δ_{CH} = 4.4 p.p.m.), owing to conjugation of the carbonyl (or thiocarbonyl) group and the heteroatoms[32,147]. The chemical shifts of the aromatic protons in 5-aryl-1,2-dithiolens indicate that the rings are non-coplanar

X=O, S;

with the preferred deformation α = 30°. The electron-acceptor inductive contributions found experimentally for 1,2-dithiolens with respect to the aryl substituent are −0.13 and −0.16 according as X = O or S.[148]

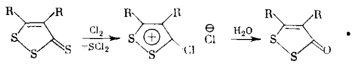
Mass spectra. 1,2-Dithiolens exhibit an intense peak due to the molecular ion, which may also indicate the aromaticity of these compounds[149,150].

3. Chemical Properties

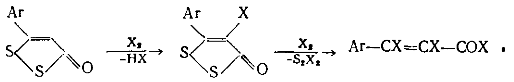
Trithiones are more reactive than 1,2-dithiolen-3-ones because of the greater polarisability of the thiocarbonyl group[151].

(*a*) Reactions with electrophilic reagents

Under mild conditions alkylated 1,2-dithiolen-3-thiones react readily with chlorine only at the thiocarbonyl bond to form a dithiolium salt, which is easily converted by interaction with the solvent (water, acetic acid) into the corresponding 1,2-dithiolen-3-one:[74,80,152,153]



As the system becomes more strongly aromatic, the ring also undergoes chlorination: the halogenation of 4-arylated or (under more severe conditions) 5-arylated 1,2-dithiolen-3-thiones, for example, yields the corresponding 5- or 4-halogenated 3-ones.[10,120,154,155] Under still more severe conditions (prolonged action of excess of halogen in boiling tetrachloromethane), however, substitutive halogenation is accompanied by ring cleavage with loss of both sulphur atoms and formation of the corresponding derivatives of αβ-dihalogenocinnamic acids[156,157]:



X=Cl, Br

Even under mild conditions unsubstituted and alkylated 1,2-dithiolen-3-ones undergo only ring fission with sulphuryl chloride, sulphenyl chlorides, and chlorine, at the S–CO bond with the chlorides and at both S–CO and S–S bonds with chlorine (Table 15):[50,51]

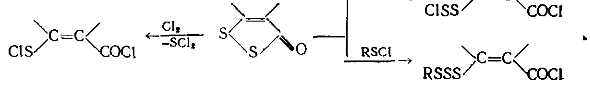


Table 15. Products of the cleavage of 1,2-dithiolen-3-ones by SO_2Cl_2,[50] RSCl,[51] and Cl_2.[50]

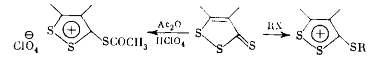
1,2-Dithiolen-3-one	Reagent	Product	Yield, %
	SO_2Cl_2 Cl_2 CH_3SCl C_6H_5SCl	ClSSCH=CHCOCl ClSCH=CHCOCl CH_3S_3CH=CHCOCl $C_6H_5S_3CH$=CHCOCl	50 72 43 83
4-Methyl-	SO_2Cl_2	ClSSCH=C(CH_3)COCl	68
5-Methyl-	SO_2Cl_2	ClSSC(CH_3)=CHCOCl	79

(*b*) Formation of 1,2-dithiolium salts

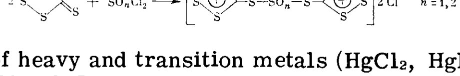
Alkylated[10,135,158–160] and acylated[105] trithiones usually yield 1,2-dithiolium salts:



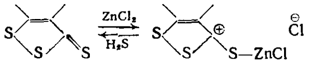
X = I, Br, Cl, HSO_4, HgI_3 etc.
R = Alk, CH_2COR[158] etc.

1,2-Dithiolen-3-ones react similarly with acetic anhydride[105] and with triethyloxonium fluoroborate[161,162]. Trithiones are converted into 3-chloro-1,2-dithiolium salts by the action of oxalyl chloride, trichloromethyl isocyanide dichloride, or thiocarbonyl chloride ten times as easily as are 1,2-dithiolen-3-ones[105,151]. These salts are formed also from 1,2-dithiolen-3-ones and phosphorus pentachloride or phosphoryl chloride[80,163], but not with phosphorus trichloride or thionyl chloride[80].

Under mild conditions trithiones form 2 : 1 ionic adducts with oxalyl[80], thionyl, or sulphuryl[101,164] chloride:



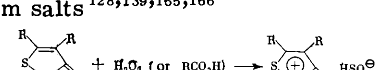
Halides of heavy and transition metals ($HgCl_2$, $HgBr_2$, HgI_2, $CdCl_2$, CdI_2, $ZnCl_2$, $FeCl_3$, $AgNO_3$, $SbCl_3$, $CuCl_2$, Cu_2Br_2, $AuCl_4$, $PdCl_2$, $PtCl_4$, $BiCl_3$, and $SnCl_4$) form with trithiones yellow crystalline complexes (1 : 1 or 1 : 2) also involving the thiocarbonyl group[10,101]:



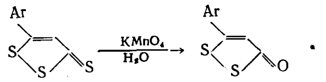
Trithiones form with 1,2-dithiolen-3-ones 1 : 2 donor–acceptor complexes[164].

(*c*) Oxidation and reduction

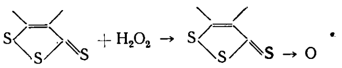
Oxidising agents convert alkylated trithiones into 1,2-dithiolium salts[128,139,165,166]



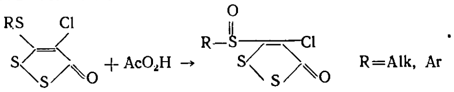
and arylated trithiones into 1,2-dithiolen-3-ones[120]



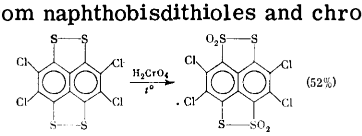
Trithiones can sometimes be oxidised to trithione *S*-oxides[167,168]:



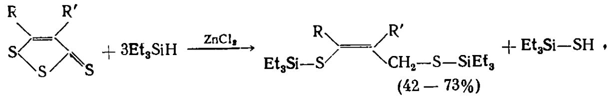
5-Alkyl(and aryl)thio-1,2-dithiolen-3-ones are oxidised only at the exocyclic sulphur atom with the formation of sulphinyl derivatives[118,169]:



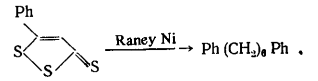
Heating with chromic and nitric acids oxidises 4,5-dimethyltrithione to acetic acid, and 5-*p*-methoxyphenyltrithione to anisic acid[101]. The only known example of oxidation of a dithiole sulphur atom is the formation of thiosultones from naphthobisdithioles and chromic acid[99]:



The reduction of trithiones by triethylsilane involves both thiocarbonyl and disulphide bonds[170]:

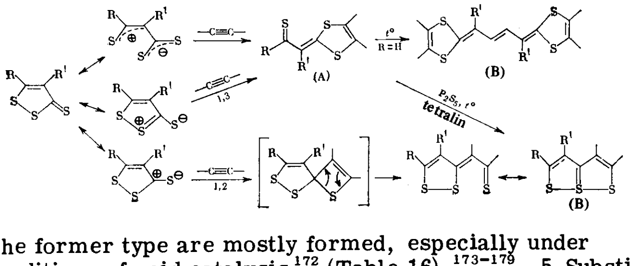


Sulphur is completely removed when trithiones undergo hydrogenation in the presence of Raney nickel, and the hydrocarbon residues dimerise[101]:



(*d*) Condensation

Alkynes. The discovery in 1964 of the reaction of trithiones with alkynes showed[171] that, depending on the reaction conditions and the nature of the substituents, the trithiones can react in one of the possible resonance structures, with the formation of compounds of types (A) and (B):



The former type are mostly formed, especially under conditions of acid catalysis[172] (Table 16).[173–179] 5-Substituted thiones are more reactive[171]. In the absence of a 5-substituent thioaldehydes (A: R = H) are formed; these are unstable, and when heated readily lose sulphur with the formation of biadducts of type (C).[174,179] In the absence of acids either a mixture of isomeric compounds (A) and (B) or solely (B) is produced (Table 17).[172–180] The isomers differ in their ultraviolet spectra[177]. 1,3-Dithiolylidene thioketones (A) are easily isomerised to thiothiophthens (B) by heating with phosphorus pentasulphide[176].

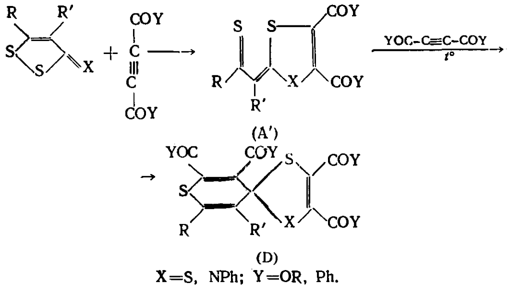
The reactivity of acetylenic compounds in these condensations falls in the sequence[175,176]

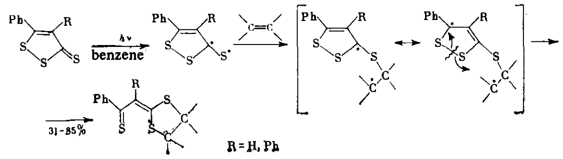
$$RO_2C—C{\equiv}C—CO_2R > HC{\equiv}C—CO_2R > Ar—C{\equiv}C—CO_2R > Ar—C{\equiv}C—H > Ar—C{\equiv}C—Ar\,.$$

Acetylenedicarboxylic esters are able to form not only 1 : 1 (A′) but also 2 : 1 (D) adducts or their mixtures in proportions depending on the reactivity of the alkyne and the temperature (Table 18):[173,174,176]



X=S, NPh; Y=OR, Ph.

Alkenes. Trithiones react with alkenes, in contrast to alkynes, only on irradiation, forming equimolecular adducts. Whereas 5-phenylated trithiones give 1,3-cycloaddition products with cleavage of the cyclic disulphide bond[181]



the 4-p-tolyl derivatives form adducts in which the ring remains intact[140]

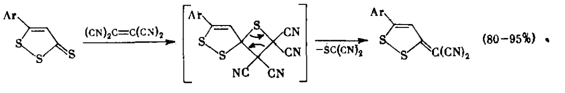
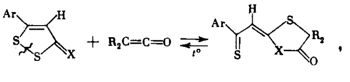
The condensation of 5-aryltrithiones with the electron-deficient tetracyanoethylene does not require exposure[182]:



In contrast to trithiones, 1,2-dithiolen-3-ones do not react with alkynes and alkenes[175,181].

Ketens. 1,2-Dithiolens containing exocyclic C=S, C=O, and C=NR double bonds react readily in the cold with ketens—more reactive unsaturated compounds—to form equimolecular addition products. However, this reaction is reversible, and at higher temperatures the adducts break down into the initial components[111,183–185]:



R = H, CH_3; X = S (30–70%); O (40%); NPh (65–90%)

Certain adducts rearrange into 1,2-dithiolylidenes on standing[112,184]:

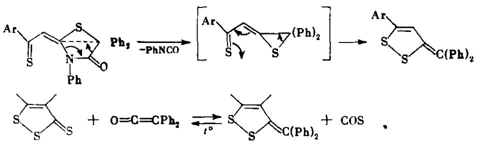


Table 18.

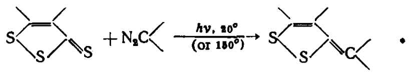
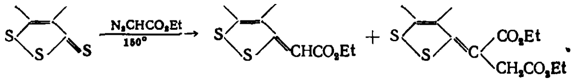
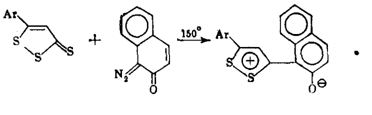
Carbenes and nitrens. Trithiones react extraordinarily readily with carbenes. Thus with diazoketones and with diphenyldiazomethane 1,2-dithiolylidenes are formed with loss of the thiocarbonyl sulphur[186]:



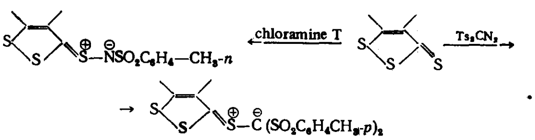
A mixture of 1 : 1 and 1 : 2 adducts is formed with the more reactive ethyl diazoacetate[186]:



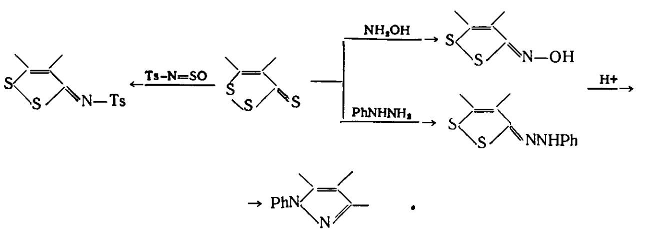
1-(1,2-Dithiolio)-2-naphthoxides are obtained from 1-diazodihydronaphthalen-2-one[186,187]



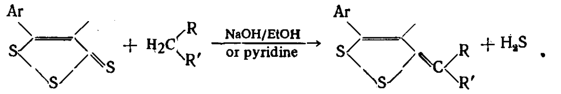
In some cases the thiocarbonyl group is preserved in the reaction of 4-phenyl- and benzo-trithiones with carbenes and nitrens. For the first time good yields have been obtained of stable thiocarbonyl ylides and their nitrogen analogues—imines[188]:



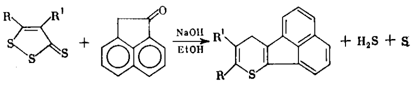
Hydroxylamine[10,189,190], phenylhydrazine[101], and *N*-sulphinyltoluene-*p*-sulphonamide[191]. Like ketones and thioketones, 1,2-dithiolen-3-thiones and -ones condense with these compounds to form the corresponding 3-imine derivatives. Phenylhydrazones are readily converted into pyrazoles[101]:

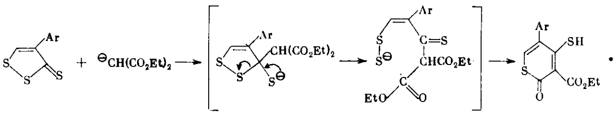


CH-Acids. Like thioketones, 5-aryltrithiones react readily with CH-acids—malononitrile, acenaphthenone, and malonic and cyanoacetic esters[101,192]—and with α-bromo-ketones[160] to form 1,2-dithiol-3-ylidenes[10,101]:

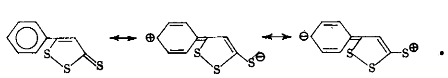


In contrast to the 5-aryl derivatives, the reaction of other trithiones with CH-acids usually involves cleavage of the ring[10,101,192]:

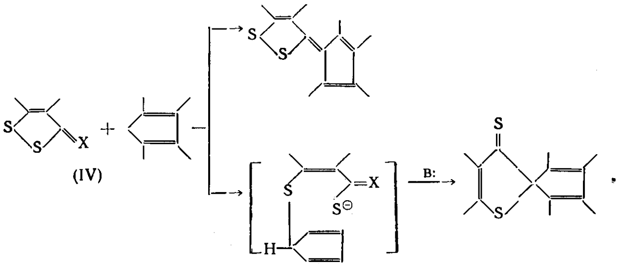




The great stability of 5-aryltrithiones towards cleavage is attributed to resonance stabilisation, which is impossible with the 4-aryl compounds:

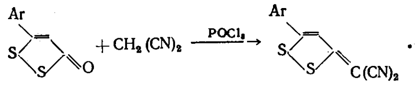


1,2-Dithiolen-3-thiones, -ones, and -ylidenes (IV) give with tetraphenylcyclopentadiene (or fluorene) in an alkaline medium a mixture of condensation and ring-cleavage products—dithiafulvalenes and spiro-compounds[123]:



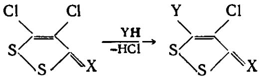
X=S, O, C(CN)2

In contrast to 5-aryl-1,2-dithiolen-3-thiones, the 3-ones can be condensed with malononitrile in the presence of phosphoryl chloride[125]:



(*e*) Substitution with preservation of the ring

Numerous reactions of 5-chloro- and 4,5-dichloro-1,2-dithiolen-3-ones and -imines have shown that the 5-halogen is very easily substituted by any nucleophile[193–198], but a 4-halogen is not replaced even with excess of a nucleophile[196] (Tables 19–21):[118,120,121,170,193–197]



X=O, NR; Y=RS, RSO₂, RO, R₂N, RO—C(=S)—S, NH₂—C(=NH)—S etc.

The difference in reactivity between substituents at positions 4 and 5 is attributed to the difference in polarity between the $C_{(4)}$ and $C_{(5)}$ carbon atoms (see above)[133]; great activity of the 5-halogen is indicated also by the vinylogy principle, since 5-chloro-1,2-dithiolen-3-one is a vinylogue of carboxylic acid chlorides[193].

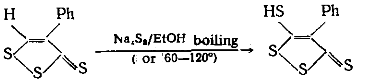
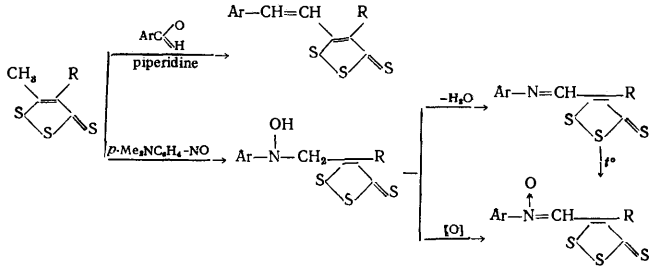
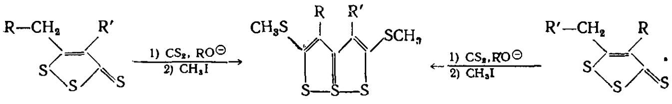
An unusual reaction has been reported[199] between sodium disulphide and 4-phenyltrithione, when 5-mercaptotrithione is obtained:



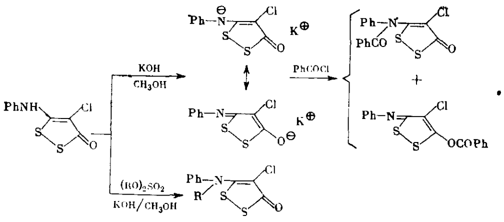
Trithiones containing a methyl or substituted methyl group at position 5 react with aromatic aldehydes to form aldol condensation products; an anil and a nitrone are obtained with p-nitroso-NN-dimethylaniline[10,81,101]:



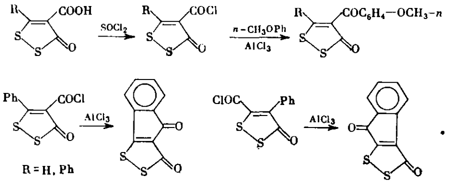
The condensation with carbon disulphide of trithiones containing a substituted methyl group at position 5, in the presence[178] or the absence[200] of a base, gives after methylation bismethylthiothiothiophthens:



A 5-amino-group present in a 1,2-dithiolen-3-one may be both acylated and alkylated[196,201]:

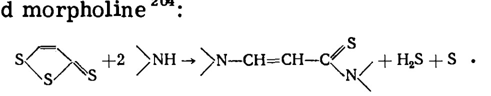


The stability of the 1,2-dithiolen ring is demonstrated by Friedel–Crafts reactions[82,202,203]:

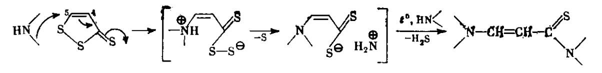


(*f*) Reactions with nucleophilic reagents accompanied by ring fission

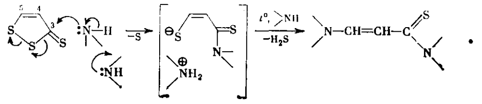
The action of nucleophiles on reactive 1,2-dithiolen-3-thiones opens the ring. Thus β-aminothioacrylamides are formed from unsubstituted trithione and its 4-cyano-derivative with excess of such amines as aniline, *p*-toluidine, and morpholine[204]:



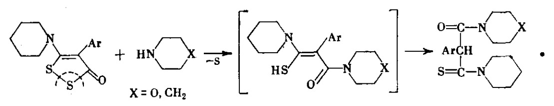
However, the authors' assumption of initial rupture of the $C_{(5)}-S_{(1)}$ bond



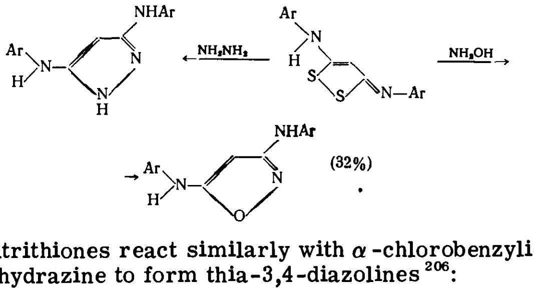
appears questionable. A more probable mechanism involves synchronous cleavage of C(S)–S and S–S bonds, with the amine attacking not $C_{(5)}$ but the thiocarbonyl $C_{(3)}$ atom:



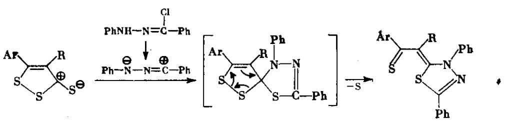
The proposed mechanism is consistent with the cleavage of 4-aryl-5-piperidino-1,2-dithiolen-3-ones by morpholine and piperidine, when diamides of arylmonothiomalonic acids are formed[197]:



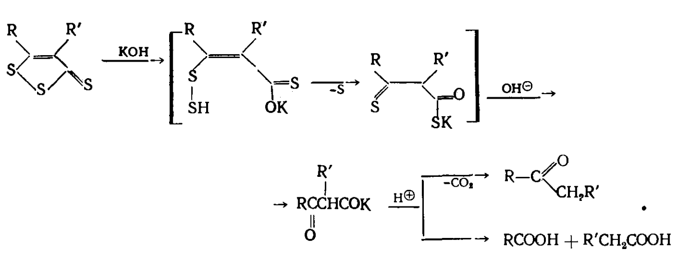
The reactions of 5-arylamino-1,2-dithiolen-3-imines with hydrazine (or phenylhydrazine) and with hydroxylamine involve ring opening with formation of a pyrazole and a 1,2-oxazole[191,205]:



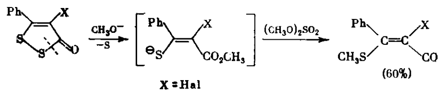
5-Aryltrithiones react similarly with α-chlorobenzylidene-phenylhydrazine to form thia-3,4-diazolines[206]:



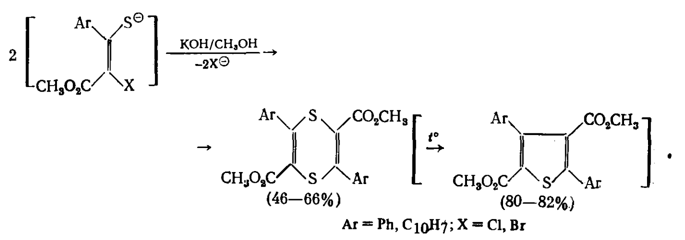
The 1,2-dithiolen ring is cleaved by alkalis[207] still more easily than by amines. Hydrolysis of trithiones with excess of alkali yields derivatives of acetoacetic acid, which then split into a ketone or the corresponding acids[10,101]:



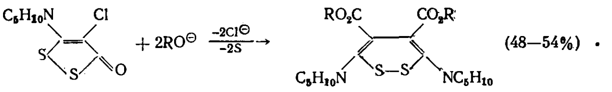
The hydrolysis of 5-phenyl-1,2-dithiolen-3-one by excess of potassium hydroxide gives acetophenone[71]. However, the action of an equimolecular quantity of methanolic alkali yields the β-methylthio-cinnamic ester[208]:



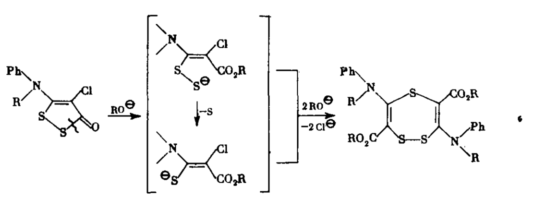
In the alkaline cleavage of 5-aryl-4-halogeno-1,2-dithiolen-3-ones the resulting fragments undergo "head to tail" condensation to 1,4-dithiacyclohexadiene derivatives with liberation of halide ions[120,207]:



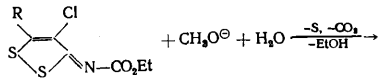
When 4-chloro-5-piperidino-1,2-dithiolen-3-ones are hydrolysed, such fragments undergo "head to head" dimerisation with formation of 1,2-dithiacyclohexadiene derivatives[208,209]:

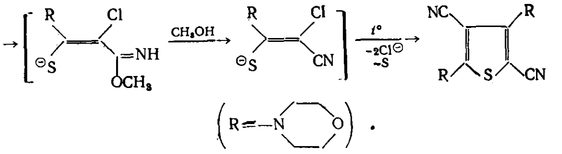


In the reaction of 5-*N*-alkylanilino-4-chloro-1,2-dithiolen-3-ones with alcoholic alkali the primary product of cleavage of the cyclic S–CO bond is preserved in only one unit of the resulting 1,2,5-trithiacycloheptadiene structure[194,210]:

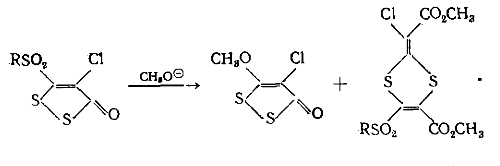


4-Chloro-1,2-dithiolen-3-imines are far more stable and are broken down only by boiling methanolic alkali, with the formation of thiophen derivatives[193]:

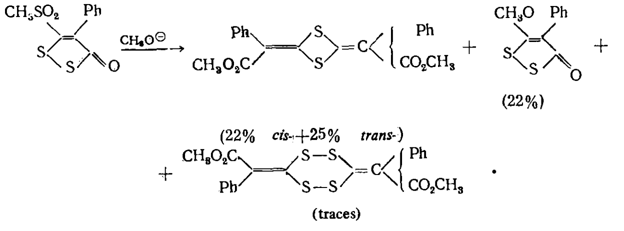




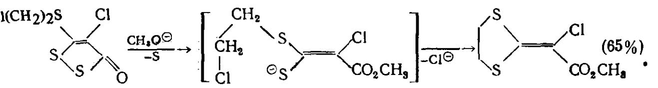
The reaction of 4-chloro-5-sulphonyl-1,2-dithiolen-3-ones with alkoxides gives 1,3-dithiafulvalenes together with the 5-alkoxy-4-chloro-1,2-dithiolen-3-one:[211]



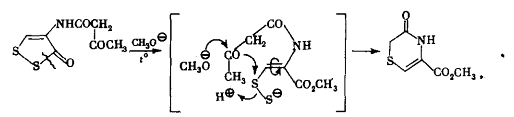
In the absence of a 4-chloro-substituent competing reactions lead to the formation of several compounds, with 2,4-dialkylidene-1,3-dithietans predominating[211]:



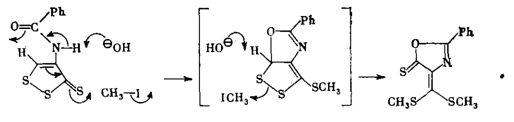
The alkaline cleavage of 4-chloro-5,2′-chloroethylthio-1,2-dithiolen-3-one yields a 2-alkylidene-1,3-dithiolan[211]:



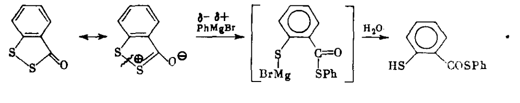
Under these conditions 4-acylamino-1,2-dithiolen-3-ones form nitrogen heterocycles. Thus the 4-acetoacetamido-derivative gives a low yield of a 3-oxodihydrothiazine derivative[212]:



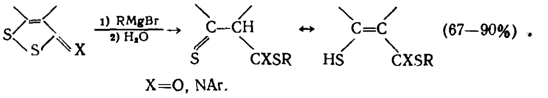
However, methylation of 4-acylamino-trithiones in the presence of potassium t-butoxide or hydroxide gives oxazoline-5-thiones[213]:



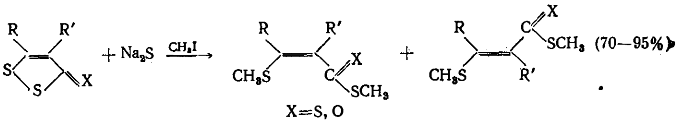
4,5-Benzo-1,2-dithiolen-3-one is cleaved by phenylmagnesium bromide at the disulphide bond with the formation of *o*-mercaptothiobenzoic *S*-esters[214]:



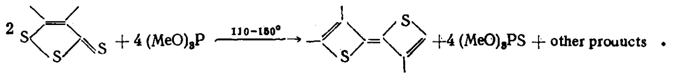
5-Amino-1,2-dithiolen-3-ones and the 5-aryl-3-imines react similarly with Grignard reagents, but the cleavage products exist predominantly in the thioketone—not the thioenolic—form[215,216]:



The reaction of trithiones and 1,2-dithiolen-3-ones with sodium sulphide also involves rupture of the disulphide bond with formation of unsaturated mono- or di-thioesters[217]:



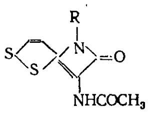
Heating alkylated trithiones with excess of an organic phosphorus(III) compound is assumed to yield a thietenylidene[218]:



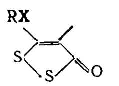
4. Applications

(*a*) Medicinals

Trithiones occur in Nature (in plants)[95]. The 1,2-dithiolen ring forms a fragment of the antibiotics thiolutin (VIa), holomycin (VIb), etc.[212] Several thiones are used in medicine to stimulate the functioning of the liver and the gall-bladder[95]. 5-*p*-Methoxyphenyl-1,2-dithiolen-thione—Sulfarlem (DDR)[219]—and -3-one[220] are non-toxic bile-producing preparations, but the 4-aryltrithiones are less effective[219]. Trithiones, especially those containing a thiophen residue at position 5, have a diuretic effect[221].



(VI); R=CH_3 (a), H(b)



(VII); X=SO_2 (a), SO(b), S(c)

(*b*) Insecticides

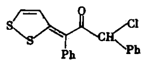
4-Aroyl-5-aryltrithiones[85], 5-chloro-4-phenyl-1,2-dithiolen-3-ones[222], and *N*-aryl-4,5-dichloro-1,2-dithiolen-3-imines[223] are fungicides suitable for the treatment of grain. 1,2-Benzodithiolen-3-thiones and -oximes both possess antifungal properties[189,190,224]. 5-Alkyl-sulphonyl-, -sulphinyl, and -thio-1,2-dithiolen-3-ones (VIIa–c)[170,195,225–227] are bactericides and fungicides effective against moulds and pathogenic fungi[170,195], as are also 5-aminated 4-chloro-1,2-dithiolen-3-ones[225,226] and -3-phenyl-imines[119]. 5-Methoxycarbonylthio- and 5-morpholinothio-4-phenyltrithiones are used as insecticides and fungicides[228,229].

(*c*) Additives to lubricating oils

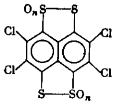
Alkylated trithiones can be used in lubricating oils as antioxidant and anti-seizing additives. 4-Neopentyl-5-t-butyltrithione is especially effective because of its better solubility in petroleum oils[230]. Trithione *S*-oxides[168,169] and products of the reaction of trithiones with polyamines[231] and phosphites[218] are multipurpose additives for lubricating oils. 4-Substituted trithiones act as corrosion inhibitors in lubricating oils[93].

(*d*) Other fields

Chlorinated 3-acylmethylene-1,2-dithiolens (VIII),[126] chlorinated naphthodithioles (IXa), and dioxides of the latter (IXb)[99]



(VIII)



(IX); *n* = 0 (a), 2 (b)

are used as yellow colorants for thermoplastics. Compounds (IX) are employed also as semiconductors and dielectrics[99]. 5-Methoxycarbonylthio- and 5-morpholinothio-4-phenyltrithiones find application as vulcanisation accelerators[228,229].

Phenylated trithiones are used in analytical practice for the extraction and the photometric or gravimetric determination of platinum(II) or mercury(II) as water-insoluble orange complexes $M^{II}Cl_2R_2$.[103,232,233]

The Concept of Vacant *d* Orbitals and the Causes of the Differences between the Properties of Nitrogen and Phosphorus Compounds

D.A.Bochvar, N.P.Gambaryan, and L.M.Epshtein

Comparison of non-empirical calculations on analogous nitrogen and phosphorus compounds shows that the presence of vacant *d* orbitals in the valence shells of the elements in the Third Period cannot be the real cause of the differences between the properties of nitrogen and phosphorus compounds and that the effects are ultimately determined by the differences between the effective sizes of the valence *s* and *p* orbitals of these elements.
The bibliography includes 47 references

CONTENTS

I. INTRODUCTION

This review discusses the problem which properties of nitrogen and phosphorus atoms determine the fundamental differences between the properties of the compounds of these elements. It begins with a brief account of the properties of isolated nitrogen and phosphorus atoms and their valence states. The discussion is based on the standpoint necessary for developing the subsequent reasoning.

II. NITROGEN AND PHOSPHORUS ATOMS AND THEIR VALENCE STATES

The properties of nitrogen and phosphorus atoms are determined by their positions in Mendeleev's periodic table. The structure of the Table became comprehensible after quantum mechanics had been developed and had yielded the solution of the problem of the hydrogen atom. It was found that the electron in the hydrogen atom can have a discrete (and not continuous as in the classical treatment) series of states whose energy E_n is determined by the principal quantum number n:

$$E_n = -\frac{me^4}{2\hbar^2}\cdot\frac{1}{n^2};\quad n = 1, 2, 3 \ldots .$$

In addition to the energy, the state of the electron is characterised by its angular momentum, which is determined by the orbital quantum number l:

$$M^2 = \hbar^2 l(l+1);\quad l = 0, 1, 2 \ldots$$

The range of momenta in states with a definite energy is limited:

$$l \leqslant n-1.$$

States with zero angular momentum ($l = 0$) are referred to as *s* states, those corresponding to $l = 1$ are *p* states, those corresponding to $l = 2$ are *d* states, etc. When the *s* states, for which the angular momentum is zero, are excluded, the states are distinguished by the direction of the angular momentum, which is determined by the magnetic quantum number m:

$$M_z = \hbar m;\quad m = 0, \pm 1, \pm 2, \ldots, \pm l.$$

Fig. 1 presents a schematic arrangement of the possible states of the electron in the hydrogen atom. The excited levels of hydrogen are degenerate, i.e. a whole set of different states corresponds to the same energy. The energy levels are degenerate not only as regards direction but also as regards momentum, i.e. the energies of the *s*, *p*, and *d* states are identical.

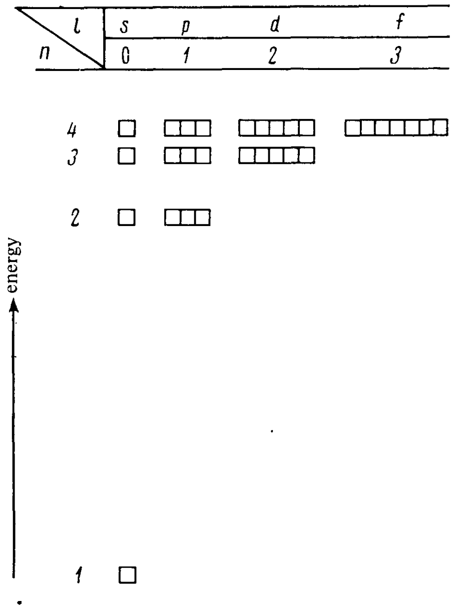

Figure 1. Schematic illustration of the possible electronic states in the hydrogen atom.

If the electrons did not interact, an identical pattern of possible electronic states would persist in a multielectron atom and it would be possible to determine the structure of any atom by filling these states in succession, taking into account the Pauli principle. In reality electrons repel one another. For example, the 2*s* electron of lithium is not only not attracted to the nucleus, but is actually repelled by the inner 1*s* electrons (Fig. 2), the overall effects of which can be described as shielding of the nucleus—the decrease of the actual nuclear charge to an "effective" charge. The shielding conditions depend on the nature of the electron cloud. The density of the electron cloud in the *s* states is a maximum in the region of the nucleus; this applies not only to the 1*s* state but also to the 2*s* and 3*s* states (Fig. 3*a*). In the *p* states, the density of the electron cloud at the nucleus is zero (Fig. 3*b*) and in the *d* states the density is again zero at the nucleus and increases very slowly (Fig. 3*c*). Accordingly, the shielding of the nucleus by other electrons is much more marked for a *d* electron than for a *p* electron and for the latter it is more marked than for an *s* electron. As a result, the degeneracy as regards momentum is removed: the energies of the *s*, *p*, and *d* electrons are no longer the same. Fig. 4 presents a schematic arrangement of the possible electronic states in a multielectron atom.

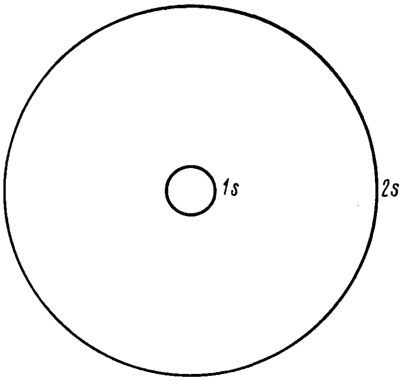

Figure 2. The lithium atom. The radii of the circumferences correspond to the maximum radial densities of the 1*s* and 2*s* electrons[1].

Nitrogen and phosphorus atoms are located in Group V but in the Second and Third Periods. We shall consider how their properties are determined by their positions. We shall begin with the ionisation potential—a property of decisive importance for chemistry (Fig. 5).

Fig. 2 shows that the valence electron of lithium is remote from the nucleus from which it is effectively shielded by the 1*s* electrons and the ionisation potential is therefore very low. In the beryllium atom, the increased nuclear charge is incompletely shielded, and the ionisation potential is greater. Although the nuclear charge has again increased in the boron atom, the additional electron is now located in a *p* orbital for which the shielding is more marked, as a result of which the ionisation potential is smaller than for beryllium. The additional electron in carbon is located in the next vacant *p* orbital and the increased nuclear charge, which is incompletely compensated by shielding, leads to an increase of the ionisation potential; this effect is even greater for nitrogen and in the oxygen atom the additional electron enters a *p* orbital already occupied by an electron. The mutual repulsion of the two electrons in the same orbital is so powerful, that, despite the increased nuclear charge, the ionisation potential of oxygen is smaller than that of nitrogen. Thus the ionisation potential of nitrogen is greater than those of its immediate neighbours—not only carbon but also oxygen:

	C	N	O
I, eV	11.256	14.53	13.614

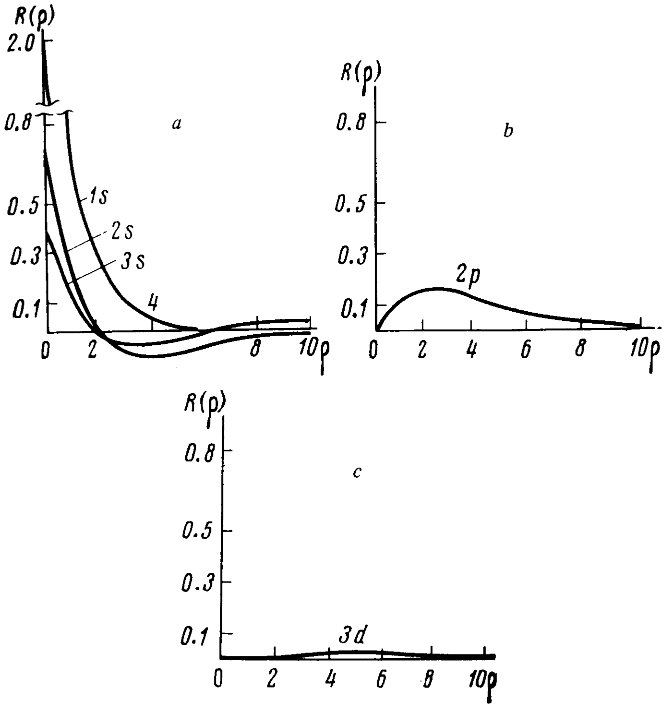

Figure 3. The radial wave functions *R*(ρ) of the hydrogen atom (ρ is the distance from the nucleus in atomic units).

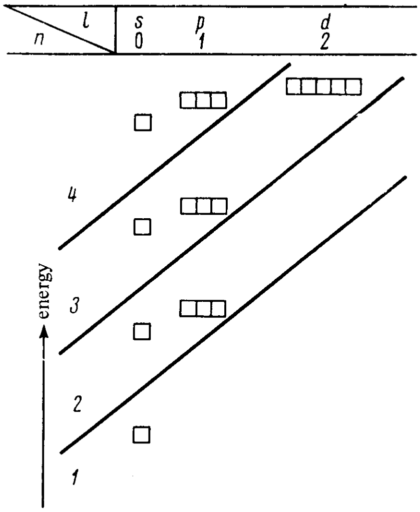

Figure 4. Schematic illustration of the arrangement of atomic orbitals in terms of energies in a multielectron atom.

The same qualitative pattern holds for the Third Period: the ionisation potential of phosphorus is greater than those of silicon and sulphur:

	Si	P	S
I, eV	8.15	10.48	10.36

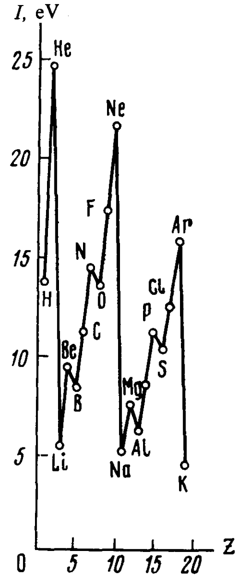

Figure 5. Ionisation potentials of atoms.

However, despite the complete repetition of qualitative features, there is a considerable quantitative difference between nitrogen and phosphorus. The valence electrons of the phosphorus atom are at a much greater distance from the nucleus than in nitrogen, so that, despite the higher effective nuclear charge, the ionisation potential of phosphorus is approximately 4 eV smaller than that of nitrogen.

Another atomic property very important for chemistry is electron affinity. In the carbon atom, the nucleus is incompletely shielded by valence electrons, there is a vacant *p* orbital, and the atom exhibits an appreciable electron affinity. In the nitrogen atom, the additional electron must enter a *p* orbital which is already occupied and the interelectronic repulsion is so great that the electron affinity is negligible. In the oxygen atom, the increased nuclear charge partly compensates this effect and the electron affinity increases:

	C	N	O
E, eV	2.1	0.05	1.47

The same qualitative pattern is repeated for the atoms of the Third Period: the electron affinity of phosphorus is smaller than that of its neighbours—silicon and sulphur:

	Si	P	S
E, eV	1.46	0.77	2.07

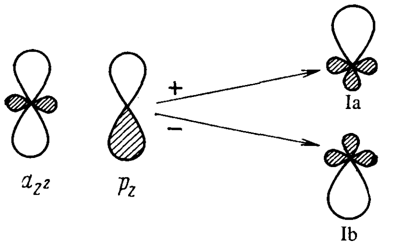
On the other hand, the mutual repulsion of the electrons located in the same orbital in the phosphorus atom with its larger valence orbitals is less marked than in nitrogen. As a result, the electron affinity of phosphorus is greater than that of nitrogen. The more ready deformation of the electron cloud of phosphorus under the influence of external fields, i.e. the greater polarisability of the phosphorus atom compared with the nitrogen atom, is associated with the greater size of the valence orbitals of the phosphorus atom and the greater diffuseness of its electron cloud. Consequently, owing to the greater size of phosphorus orbitals compared with nitrogen orbitals, the ionisation potential of phosphorus is much smaller, its electron affinity is much greater, and its polarisability is greater.

We shall consider yet another difference between phosphorus and nitrogen. The valence shell of the phosphorus atom contains *d* orbitals and the question of their properties arises. The states of hydrogen are arranged in Fig. 1 in terms of energies on a uniform scale. A similar arrangement of the electrons in phosphorus is impossible (the ionisation potential of the valence electron of the phosphorus atom is of the order of 10 eV, while the ionisation potential of the 1*s* electrons of phosphorus is of the order of thousands of electron-volts). Fig. 4 merely shows qualitatively that the energy of the vacant *d* orbitals is higher than that of the *s* and *p* orbitals of the next shell. It is seen from the atomic spectra of phosphorus[2] that the first transitions are $3p \rightarrow 4s$ (7–8 eV), are followed next by $3p \rightarrow 4p$ transitions (8–8.5 eV), and only then by transitions to 3*d* orbitals (about 9 eV). Consequently, despite the fact that the *d* orbitals of the phosphorus atom are located in the valence shell, they are less favourable than the 4*s* and 4*p* orbitals in the next shell. As already mentioned, this is because the shielding of the *d* orbitals from the nucleus by other electrons is particularly effective. The weak attraction of *d* electrons to the nucleus leads to the expansion of their orbitals. As a result of the diffuseness of the *d* orbitals of phosphorus, their overlapping with the valence orbitals of neighbouring atoms is negligible. With this statement, we complete the consideration of the properties of isolated phosphorus and nitrogen atoms and proceed now to an examination of their valence states.

Phosphorus and nitrogen atoms each have three unpaired electrons located in *p* orbitals. The p^3 state may be regarded as their ground valence state, despite the fact that the bonding orbitals acquire some *s* character and the lone electron pair occupies an orbital with an admixture of *p* character and not a pure *s* orbital[3].

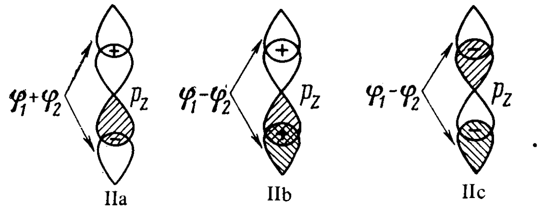
The lone electron pair can form a bond with a proton, with an alkyl cation, with BF_3, and in general with Lewis acids. This results in the formation of ammonium and phosphonium compounds in which tetravalent nitrogen and phosphorus cations are in a tetrahedral sp^3-hybrid valence state. If the substituents are not the same, the tetrahedron is distorted, the distortion being particularly pronounced in compounds such as phosphine and amine oxides; nevertheless, the valence states in these compounds can be regarded as largely sp^3 states. Compounds of the type NR_5 are known, but their discoverer (Schlenck) already showed that the bonds in such compounds are non-equivalent[4]. They are salt-like and contain the tetravalent ammonium cation NR_4^+ and the carbanion R^-.

On the other hand, penta- and hexa-coordinate compounds with more or less equivalent bonds are known for phosphorus. Pentacoordinate phosphorus compounds, for example PF_5, have a trigonal bipyramidal structure. It has come to be assumed that the valence shell of phosphorus is expanded in these compounds owing to the vacant *d* orbital. Bonds with three equatorial ligands are formed by the trigonal sp^2-hybrid phosphorus orbitals, while the remaining p_Z orbital is hybridised with the d_{Z^2} orbital in order to form bonds with the axial ligands. The hybrid *dp* orbital (Ia) obtained when the above orbitals are combined is involved in the formation of a bond with the upper ligand and the residual hybrid *dp* orbital (Ib) forms a bond with the ligand located at the lower vertex of the bipyramid.



It is therefore usually assumed[5] that phosphorus exists in the dsp^3 valence state.

Nevertheless the involvement of *d* orbitals is by no means necessary for the description of the bonding in pentacoordinate phosphorus compounds. This is easily shown using the molecular orbital method[6]†. The linkages with the three ligands in the equatorial plane are again regarded as two-centre bonds formed by the trigonal sp^2-hybrid orbitals of phosphorus. In order to describe the bonds with the axial ligands, we construct molecular orbitals from the p_Z orbital of phosphorus and the atomic orbitals of the ligands. The overlap integral for the symmetrical combination of the ligand orbitals $\varphi_1 + \varphi_2$ with the p_Z orbital of phosphorus is zero‡ [the positive overlap with the upper lobe of the p_Z orbital is compensated by the negative overlap with the lower lobe of this orbital (IIa)]. The interaction is therefore impossible and this combination constitutes the non-bonding orbital ψ_2, the energy of which is equal to the energy of the atomic orbitals of the ligands (Fig. 6).



On the other hand, the antisymmetric combination of the ligand orbitals $\varphi_1 - \varphi_2$ forms with the p_Z orbital of phosphorus the energetically extremely favourable and highly bonding three-centre molecular orbital ψ_1 (Fig. 6) [the positive overlap of the ligand orbitals with the upper lobe of the p_Z orbital of the phosphorus atom $\oplus\cdot\oplus$ is supplemented by the positive $\ominus\cdot\ominus$ overlap with the lower lobe (IIb)] and the three-centre antibonding molecular orbital ψ_3 [the negative overlap $\oplus\cdot\ominus$ with the upper lobe of the p_Z orbital is added to the negative $\ominus\cdot\oplus$ overlap with the lower lobe (IIc)].

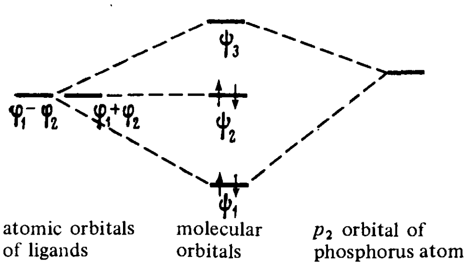


Figure 6. Correlation diagram for a three-centre bond.

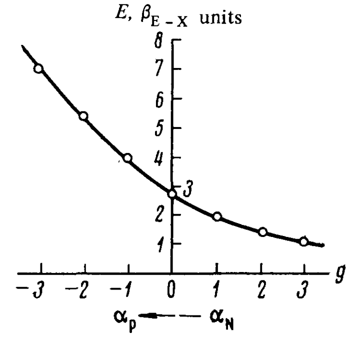

Figure 7. Dependence of the energy E of the three-centre bond X–E–X on the Coulombic integral of the central atom $\alpha_E = \alpha_X + g\beta(E - X)$ (the Hückel approximation). The arrows show the direction of the change in α_E from N to P in parallel with the change in the ionisation potential.

In the resulting molecular orbitals—the bonding orbital ψ_1, the non-bonding orbital ψ_2, and the antibonding orbital ψ_3—four-electrons should be located: the two electrons of the lone pair of phosphorus and one electron from each ligand. They occupy the bonding ψ_1 molecular orbital and the non-bonding ψ_2 orbital and, although the electrons in the non-bonding orbital give no energy gain, the bonding molecular orbital is energetically so favourable that the two electrons located in it are sufficient to ensure the formation of a linkage between the phosphorus atom and the ligands located at the upper and lower vertices of the bipyramid. The energy of the three-centre "four-electron" bond depends strongly on the energy of the lone pair electrons. This energy increases rapidly with decrease of the ionisation potential of the lone electron pair and the three-centre bond must therefore be much more favourable for phosphorus than for nitrogen (Fig. 7).

We shall consider now how the above description is altered when account is taken of the *d* orbital of the phosphorus atom. In contrast to the p_Z orbital, the *d* orbital

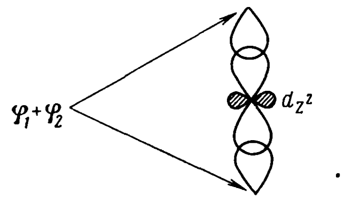
---

† The description by the valence bond (VB) method without resorting to *d* orbitals corresponds to the resonance of five ionic structures:

.

‡ The overlapping of the functions is described by the integral of the product of these functions (the overlap integral S): $S = \int \bar{\Phi}_1 \Phi_2 d\tau$ (integration over the entire space). The parts of the space where the two overlapping functions have the same sign make a positive contribution to the integral, while those regions where the signs of the functions are different make a negative contribution.

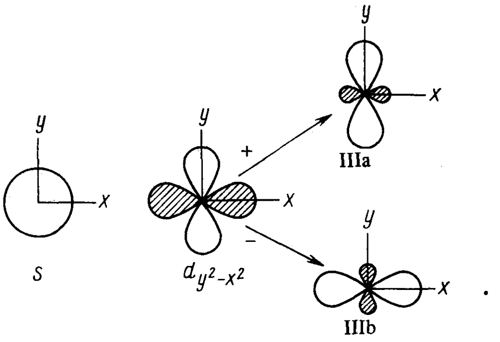
of phosphorus can interact with the symmetrical combination $\varphi_1 + \varphi_2$ of the ligand orbitals (IId):



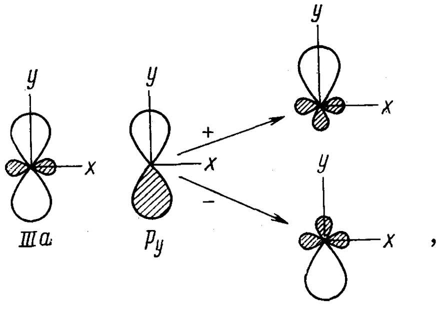
IId

But, since the d orbital is energetically unfavourable and very diffuse, its interaction can only be very weak. Because of it, the non-bonding molecular orbital ψ_2 becomes slightly bonding. However, this weak interaction does not play a fundamental role.

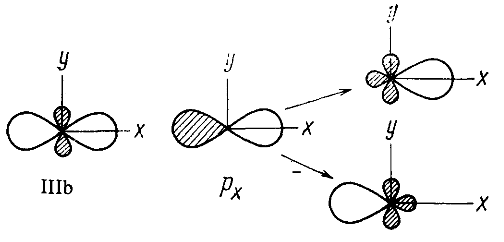
In the traditional description of ions containing hexacoordinate phosphorus such as PF_6^-, one postulates an expansion of the valence shell of phosphorus by two d orbitals. One of these, the d_{z^2} orbital, is hybridised with the p_z orbital, forming hybrid dp orbitals directed to the upper and lower ligands. This description is exactly the same as that of the bonds with the axial ligands in PF_5. A second d orbital of phosphorus, namely the $d_{y^2-x^2}$ orbital, is invoked, in addition to the s, p_x, and p_y orbitals to describe the bonds with the four ligands in the equatorial plane. We shall describe the hybridisation in stages. On combining the $d_{y^2-x^2}$ orbital with the s orbital, we obtain orbitals extended along the y axis, ($s + d_{y^2-x^2}$, IIIa) and along the x axis ($s - d_{y^2-x^2}$, IIIb):



The first of these forms with the p_y orbital two orbitals directed to the ligands located on the y axis:



while the second forms with the p_x orbital two orbitals directed to the ligands located on the x axis:



Each of the six hybrid phosphorus orbitals obtained forms a two-centre bond with the atomic orbitals of the ligands. In this description, it is assumed that phosphorus is in the d^2sp^3 valence state.

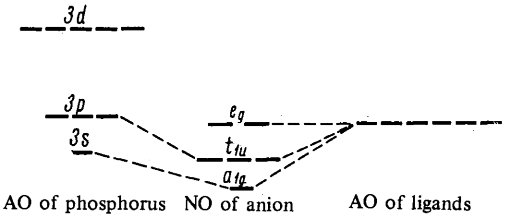


Figure 8. Correlation diagram for an octahedral anion.

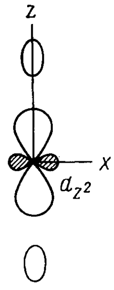
However, as for the pentacoordinate phosphorus compounds, it is found that the hypothesis of the expansion of the valence shell is not essential for a description of the bonds between phosphorus and the ligands in its hexacoordinate compounds. Indeed, the sum of the atomic orbitals of all the ligands is combined with the s orbital of phosphorus, forming an energetically very favourable bonding seven-centre molecular orbital (group designation a_{1g}, Fig. 8).

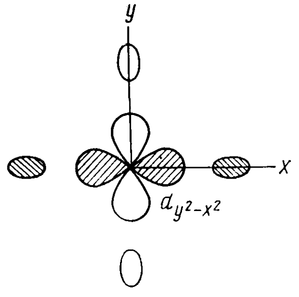
The antisymmetric combination of the ligand orbitals located on the z axis forms a strongly bonding three-centre molecular orbital with the p_z orbital of the phosphorus atom [similar to the three-centre linkage (IIb) between phosphorus and the axial ligands in PF_5]. Exactly the same three-centre molecular orbitals are obtained from the p_x (and p_y) orbitals of the phosphorus atom and the antisymmetric combination of the orbitals of the ligands located along the x (and y) axis. The energies of these three three-centre molecular orbitals are the same, i.e. they are degenerate (group designation t_{1u}, Fig. 8).

Eight electrons are located in the resulting orbitals—one seven-centre and three three-centre orbitals. The remaining four electrons (there are altogether twelve electrons: six from the ligands, five from the phosphorus atom, and one additional electron, since hexacoordinate phosphorus species exist in the form of anions) are distributed in two degenerate non-bonding molecular orbitals formed from the ligand orbitals alone (group designation e_g, Fig. 8). These two non-bonding molecular orbitals are shown in diagrams IVa and IVb. Although the last four electrons make no contribution to the bonding, the energy gain due to the eight electrons located in the strongly bonding molecular orbitals is so great that it is quite sufficient to account for the bonding between phosphorus and the ligands in its octahedral anions (Fig. 8).

We shall now consider the changes in the above pattern when account is taken of the phosphorus *d* orbitals. The symmetry of two of the phosphorus *d* orbitals (the d_{z^2} and $d_{y^2-x^2}$ orbitals) is such that they can interact with the non-bonding molecular orbitals e_g.



(IVa)



(IVb)

Next one can repeat what has already been said in the discussion of the pentacoordinate phosphorus compounds. Owing to the diffuseness and the energetically unfavourable nature of the phosphorus *d* orbitals, this interaction makes no significant contribution to the bonding: the non-bonding orbitals e_g become slightly bonding. It is clear from the foregoing that the concept of the expansion of the valence shell of phosphorus and of the existence of its dsp^3 and d^2sp^3 valence states is not essential for the description of the bonding in its pentacoordinate and hexacoordinate compounds.

III. NON-EMPIRICAL CALCULATIONS ON ANALOGOUS NITROGEN AND PHOSPHORUS COMPOUNDS

We shall now proceed to a comparison of the main classes of nitrogen and phosphorus compounds and shall attempt to find a fairly probable physical explanation of the differences between their properties. The traditional explanation of these properties is based on the concept of *d* orbitals. The concept of vacant *d* orbitals of silicon, phosphorus, and sulphur is widely used in the discussion of the properties of the compounds formed by these atoms[7-9]; *d* orbitals are invoked to account for the characteristics of the elements of the Third Period in relation to those of the Second Period.

The concept of *d* orbitals is based on the fact that the valence electrons of the elements of the Second Period are in the second shell, where there are no *d* orbitals, while the valence electrons of the elements in the Third Period are in the third shell. Apart from the *s* and *p* states, *d* states are possible in the third shell. Consequently, in contrast to the elements of the Second Period, those of the Third Period have vacant *d* orbitals in the valence shell. This led to the conclusion that the valence shell may be expanded and that additional bonds may be formed in pentacoordinate and hexacoordinate compounds via the *d* orbitals. The electron-accepting properties of the elements of the Third Period are accounted for by these orbitals and bonding with these elements and reactivity have been described with their aid, for example, by Ivanov and Zheltukhin[10]. This concept proved attractive and has been rapidly and extensively adopted[11]. This is, as it were, the chemical aspect of the problem of vacant *d* orbitals.

Qualitative considerations were followed by attempts to confirm them by calculations, which immediately encountered difficulties[12,13]. It was shown above that the *d* orbitals of the phosphorus atom are energetically very unfavourable and diffuse and are therefore incapable of effective interaction. This is also true of the *d* orbitals of the silicon and particularly sulphur atoms[2]. When atomic *d* orbitals are used in the calculation, as has been done for other valence orbitals, it is therefore immediately found that the *d* orbitals can play no role. It was then postulated that the atomic *d* orbitals in the molecule are altered (compressed), and modified *d* orbitals began to be used in calculations in place of the *d* orbitals of the free atoms. Since the contribution of these modified orbitals is found to be appreciable (see, for example, Refs. 14–17), it was concluded on this basis that the calculation confirms the *d* orbital concept.

Nevertheless the modified *d* orbitals have essentially no relevance to the vacant orbitals in the valence shell of the atom. They play the role of corrections in the calculation[18]. Thus a new aspect of the problem of *d* orbitals arose. In recent years there has been a vigorous growth of the number of quantum-chemical calculations, increasingly complex computational methods being devised and applied. For each new version of the calculation, the methodological problems have been solved, particularly the problem of the basis set—the set of initial functions from which the wave function of the molecule is constructed. The specific problem of the advantages of expansion of the basis set by additional functions of the *s* and *p* type or functions of the *d* type has been solved among others. This problem is associated with purely methodological difficulties and its chemical significance is almost or completely nil. The inadequate separation of these two aspects of the *d* orbital problem entails a multiplicity of misunderstandings. In the discussion of the concept of *d* orbitals, it is therefore useful to enumerate the possible situations in order to examine the available data and to attempt to discover which situation corresponds to reality.

1. Vacant atomic *d* orbitals of the valence shell of the elements of the Third Period influence directly the chemical properties of the latter, interacting effectively with the valence orbitals of the neighbouring atoms.

2. Orbitals of the *d* type have nothing in common with the atomic orbitals. They are introduced into the calculations in order to expand the basis set and play the role of corrections. Such corrections, which are in no way related to the presence or absence of *d* orbitals in the valence shell, can be introduced also into calculations on compounds of the elements of the Second Period. It may then be found that (a) the role of the *d*-type corrections in calculations on compounds of the elements of the Second and Third Periods is approximately the same or (b) the role of *d*-type corrections in calculations on compounds of the elements of the Third Period is much greater than in calculations on compounds of elements of the Second Period.

The considerations adduced in Section II are sufficient to rule out the first possibility. Orbitals whose energy exceeds that of the valence orbitals approximately by 10 eV (this is in fact the energy of the vacant *d* orbitals of the phosphorus atom) cannot have an appreciable influence on chemical properties and cannot effectively interact with the valence orbitals of the neighbouring atoms. The chemistry of the elements of the Third Period also provides evidence against the first possibility. However great the differences between the chemical properties of the elements of the Third and Second Periods, they are in no way comparable to the truly radical changes which occur in the presence of "working" vacant orbitals. Indeed, the appearance of such *d* orbitals alters the initial form of Mendeleev's periodic table and leads to the appearance of a class of completely unusual elements—the transition metals [$(n-1)$ *d* orbitals]. The presence of "working" vacant orbitals in the second shell is responsible for the tervalence of boron and the quadrivalence of carbon, which determine the entire chemistry of these elements (*p* orbitals). The existence of five chemically significant vacant *d* orbitals should have converted phosphorus into an electron-deficient element, which is not the case. The differences between the properties of phosphorus and nitrogen are large, but, as we shall see below, can be fully accounted for by the differences between the properties of the *s* and *p* valence orbitals of these elements.

However, having recognised that the role of *d* orbitals reduces to that of computational corrections, one must nevertheless elucidate the comparative importance of these corrections in calculations on compounds of the elements of the Third and Second Periods[19]. It is quite likely that the *d*-type corrections for elements of the Third Period are much greater than for elements of the Second Period, since the electronic systems of the former are much more complex and their orbitals are larger and more diffuse. If the *d*-orbital type corrections were indeed larger for the elements of the Third Period, they might assume a new importance. Without being in any way a true physical cause of the differences between the properties of the elements of the Third and Second Periods, the *d* orbitals might be used as a convenient language for the description of these differences. The widespread occurrence of the *d*-orbital "explanations" in the chemical literature might then be in a sense justified (with the essential proviso that the language be used correctly). Clearly, in view of the approximately identical values of the *d*-orbital corrections in calculations on compounds of elements of the Third and Second Periods (situation 2*a*), *d* orbitals can be used neither for the explanation nor for the description of the differences between the properties of these compounds. Thus the special role of *d* orbitals in phosphorus might be considered only if it were found that the *d*-orbital corrections for the phosphorus atom are much greater than for the nitrogen atom. Since this formulation of the problem is as yet not altogether usual, the comparison will have to be made largely on the basis of studies of different workers carried out at different times for quite different purposes.

We shall begin the comparison with elemental phosphorus and nitrogen. In 1967 Boyd and Lipscomb[20] carried out a calculation on the P_2 molecule and reached the following conclusion: "This study establishes a quantitative evaluation of the large participation of 3*d* orbitals in molecular bonding of P, and hence qualitatively of second-row atoms.... The total energies ... are significantly improved, and the electron densities are significantly changed upon the inclusion of 3*d* orbitals". Indeed the application of *d*-orbital corrections led to an energy gain of 3.75 eV. However, in their conclusion the authors failed to take into account the studies of Nesbet[21], who introduced orbitals of the *d* type into a calculation on the N_2 molecule and obtained as a result an energy gain of 3.25 eV, i.e. almost the same as above. In 1971 Mulliken and Liu[22] compared in the same calculation and by the same method the role of *d* corrections for N_2 and P_2. In particular, the energy gain for N_2 (2.58 eV) actually proved to be greater than for P_2 (2.53 eV).

It is clear from these investigations that the differences between the properties of elemental nitrogen and phosphorus are not associated with the contribution of *d* orbitals. Nevertheless the differences between N_2, an inert gas, which condenses at −196°C, and P_4, which is an extremely reactive crystalline substance, are very great. They can be accounted for in the following way. In the N_2 molecule, the σ bond is formed from compact orbitals and the optimum distance for their overlap is small. At this distance, the p_x orbitals overlap very markedly forming a strong π bond. A similar strong π bond is also formed by p_y orbitals. This results in a very stable N_2 molecule, in which the nitrogen atoms are linked by a strong triple bond. In phosphorus, the orbitals are much larger and much more diffuse than in nitrogen. The optimum distance for the formation of the σ bond is so great that π overlapping at this distance is very slight and π bonds are energetically unfavourable; this is why multiple bonds are altogether uncharacteristic of the elements of the Third Period. In the case of phosphorus, the formation of three single bonds with three adjacent atoms at the vertices of the tetrahedron is energetically more favourable than the formation of a triple bond in the P_2 molecule§. Admittedly, all these bonds are of the "banana" type, since the orbitals deviate from the bond axes. However, for large diffuse orbitals, this does not unduly impair the conditions for overlap.

Thus the differences between the properties of elemental nitrogen and phosphorus are due to the differences between the sizes of the orbitals.

We shall now consider tricoordinate compounds. We shall begin with the simplest examples: phosphine (PH_3) and ammonia (NH_3). Boyd and Lipscomb[20] carried out a calculation on the PH_3 molecule and found that the contribution of *d* orbitals is very significant. The importance of *d* orbitals for ammonia was established by Clementi and coworkers[23].

The values of the *d*-orbital corrections depend very strongly on the quality of the calculation. Thus in the calculation of Hillier and Saunders[24] the population of the *d*-type orbitals of phosphorus in PH_3 was 0.26*e*. On the other hand Rothenberg et al.[25] obtained 0.08*e* for this population in a more accurate calculation, which led them to the conclusion that the role of *d*-type orbitals is great in those cases where they compensate the defects of an inadequate *s*,*p*-basis set. Finally a comparison of PH_3 and NH_3 in a single calculation was carried out by Petke and Whitten[26], who found that the *d* corrections for ammonia are no less important than for phosphine and for this reason the *d* orbitals do not play a special role in PH_3. However, it may be that in phosphine *d* orbitals do not play a special role simply because of the lack of π-donor ligands. It is therefore necessary to examine calculations on molecules with such ligands. There are literature data for PF_3. Hillier and Saunders[27] obtained 0.71*e* for the population of the *d*-type orbitals in PF_3 and concluded that the population of the *d* orbitals of phosphorus increases with increase of the π-donor capacity of the ligands. However, calculation on this molecule using a much better approximation[28] yielded no population for *d* orbitals. Thus one may assume that in tricoordinate compounds the

---

§These molecules exist only in the vapour phase.

role of *d*-type corrections for phosphorus and nitrogen is the same.

The different properties of these compounds are also caused by the sizes of the orbitals. Owing to the larger size of the valence orbitals of the phosphorus atom, its bonds are longer, which is very important for molecular geometry. A calculation was carried out in 1973 on ammonia[29], in which the N-H bond length has varied. For smaller bond lengths than the experimental value, the molecule was found to be planar; with increase of bond length, it became non-planar and the angle of the pyramid decreased. The angle reached the experimental value when the N-H bond length became equal to the experimental bond length. On further increase of bond length, the pyramid became increasingly sharp, the angle reaching 90° ultimately. In phosphine, the bonds are so long that the angle is almost 90°.

We shall now consider how the difference between the angles of the pyramid affects the properties of aromatic compounds, for example, aniline and phenylphosphine. The pyramid is flattened at the nitrogen atom and the lone electron pair has a greater amount of *p* character, i.e. it is virtually located in a *p* orbital. The N-C bond length is such that π overlapping is effective,

and there is conjugation between the electron pair and the ring, so that the nitrogen atom in aniline is a stronger donor. On the other hand, the N-H bonds are located in the plane of the ring and their orbitals cannot overlap with the p_Z orbitals of the carbon atom. Consequently, they hardly interact with the π-electron system of the benzene ring. In phenylphosphine, the valence angle is close to 90° and the orbital of the lone electron pair has almost pure *s* character. It cannot therefore interact with the antisymmetric p_Z orbitals of the carbon atom and there is no conjugation with the ring and no electron transfer to the latter:

 .

However, one of the P-H bonds is formed by the p_Z orbital of the phosphorus atom, which may interact with the p_Z orbital of the carbon atom. Thus, in contrast to aniline, in phenylphosphine the bonds (and not the lone electron pair) interact with the benzene ring.

The concept of σ, π conjugation (hyperconjugation) is widely used in chemistry[30,31]. Hyperconjugation is understood as symmetry-allowed interaction of σ bonds with π-electron systems. The direction of the hyperconjugation effect depends on the polarisation of the σ bonds. The hyperconjugation effect of methyl groups is believed to be of the donor type and is represented by arrows

$$H_3{\equiv}C{-}CH{=}CH_2$$

or by resonance structures of the type

 .

$$H^+\ \ H_2C{=}CH{-}\bar{C}H_2$$

The hyperconjugation effect of trifluoromethyl groups is believed to be of the acceptor type and is represented by arrows

$$F_3{\equiv}C{-}CH{=}CH_2$$

or by resonance of structures of the type[32]

$$F^-\ \ F_2C{=}CH{-}\overset{+}{C}H_2.$$

The electronegativity of the phosphorus atom is less than that of the carbon atom and even less than that of oxygen, the halogens, etc. As a result the σ bonds of phosphorus with the substituents are polarised in the direction $P^{\delta+}-X^{\delta-}$. The σ,π conjugation with the σ bonds of phosphorus, can therefore be of the acceptor type. The reality of the hyperconjugation effects of both methyl[33] and trifluoromethyl[34-36] groups has been questioned in recent years. Indeed, the interaction of the very strong and compact C-H bonds and even more so the C-F bonds with π-electron systems should be so slight that it can hardly be a real cause of the phenomena for the explanation of which the hyperconjugation effect is invoked. For elements of the Third Period, the situation is different. The bonds of silicon, phosphorus, and sulphur are formed by the much more diffuse valence orbitals of these elements. For this reason, the strength of these bonds, their polarisability, and their mobility are comparable to the corresponding characteristics of π orbitals. This is why the effects of σ,π conjugation with the σ bonds of the elements of the Third Period should be observed.

Thus the acceptor properties of tricoordinate phosphorus can be explained by the size and diffuseness of its *s* and *p* orbitals and not by the presence of *d* orbitals in its valence shell. The change in the size of the valence orbitals led to a change in geometry, i.e. a change in conjugation conditions (conjugation with σ bonds and not with a lone electron pair), and to an increase in the extent of σ,π conjugation[37-39].

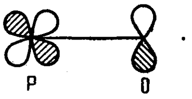
Using tetracoordinate phosphorus and nitrogen compounds as examples, one can conveniently explain what is understood by *d* corrections. In amine oxides the bond is believed to be semipolar and its formation is represented as follows. An electron passes from the nitrogen atom to oxygen. One unpaired electron, which remains in O^-, forms a σ bond with the quadrivalent ammonium nitrogen atom and the six other electrons (five from O and one from N) form lone pairs. Two of these are located in the p_X and p_Y orbitals, i.e. have π character. This description conveys only very approximately the real form of the electron cloud, since the form of the p_π orbitals of the oxygen atom in this cloud remains the same as in the isolated oxygen atom:

 .

Furthermore, the molecule of the oxide contains the positively charged N^+ atom next to O^-. Under the influence of the positive charge, the electron cloud should be deformed and drawn into the region of the bond:

 .

The traditional description of amine oxides does not reflect this deformation. Here the attraction of the electron cloud to the region of the bond is represented with the aid of the *d* orbitals of the phosphorus atom. For example, it is assumed that the p_X orbital of the oxygen atom interacts with the d_{xz} orbital of the phosphorus atom and forms a π bond:

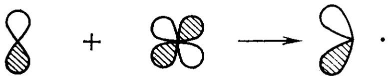


A similar bond is formed by the p_y orbital of the oxygen atom with the d_{yz} orbital of the phosphorus atom. Thus in phosphine oxides the linkage is partly of the triple bond type:

$$P \equiv O.$$

The attraction of the electron cloud into the region of the bond in amine oxides might be described in exactly the same way with the aid of fictitious d orbitals of nitrogen, since in the case of phosphorus one employs fictitious and not atomic d orbitals. However, this attraction in both phosphine and amine oxides can be represented in a different way. It is required that the form of the orbitals of the oxygen atom should be modified so that they become extended into the region between the atoms:

This can be achieved with the aid of the d orbitals of the oxygen atom. We combine the p_x orbital with an orbital of the d_{xz} type:



Naturally, the latter orbital has nothing in common with the atomic d orbitals: this is the so called polarisation correction and the admixture of the d-type orbital is postulated only in order to account for the change in the shape of the electron cloud. The particular atom in the molecule to which the polarisation correction is applied has no fundamental importance, since it is a purely formal procedure—it can be applied to phosphorus, nitrogen, and oxygen. Such calculations have not been made for oxides, but one cannot rule out the possibility that d orbitals in oxygen would give a good description of the change in the shape of the electron cloud. On the other hand, it is known that the d-orbital corrections for silicon hardly affect the results of calculations on silylamine, while the d-orbital corrections for nitrogen greatly improve the result.[40]

There are very few quantitative data for amine and phosphine oxides. Nevertheless Hillier[41] has carried out a calculation on the F_3PO molecule and obtained a high population of the phosphorus d orbitals (0.5e) in the PO bond. Choplin and Kaufmann[42] performed a calculation on the same molecule and on the oxide F_3NO without taking into account the d orbitals for the nitrogen atom. We mention this study, because its authors understood the necessity of including also the d orbitals for the nitrogen atom, although they were unable to do this for technical reasons. Frost et al.[43] carried out a calculation on the PO and NO linkages in the F_3PO and F_3NO molecules taking into account the d orbitals and obtained approximately equal contributions of the d orbitals for nitrogen and phosphorus atoms; however, they performed only a model calculation by the valence bond method. Unfortunately comparable non-empirical calculations on amine and phosphine oxides have not so far been made.

It must be emphasised that the differences in the chemistry of nitrogen and phosphorus compounds are to a large extent determined by the ease of formation of the phosphoryl linkage, i.e. its greater strength. The illusory nature of the traditional explanation of the comparative strength of the PO linkage and its triple bond character was demonstrated above. It is reasonable to suppose that the increased tendency of the lone electron pair of the phosphorus atom towards oxidation is determined mainly by the properties of the initial lone pair and not of the oxide linkage formed. The electrons of the compact lone pair of the nitrogen atom are comparatively more strongly attracted to the nucleus, which increases the energy expenditure on the removal of the electron and makes the formation of the N-oxide linkage less favourable compared with the phosphoryl linkage and makes it weaker.

These considerations can be confirmed by a comparison, using a fairly clear-cut example, of the ionisation potentials of the lone pairs with the strengths of the oxide linkages formed in analogous phosphorus and nitrogen compounds. It is difficult to compare the hydrides owing to the large differences between the geometries and the associated differences between the hybridisations of the lone pairs. Comparison of alkyl and particularly aryl derivatives is hindered by the appreciable delocalisation of the lone pair of the nitrogen atom in these compounds. Fluorides are the most suitable for the comparison, since the differences between their geometrical structures and hence between the hybridisations of the lone pairs are slight ($\angle FPF \simeq 98°$, $\angle FNF \simeq 102°$) and the changes in geometry on oxidation are also small ($\Delta\angle FPF \simeq +3.5°$, $\Delta\angle FNF \simeq -1.2°$).[142] Owing to the exceptionally high electronegativity of fluorine, the ionisation potential in this instance can be attributed to the lone pair with a greater degree of justification than for any other substituents. The ionisation potential of NF_3 does indeed exceed that of PF_3 by 80 kcal mole^{-1}. It is not therefore surprising that the PO linkage in F_3PO is much stronger than the NO linkage in F_3NO (by more than 30 kcal mole^{-1}). Thus in this case too the differences between the properties are ultimately determined by the differences between the sizes of the valence orbitals of the nitrogen and phosphorus atoms.

We shall now turn to penta- and hexa-coordinate compounds. Santry and Segal[15] carried out a calculation on the PF_5 molecule and obtained a population of the d orbitals of the phosphorus atom equal to 1.6e. Later Brown and Peel[44], made a similar calculation, obtained a population of the phosphorus d orbitals of 0.3e, and concluded that there is no reason for invoking d orbitals in order to describe the electronic structure of this molecule. Highly accurate non-empirical calculation on the PH_3F_2 molecule and the hypothetical PH_5 and NH_3F_2 molecules have been published recently[45]. The authors concluded that the stability of the PH_3F_2 and PF_5 molecules can be accounted for without invoking d orbitals and that the decisive factor responsible for the stability of the PH_3F_2 molecule, on the one hand, and the instability of NH_3F_2, on the other, is the difference between the ionisation potentials of the planar PH_3 (7.8 eV) and NH_3 (10.3 eV) species. On the other hand, the authors[45] note that the energy gain following the expansion of the basis set by including d-type orbitals and the population of these orbitals are greater for PH_3F_2 than for NH_3F_2. However, it must be emphasised that the roles of the d-orbital corrections were compared for a configuration which is stable in one of the molecules (PH_3F_2) and unstable in the other (NH_3F_2). Indeed, when the basis set was expanded by including *d*-type orbitals in the nitrogen atom, it was found that the stable configuration of NH_3F_2 is of the C_{3v} type, corresponding to the tetrahedral ammonium cation NH_3F^+ and the F^- anion associated with it by purely electrostatic forces, and not a trigonal bipyramid (D_{3h}) as in the PH_3F_2 molecule. The latter result suggests in addition that the differences between PH_3F_2 and NH_3F_2 are associated with steric hindrance (see below).

A calculation has been performed on the PF_6^- anion[46], which yielded an appreciable population of the *d* orbitals (1.2*e*). However, exactly the same calculation on SF_6 yielded a charge of $-0.3e$ on the sulphur atom. It is unlikely that the sulphur atom surrounded by fluorine atoms should have a negative and not a positive charge. Thus, from the chemical standpoint alone, the *d*-orbital population in this calculation is much too high. On the other hand, theoretical analysis demonstrates the necessity for a high population of the *d* orbitals of the central atom in octahedral molecules[47]. One must therefore expect that, in the calculation by the same method on the octahedral NF_6^- anion, a high population of the *d* orbitals would also have been obtained for the nitrogen atom. Unfortunately a calculation on this hypothetical anion has not been made.

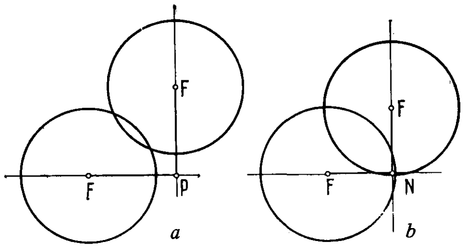


Figure 9. Comparison of the P–F (*a*) and N–F (*b*) bond lengths with the van der Waals radius of the fluorine atom.

We shall now consider why the anion does not exist. Fig. 9*a* illustrates the P–F bond length and the van der Waals radius of the fluorine atom. Evidently fluorine atoms hardly overlap and only a slight increase in bond length is required for the disappearance of steric hindrance to the formation of the molecule; at the same time, the diffuse phosphorus orbitals are relatively insensitive to a slight increase in bond length. Fig. 9*b* illustrates the same situation for the nitrogen atom. Evidently fluorine atoms overlap very strongly. In order to eliminate steric hindrance, it is necessary to extend the N–F bond to such an extent that it is ruptured. In other words, penta- and hexa-coordinate compounds of nitrogen cannot exist owing to considerable steric hindrance. Consequently penta- and hexa-coordinate compounds of phosphorus exist simply because its atom is sufficiently large to accommodate five (or six) ligands around it and not because it has a *d* orbital available for the formation of additional linkages. Therefore, bonding in these compounds can be accounted for, as shown above, without invoking *d* orbitals.

---o0o---

Thus the differences between the properties of phosphorus and nitrogen compounds can be explained by a very simple but very important factor: the difference between the effective sizes of the *s* and *p* orbitals of the nitrogen and phosphorus atoms.

The presence of vacant *d* orbitals in the valence shell of the phosphorus atom can in no way influence the properties of phosphorus compounds, since these orbitals are so unfavourable energetically and so diffuse that they are incapable of any appreciable interaction with other valence orbitals.

d Orbitals can play the role of polarisation corrections, which is important from the standpoint of the method of calculation but has almost no chemical importance or no chemical importance whatsoever. As far as one can judge, from the available data, the roles of these corrections for nitrogen and phosphorus are approximately the same.

In view of the identical orders of magnitude of the *d*-orbital corrections in the case of nitrogen and phosphorus, the concept of *d* orbitals cannot be used correctly as a language suitable for the description of the differences between the properties of compounds of these elements.

Molecular Rearrangements in the Series of Carane Derivatives

B.A.Arbuzov and Z.G.Isaeva

The available information about the molecular rearrangements of carane derivatives in addition, elimination, and substitution reactions are examined and the structural and steric principles which determine the nature of the rearrangements are analysed. A systematic account is given of data concerning the changes in the carane structure in various reactions involving rearrangements with participation of three-membered and six-membered rings.
The bibliography includes 100 references.

CONTENTS

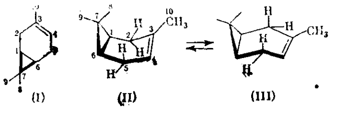
I. INTRODUCTION

Extensive factual data have now accumulated on the chemistry of bicyclic terpene derivatives of the carane series. Since the beginning of the 1960's, the stereochemistry of carane derivatives has been investigated vigorously, largely as a result of the application of various physical methods for the study of steric structure and the principles of conformational analysis. In the course of this research, numerous stereoisomeric carane derivatives have been synthesised, their configurations and conformations have been elucidated, and extensive information has been obtained about their reactivities. Data concerning the transformations of carane derivatives in various reactions have been partly surveyed in a number of reviews[1,2], but the results of stereochemical investigations on caranes have not yet been described systematically.

The present review deals with publications in the last ten years containing information about the molecular rearrangements of carane derivatives in addition, elimination, and substitution reactions, and analyses the structural and steric principles which determine the nature of the rearrangements.

II. THE STERIC STRUCTURES AND STEREOISOMERISM OF CARANE DERIVATIVES

The results of studies on the photosensitised oxygen-transfer reaction and an examination of Dreiding models have led to the hypothesis[4,5] that 3-carene (I)† molecules can exist in an equilibrium 1 : 1 mixture of two "boat" forms (II) and (III):

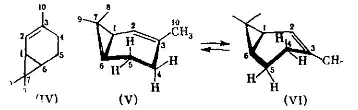


(I) (II) (III)

It follows from electron diffraction data[6] that the *syn*-boat conformation (II) exists. Examination of the ^{1}H NMR spectra demonstrated the possibility that 3-carene molecules exist as a mixture of two conformers, again with the *syn*-boat form (II) predominating[7,8].

On the basis of the results of a study of the conformational structure by the method of molar Kerr constants and of calculations of the energy difference between the conformers, taking into account steric and electrostatic interactions, Vereshagin and Vul'fson[9] concluded that conformer (II) predominates (to an extent of at least 90%) in the equilibrium mixture of (II) and (III). Despite its being sterically "filled" from the inner or *p*-side, the stability of form (II) has been accounted for[7] by the absence of a rigid interaction between the non-bonded 8-CH_3 group and the *p*-hydrogen atoms at $C_{(2)}$ and $C_{(5)}$, which is present in the boat form (III).

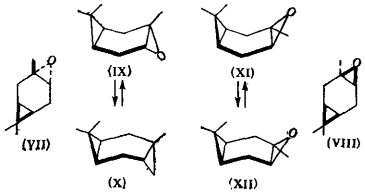
The conformation of the isomeric 2-carene (IV) was determined in a similar way. Of the two possible conformations (V) and (VI), the partial boat form (V) is preferable[7,10]:



(IV) (V) (VI)

It is seen from Dreiding models that the interatomic distance between 8-CH_3 and 4β-H in conformer (VI), amounting to 0.2 Å, is responsible for the steric hindrance in the molecule, which makes this conformation unfavourable. The results of the analysis of the steric interactions of the atoms on the basis of the correlations between the spin-spin coupling constants and the dihedral angles led to the adoption of conformation (V) also for 2-carene and its 4-substituted derivatives[11]. Arbuzov et al.[12] explained why conformation (V) is preferable by analysing the relative chemical shifts of the protons of the *gem*-dimethyl groups using dipole moments and molar Kerr constants.

The configurations and conformations of the stereoisomeric 3,4-epoxycaranes (VII) and (VIII) and of 2,3-epoxycarane (XIII) have been determined with the aid of the same set of methods for the investigation of steric structure[8,9,12-16].



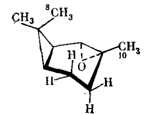
---

† In this review the carane system is numbered in accordance with the IUPAC nomenclature[3].

As for the corresponding olefin (I), conformations with the six-membered ring in the *syn*- and *anti*-boat forms are possible for the stereoisomeric 3,4-epoxycaranes. Form (IX) predominates in the equilibrium mixture of the conformers of the α- or *trans*-isomer (VII)(with respect to the steric orientation of the three-membered ring relative to the plane of the cyclohexane ring)[8,15]. Completely unanimous conclusions have not been reached concerning the choice of the preferred conformation of the β- or *cis*-isomer (VIII).[8,15-17]

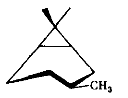
α-2,3-Epoxycarane (XIII) has the partial boat conformation (XIV):[12]

(XIII)

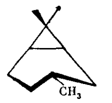


(XIV)

It is evident from an examination of Dreiding models and ^{1}H NMR spectra of the stereoisomeric saturated *cis*- and *trans*-caranes‡ that their most probable steric structures must be the half-chair conformations (XV) and (XVI) with the equatorial (*e*) 10-CH$_3$ group[18]:

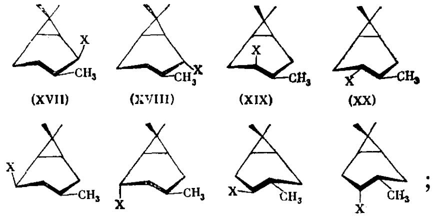


(XV)



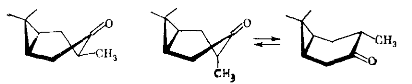
(XVI)

It has been shown by ^{1}H NMR spectra that the amines of the *cis*-carane series, stereoisomeric with respect to the position of the NH$_2$ group and the carbon atoms of the six-membered ring, have the half-chair conformation (XVIIIa–XXIIa), with rare exceptions[19]:

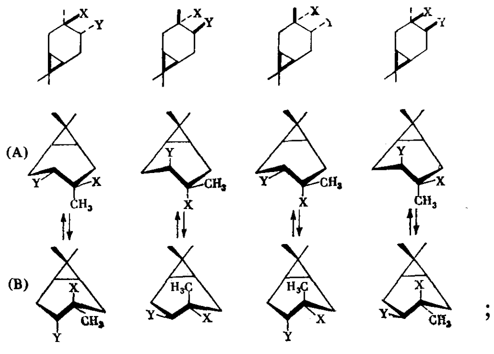


(a) X = NH$_2$; (b) X = OH .

In studies on the stereochemical structures using both physical and chemical methods, the half-chair conformation with the *e*-10-CH$_3$ group (XVIIb–XXIIb) was assigned to the isomeric secondary alcohols of the *cis*-carane series[20]. Preferred half-chair conformations have been found also for the stereoisomeric *trans*-4-caranols (XXIIIb, XXIVb).[14] Different conformations have been proposed for the two stereoisomeric 4-caranones (based on the results of studies by ^{1}H NMR and optical rotatory dispersion[14], dipole moment, and Kerr effect[21] methods and an examination of models): half-chair with the *e*-10-CH$_3$ group [form (XXV)] for the *cis*-isomer and a conformer intermediate between the half-chair with an axial (*a*) 10-CH$_3$ group [form (XXVI)] and a boat with the *e*-10-CH$_3$ group for the *trans*-isomer:



Calculations (based on Kitaigorodskii's mechanical model) on the equilibrium optimal conformations of the four isomers of carane-3,4-diol[22], two *trans*-3,4-dichlorocaranes[23], and *trans*-4-bromo-3-hydroxycarane[24], also led to the assumption that the half-chair conformation is preferred for the six-membered carane system of these compounds and it has been shown that 3,4-disubstituted caranes (XXVIII–XXXI) can exist in the form of equilibrium mixtures of conformers (A) and (B).

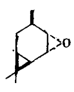


(a) X=Y=OH; (b) X=Y=Cl; (c) X=OH, Y=Br; (d) X=OH, Y=OAc; (e) X=OH, Y=OTs; (f) X=Hal, Y=OAc; (g) X=Y=Br; (h) X=OH, Y=Cl.

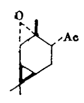
Similar results were obtained in a study of 3,4-dihalogencaranes from dipole moments and Kerr effects[25,26] and of carane-3,4-diols, their monoethers, and ketols by infrared spectroscopy (an intramolecular hydrogen bond was detected)[27,28].

The conclusions concerning the steric structure of carane derivatives agree with the steric relations governing the occurrence of the corresponding reactions. In this respect carane derivatives have proved to be convenient objects for the elucidation of the stereochemical aspects of particular reactions, for the investigation of reaction mechanisms, since they make it possible to make comparative estimates of the influence of electronic, configuration, and conformation factors.

One of the characteristic features of the stereochemistry of carane derivatives is the stereospecificity of electrophilic addition to isomeric carenes having a double bond within the tricyclic system. In all the reactions investigated hitherto the double bond of carenes is attacked by the electrophilic species in the *trans*-position (or from the "α-side") with respect to the *endo*-condensed cyclopropane ring. Thus the only products of epoxidation by peracids are the *trans*-isomers (with respect to the mutual orientation of the three-membered rings) of epoxycaranes[11,12,14,29-33] (VII), (XIII), and (XXXII) and 4α-acetyl-2α, 3α-epoxycarane[34] (XXXIII).



(XXXII)



(XXXIII)

Reactions involving photosensisised oxygen transfer to carenes[4,32], oxidative hydroboration of carenes[10,14],

---

‡The conformational relations of carane derivatives are determined, on the one hand, by the mutual disposition of the 10-CH$_3$ group and the three-membered ring relative to the plane of the cyclohexane ring and, on the other hand, by the steric orientation of the functional groups in relation to the three-membered ring. Carane derivatives can be divided into two series, with *cis*- and *trans*-carane structures, on the basis of the type of the hydrocarbon skeleton.

hydroxylation with KMoO$_4$ and OsO$_4$–H$_2$O,[8,22,35] Friedel–Crafts acetylation, and the Prins reaction[11] lead to the formation of products with the α- (or *trans*-) orientation of the functional groups. Such stereospecificity of the attack on the double bond of carenes is caused, as can be seen from Dreiding models, by the hindered approach by the bulky electrophilic agents from the β-side shielded by the 8-CH$_3$ group.

A second distinctive feature of the behaviour of carane derivatives is a tendency towards a rearrangement of the hydrocarbon skeleton of the carane in different reactions.

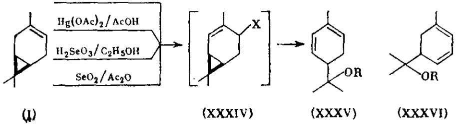
III. MOLECULAR REARRANGEMENTS OF THE CARANE STRUCTURE

The possibility of skeletal rearrangements due to the involvement of both rings is inherent in the very structure of the carbon system of carane, which contains condensed alkyl-substituted six- and three-membered rings.

1. HOMOALLYL REARRANGEMENTS

(a) Rearrangement Involving the Conjugated System of a Double Bond and the Cyclopropane Ring

The first evidence for the possibility of an allyl type of rearrangement of 1,3-diene systems in the series of carane derivatives was obtained in a study of the oxidation of 3-carene by Pb(OAc)$_4$, Hg(OAc)$_2$, and H$_2$SeO$_3$ under various conditions[36-39]. In all cases one of the main reaction products proved to be the ester of the dienol of the *p*-methane series (XXXV); the reaction with Pb(OAc)$_4$ also gave the ester of the dienol of the *m*-menthane series (XXXVIb):



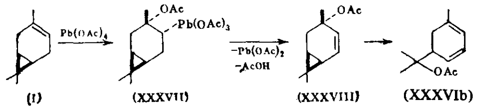
(I) (XXXIV) (XXXV) (XXXVI) ;

(1) X=Pb(OAc)$_3$
(2) X=HgOAc
(3 and 4) X=SeO$_2$H

(a) R=H
(b) R=Ac
(c) R=Et .

The conversion of 3-carene into *p*-menthadienol derivatives under the influence of these agents has been explained by postulating the intermediate formation of allyl-substituted 2-carene derivatives of the elements of type (XXXIV), the solvolysis of which is accompanied by the allyl rearrangement with participation of the vinyl cyclopropane fragment.

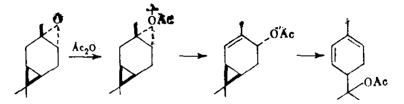
In order to convert olefins into acetates derived from allyl alcohols under the influence of Pb(OAc)$_4$, one can use also another pathway, involving the formation of an adduct of the olefin and Pb(OAc)$_4$ as an intermediate[40]. Accordingly, the oxidation of 3-carene with Pb(OAc)$_4$ should lead to the acetate of *m*-mentha-4,6-dien-8-ol (XXXVIb)[41,42] via the mechanism of the "4-carene → *m*-mentha-4,6-diene" rearrangement:



(I) (XXXVII) (XXXVIII) (XXXVIb) .

According to Whitham[43], Pb(OAc)$_4$ forms a *cis*-adduct with olefins. The adduct (XXXVII) is converted, with liberation of Pb(OAc)$_2$ and an AcOH molecule, into the acetate of *cis*-car-4-en-*trans*-3-ol (XXXVIII), which rearranges to (XXXVIb) under the reaction conditions.

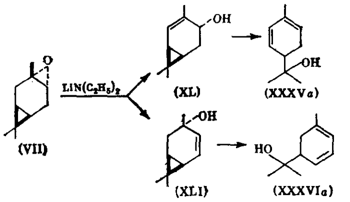
The formation of compound (XXXVb) from α-3,4-epoxycarane (VII) in the reaction with acetic anhydride has been explained similarly[44,45]:



(VII) (XXXIX) (XXXVb) .

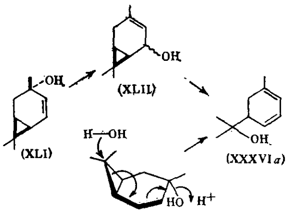
The identification of car-2-en-*trans*-4-ol (XXXIX) together with compound (XXXVb) in the products of these reactions was regarded as evidence for the possibility of the "2-carene → *p*-mentha-1,5-diene" rearrangement. The two isomeric products (XXXVb) and (XXXIX) were also identified in the products of the reaction of 3β,4α-dihalogenocaranes with AgOAc in acetic acid[46,47].

Presumably the rearrangement investigated occurs in the reaction of the allylic carenols (XL) and (XLI) (the products of the isomerisation of α-3,4-epoxycarane by a base[49]) with phthalic anhydride[49]; the rearranged alcohols were identified in the reaction mixture.



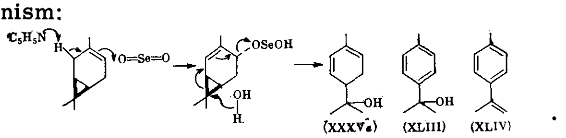
Thus in the examples quoted above the allyl rearrangements involving the vinylcyclopropane fragment were observed only indirectly. The "4-carene → *m*-mentha-4,6-diene" rearrangement has been achieved directly.

Gollnick et al.[50] showed that car-4-en-*trans*-3-ol (XLI) is converted quantitatively into *m*-mentha-4,6-dien-8-ol (XXXVIa) on refluxing with water and under the influence of acetic or dilute sulphuric acid at room temperature.

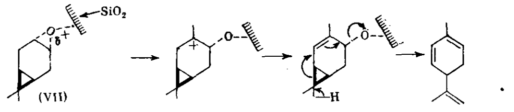


Gollnick et al.[50] suggested that this transformation can occur either as a concerted process or via car-3-en-5-ol (XLII), which undergoes a homoallyl rearrangement with participation of the cyclopropane ring under the reaction conditions.

According to the latest report by Cocker and coworkers[51], the oxidation of 3-carene by SeO$_2$ in pyridine (after refluxing for 3 h) with subsequent steam distillation of the reaction products yields preferentially compounds of the *p*-menthane series (XXXVa) (50%) and its degradation and dehydration products 2-(*p*-tolyl)-2-propanol (XLIII) (11%) and *p*-isopropenylmethylbenzene (XLIV) (11%). The authors explain their formation from 3-carene by the "interference" of the "2-carene → *p*-mentha-1,5-diene" rearrangement occurring analogously[50] to the concerted mechanism:

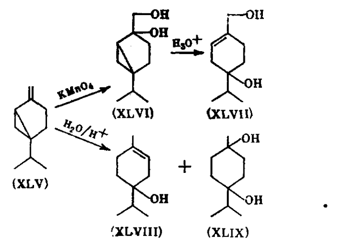


There is an interesting interpretation[52] of the transformations of *α*-3,4-epoxycarane (VII) under the influence of silica gel, which is regarded as a matrix with an electron-accepting surface responsible for the carbonium mechanism of the process; one of the pathways in the reactions involves a rearrangement similar to that already described above



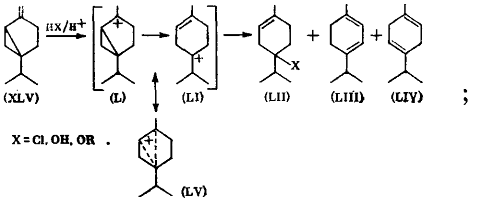
(b) Homoallyl Rearrangement with Participation of the Cyclopropane Ring

The homoallyl rearrangement in the series of bicyclic terpenes was observed previously for derivatives of bicyclo[3,1,0]hexane with a system of condensed three- and five-membered rings. Thus Semmler[53] found that the hydroxylation of Sabinene (XLV) by $KMnO_4$ leads to the diol (XLVI), which readily isomerises to the diol (XLVII) under the influence of dilute H_2SO_4 in the cold:



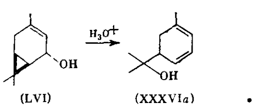
The hydration of sabinene (XLV) with 10% H_2SO_4 also leads to the monocyclic products (XLVIII) and (XLIX).[54]

Goryaev and coworkers[55–57] obtained analogous results in the study of the transformations of sabinene (XLV) in reactions with HCl—the hydration and alcohol addition reactions in an acid medium:

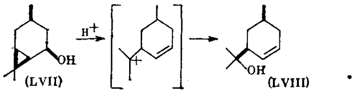


It is evident from the above scheme that the formation of monocyclic products is the result of the rearrangement of the cyclopropylmethyl ion (L) to the homoallylcyclohexyl ion (LI) and the stabilisation of the latter by the attack of a nucleophile to give the terpenen-4-ol ether (LII) or the ejection of β-H^+ leading to the hydrocarbons (LIII) and (LIV). The authors also believe that the hydration of sabinene via the non-classical ion (LV) is probable.

In the carane series, the rearrangement of the cyclopropylmethyl derivative to the homoallyl compound was also achieved somewhat later by the conversion of car-3-en-*trans*-5-ol (LVI) into *m*-mentha-4,6-dien-8-ol (XXXVIa):[32]



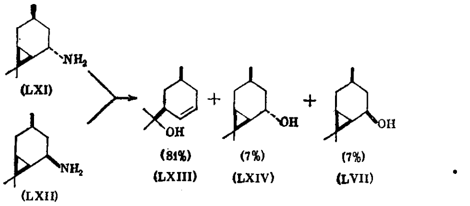
According to the data of Cocker and coworkers[58], *cis*-caran-*cis*-5-ol (LVII) partly isomerises to *cis*-*m*-menth-4-en-8-ol (LVIII) under the influence of dilute hydrochloric acid at room temperature or on heating with acetic acid in sealed tubes:



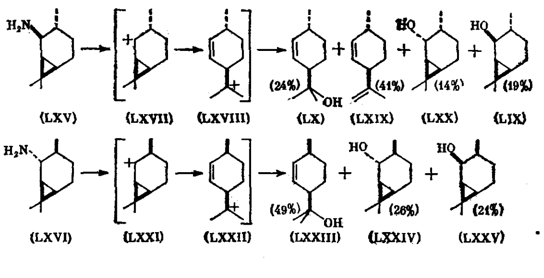
The rearrangement (LVII) → (LVIII) has also been noted under the conditions of the oxidation of compound (LVII) with chromic acid, particularly in oxidation in 75% acetic acid; in acetate buffer (pH 2.24), the rate of rearrangement is insignificant[20].

The homoallyl rearrangement has also been observed for *trans*-caran-*cis*-2-ol (LIX),[59] which is converted into *trans*-*p*-menth-2-en-8-ol (LX) under the conditions mentioned above for *cis*-caran-*cis*-5-ol (LVII):

More complete data on the rearrangement of cyclopropylmethyl derivatives were obtained by Cocker and coworkers in a study of the deamination of stereoisomeric amines of the carane series[60]. The deamination of the epimers (LXI) and (LXII) leads preferentially to the rearrangement of the product (LXIII), the composition of the deamination products being independent of the configuration of the initial amine:



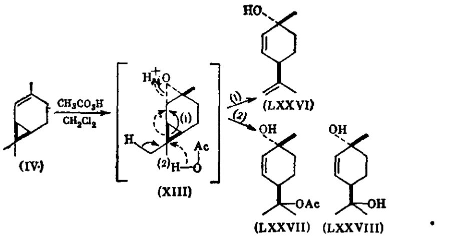
Stereoisomeric 2-amines with the *trans*-carane structure (LXV) or the *cis*-carane structure (LXVI) give a mixture of products having various compositions (different from those obtained previously); in this case the content of the rearranged products is smaller.



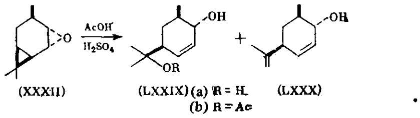
The authors explain the difference on the hypothesis that steric and electronic factors influence the ease of the rearrangement. While the formers promote to an equal extent the rearrangement of the corresponding α-cyclopropylcarbonium ions, with migration of the carbonium ion centre to a side chain, the influence of the electronic factors must be different, Owing to the $+I$ effect of the 10-CH_3 group in compounds (LXVII) and (LXXI), which stabilises the positive charge on the 2-C atom, there is an increase of the possibility of the formation of the non-rearranged products (LIX), (LXX), (LXXIV), and (LXXV). For the isomeric amines (LXI) and (LXII), the formation of the rearranged product (LXXIII) should be the dominant process.

Thus expansion of the range of isomeric carane derivatives investigated and the extension to them of the reactions accompanied by the formation at some stage of an electron-deficient centre in the α-position relative to the cyclopropane ring made it possible to observe directly in a number of instances their homoallyl rearrangement. The observations were used to elucidate the mechanism of the reactions, the pathways followed in the formation of particular products, and hence individual reaction pathways.

In an attempt to synthesise α-2,3-epoxycarane (XIII) by the epoxidation of 2-carene with peracetic acid, Gollnick and Schade[32] isolated *cis*-*p*-mentha-2,8-dien-1-ol (LXXVI), which they regard as the product of the acid-catalysed isomerisation of the α-2,3-epoxycarane (XIII) formed initially:

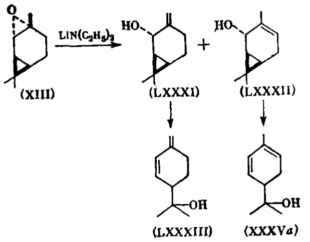


The rearrangement of α-2,3-epoxycarane (XIII) under the conditions of the epoxidation of 2-carene (IV) by a solution of peracetic acid in a mixture of acetic acid and methylene chloride buffered with sodium acetate was reported somewhat later[61]. The reaction products consisted of a mixture of compound (LXXVI) and the monoacetate of *cis*-*p*-menth-2-ene-1,8-diol (LXXVII). The diol (LXXVIII) was isolated as the sole product of the hydration of the epoxide (XIII) by 1% sulphuric acid[62]. It has been shown[32,61,63] that α-4,5-epoxycarane (XXXII) can be obtained by the epoxidation of *cis*-4-carene, which rearranges just as readily under the influence of acids; in the reaction with acetic acid, even in the cold (0°C), it gives the monoacetate of *m*-menth-4-ene-6,8-diol (LXXIXb) and *cis*-*m*-mentha-4,8-dien-6-ol (LXXX) as the main products:

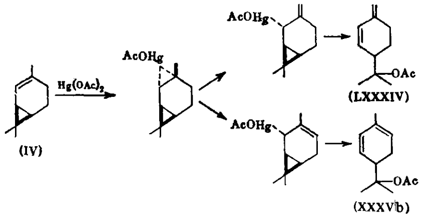


The diol (LXXIXa) has been obtained by Chabudzinski and coworkers[61,63] by treating the epoxide (XXXII) with 1% sulphuric acid, although the authors regarded it as carane-4,5-diol.

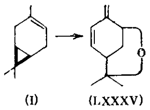
It is interesting to note that both allyl and homoallyl alcohols (LXXXI) and (LXXXII), the products of the isomerisation of α-2,3-epoxycarane (XIII) by $LiN(C_2H_5)_2$, rearrange even under the conditions of gas-liquid chromatography in a column with 10% of polyethylene glycol adipate on refractory brick at 140°C.[64] The carenols (LXXXI) and (LXXXII) rearrange rapidly in boiling water:



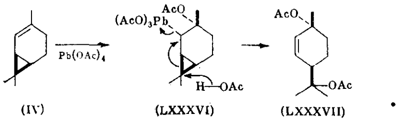
A study of the oxidation of 2-carene (IV) by $Hg(OAc)_2$ in acetic acid[65] showed that the formation of *p*-menthadienyl acetates (XXXVb) and (LXXXIV) involves a similar rearrangement at the stage where allylmercury acetates are solvolysed:



One cannot rule out the possibility that the formation of 2,8-oxy-*p*-mentha-1(7),5-diene (LXXXV) from 3-carene (I) when the latter is oxidised by SeO_2 in acetic anhydride[39,66] is also associated with the homoallyl rearrangement in the α-cyclopropylmethyl system:

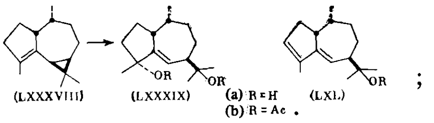


Assuming the homoallyl rearrangement at the stage involving the decomposition of allylic organolead intermediates, one can explain also the formation of the association complexes of the acetates (XXXVb) and (LXXXIV) in the oxidation of 2-carene (IV) by $Pb(OAc)_4$ in benzene[62]. As already mentioned, in agreement with the proposed mechanism[40], the oxidation of 2-carene by $Pb(OAc)_4$ can also proceed via another pathway involving an intermediate adduct (LXXXVI) of the olefin and $Pb(OAc)_4$. During its subsequent reactions, conditions also arise for the homoallyl rearrangement with opening of the cyclopropane ring and the formation of a monocyclic adduct:



In this case the acetate of *cis*-*p*-menth-2-ene-1,8-diol (LXXXVII) was identified in the reaction products.

It is of interest to compare the reactions involving the epoxidation and oxidation by $Pb(OAc)_4$ and SeO_2 of 2-carene (IV) and α-gurjunene (LXXXVIII), which contains the same vinylcyclopropane fragment as 2-carene (IV), but the latter is located in neighbouring rings[67-69]:

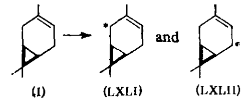


(LXXXVIII) (LXXXIX) (LXL)

(a) R = H
(b) R = Ac .

Comparison of the products of the above reactions of compounds (LXXXVIII) and (IV) demonstrates their fairly complete similarity.

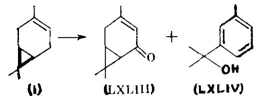
Under the influence of "allylic" oxidants, the "cyclopropylmethyl" fragment may arise in the 3-carene molecules in two ways:



(I) (LXLI) (LXLII) .

Presumably investigators encountered the rearrangement of the bicyclic 3-carene system to the *p*-menthadiene system, i.e. the rearrangement "2-carene → *p*-mentha-1,5-diene", already in the study of the catalytic autoxidation of 3-carene[70-72]. On the other hand, the structures of the corresponding rearranged reaction products were not finally elucidated, although it was shown subsequently that *p*- and *m*-menthadienols (XXXVa) and (XXXVIa) are formed as a result of the homoallyl rearrangement of the corresponding 3-carenyl derivatives (LXLI) and (LXLII) under the reaction conditions or during the separation of the reaction mixtures.

Cocker and coworkers[73], who investigated the oxidation of 3-carene by $KMnO_4$, found that the neutral products contain, apart from the main component car-3-en-5-one (LXLIII), also 8-hydroxy-*m*-cymene (LXLIV):

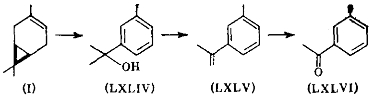


(I) (LXLIII) (LXLIV)

According to the results of Cocker and coworkers[74], compound (LXLIV) constitutes the bulk of the neutral oxygen-containing products of the oxidation of 3-carene by CrO_3 in acetone. However, when an acetone solution of CrO_3 buffered by sodium acetate is used, the yield of compound (LXLIV) is reduced by a factor of 2 and in pyridine by a factor of 4. Consequently, in an acid medium the stage responsible for the formation of compound (LXLIV) may involve the homoallyl rearrangement with opening of the three-membered ring.

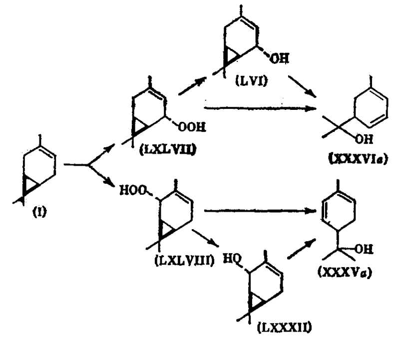
The same dependence of the yield of the rearranged products on the acidity of the medium was found in a study of the oxidation of 3-carene by t-butyl chromate[75,76].

The oxidation products of the *m*-series are represented by 8-hydroxy-*m*-cymene (LXLIV), 1-isopropenyl-3-methylbenzene (LXLV), and 3-methylacetophenone (LXVI). Their overall content in the reaction products reaches 70% when the oxidation reaction is carried out in a mixture of benzene, acetic acid, and acetic anhydride.



(I) (LXLIV) (LXLV) (LXLVI) .

The autoxidation of 3-carene in the presence or absence of a catalyst (cobalt stearate), using several methods for the reduction of the mixture of hydroperoxides formed initially, has been reinvestigated in detail by Baines and Cocker[51]. The products of the homoallyl rearrangement are represented by the *p*- and *m*-menthadienols (XXXVa) and (XXXVIa), their ratio depending primarily on the autoxidation reaction conditions: in the presence of a catalyst, a 1 : 4 mixture is formed, while in its absence the product is a 4 : 5 mixture with an increase of the overall yield of the two isomers by a factor of 2. Thus the preferential formation of products of the *m*-menthane series is evidence for the preferential attack on the 5-CH_2 group of 3-carene. The homoallyl rearrangement can occur in the reduction of carenyl hydroperoxides (LXLVII) and (LXLVIII):



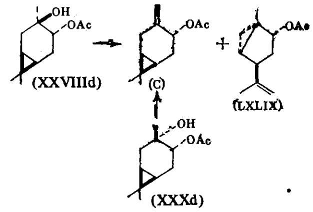
(I) (LXLVII) (LVI) (XXXVIa) (LXLVIII) (LXXXII) (XXXVa)

There is also the possibility of a rearrangement of the carenols (LVI) and (LXXXII) under the influence of an acid medium.

2. REARRANGEMENT WITH TRANSANNULAR CYCLOPROPYL PARTICIPATION

As in the homoallyl rearrangement, data concerning the transannular cyclopropyl participation in the chemistry of carane compounds have been obtained comparatively recently, although many such instances are known for the related bicyclic derivatives of the thujane series[77,78].

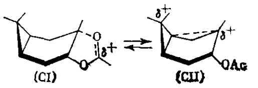
In 1966, Kropp[8,79] found that one of the products of the degradation of the monoacetate of carane-3-β,4α-diol (XXVIIId) by $POCl_3$ in pyridine has the structure of the acetate of 4-isopropenyl-1-methylbicyclo[3,1,0]-hexan-*trans*-2-ol (LXLIX):



(XXVIIId) (C) (LXLIX) (XXXd) .

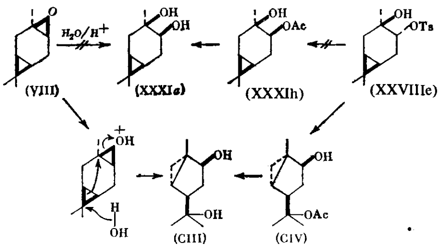
The degradation of the monoacetate of the stereoisomeric carane-3α,4α-diol (XXXd) under the same conditions yields only the acetate of car-3(10)-en-*trans*-4-ol (C) without appreciable admixtures of compound (LXLIX). Having compared the dehydration products of the two carane-3,4-diol ethers epimeric with respect to the 3-C atom, Kropp suggested that the condition determining the rearrangement with 1,3-transannular cyclopropyl participation is the *cis*-orientation of the eliminated OH group with respect to the cyclopropane ring. However, the absence of a rearrangement in the analogous dehydration of "model" epimeric alcohols, i.e. *trans*- and *cis*-3-caranols, showed that this condition alone is insufficient.

The formation of compound (LXLIX) and hence the occurrence of the rearrangement was interpreted by Kropp on the assumption of the equilibrium conformation (CI) ⇌ (CII) for the intermediate homocyclopropyl derivative in which the involvement of the cyclopropyl group is facilitated by the presence of the acetoxy-group, which "fixes" the six-membered ring of (CI) in the *syn*-boat conformation:



(CI) (CII) .

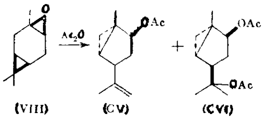
Having analysed the data available at the time on the transformations of the carane structure, Kropp concluded that the rearrangement constitutes the "first 'documented' example of the transannular cyclopropyl participation in the chemistry of carane". However, this rearrangement was presumably achieved in 1962 by Chabudzinski and Kuczynski[80] (who failed to notice it) in the hydration of β-3,4-epoxycarane (VIII) in an acid medium:



They erroneously attributed the structure of carane-3β,4β-diol (XXXIa) ("*cis*-carane-3,4-diol") to one of the two diols obtained in this reaction, having "confirmed" it by synthesis via the acetolysis of the monotosylate of carane-3β,4α-diol (XXVIIIe). It was subsequently found by the present authors[81] that the relevant diol has the structure of 4-(α-hydroxyisopropyl)-1-methylbicyclo[3,1,0]hexan-*cis*-2-ol (CIII). Consequently a rearrangement with the 1,3-transannular cyclopropyl participation occurred in both the hydration of β-3,4-epoxycarane (VIII) and in the acetolysis of the monotosylate (XXVIIIe); because of this coincidence, the rearrangement was not noticed.

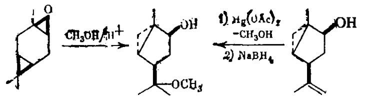
In connection with the elucidation of this finding, it became necessary to reanalyse the experimental data of the studies where "*cis*-carane-3,4-diol" had been identified[80]. As a result, the rearrangement with transannular cyclopropyl participation was observed in the reactions of 3β,4α-dibromocarane with Ag_2O,[82,83] or 3β,4α-dichlorocarane with AgOAc,[47] and of β-3,4-epoxycarane with $NaHSO_3$ in an aqueous solution[84].

In a study of the reaction of β-3,4-epoxycarane (VIII) with acetic anhydride, it was found[85,86] that approximately 50% of the mixture of reaction products consists of the acetates of 4-isopropenyl-1-methylbicyclo[3,1,0]hexan-*cis*-2-ol (CV) and the corresponding diol (CVI):



(VIII) (CV) (CVI) .

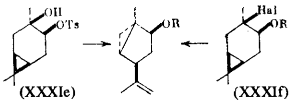
According to the results of Arbuzov et al.[87], the reaction of β-3,4-epoxycarane with methanol in the presence of an acid gives a low yield of the monoether (CIII) of the diol (CVII); the structure of compound (CVII) was confirmed by a synthesis involving hydration using the method of Arbuzov et al.[89]:



(VIII) (CVII) (CVIII) .

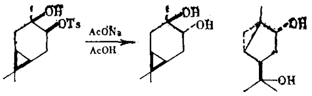
It is therefore of interest to note that one of the adducts of β-3,4-epoxycarane with methanol, obtained by Kropp[8], to which the latter attributed the structure of the monoether of "*cis*-carane-3,4-diol" by analogy with "*cis*-carane-3,4-diol itself", also has the structure of compound (CVII).[80]

The formation of derivatives of the alcohol (CVIII) was likewise demonstrated in reactions of β-3,4-epoxycarane with sodium acetate in acetic acid[90], by the dehydration of the monotosylate of carane-3β,4β-diol (XXXIe),[91] and by the dehydrohalogenation of ethers of *cis*-3-halogeno-4-hydroxycaranes (XXXIf) under the influence of bases[92,93]:



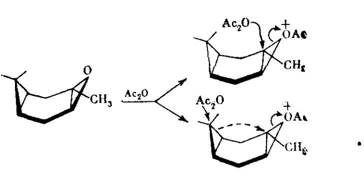
(XXXIe) (XXXIf) .

The acetolysis of compound (XXXIe) with subsequent hydrolysis leads to the diol (CIX),[94] but with an appreciably lower yield than that of the epimeric diol (CIII) in the acetolysis of the monotosylate of carane-3β,4α-diol (XXVIIIe):



(XXXIe) (XXVIIIa) (CIX) .

Comparison of the steric structures of 3,4-disubstituted caranes, the reactions of which are accompanied by a rearrangement with transannular cyclopropyl participation, permits the conclusion that a precondition for the rearrangement is the *cis*-configuration with respect to the relative positions of the cyclopropane ring and the functional groups at the 3-C atom located on the opposite side across the cyclohexane ring. Under the conditions of reactions involving electrophilic addition to β-3,4-epoxycarane, the comparative "activities" of the nucleophilic species attacking the electron-deficient 3-C atom in the intermediate 'onium compound and of the $C_{(1)}-C_{(7)}$ bond in the cyclopropane ring, behaving as an intramolecular nucleophile in the 1,3-transannular shift, are no less important:



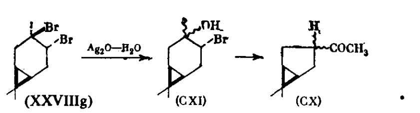
It follows from an examination of the literature data that electrophiles can be arranged in the following sequence in terms of the degree of rearrangement in the reactions of β-3,4-epoxycarane: $Ac_2O > H_2O/H^+ > AcOH/AcONa$.[80,85,86,90]

In the reactions of β-3,4-epoxycarane (VIII) with AcBr in acetic anhydride[92], rearrangements with a 1,3-transannular shift are not observed at all.

3. REARRANGEMENTS WITH CONTRACTION OF THE SIX-MEMBERED RING

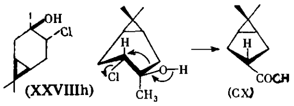
In the last decade studies on the reactions of carane derivatives with substituents at the vicinal secondary and tertiary carbon atoms revealed rearrangements with contraction of the six-membered ring of the Wagner–Meerwein type of rearrangement.

The first data on this rearrangement were obtained by Kuczynski and coworkers[82,83], who showed that, when 3β,4α-dibromocarane (XXVIIIg) is treated with an aqueous suspension of Ag_2O, the main product is 3-acetyl-6,6-dimethylbicyclo[3,1,0]hexane (CX); the configuration at the 3-C atom was not elucidated. The formation of the ketone (CX) from the carane derivative under the conditions of the nucleophilic substitution reaction was explained by the authors on the assumption that there is an intermediate stage involving the conversion of the carane derivative into 4-bromo-3-hydroxycarane (CXI) as an intermediate:



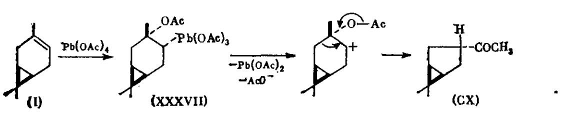
The elimination of HBr from the intermediate is accompanied by a 1,2-shift of the $C_{(2)}-C_{(3)}$ bond in the six-membered ring.

The probability of the involvement of 4-bromo-3-hydroxycarane (CXI) in the conversion of 3β,4α-dibromocarane (XXVIIIg) into the ketone (CX) was confirmed by data obtained in a study of the structures of the stereoisomeric 4-chloro-3-hydroxycarane (XXVIIIh) and 4-bromo-3-hydroxycarane (XXVIIIc). Under these conditions, 4-hydroxy-3-halogenocaranes give a high yield of the ketone (CX):[24,95]

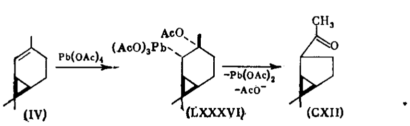


On treatment with silver acetate in acetic acid, 4α-chloro-3β-ethoxycarane forms the ketone (CX) with elimination of a molecule of C_2H_5Cl. 3β,4α-Dichlorocarane (XXVIIIb) is also partly converted into the ketone (CX).[47]

The ketone (CX) has been found in the products of the reaction of 3-carene with $Pb(OAc)_4$.[41,45] It was noted that this reaction may lead to the formation of a *cis*-adduct of the olefin with $Pb(OAc)_4$, the decomposition of which can also involve the contraction of the six-membered ring:

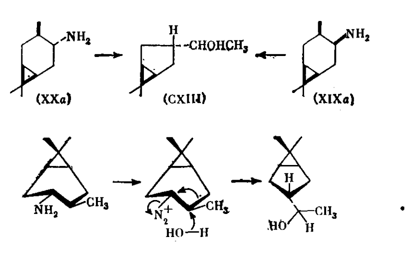


The bicyclic ketone (CXII) is apparently formed similarly in the reaction of 2-carene with $Pb(OAc)_4$:[62]

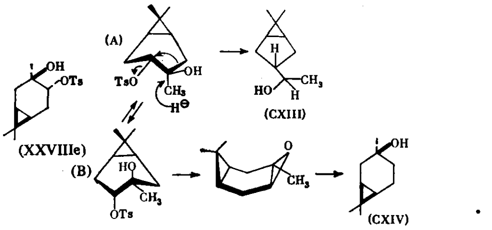


The rearrangement with contraction of the six-membered ring as a result of the 1,2-shift of the $C_{(3)}-C_{(4)}$ bond to the electron-deficient 2-C atom on decomposition of the adduct (LXXXVI) competes with the homoallyl rearrangement in which the cyclopropane ring is involved.

Cocker and coworkers[60] showed that the deamination of the amino-derivatives of *cis*-carane (XIXa) and (XXa), epimeric with respect to the 4-C atom, leads to the formation of appreciable amounts (up to 14% of the mixture of the reaction products) of *trans*-3-(α-hydroxyethyl)-6,6-dimethylbicyclo[3,1,0]hexane (CXIII). The rearrangement can also occur in the diozonium ion as in the case of the 4α-isomer (XXa) and in the carbonium ion with *trans*-attack by the nucleophile relative to the cyclopropane ring:

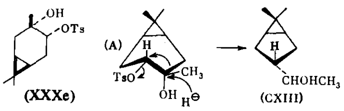


The rearrangement with a 1,2-shift of the $C_{(2)}-C_{(3)}$ bond via a concerted mechanism has been clearly observed in the hydrogenolysis of the monotosylates of carane-3,4-diols. The steric structures of the stereoisomeric carane-3,4-diols (XXVIIIa), (XXXa), and (XXXIa) and possibly of their monoethers consist of equilibrium mixtures of the conformers (A) and (B) with the six-membered ring in the half-chair form[22]. The hydrogenolysis of the monotosylate (XXVIIIe) leads to a 2 : 3 mixture of the two alcohols (CXIII) and (CXIV):

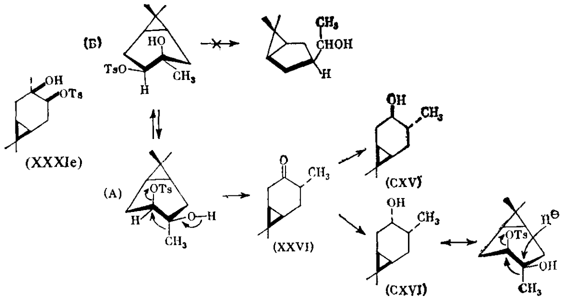


The formation of the former is due to the reaction of the monotosylate (XXVIIIe) in the di-*e*-form (A), since the stereoelectronic requirement imposed on the geometry of the transition state in the rearrangement with ring contraction, namely the anticoplanar disposition of the corresponding bonds, is met in this case. The behaviour of 4α-bromo-3β-hydroxycarane (XXVIIIc) under the same conditions is similar[24].

The hydrogenolysis of the monotosylate (XXXe) proceeds unambiguously with formation of the rearranged alcohol (CXIII); consequently the monotosylate (XXXe) likewise reacts in the preferred conformation (A) having the equatorial $C_{(4)}-O$ linkage:

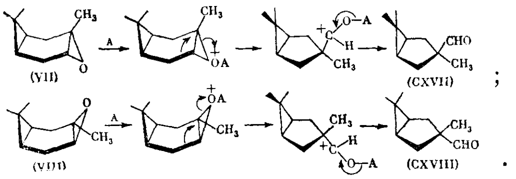


For the monotosylate (XXXIe), conformation (A) with the axial $C_{(4)}-O$ bond is preferred. The rearrangement with contraction of the six-membered ring does not occur here: the processes occurring in the hydrogenolysis by $LiAlH_4$ involve a rearrangement with a 1,2-shift of the $10-CH_3$ group, the stereoelectronic requirement of which (an anticoplanar disposition of the $C_{(4)}$–O and $C_{(3)}$–$C_{(10)}$ bonds)[91] is fulfilled in conformer (A):

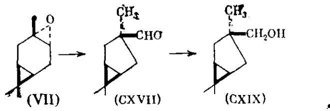


The formation of a 2 : 1 mixture of the epimeric alcohols (CV) and (CVI) as the hydrogenolysis products can be explained if it is assumed that the *E*2 elimination reaction yielding the *trans*-4-caranone (XXVI) takes place under the influence of $LiAlH_4$ together with the hydrogenolysis proper of the monotosylate (XXXIe), leading to *trans*-caran-*trans*-4-ol (CXVI); the stereoselective reduction of the *trans*-4-caranone by $LiAlH_4$ leads preferentially to the alcohol (CXV) with a *cis*-orientation of the OH group relative to the three-membered ring.

It is interesting to note that, among the 3,4-disubstituted carane derivatives, a rearrangement with a different type of contraction of the six-membered ring is characteristic of the stereoisomeric 3,4-epoxycaranes (VII) and (VIII). It involves a 1,2-shift of the $C_{(4)}$–$C_{(5)}$ bond. In 1967, three groups of investigators[97–99] published the results of studies on the isomerisation of 3,4-epoxycaranes under the influence of Lewis acids. The stereoisomeric aldehydes (CXVII) and (CXVIII), the formation of which has been explained by the rearrangement of the carbonium ion intermediates with a 1,2-shift of the ring $C_{(4)}$–$C_{(5)}$ bond, were found among the carbonyl reaction products:



The aldehydes (CXVII) and (CXVIII) are formed from the corresponding stereoisomeric 3,4-epoxycaranes also in the reaction with acetic anhydride[44,86]. According to Teisseire et al.[98], the conversion of 3,4-epoxycaranes into aldehydes is observed under the conditions of gas–liquid chromatography. Silica gel, acting as an electron-accepting agent, also promotes the rearrangement of α,3,4-epoxycarane into the aldehyde (CXVII).[52] On treatment with Al_2O_3, α-3,4-epoxycarane (VII) is partly converted into the alcohol (CXIC), corresponding to the product of the Cannizzaro reaction of the aldehyde (CXVII) formed initially[100]:



---o0o---

The studies by S. S. Nametkin on terpenes made a most valuable contribution not only to the investigation of this class of natural products but also to organic chemistry as a whole. His brilliant research on camphor homologues enabled him to discover the camphene rearrangement of the second kind or the Nametkin rearrangement (given this name to distinguish it from the camphene rearrangement of the first kind or the Wagner rearrangement). One should mention particularly that Nametkin considered the stereochemical aspect of the complex rearrangements in the reactions investigated, which is a characteristic feature of modern organic chemistry.

Petroleum Hydrocarbons

P.I.Sanin

The review considers the present state of research on petroleum hydrocarbons and presents the results of studies on the individual hydrocarbons in various fractions of petroleum as well as individual types of petroleum hydrocarbons; in some cases, the possible pathways to the formation of the hydrocarbons are considered. The general characteristics of the distribution of hydrocarbons in petroleum are discussed and certain features of further research on petroleum hydrocarbons are outlined.

The bibliography includes 85 references.

CONTENTS

I. INTRODUCTION

The studies on petroleum hydrocarbons (and other components) are of exceptionally great theoretical importance, since they extend our knowledge concerning the nature and origin of one of the commonest mineral fuels. At the same time the results of such research have been assuming increasing practical importance.

The main raw material for the petroleum processing and petrochemical industries consists of hydrocarbons isolated from petroleum distillates, liquid and gaseous hydrocarbons formed in different thermal and catalytic types of petroleum processing, as well as the hydrocarbons in natural gases. The study of the chemical composition of petroleum—the determination of the nature and structure of hydrocarbons and other petroleum components, the study of the products of the processing of petroleum, the study of natural gases, and the development of new methods for the separation and investigation of complex mixtures of hydrocarbons—is one of the most important fields in petrochemical research. The investigation of the hydrocarbon composition of petroleum is of primary importance also for the development of new methods whereby one can obtain the principal products of the petroleum industry—fuels and lubricating oils, the properties of which are determined in the first place by their chemical composition.

The study of petroleum hydrocarbons has a relatively long history and in our country has always been considered as one of the most interesting fields of chemical science both as regards theory and practice. It is sufficient to point out that research on petroleum hydrocarbons is associated with the names of F.F.Bel'shtein, A.A.Kurbatov, D.I.Mendeleev, A.A.Markovnikov, V.Ogloblin, M.I.Konovalov, N.D.Zelinskii, S.S.Nametkin, B.A.Kazanskii, and others.

Research by foreign scientists has made a significant contribution to our knowledge of petroleum hydrocarbons. Here mention should be made of the systematic investigation of the composition of petroleum based on the programme of the American Petroleum Institute Project 6, carried out from 1928 under Washburn's supervision, from 1935 under Rossini's supervision, and at the present time under Mair's supervision, as well as the research of Waterman, Vlugter, and coworkers (1928–1940), van Nes and van Westen (1950–1959), etc.

The modern period (from 1960) of research on petroleum hydrocarbons is characterised by the application of various physicochemical methods. Techniques for the isolation and separation of hydrocarbons have been improved: different versions of adsorption chromatography, the thermal diffusion method of separation, and methods based on the formation of clathrate compounds—the clathrate method (the use of urea and thiourea), etc. Gas–liquid chromatography, spectroscopic methods, including infrared and ultraviolet absorption spectroscopy, mass-spectrometry, and nuclear magnetic resonance have found very extensive applications in the characterisation and identification of hydrocarbons.

One should note here that progress in the study of petroleum hydrocarbons is to a large extent determined by the development and application of new research techniques. The use of a new, effective method usually leads to a deepening of our knowledge of petroleum hydrocarbons. A striking example is the application of chromatographic methods to the investigation of such hydrocarbons.

Since the present issue of the journal is devoted to the hundredth anniversary of the birthday of the outstanding scientist Sergei Semenovich Nametkin, a separate section of the review describes the fundamental results of the research by Nametkin together with his pupils and coworkers in the field of petroleum hydrocarbons.

Nametkin's Contribution to Research on Petroleum Hydrocarbons

At the beginning of his scientific career, while still a student at Moscow University, Sergei Semenovich Nametkin already wrote his Diploma Thesis "Hydrocarbons in the Caucasus Petroleum, Their Properties and Chemical Reactions" (1902)†. Before entering his chosen

---

† Nametkin's work quoted in this section has been published in special collections[1].

field of study, the young scientist surveyed in this report the results of previous investigations of the hydrocarbons in Caucasus petroleum.

The first studies on the Caucasus petroleum, carried out at the time when petroleum processing consisted merely in the preparation of lighting kerosene and fuel mazut, already yielded general ideas about the chemical nature of petroleum. It was established that petroleum includes hydrocarbons of three different series: aromatic hydrocarbons, hydrocarbons of the methane series or paraffins, and other saturated hydrocarbons, which Markovnikov called naphthenes. Nametkin, who already showed his characteristic thoroughness and objectivity in the solution of scientific problems, summarised the results of research on petroleum hydrocarbons, and outlined the problems which required further development. The classical studies by the first investigators of Caucasus petroleum had a strong and fruitful influence on his future career.

In 1907, Nametkin began his research, related to Konovalov's familiar studies, on the interaction of dilute nitric acid with hydrocarbons. These experiments, which were initially undertaken to investigate the hydrocarbons in the Caucasus petroleum, led him to new views on the mechanism of the nitration reaction. The mechanism of the nitrating and oxidising action of nitric acid on saturated hydrocarbons, which Nametkin proposed and justified experimentally, is undoubtedly one of the greatest generalisations in organic chemistry. Nametkin described the fundamental results of this research in his Master's Dissertation (1911). He subsequently used the nitration reaction to investigate petroleum hydrocarbons—paraffin and ceresin.

The range of Nametkin's interest in the field of petroleum chemistry was extremely wide, and in the second half of his career embraced the most important types of research on petroleum chemistry, among which studies on the chemical composition of petroleum occupied an exceptional place. These studies may be conventionally combined in the following groups: methodological problems; investigation of petroleum, petroleum fractions, and natural gases; investigation of certain types of hydrocarbons; the synthesis and study of model petroleum hydrocarbons.

Natural gases from a number of deposits in different regions (Baku, Daghestan, Groznyi, Melitopol, Taman', and Chusov), were investigated for the first time in the Soviet Union on a wide scale under Nametkin's supervision (1931–1933) (together with Zabrodina, Karkanas, Kursanov, Sokolov, and Uspenskii). This systematic research was of interest as regards its methodological aspects and at the same time yielded valuable information about the composition of natural gases, which was also of practical importance. Apart from the main component of the gas (methane), ethane, propane, butane, higher hydrocarbons, and carbon dioxide were determined.

The series of Nametkin's studies was devoted to the investigation of petroleum from new and relatively little investigated deposits in the Soviet Union (1928–1930), Sakhalin petroleums (from the Okha, Nutovo, Katangli, Ekhabi, Chakry, and Lyangri deposits) (together with Putsillo, Shakhnazarova, Abakumovskaya, and Nifontova), Kamchatka petroleum {the Bogachev [tentative transcription] deposit}, and the Urals (Perm) petroleum {the Chusovsko [tentative transcription] settlements}. It is noteworthy that the study of the petroleum from the Chusovsko settlements constituted the first research on petroleums from Second Baku. The petroleum investigated had a high content of sulphur compounds (which reached approximately 5.5%) and in this respect differed sharply from the familiar Caucasus petroleums.

An exceptional growth of production of petroleum from the deposits of Second Baku faced investigators with a new problem—the utilisation of the most effective methods for the processing of sulphur-containing petroleums. Nametkin frequently pointed out that this important problem can be solved only on the basis of a comprehensive study of the chemical composition of sulphur-containing petroleums and their sulphur compounds. The nature of the sulphur compounds in the petroleums from Second Baku was almost unknown.

Nametkin and his coworkers obtained the general characteristics of the first petroleum from Second Baku. Subsequently research was undertaken on the sulphur compounds contained in distillates from certain sulphur-containing petroleums. In the first study, on the kerosene distillate from the Urals petroleum (the Chusovsko settlement deposit), it was already shown that thiophans constitute a considerable proportion of the sulphur compounds of petroleum. This conclusion was reached indirectly, on the basis of the results of the oxidation of sulphur compounds by nitric acid. Subsequent investigations confirmed this conclusion. Thus, hexyl-, heptyl-, and octyl-thiophans were isolated from the light distillates of Ishimbai petroleum (via the corresponding mercury complexes). In addition an aliphatic sulphide (dipropyl sulphide) and mercaptans (butane-2-thiol and pentane-1-thiol) were isolated (together with Sosnina; 1948). Together with Putsillo, Nametkin undertook a systematic study of the proposed methods for the group analysis of sulphur compounds (1943). Tests of the methods, using a wide assortment of synthetic materials comprising individual sulphur compounds, made it possible to establish the limits of the applicability of the individual methods and to outline ways whereby an improved analytical technique for complex mixtures of sulphur compounds could be developed.

Further investigation of the nature of sulphur compounds in petroleum, the development of methods for their isolation from petroleum, and methods for their analysis, which were all problems featuring in Nametkin's research, constitute at the present time one of the most urgent problems in the chemistry of petroleum.

The general research on petroleum convinced Nametkin of the necessity for a more detailed investigation of the chemical composition of the petrol, kerosene, and oil distillates from petroleum. Even an approximate knowledge of the chemical composition of the higher distillates of petroleum is of great significance for the solution of many important theoretical and practical problems. At the same time, investigators in this field encountered the greatest methodological difficulties due to the extreme complexity of the objects of study. On the other hand, it was necessary to refine the existing methods for the determination of the group composition of petroleum distillates, and in many cases to develop new methods. Nametkin's methodological research is in fact associated with this period.

Together with Abakumovskaya (1926–1929), he proposed a new method for the determination of unsaturated compounds in petroleum products—the method of oxygen numbers based on the Prilezhaev reaction (the interaction of benzoyl hydroperoxide and unsaturated hydrocarbons with formation of epoxyalkanes). Together with Robinzon (1928–1938), a method was also developed for the quantitative determination of unsaturated and aromatic hydrocarbons in petrols, which was widely used at the time.

Apart from research on petroleum and the group chemical composition of various petroleum distillates, two other types of research feature in Nametkin's work. The first concerns the isolation of hydrocarbons from petroleum fractions and their identification and the second the synthesis and investigation of the properties of "model" hydrocarbons corresponding to petroleum hydrocarbons as regards their structure and molecular weight. Both these types of research have greatly developed in recent years and are of fundamental importance in the study of the structure of petroleum hydrocarbons.

As an example of the first type of research, one may quote Nametkin's investigations (together with Pokrovskaya and Stepantseva; 1949–1950) on hydrocarbons belonging to the naphthalene series. The picrate method was used; the corresponding petroleum fractions were treated with a solution of picric acid and the resulting alkylnaphthyl picrates were isolated in a pure form after recrystallisation and identified; in some cases, the picrates were decomposed (by steam distillation) and the alkylnaphthalenes isolated were also identified. It was possible to establish in this way the presence of naphthalene, β-methylnaphthalene, and 1,6-dimethylnaphthalene in the middle fractions of the light oil from Surakhany petroleum (the 190–252°C distillate) and of naphthalene, monomethylnaphthalenes, 1,6- and 1,7-dimethylnaphthalenes, trimethylnaphthalenes, and other higher naphthalene homologues in Maikop petroleum (185–265°C and 105–135°C distillates at 2 mmHg). Alkylnaphthalenes constitute 15–20% of all the aromatic hydrocarbons in the middle fractions of the above petroleums. At the same time it was shown that the middle fractions of Emba petroleums (the Dossor and Makat deposits) contain virtually no naphthalene or its homologues. These differences in the content of naphthalene homologues are apparently consistent with the general chemical compositions of the petroleums and are possibly due to their age—the Maikop petroleum deposit belongs to the Tertiary Period and that of Emba petroleums belongs to the Jurassic Period.

Studies on the high-molecular-weight hydrocarbons comprising paraffin and ceresin (together with Nifontova; 1936) should be included in the same group of Nametkin's investigations. They constitute an excellent application of the nitration of saturated hydrocarbons with dilute nitric acid, which had been comprehensively studied by Nametkin in his previous work. It was postulated that it is possible to approach in this way a solution to the problem of the structure of the paraffin and ceresin hydrocarbons, which are difficult to investigate chemically. Nitration under appropriate conditions might lead to the formation of secondary and tertiary nitro-compounds and hence to an experimental solution of the problem of whether or not these hydrocarbons contain tertiary carbon atoms.

It was established that, following the nitration of the hydrocarbons of petroleum paraffin, tertiary nitro-compounds as well as secondary nitro-compounds are formed; the hydrocarbons of petroleum ceresin give rise almost exclusively to tertiary nitro-compounds under the same nitration conditions. Thus it was shown that petroleum paraffins and ceresins contain hydrocarbons with a tertiary carbon atom or, in other words, branched hydrocarbons.

These results constituted a new stage in the understanding of the chemical structure of the hydrocarbons in paraffins and ceresins and stimulated chemists to undertake further research on these complex natural petroleum products. It has now been established that paraffins and ceresins contain, apart from saturated hydrocarbons with normal and branched structures, also high-molecular-weight cyclic hydrocarbons (with long paraffinic chains), this is fully consistent with Nametkin's research—cyclic hydrocarbons in paraffins and ceresin also contain a tertiary carbon atom.

Nametkin's study (together with Pokrovskaya; 1937 to 1938) on the synthesis and properties of hydrocarbons in cyclohexylbenzene and cyclopentylbenzene series as well as other polycyclic hydrocarbons constitutes one of the most important stages in the synthesis of model petroleum hydrocarbons. In terms of their molecular weight, these hydrocarbons serve as models of lubricating oils. The hydrocarbons of the cyclohexylbenzene series were obtained by the condensation of benzene with cyclohexene in the presence of aluminium chloride (the Friedel–Crafts reaction). Cyclohexylbenzene ($C_{12}H_{16}$), 1,4-dicyclohexylbenzene ($C_{18}H_{26}$), 1,3,5-tricyclohexylbenzene ($C_{24}H_{36}$), and, tentatively, 1,2,4,5-tetracyclohexylbenzene ($C_{30}H_{46}$) were obtained in this way. The structures of the hydrocarbons were confirmed by analysis and by the catalytic dehydrogenation of their cyclohexane rings; subsequent hydrogenation led to the reformation of the initial hydrocarbons. The study of the hydrocarbons (their viscosities, solubilities, etc.) led to conclusions about their properties as models of lubricating oils. The hydrocarbons of the cyclopentylbenzene series were investigated and described in the same way: cyclopentylbenzene, two dicyclopentylbenzene isomers, and two tricyclopentylbenzene and tetracyclopentylbenzene isomers.

It is seen from the brief review of his studies on petroleum hydrocarbons that Nametkin developed various branches of this important field in petroleum chemistry. His broad view of the problem and the depth of his research enabled him to obtain results, which in many instances still remain important. On the other hand, the fundamental types of research on petroleum hydrocarbons begun, or suggested, by Nametkin have now been developed by his students and later investigators. In this we see the main importance of Nametkin's work, which constitutes a remarkable stage in the general understanding of petroleum.

A brief outline of the present state of research on petroleum hydrocarbons is given below. The first studies on each type of petroleum usually begin with its general characteristics which are of practical importance. More detailed investigations of petroleum hydrocarbons carried out in different laboratories are in most instances devoted to the solution of individual aspects of the given problem and systematic studies are unfortunately undertaken extremely rarely. Nevertheless, all the more detailed investigations of petroleum can be conventionally divided into three groups: studies on the individual compositions of petroleums and petroleum fractions; studies on specific types of hydrocarbons; determination of the general structures of individual types of hydrocarbons (the modern version of structural-group analysis). Certain general features of the hydrocarbon composition of petroleum have also been outlined as a result of this research.

II. PETROLEUMS FROM NEW DEPOSITS

In the general research on different types of petroleum, investigation of petroleums from newly discovered deposits occupied a significant place. The main aim of the initial study of each petroleum is to obtain its general characteristics, to determine the position of the petroleum in the existing classification of different types, and to establish possible procedures for its processing. In order to characterise the petroleum, one employs established methods and procedures, which in some measure determine the extent to which the petroleum is investigated. At the same time, such characteristics of the petroleum must be consistent with the present development of the petroleum processing and petrochemical industry and must therefore be continuously improved.

There exists at the present time an extended programme of research on petroleums from new deposits. There are also shorter programmes of research on such petroleums. Apart from the usual physicochemical characteristics of petroleum and its fractions, whereby their potential content of commercial products (petrols—aviation and automobile fuels, reactive fuel, kerosene, diesel fuel, raw material for catalytic reforming and catalytic cracking, oil fractions, and bitumen) can be found, provision is made in the extended programme for the determination of the group composition of the fractions, for the determination of straight-chain paraffins in certain fractions by the urea method for the elimination of paraffins (for example the paraffins of the 240–350°C fraction used for the microbiological synthesis of protein), the determination of straight-chain paraffins with the aid of molecular sieves (the fraction boiling up to 200°C), and the determination of the structural-group composition of certain oil fractions.

The results of research on petroleums in the individual Republics and Regions of the Soviet Union are reviewed in monographs and handbooks (see, for example, Refs. 2 to 12).

III. INDIVIDUAL PETROLEUM HYDROCARBONS

Quite naturally, complete determination of individual hydrocarbons can be considered only in relation to light petroleum fractions (petrols). On passing to higher-boiling fractions, the number of possible isomers of individual classes of hydrocarbons becomes so great that the determination of the composition in terms of individual compounds is no longer possible.

Systematic studies over a period of many years on the composition of straight-run petrols in terms of individual compounds were undertaken in 1959 under the supervision of Kazanskii and Landsberg[13]. The combined research technique involved accurate fractionisation, the isolation of aromatic hydrocarbons by adsorption chromatography on silica gel, catalytic dehydrogenation of six-membered naphthenes, and analysis of fractions by Raman spectroscopy. In the course of the investigation, approximately 160 individual hydrocarbons were synthesised and the wavenumbers and the line intensities in the spectra of a large number of individual hydrocarbons were obtained. The combined method made it possible to determine hydrocarbons with boiling points up to 125°C and to find qualitatively, and to some extent quantitatively, the contents of a number of hydrocarbons with boiling points between 125° and 150°C.

It was shown with the aid of the combined method, that the composition of straight-run petrols in terms of individual compounds can be elucidated to the extent of 80 to 90%.[14] In the study of a series of petrols from different types of petroleum, up to 90% of the hydrocarbons was determined—alkanes, cyclopentane and cyclohexane hydrocarbons, and aromatic hydrocarbons. Certain characteristics of the distribution of hydrocarbons in petrol as a function of the type of petroleum were established. Of particular interest is the conclusion that, although petrols derived from different types of petroleum contain approximately the same set of hydrocarbons, their quantitative proportions are extremely different, 10 hydrocarbons present in petrol in greatest amounts constituting about 50% of the petrol from each type of petroleum (Table 1).

One should also note a study[15] of the composition of petrols from Nebit-Dag and Romashkino petroleums in terms of the individual hydrocarbons.

Table 1. Hydrocarbons present in greatest amounts in petrols derived from different types of petroleum.

Surakhany (selected)		Tuimazinsk*		Koschagyl	
hydrocarbon	%	hydrocarbon	%	hydrocarbon	%
Methylcyclohexane	20.05	n-Heptane	9.74	Methylcyclohexane	13.06
Cyclohexane	7.37	n-Hexane	8.43	1,3-Dimethylcyclohexane	6.19
1,3-Dimethylcyclohexane	5.68	n-Octane	7.12	Cyclohexane	4.64
1,2-Dimethylcyclopentane	5.49	n-Pentane	6.32	1,2,4-Trimethylcyclopentane	4.10

		2-Methylpentane	3.06		
Total	57.06		54.79		45.62

*Tentative transcription (Ed. of Translation).

In the determination of the composition of the light fractions of petroleum in terms of individual compounds, aromatic hydrocarbons are nowadays first separated from alkanes and cyclanes by adsorption chromatography, accurate fractionation, and spectroscopic methods. The advances in the development of chromatographic methods have greatly extended the scope of research and at the same time greatly reduced the time required for the determination of the composition of light petroleum fractions in terms of their individual compounds.

Here one should note the investigation of hydrocarbons in the petrol fractions in the "reference" Ponca (Oklahoma) petroleum carried out in accordance with the programme of the American Petroleum Institute Project 6. This programme led to the determination of the first characteristics of the composition of petrol fractions boiling in the range 40–180°C from seven types of petroleum (Rossini et al.[16], p. 345; Rossini and Mair[17]). The composition of the hydrocarbon fractions was characterised in terms of the individual hydrocarbons of five classes: straight-chain paraffins, branched paraffins, alkylcyclopentanes, alkylcyclohexanes, and alkylbenzenes; bicycloparaffins and cycloheptanes were present in extremely low amounts and could be neglected. It was already noted at the time that the petrol fractions from different types of petroleum consist of the same hydrocarbons,[*] differing only in the relative contents of the above five classes; on the other hand, within the limits of each class, the relative amounts of the individual hydrocarbons remain approximately constant and vary within the same limits.

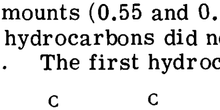
Next a study was made of the 140–180°C distillate from the Ponca petroleum in terms of the individual hydrocarbons, namely branched paraffins and cycloparaffins[18].

The hydrocarbons were isolated by fractionating the distillate (45 litres) on a high-efficiency column using also preparative gas–liquid chromatography; the hydrocarbons were identified by analytical gas–liquid chromatography and by determining the physical as well as spectroscopic characteristics of the hydrocarbons isolated (infrared spectroscopy, NMR, and mass-spectrometry); model hydrocarbons were widely used for identification. 160 fractions, distilling in the range 0.2–0.3°C, were used for the analytical chromatography, which served also for the determination of the quantiative contents of the hydrocarbons. The stationary chromatographic phases were diethylene glycol succinate, silicone nitrile, and *m*-bis-[*m*-(*m*-phenoxyphenoxy)phenoxy]benzene.

As an example of the identification, one may quote 2,4-dimethyloctane[18]. This hydrocarbon was isolated from the fraction boiling at about 156°C and had the refractive index $n_D^{25} = 1.4077$, which is close to the literature value. The mass-spectrometric determination showed that it is a C_{10} paraffin whose molecule contains four methyl groups according to NMR measurements. The results could refer to three hydrocarbons: 2,4-dimethyloctane (b.p. 155.9°C, $n_D^{25} = 1.4069$), 2,2-dimethyloctane (156.9°C and 1.4060), or 1,4-dimethyloctane (157.5°C and 1.4122). The infrared spectrum showed that the hydrocarbon does not contain a tertiary butyl group; the absence of three equivalent methyl groups was likewise confirmed by NMR; thus 2,2-dimethyloctane was excluded. The 4,4-dimethyloctane structure was eliminated by the same type of analysis. At the same time the infrared spectrum showed that the hydrocarbons contain a terminal isopropyl group as well as a butyl group; the structure of the hydrocarbon, corresponding to 2,4-dimethyloctane, was additionally confirmed by the mass spectrum (on the basis of the fragment ions).

Forty-nine paraffins and cycloparaffins, constituting 84% of all possible hydrocarbons in the distillate or 10% in relation to petroleum, were isolated (and identified) from the 140–180°C petroleum distillate, which might contain C_9 and C_{10} hydrocarbons. Six dimethyloctanes of the twelve possible isomers were isolated and identified, namely 2,4-, 2,5-, 2,6-, 3,4-, 4,4-, and 4,5-dimethyloctanes. The remaining six dimethyloctanes, the 2,2-, 2,3-, 2,7-, 3,3-, 3,5-, and 3,6-isomers, are probably present in the petroleum in insignificant amounts only.

It is noteworthy that two paraffins, 2,6-dimethyloctane and 2-methyl-3-propylhexane, were present in petroleum in unusually large amounts (0.55 and 0.64%); the content of each of the other hydrocarbons did not exceed a few hundredths per cent. The first hydrocarbon



$$C{-}\overset{C}{\overset{|}{C}}{-}C{-}C{-}C{-}\overset{C}{\overset{|}{C}}{-}C{-}C$$

can be assigned to isoprenanes—the hydrogenated analogues of acyclic isoprenoids; it was suggested that the second hydrocarbon might have originated from a monocyclic terpene—sylvestrene.

Among the cyclopentanes, 1-methyl-*trans*-2-n-propylcyclopentane, 1-methyl-3-n-propylcyclopentane, and n-butylcyclopentane were identified. Ten of the possible eighteen C_{10} alkylcyclohexanes were also identified. The structural and geometrical isomers of ethylmethylcyclohexane and methylpropylcyclohexane were mainly isolated from C_9 and C_{10} alkylcyclohexanes and identified; also identified were 1-*trans*-2-*cis*-3-trimethyl-, 1-*cis*-2-*trans*-3-trimethyl-, 1,1,2-trimethyl-, and 1,1,3-*cis*-5-tetramethyl-cyclohexanes as well as n-propyl-, isopropyl-, and n-butyl-cyclohexanes.

It is interesting to note that, although the 140–180°C distillate might have contained theoretically a large number of different bicycloparaffins, only nine hydrocarbons belonging to the bicyclo[3,3,0]octane, bicyclo[4,3,0]nonane, bicyclo[3,2,1]octane, and bicyclo[3,3,1]nonane series were isolated and identified:

Judging from the literature data, the hydrocarbon composition of the petrol fractions of petroleum can be found also on the basis of a simplified technique involving only the application of capillary chromatography, the hydrocarbons being identified solely in terms of their retention times without their isolation and characterisation. The saturated hydrocarbons (alkanes and cyclanes) of the 125° to 150°C fraction of the Groznyi petroleum (the Ozek-Suat deposit) were determined in this way[19]. The analysis was carried out using a capillary column equivalent to 60 000 theoretical plates with squalane as the stationary phase. The identification was based on the elution sequence of the hydrocarbons under the chromatographic conditions at 80° and 106°C. The chromatograms of the 125–150°C fraction were interpreted with the aid of a calibration mixture consisting of the products of the isomerisation of n-nonane in the presence of aluminium bromide, which contained a mixture of nonane isomers as well as C_4–C_{10} alkanes (as a result of destructive alkylation). The relative retention times (elution sequence) of the hydrocarbons in the calibration mixture were determined with the aid of model hydrocarbons. After the addition of model hydrocarbons (cyclanes) to the test fraction and the calibration mixture, the cyclanes were identified from the chromatograms. The presence of 61 hydrocarbons (out of the 130 possible compounds), mainly C_9 hydrocarbons, was established in the 125–150°C fraction of the Groznyi petroleum; among the cyclanes, the methyl and ethyl derivatives of cyclopentane and cyclohexane were widely represented.

It is noteworthy that the chromatographic method for the determination of hydrocarbons described above is relatively rapid and is widely used; however, apart from the fact that one cannot characterise hydrocarbons by this procedure (they are not isolated), there are limitations associated with the poor chromatographic separation of certain types of hydrocarbons. Thus the chromatographic peaks of monosubstituted nonane isomers overlap the peaks of cyclopentane hydrocarbons. The six geometrical isomers of 1,2,3,4-tetramethylcyclopentane are also not separated by the chromatographic method.

The research on the hydrocarbons in the petrol fractions of petroleum is related to the research on the hydrocarbons from the gas-condensate deposits. Here mention should be made primarily of extensive systematic investigations of the gas condensates from Central Asian deposits—in Turkmenistan and Uzbekistan[20–23]. A large proportion of the gas deposits which have been prospected and brought into production in recent years are known to be of the gas-condensate type; the gases from these deposits contain 2–5% and more of liquid hydrocarbons. In view of the enormous production of natural gas, amounting to hundreds of thousand millions of cubic metres, liquid hydrocarbons (condensates) are a valuable and readily available raw material for chemical processing. In the study quoted above[19], it was shown that the hydrocarbon composition of the 125–150°C fraction of the condensate from the Shur-Tepe deposit (Turkmenistan) is close to that of the similar fraction of the Groznyi petroleum (the Ozek-Suat deposit).

The bulk of the condensates from all the gas-condensate deposits in Central Asia investigated (50 different condensates have been studied) consist of ligroin fractions (100–200°C) or C_7-C_{13} hydrocarbons; the content of the lightest fraction in the condensate (boiling up to 100°C) rarely exceeds 10%. Certain condensates are distinguished by a high content of benzene homologues (20–30% and more) and cyclohexane homologues (up to 20–25%); on the other hand, another group of condensates have a low content of these hydrocarbons and a high content of cyclopentane homologues.

Certain general characteristics of the hydrocarbon composition of the condensates may be noted. Among branched paraffins, the monomethyl derivatives predominate, namely 2-, 3-, and 4-methyl-alkanes, the substances present in largest amounts being 2-methylalkanes, namely 2-methylpentane, 2-methylhexane, and 2-methylheptane. The dimethylalkanes contain mainly 2,3- and 2,4-dimethylalkanes. Apart from cyclopentane itself, the cyclopentane hydrocarbons consist mainly of methyl- and ethyl-cyclopentanes as well as 1,2- and 1,3-dimethylcyclopentanes. The condensates usually contain all three dimethylcyclohexane isomers (1,2- 1,3-, and 1,4-), the proportion of 1,3-dimethylcyclohexane ranging from 50 to 70% of the total content of all three isomers. It is of interest that the same proportions have been observed for dimethylbenzenes, the 1,3-isomer (*m*-xylene) predominating. One may also note that toluene and 1,2,4-trimethylbenzene predominates in the condensate.

One can now assume that the determination of the composition of the light petroleum fractions (boiling up to about 150°C) in terms of the individual hydrocarbons presents no difficulties. The study of such composition of the middle petroleum distillates has naturally been carried out on a smaller scale. As an example, one may quote the results of the investigations of the Romashkino[24] and Arlansk[25] petroleums. Both types of petroleum have a high content of sulphur compounds (containing 1.8 and 2.84% of sulphur) and tars (9.9 and 20.3%); they can be classified as paraffinic petroleums (their paraffin contents are 4.9 and 4.7%). The petroleums were investigated on the basis of a single programme. Their general characteristics and information about their composition in terms of individual hydrocarbons were obtained. After deasphalting at a low temperature, the petroleum was distilled with isolation of the 180–350°C fraction (the kerosine–gas oil distillate), which was then investigated further. The distillate contained about 19% of straight-chain paraffins and 20% of aromatic hydrocarbons. Various methods for the separation and identification of the hydrocarbons were used in the course of the investigation: clear-cut fractionation, complex formation with urea, adsorption chromatography, gas–liquid chromatography, spectroscopic methods, and catalytic dehydrogenation.

The 180–200°C, 200–300°C, and 300–350°C fractions of the distillate were separated into two components by adsorption chromatography on silica gel: a mixture of paraffins and cycloparaffins and a mixture of aromatic hydrocarbons and sulphur compounds. The straight-chain paraffins were isolated from the mixture of paraffins and cycloparaffins by complex formation with urea and then identified in the usual way by gas–liquid chromatography. It is noteworthy that the hydrocarbons isolated with urea contained, apart from straight-chain paraffins, a certain amount of branched paraffins and cycloparaffins. For example, it has been established that the hydrocarbons crystallising from the 300–350°C fraction of the Romashkino petroleum and forming a complex with thiourea contained 60% of straight-chain paraffins and approximately 40% of branched paraffins and alkylcycloparaffins. Another method for the isolation of straight-chain paraffins from the mixture of saturated hydrocarbons by adsorption chromatography on activated charcoal was developed in the course of the investigation. Subsequently this method was improved and used to separate naphthenes and branched paraffins—the mixture of petroleum hydrocarbons which is most difficult to separate[26].

The list of straight-chain paraffins contained in the 180–350°C distillate is given below. The boiling points of the hydrocarbons, based on the literature data, make it possible to infer the range corresponding to their ebullition.

Straight-chain paraffins

		B.p., °C
$C_{11}H_{24}$	undecane	195.8
$C_{12}H_{26}$	dodecane	216.3
$C_{13}H_{28}$	tridecane	235.5
$C_{14}H_{30}$	tetradecane	253.6
$C_{15}H_{32}$	pentadecane	270.6
$C_{16}H_{34}$	hexadecane	287.1
$C_{17}H_{36}$	heptadecane	302.7
$C_{18}H_{38}$	octadecane	317.5
$C_{19}H_{40}$	nonadecane	331.7
$C_{20}H_{42}$	eicosane	345.3

Thus the distillate contains all ten possible straight-chain paraffins; the content of each hydrocarbon is about 0.4–0.5% in both Romashkino and Arlansk petroleums.

As mentioned above[24,25], the aromatic hydrocarbons isolated by adsorption chromatography contain an appreciable amount of organosulphur compounds; these were oxidised by hydrogen peroxide in glacial acetic acid to sulphoxides, and the latter were separated from aromatic hydrocarbons by adsorption chromatography on silica gel. The purified aromatic hydrocarbons were separated by adsorption chromatography on alumina gel into aromatic hydrocarbons containing one and two benzene rings. The content of aromatic hydrocarbons in the initial distillate was approximately 20% and most of them (80–90%) consisted of alkylbenzenes. The hydrocarbons were distilled with isolation of narrow fractions (2° and 5°C fractions). They were identified by gas–liquid chromatography and infrared and ultraviolet spectroscopy. Model hydrocarbons were used for comparison.

Twenty benzene homologues, mainly with the composition $C_{10}H_{14}$ and $C_{11}H_{16}$, were determined on the basis of the boiling points of the corresponding 170–215°C fractions:

Benzene homologues in petroleum (b.p.170–215°C)

		B.p., °C
C_9H_{12}	1,2,4-trimethylbenzene	169.35
$C_{10}H_{14}$	s-butylbenzene	173.30
$C_{10}H_{14}$	4-isopropyl-1-methylbenzene	177.25
$C_{10}H_{14}$	1-methyl-3-n-propylbenzene	181.75
$C_{10}H_{14}$	n-butylbenzene	183.85
$C_{10}H_{14}$	1-methyl-2-n-propylbenzene	184.75
$C_{10}H_{14}$	2-ethyl-1,4-dimethylbenzene	186.45
$C_{10}H_{14}$	4-ethyl-1,3-dimethylbenzene	188.45
$C_{10}H_{14}$	2-ethyl-1,3-dimethylbenzene	189.95
$C_{10}H_{14}$	3-ethyl-1,2-dimethylbenzene	193.80
$C_{10}H_{14}$	1,2,4,5-tetramethylbenzene	196.85
$C_{10}H_{14}$	1,2,3,5-tetramethylbenzene	198.15
$C_{10}H_{14}$	1,2,3,4-tetramethylbenzene	205.10
$C_{11}H_{16}$	3-phenylpentane	191.0
$C_{11}H_{16}$	4-s-butyl-1-methylbenzene	192.8
$C_{11}H_{16}$	2-phenylpentane	193.0
$C_{11}H_{16}$	3-n-butyl-1-methylbenzene	205.0
$C_{11}H_{16}$	n-pentylbenzene	205.3
$C_{12}H_{18}$	1,4-di-isopropylbenzene	210.4
$C_{12}H_{18}$	4-s-butyl-1,2-dimethylbenzene	215.1

It is seen from the above list that only a small proportion of the hydrocarbons which may be present in the distillate were determined. This is because the difficulty of identifying the hydrocarbons increases with increase of their molecular weights and boiling points. It is also well known that the determination of hydrocarbons in petroleum depends directly on the availability of model hydrocarbons, the synthesis of which also becomes more complicated with increase of the molecular weight of the hydrocarbon.

The high content of tetramethylbenzene isomers in petroleum is striking. Whereas the content of each hydrocarbon [of each of the other hydrocarbons?] does not exceed 0.02–0.04%, the contents of 1,2,4,5-, 1,2,3,5-, and 1,2,3,4-tetramethylbenzenes were found to be 0.064, 0.13, and 0.22%. It is interesting to note that high contents of tetramethylbenzenes for the same proportions of the isomers were found by American investigators in the petroleum from the Ponca deposit[17].

As will be shown below, aromatic hydrocarbons with methyl groups in general predominate among the aromatic hydrocarbons in petroleum. Twenty hydrocarbons boiling in the range 215–300°C have been determined in the fractions containing hydrocarbons with two benzene rings. They consist mainly of naphthalene homologues:

Hydrocarbons with two benzene rings
(b.p. 215-300°C)

		B.p., °C
$C_{10}H_8$	naphthalene	217.96
$C_{11}H_{10}$	2-methylnaphthalene	241.05
$C_{11}H_{10}$	1-methylnaphthalene	244.64
$C_{12}H_{10}$	biphenyl	254.9
$C_{12}H_{12}$	2-ethylnaphthalene	257.9
$C_{12}H_{12}$	1-ethylnaphthalene	258.7
$C_{12}H_{12}$	2,6-dimethylnaphthalene	262.0
$C_{12}H_{12}$	2,7-dimethylnaphthalene	262.3
$C_{12}H_{12}$	1,7-dimethylnaphthalene	263.0
$C_{12}H_{12}$	1,6-dimethylnaphthalene	264.0
$C_{12}H_{12}$	1,3-dimethylnaphthalene	265.0
$C_{12}H_{12}$	1,5-dimethylnaphthalene	265.0
$C_{12}H_{12}$	1,2-dimethylnaphthalene	266.0
$C_{12}H_{12}$	2,3-dimethylnaphthalene	268.0
$C_{12}H_{12}$	1,4-dimethylnaphthalene	130 (12 mmHg) . *cm.*)
$C_{12}H_{12}$	1,2-dimethylnaphthalene	268.5
$C_{12}H_{12}$	1,5-dimethylnaphthalene	269.1
$C_{13}H_{14}$	1-propylnaphthalene	272.0
$C_{13}H_{14}$	2-propylnaphthalene	273.5
$C_{14}H_{16}$	2-s-butylnaphthalene	274—276
$C_{12}H_{10}$	acenaphthene	277.3
$C_{14}H_{14}$	1,2-diphenylethane	284.7
$C_{13}H_{14}$	2,3,6-trimethylnaphthalene	286.0
$C_{13}H_{10}$	fluorene	297.2

Each hydrocarbon of this series was present in the petroleum in an amount corresponding to several thousandths per cent. There were high contents of naphthalene (0.014%), 1-methyl- and 2-methyl-naphthalenes (0.023 and 0.029%) and certain dimethylnaphthalenes.

Of the ten possible dimethylnaphthalene isomers, nine were found in the petroleum, the missing isomer being 1,8-dimethylnaphthalene. The bulk of the dimethylnaphthalenes (70–80% of the total naphthalenes) consisted of four isomers: 1,6-, 2,6-, 2,7-, and 1,7-dimethylnaphthalenes. It is remarkable that the quantitative proportions of the isomers are very similar in a wide variety of petroleums.

Table 2 presents as an example data for two types of petroleum.

It is interesting that the quantitative proportions of the dimethyldecalins found in the petroleums are close to the proportions obtained after prolonged disproportionation of dimethyldecalin isomers on an aluminosilicate catalyst at 450°C.[27] The similarity of the compositions of the dimethylnaphthalenes from different types of petroleum demonstrate yet again the common features in the composition of petroleum hydrocarbons in general.

Apart from naphthalene homologues, biphenyl, 1,2-diphenylethane, acenaphthene, and fluorene were detected in the petroleum. A number of decalin homologues were also determined. For this purpose, the fractions of naphthenoparaffinic hydrocarbons were dehydrogenated in the liquid phase in the presence of an iron-platinum catalyst after the elimination of straight-chain paraffins[28]. The resulting naphthalene homologues were isolated and identified as described above. Many decalin homologues were determined by this indirect procedure in the 200° to 300°C distillate; their structures corresponded to those of the naphthalene homologues determined previously in the petroleum: 2-methyl- and 1-methyl-decalins, 2-ethyldecalin, and all the isomeric dimethyldecalins except 1,8-dimethyldecalin. Using the dehydrogenation reaction, hydrocarbons with mixed structures were also found in the petroleum: cyclohexylbenzene and 1-cyclohexyl-2-phenylethane.

Table 2. The comparative contents of dimethylnaphthalene isomers in different types of petroleum.

Hydrocarbon	Contents of dimethylnaphthalene isomers, wt.% (relative to total content of dimethylnaphthalenes	
	Arlansk petroleum	American petroleum (Ponca)
2,6-Dimethylnaphthalene	17.2	19.4
2,7-Dimethylnaphthalene	13.4	14.4
1,7-Dimethylnaphthalene	14.6	21.2
1,6-Dimethylnaphthalene	27.2	28.2
1,3-Dimethylnaphthalene	7.2	0.2
2,3-Dimethylnaphthalene	5.9	7.2
1;4-Dimethylnaphthalene	4.6	2.8
1,5-Dimethylnaphthalene	2.9	3.7
1,2-Dimethylnaphthalene	7.0	2.4
1,8-Dimethylnaphthalene	nil	nil

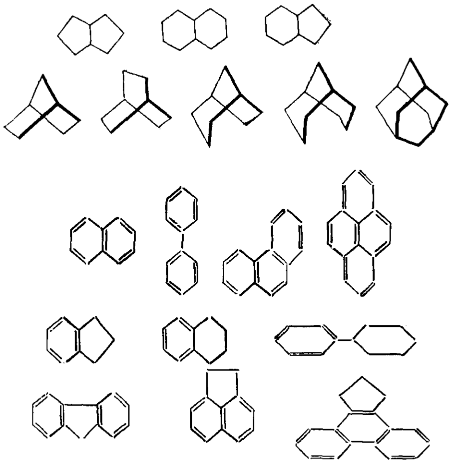
Summarising the results of studies on the composition of petroleum hydrocarbons in terms of individual compounds, we see that more than 600 hydrocarbons have now been isolated from petroleum or determined in petroleum. Different classes of hydrocarbons have been investigated to different extents. Paraffinic hydrocarbons with straight-chain structures have been studied most thoroughly. This is understandable, since straight-chain paraffins do not have isomers. Their isolation from petroleum fractions (adsorption chromatography, the formation of a complex with urea, isolation with the aid of zeolites—molecular sieves) and identification (gas–liquid chromatography) do not present difficulties at present, as already mentioned above. Preliminary detailed investigations of the physicochemical properties of straight-chain paraffins, particularly their tendency to form solid solutions, have proved of much assistance in their identification[29].

The presence of all straight-chain paraffins from n-butane (b.p. −0.5°C) to n-tritriacontane $C_{33}H_{68}$ (b.p. 475°C) in petroleum has been demonstrated; some of the straight-chain paraffins have been isolated in a pure form with a purity exceeding 99 mole %. The content of straight-chain paraffins in petroleum decreases with increase of their molecular weight; that of the highest straight-chain paraffins is 0.1% or less[30].

It is of interest that, in the solution of the problem of the microbiological synthesis of protein from the paraffinic hydrocarbon of petroleum, the past studies on hydrocarbons of this series made it possible to solve over a short period methodological problems associated with the determination of the paraffins (and to some extent aromatic hydrocarbons) in the initial fractions used for the synthesis and in the biological products obtained.

The list of the hydrocarbons detected in petroleum shows how limited is our knowledge of the hydrocarbons in the middle fractions of petroleum, particularly of branched paraffins and cyclanes as well as hydrocarbons with mixed structures containing benzene and cycloparaffin rings. Only a few of the hydrocarbons detected in petroleum boil above 200°C.

The structural formulae of the principal types of cyclanes and aromatic hydrocarbons containing two and more rings, which have been detected in the middle fractions of petroleum, are listed below:



Certain homologues of these hydrocarbons and their isomers have been found.

It is of interest to compare the results of the study of the hydrocarbon composition of petroleum obtained in the reserach laboratories of the Soviet Union and abroad, in the first place those of the American Petroleum Institute Project 6.[16,18,30–34] The total numbers of hydrocarbons determined are approximately the same, but the alkyl derivatives of cyclopentane and bicyclanes have been studied more fully in the Soviet Union. Foreign investigators have paid more attention in recent years to the isolation and determination of aromatic petroleum hydrocarbons. It is noteworthy that nowadays investigators endeavour in most cases to determine the hydrocarbon chromatographically without isolating it from petroleum. Because of this, the properties of certain hydrocarbons detected in petroleum have sometimes not been investigated.

The enormous number of structural and geometrical isomers in the middle fractions of petroleum limits the possibility of their determination. Other research techniques described below are of considerable importance in this field.

IV. INDIVIDUAL TYPES OF HYDROCARBONS

We may note one group of hydrocarbons in the middle fractions of petroleum, namely methylnaphthalenes, the composition of which in terms of individual compounds was investigated within certain limits as early as the 1950s. Naphthalene homologues form crystalline picrates (molecular compounds) by reaction with picric acid and for this reason they were isolated from petroleum fractions relatively long ago. The modern methods for their identification were described above.

Four types of hydrocarbons, namely alkyl derivatives of adamantane and hydrocarbons which are the hydrogenated analogues of terpenes (isoprenanes, steranes, and triterpanes), have been actively investigated recently.

(a) Adamantane and Its Homologues

Adamantane or tricyclo[3,3,1,$1^{3,7}$]decane, which has a very unusual polyhedral structure, has been isolated from Godonin petroleum (Czechoslovakia) and has been investigated by Landa and Machacek[35] in 1933. It is a crystalline substance with a melting point of 269°C (the highest among the known hydrocarbons). The adamantane molecule consists of three condensed cyclohexane rings in the chair form; the steric dispositions of the carbon atoms in the adamantane molecule forming, as it were, a cage closed on all sides, is the same as in the crystal structure of diamond—hence its name:

 .

Mention should be made of yet another factor—the discovery in petroleum of this hydrocarbon with its remarkable structure and properties initiated the development of an extremely important field in modern organic chemistry—the chemistry of adamantane. Adamantane derivatives have now found a wide variety of applications (as medicinal substances, polymers, etc.).

Adamantane is usually obtained by the isomerisation of the fully hydrogenated cyclopentadiene dimer (*endo*-trimethylenenorbornane) in the presence of aluminium chloride[36]:

 .

The isomerisation takes place also over the aluminosilicate catalyst[37]. We are unable to consider here the reaction mechanism, which is discussed by Schleyer and Donaldson[38].

The adamantane content in the middle fractions of Soviet petroleums has been determined by the method of Landa and Hala[39]. The entire distillate which may contain adamantane is obtained from petroleum by steam distillation; adamantane is concentrated by repeated complex formation with thiourea and is isolated by preparative gas–liquid chromatography. The adamantane contents in various Soviet petroleums, even those with a high content of cyclanes such as the petroleums from the Balakhansk [tentative transcription] and Surakhany deposits, are small and usually amount to 0.004–0.01%.[39] Petroleum from the Ponca deposit (USA) was found to contain 0.004% of adamantane[40]. The content of adamantane is somewhat higher in the petroleum from the Godonin deposit, where it was first discovered[41].

The presence of a number of alkyladamantanes in petroleum has now been established. They can be isolated and identified as follows. The petroleum fraction consisting of branched paraffins and cyclanes is separated by thermal diffusion, which yields a concentrate of tricyclic hydrocarbons containing alkyladamantanes. The efficiency of the thermal diffusion method in this case has been confirmed with the aid of artificial mixtures of synthetic hydrocarbons. The concentrate, containing a considerable amount of "non-adamantane" structures in addition to the alkyladamantanes, is subjected to catalytic cracking and dehydrogenation under pulsed conditions over a platinum catalyst (0.5%) on alumina at 420°C and the resulting unsaturated and aromatic hydrocarbons (formed by the dehydrogenation of the cyclanes containing the cyclohexane ring) are removed by adsorption chromatography on activated silica gel. Under the conditions described, alkyladamantanes, which are very stable, are hardly altered. Only partial epimerisation is observed, for example, there is partial conversion of *cis*-1,4-dimethyladamantane into *trans*-1,4-dimethyladamantane[43]. The alkyladamantanes in the concentrate are then identified by capillary gas–liquid chromatography (with squalene as the stationary phase)[42,43].

The 200–250°C fraction of heavy Balakhansk petroleum (Baku), which might have contained methyl- and ethyladamantanes, was investigated in this way. The yield of the 200–225°C fraction was 2.8% and its content of the mixture of branched paraffins and cyclanes was 85%. A concentrate of tricyclanes was isolated from the mixture and a concentrate of alkyladamantanes was obtained.

Twenty-four $C_{11}-C_{14}$ alkyladamantanes with methyl and ethyl substituents were identified. The total content of alkyladamantanes was 0.02%, which is ten times more than the content of adamantane itself in this petroleum (0.001%).

The presence of mono-, di-, tri-, and tetra-substituted alkyladamantanes, containing methyl and ethyl substituents in various positions in the adamantane ring, has now been established in different types of petroleum[42-46].

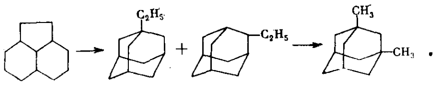
Petroleum alkyladamantanes
(The alkyl groups and their positions in the adamantane nucleus are indicated)

C_{11}	C_{13}	C_{14}
1-methyl-	1,3,5-trimethyl-	1,3,5,7-tetramethyl-
2-methyl-	1,3,6-trimethyl-	1,3,5,6-tetramethyl-
	1,3,4-trimethyl	1-ethyl-2,5-dimethyl-
	1-ethyl-3-methyl-	1,2,3,5-tetramethyl-
C_{12}	4-ethyl-1-methyl-	
	1,2,6-trimethyl-	
1,3-dimethyl-	1,2,4-trimethyl-	
1,4-dimethyl-		
1,2-dimethyl-		
1-ethyl-		
2-ethyl-		
2,2-dimethyl-		
2,4-dimethyl-		

It is remarkable that, together with the most stable alkyladamantanes having substituents at the tertiary bridgehead carbon atoms in the adamantane nucleus (in the 1-, 3-, 5-, and 7-positions), alkyladamantanes with substituents at secondary carbon atoms (in the 2-, 4-, and 6-positions) have been detected in petroleum in considerable amounts. Consequently, the proportions of the alkyladamantane isomers in different types of petroleum do not correspond to equilibrium.

Compounds containing the adamantane nucleus have not been detected among substances of plant and animal origin. One must therefore suppose that the hydrocarbons of the adamantane series have been formed as a result of secondary processes—for example as a result of the isomerisation of other tricyclic hydrocarbons present in petroleum.

Tricyclic (perhydroaromatic) hydrocarbons, namely perhydroacenaphthene (C_{12}), perhydrofluorene (C_{13}), and perhydroanthracene (C_{14}), are known to isomerise to alkyladamantanes in the presence of $AlBr_3$.[47] The mechanism of the process involving perhydroacenaphthene is as follows:



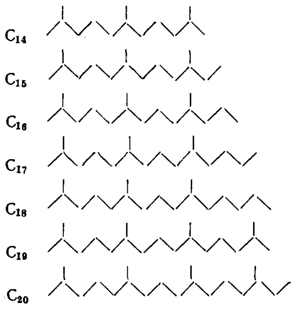
The isomerisation takes place also under the influence of other metal halides[44] and the corresponding bicyclic hydrocarbons are likewise capable of isomerising adamantanes[48].

Tricyclic hydrocarbons undergo an analogous transformation also under the conditions of heterogeneous catalysis over an aluminosilicate catalyst or alumina at moderate (between approximately 180 and 250°C) and higher temperatures[48-51]. The alkyladamantanes formed in the reaction then undergo further isomerisation, there is an increase in the total number of substituents, a decrease in the length of the substituents, and preferential formation of the most stable alkyladamantanes containing methyl or other groups only at the bridgehead positions of the adamantane nucleus.

As already mentioned above, in the series of alkyladamantane isomers with the same molecular weight the proportions of petroleum adamantanes are far from the equilibrium values. Thus the contents of 1,3,5-, 1,3,6-, and 1,3,4-trimethyladamantanes in petroleum were (relative to the sum of C_{13} alkyladamantanes) 21.5, 14, and 28.5%, while the contents in the equilibrium mixture (obtained by isomerisation over alumina) were 92.5, 3, and 3% respectively. At the same time, there is a fairly satisfactory correspondence between the relative contents of petroleum alkyladamantanes and their contents in the non-equilibrium mixtures obtained in the catalytic isomerisation of tricyclanes. Thus, even if alkyladamantanes were formed from tricyclanes, this must have occurred under conditions preventing the completion of the isomerisation reaction with formation of stable isomers alone; kinetic factors may have played a significant role in this process.

(b) Petroleum Isoprenanes

Alkanes with the isoprenoid structure were discovered in petroleum in the 1960s. Aliphatic polyperterpenes, having a polyisoprene skeleton with a characteristic alternation of methyl chain substituents at intervals corresponding to three methylene groups, which may be regarded as isoprene polymerisation products, are classified as aliphatic isoprenoids in organic chemistry. The term "isoprenoid petroleum hydrocarbons" has been very arbitrarily attributed to saturated branched alkanes, which are hydrogenated analogues of isoprenoids. The present author believes that the above hydrocarbons should be called isoprenanes, by analogy with terpanes (hydrogenated analogues of terpenes) and steranes (hydrogenated analogues of steroids). The structures of $C_{14}-C_{20}$ isoprenanes can be represented as follows:



Mainly 2,6-dimethylalkanes, 2,6,10-trimethylalkanes, and 2,6,10,14-tetramethylalkanes are assigned to hydrocarbons of this type.

The syntheses of the majority of isoprenane hydrocarbons as models of petroleum hydrocarbons have now been described[52,53]. Thus 2,6-dimethylalkanes ($C_{10}-C_{13}$) can be obtained from acyclic terpenoids—citronellol, citral, pseudoionone; 2,6,10-trimethylalkanes ($C_{14}-C_{18}$) can also be obtained from pseudoionone. In a general form, the synthesis of alkanes of this type can be carried out via the following scheme:

corresponding ketone → alcohol → unsaturated hydrocarbon → alkane.

For example the alcohol 2,6,10-trimethylundeca-2,6-diene-10-ol has been obtained by the Grignard reaction from geranylacetone, synthesised by the condensation of linalool and ethyl acetoacetate; the alcohol was then dehydrated to the corresponding triene and the hydrogenation of the latter yielded 2,6,10-trimethylundecene:

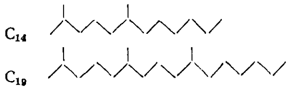
Phytane (2,6,10,14-tetramethylhexadecane) can be obtained by the dehydration of isophytol (2,6,10,14-tetramethylhexadec-15-en-14-ol) and subsequent reduction of the resulting tetramethylhexadiene to tetramethylhexadecane:

The physicochemical characteristics of the isoprenanes synthesised are listed in Table 3.

Table 3. Physicochemical characteristics of isoprenanes.

Hydrocarbon	B.p., °C (mmHg)	B.p., °C (at 760 mmHg; recalc.)	Solidification temp., °C	n_D^{20}	ρ_4^{20}
2,6,10-Trimethylundecane	103.2—103.8 (11)	236.2—237.5	<—100	1.4270	0.7593
2,6,10-Trimethyldodecane (farmesane)	118.0 (10)	253	<—90	1.4335	0.7714
2,6,10-Trimethyltridecane	123.5 (9)	272	<—90	1.4349	0.7773
2,6,10-Trimethyltetradecane	127.5 (7)	285	<—80	1.4361	0.7806
2,6,10-Trimethylpentadecane	140.3 (8)	300	<—70	1.4400	0.7845
2,6,10,14-Tetramethylpentadecane (pristane)	146—147 (4)	331.2—332.5	<—70	1.4390	0.7845
2,6,10,14-Tetramethylhexadecane (phytane)	139.7—140.2 (3)	352.5—353.0	—70	1.4420	0.7935

Branched alkanes, whose molecules contain only fragments of the isoprenane (polyisoprene) structure have also been synthesised, for example, 2,6-dimethyldodecane, 2,6,10-trimethylhexadecane, etc.[54]:



The isoprenanes pristane and phytane were first detected in Iranian[55] and Western Texas[56,57] petroleums. It has now been established that all petroleums contain some isoprenanes; they have also been detected in shale, bituminous coal, and various bituminous sedimentary rocks[58,59]; their formation is apparently associated with a plant substance (phytol), which has a definite bearing on the problem of the origin of petroleum and caustobioliths in general. The wide occurrence of these unusual hydrocarbons and their biogenic origin ("biological labels") has attracted the attention of investigators.

Various methods, particularly capillary gas chromatography and mass spectrometry, are used to determine isoprenanes. Two approaches to the identification of isoprenanes in petroleum have been devised; the first provides for a preliminary preparation in one way or another of isoprenane concentrates from fairly narrow fractions and their subsequent analysis and the second involves direct determination of isoprenanes in broad fractions with the aid of analytical gas chromatography.

A scheme has been described for the investigation of hydrocarbons of the type of isoprenanes in 180–350°C petroleum fractions, which involves the elimination of aromatic hydrocarbons (adsorption on silica gel) and straight-chain alkanes (complex formation with urea) from the fraction, separation of branched alkanes and cyclanes by adsorption chromatography on activated charcoal, and their vacuum distillation[60]. The development of a method for the separation of branched alkanes and cyclanes presented the greatest difficulties—separation of this kind is still an urgent problem and in this connection we may mention, together with the use of activated charcoal as an adsorbent, the work by American investigators in which Sephadex has been used as the adsorbent[61]. Branched alkane fractions, in which isoprenanes were determined by capillary chromatography and mass-spectrometry, were thus obtained. A mass-spectrometric method has been developed for the quantitative determination of isoprenanes in petroleum[62]. The entire study has been carried out using model hydrocarbons.

Isoprenanes can be determined also by methodologically simpler methods. The 150–350°C broad petroleum fraction, containing the main bulk of petroleum isoprenanes (with the $C_{11}-C_{20}$ composition), was directly analysed for isoprenanes by capillary gas chromatography (with Apiezon L as the stationary phase) after preliminary elimination of aromatic hydrocarbons by adsorption on silica gel[53]. The contents of isoprenanes in various types of petroleum[57,60] are listed in Table 4.

Table 4. The contents of isoprenanes in different types of petroleum (wt.%).

Hydrocarbon	Composition	B.p., °C	Petroleum		
			Romashkino	Irkutsk	Western Texas
2,6,10-Trimethylundecane	C_{14}	236.2—237.5	0.2	0.20	0.10
2,6,10-Trimethyldodecane (farmesane)	C_{15}	253	0.2	0.20	0.20
2,6,10-Trimethyltridecane	C_{16}	272	0.2	0.15	0.20
2,6,10-Trimethyltetradecane	C_{17}	285	0.1	0.10	not found
2,6,10-Trimethylpentadecane	C_{18}	300	0.2	0.30	0.06
2,6,10,14-Tetramethylpentadecane (pristane)	C_{19}	331.2—332.5	0.2	0.30	0.50
2,6,10,14-Tetramethylhexadecane (phytane)	C_{20}	352.5—353	0.4	0.50	0.20

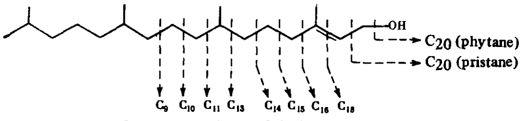
The Table shows that petroleums contain all seven $C_{14}-C_{20}$ isoprenanes (2,6,10-trimethyl- and 2,6,10,14-tetramethyl-alkanes). Their overall content in petroleum is approximately 1.5–2.0% and the amount of each hydrocarbon is approximately 0.2–0.3%. Certain types of petroleum have enhanced contents of pristane (C_{19}) and phytane (C_{20}).

The contents of isoprenane hydrocarbons in four Soviet paraffinic petroleums {Ronashkino, Groznyi, Surgut

(Western Siberia), and Usinsk [tentative transcription] (Ukhta)} have been determined[53], and, apart from the $C_{14}-C_{20}$ hydrocarbons mentioned above, $C_{11}-C_{13}$ dimethylalkanes were found, namely 2,6-dimethylnonane, 2,6-dimethyldecane, and 2,6-dimethylundecane. The overall content of ten $C_{11}-C_{20}$ isoprenane hydrocarbons (2,6-dimethyl-, 2,6,10-trimethyl-, and 2,6,10,14-tetramethylalkanes) was 2–3%.

Thus the petroleums are distinguished by a high content of isoprenanes, the main bulk of which (30–40%) consists of pristane and phytane. The isoprenane contents in petroleum may vary as a function of the overall composition of the petroleum; the largest amounts of isoprenanes are present in paraffinic petroleums. In comparing quantitative contents of isoprenanes in different types of petroleum, account must also be taken of the deviations associated with the characteristics of the methods used to identify the hydrocarbons.

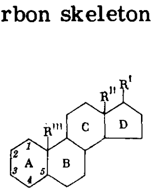
The majority of investigators assume, quite correctly, that the main source of isoprenanes is phytol, an unsaturated aliphatic alcohol, which can be isolated from plant chlorophyll by hydrolysis. Phytane (C_{20}) might have been formed from phytol under appropriate conditions by its dehydration and subsequent hydrogenation of the resulting unsaturated hydrocarbon. The thermocatalytic degradation of phytol itself or phytane (also with subsequent hydrogenation) might have led to the formation of hydrocarbons of this type[57,63,64]. This can be clearly illustrated by the following diagram[64]:



The experimental data for the thermocatalytic degradation of phytol and the composition of the petroleum isoprenanes confirm the validity of the above scheme. However, we may note that some of the isoprenanes might have been formed from the corresponding acids—fornesanoic, phytanic, etc., which have been detected in certain paraffinic types of petroleum.

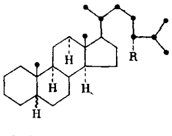
(c) Steranes and Triterpanes

Steranes are saturated tetracyclic hydrocarbons based, like steroids, on the carbon skeleton of cyclopentanoperhydrophenanthrene:



The origin of the steranes detected in petroleum and other caustobioliths is naturally associated with steroids. Steroids are substances of plant and animal origin, which differ in the nature of their substituents (they can contain hydroxy-, keto-, and other groups), the nature of the alkyl groups, and the degree of unsaturation of the tetracyclic nucleus. Thus steranes might have been formed from steroids as a result of a number of chemical transformations, among which reduction (under natural conditions, apparently associated with the disproportionation of hydrogen) should have played a significant role. The biological origin of steranes in fact made it possible to regard them, like isoprenanes, as biological "labels" and to relate the results of the study of petroleum steranes to the general problems of the origin of petroleum.

Steranes have been found in bituminous sedimentary rocks, in oil-bearing shales, in brown coal, and in petroleum. Here special attention must be made of the study of Nigerian petroleum and the oil-bearing shale from the Green River deposit (Colorado), the results of which have been described in reviews[65,66]. Cholestane, ergostane, and stigmastane have been detected in the 458–526°C fraction of Nigerian petroleum:

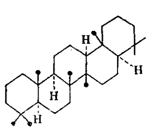


cholestane ($C_{27}H_{48}$), R = H;
ergostane ($C_{28}H_{50}$), R = CH_3;
stigmastane ($C_{29}H_{50}$), R = CH_2CH_3;

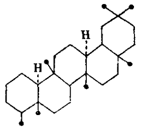
The same steranes, as well as lanostane, have been detected in the 450–500°C fractions of the Soviet petroleums from the Gyurgyansk [tentative transcription] and Anastasievsko-Troitsk [tentative transcription] deposits[67].

The hydrocarbon cholestane is an analogue of the steroid cholesterol {$C_{27}H_{46}O$, m.p. 149°C, $[\alpha]_D = -39°$}, which is one of the zoosterols, ergostane is an analogue of ergosterol {$C_{28}H_{50}$, m.p. 165°C, $[\alpha]_D = -130°$}, which is one of the microsterols, and stigmastane is an analogue of stigmasterol {$C_{29}H_{52}$, m.p. 170°C, $[\alpha]_D = -40°$}, which is a well known phytosterol.

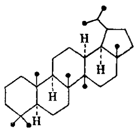
A number of analogues of cyclic polyterpenes, namely diterpanes (C_{20}) and triterpanes (C_{30}) have also been detected in petroleum (and other caustobioliths). The pentacyclic triterpanes detected included gammacerane, friedelane, and lupane:



gammacerane



friedelane



lupane

The presence in petroleum of hydrocarbons with the oleanane (a triterpane) structure has also been established.

Several triterpanes, which are solids melting at relatively high temperatures, have been isolated from Nigerian petroleum[68–70]. The triterpane gammacerane has been isolated from petroleum (and from the bitumen of the Green River shale) and has been thoroughly investigated by mass-spectrometry; it has a melting point of 290°C and $[\alpha]_{546}^{21} = +31.9 \pm 0.4°$.[69] Friedelane has been detected in the petroleums from the Gyurgyansk and Anastasievsko-Troitsk deposits[67]; the triterpanes lupane and moretane have been found in the Baku petroleum from the Surakhany deposit[71]. Furthermore, one should note that an unusual pentacyclic terpane, containing two rings with a spiro-junction, has also been found in Nigerian petroleum[70].

Since steroids and triterpanes consist of condensed alicyclic rings, there is a possibility of their stereoisomerism depending on the *cis*- and *trans*-disposition of the rings relative to one another, similar to the stereoisomerism of perhydrophenanthrene. In natural steroids, ring C occupies the *trans*-position relative to rings B and D, while ring A can have both *cis*- and the *trans*-configuration in relation to ring B. Indeed, it is proved possible to isolate from the Green River shale bitumen two isomers of cholestane, ergostane, and stigmastane in each case, namely the 5α- and 5β-isomers, depending on the position of the hydrogen atom at the fifth carbon atom. The 5β-isomer (*trans*-junction of rings A and B) usually predominates.

Like steroids, steranes are optically active, since the carbon atoms at the junctions between the rings are arranged asymmetrically. The latter should have led to a large number of stereoisomers. For example, pregnane (a C_{21} sterane) might have 128 isomers due to stereoisomerism alone, and, when two additional asymmetric centres are present (after the introduction of substituents into the ring), the number of possible isomers reaches 512. In reality, steroids are synthesised in nature with considerable selectivity and among the enormous number of steroids only four steric forms of the skeleton, corresponding to the energetically most favourable configuration, have been found. This naturally applies also to steranes.

The optical activity of steranes is of special interest. It has been noted for a long time that petroleums exhibit optical activity, which has served as a basis for the claim that petroleum contains components related to natural organic compounds with asymmetric molecules. The optical activity of petroleum is probably largely caused by the presence in the latter of sterane and triterpane hydrocarbons. More complete data on the optically active substances in petroleum can be found in Louis's paper[72].

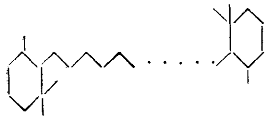
Different methods have been used to isolate and identify steranes and triterpanes. The concentrate of tetracyclic and pentacyclic hydrocarbons is isolated from the corresponding fraction containing branched paraffins and cycloparaffins using separation by thermal diffusion, adsorption chromatography on activated charcoal, gel-penetration chromatography on dextran, etc. Sterane (C_{27}, C_{28}, and C_{29}) and triterpane (C_{30}) concentrates are in their turn isolated from the resulting concentrate by preparative gas–liquid chromatography. Sterane concentrates are sometimes treated with thiourea in order to separate α(*trans*)- and β(*cis*)-steranes[73]. Steranes and triterpanes are identified by analytical gas–liquid chromatography, mass-spectrometry, and chromato-mass-spectrometry. The application of chromato-mass-spectrometry proved to be extremely effective, since the nature of the fragmentation of model steranes and triterpanes under the influence of electron impact had been thoroughly investigated beforehand[66].

It is noteworthy that the preparation of individual steranes and triterpanes, which are absolutely essential model hydrocarbons for their determination in petroleum, involves certain difficulties. The steranes described above (cholestane, ergostane, and stigmastane) are usually obtained from the corresponding sterols, containing double bonds and a hydroxy-group. Sterols are reduced under pressure in an atmosphere of hydrogen in the presence of catalysts or dehydration and hydrogenation are carried out in succession. It is then necessary to maintain reaction conditions such that the resulting saturated hydrocarbon (sterane) has a structure corresponding to that of the initial compound; in other words, one must make sure that there are no rearrangements and especially no rupture of the cyclopentane ring.

As already mentioned, steranes and terpanes have been found in various caustobioliths belonging to different, sometimes extremely ancient geological ages. The bituminous Green River shale, the steranes and triterpanes of which have been most thoroughly investigated, belongs to the Eocene Era in terms of its age (about 52 × 10^6 years). Steranes and terpanes have been detected in the organic material of more ancient sedimentary rocks in Precambrian deposits (more than 10^9 years old).

It is at present difficult to estimate quantitatively the content of steranes and terpanes in petroleum, since the majority of determinations have been qualitative. One can only note that the extract from the Green River bitumen, consisting of branched paraffins and cycloparaffins (average molecular weight 226–558) consisted to the extent of 10% of hydrocarbons of biological origin, among which there was 10% of isoprenanes, 20% of terpanes, and 20% of steranes. Steranes and triterpanes are probably also present in relatively large amounts in petroleum, at any rate in amounts comparable to that of isoprenanes.

Apart from isoprenanes, steranes, and triterpanes, other biogenic hydrocarbons have been detected in petroleum and other caustobioliths. These include, for example, perhydro-β-carotene[63,66]:



Perhydro-β-carotene ($C_{40}H_{56}$) is a hydrogenated analogue of β-carotene—a plant pigment.

In conclusion of this Section, one must note that further research on biogenic hydrocarbons from different types of petroleum will be useful not only for the extension of our knowledge of the chemical composition of petroleums, but also for the solution of geochemical problems of the origin of petroleum.

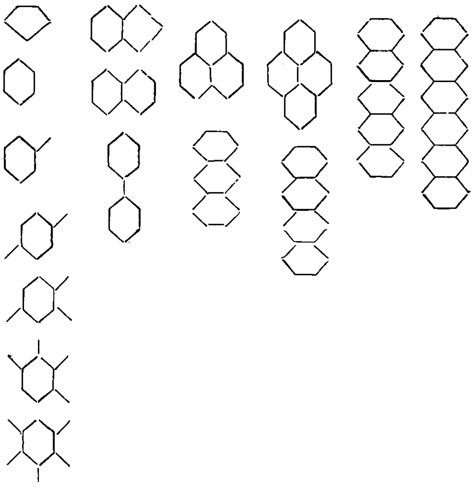
V. DETERMINATION OF THE OVERALL STRUCTURE OF INDIVIDUAL GROUPS OF HYDROCARBONS

The application of structural-group methods to the analysis of higher fractions of petroleum containing hydrocarbons with relatively high molecular weights was already noted above. These include, for example, the *n–d–M* method of van Nes and van Westen for the analysis of oil fractions of petroleum[74]. As a result of the extensive application of various methods for the separation of hydrocarbons and the use of spectroscopic research techniques, general and far-reaching characteristics of the structure of different groups of hydrocarbons can now be formulated over a wide range of boiling points.

Paraffinic hydrocarbons and naphthenes can be characterised, cyclopentane and cyclohexane rings can be determined, and the number of rings in the molecule, the number of substituents, and their size can be found from the mass and infrared spectra of the fractions isolated by the appropriate procedure. Mass-spectrometric, ultraviolet spectroscopic, and NMR methods are used to investigate aromatic hydrocarbons. It is then possible to establish the type of aromatic nucleus of the molecule (benzene, naphthalene, phenanthrene, etc.)[75]. The number of rings in polycyclic hydrocarbons and, in only a few instances, their positions have been determined by molecular spectroscopy.

A series of petroleums from different deposits, including fractions boiling at high temperatures (up to 470°C), have been investigated. The structural formulae (fragments) of the hydrocarbons which may be determined by modern methods are listed below. Polycycloparaffins and mixed hydrocarbons containing cyclohexane benzene rings are shown here by convention in the form of condensed systems.

Cyclanes



Aliphatic chains

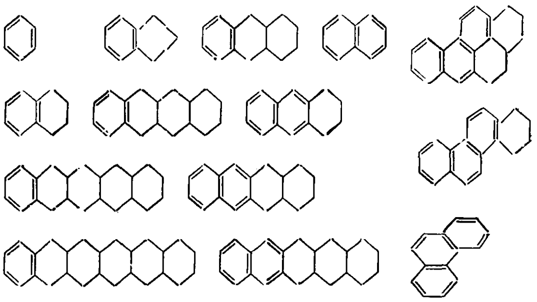
$—CH_2—$

$—CH_2—CH_2—$

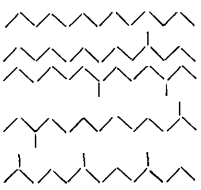
$—CH_2(CH_2)_nCH_2—$

$—CH_3$

Aromatic hydrocarbons



Alkanes



The general characteristics of petroleum hydrocarbons determined by the most modern research techniques are of considerable practical importance apart from their theoretical significance, since the results obtained can be used to assess the fractions processed into fuels and lubricating oils. At the same time, the general characteristics of the petroleum constitute a basis for subsequent more far-reaching research on specific types of hydrocarbons.

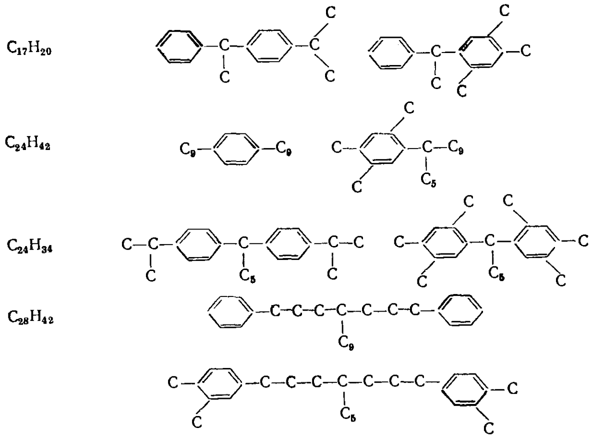
VI. CERTAIN REGULARITIES IN THE HYDROCARBON COMPOSITION OF PETROLEUM

The study of hydrocarbons from the middle and higher fractions of petroleum is extremely difficult owing to the presence in the latter of a large number of isomers. For this reason, chemists have endeavoured for a relatively long time to find regularities in the contents and distribution of various types of petroleum hydrocarbons; such regularities should be observed if the composition of petroleum is determined by certain general conditions governing its genesis from more or less similar organic material. The regularities would naturally facilitate also the investigation of the chemical composition of petroleum.

For example, one can reach an extremely important general conclusion about the composition of aromatic hydrocarbons in petroleum fractions. The studies by the American Petroleum Institute showed at one time that the hydrogenation of synthetic polycyclic hydrocarbons consisting of condensed benzene rings leads to the formation of cyclanes with a reduced viscosity and an enhanced viscosity index, while hydrogenation of aromatic hydrocarbons containing isolated benzene rings actually leads to an increase of viscosity and a decrease of the viscosity index[16,74,76]. It was established at the same time that the hydrogenation of narrow oil fractions leads to an appreciable reduction of their viscosity, which is greater the larger the number of benzene rings in the hydrocarbons. On this basis, it was concluded that polycyclic aromatic hydrocarbons in the oil fractions of petroleum virtually all belong to different kinds of condensed systems (see Rossini et al.[16], p. 327). For example, alkylated derivatives of anthracene, phenanthrene, and naphthacene are such "exceptional" types of polycyclic hydrocarbons, the hydrogenation of which results in a decrease of viscosity. However, it is known that naphthalene homologues containing long alkyl groups ($C_{18}-C_{26}$) behave on hydrogenation like the majority of aromatic hydrocarbons—their viscosity increases. Thus not all aromatic hydrocarbons with condensed benzene rings exhibit a decrease of viscosity on hydrogenation.

The study of the physicochemical properties of about fifty hydrocarbons, namely cyclohexane and benzene homologues, polycyclic (mainly bicyclic) C_{24} and C_{28} hydrocarbons (corresponding to the oil fractions of petroleum) provided grounds for a new interpretation of the structure of aromatic hydrocarbons in higher petroleum fractions[77,78]. It has been established that aromatic hydrocarbons containing methyl groups in the ring are in general anomalously viscous compared with other alkyl-substituted aromatic hydrocarbons having the same molecular weight. Aromatic hydrocarbons containing methyl groups have higher viscosities and refractive indices, smaller molecular volumes, and higher heats of evaporation. Table 5 lists the physicochemical characteristics of certain alkylbenzenes.

Similar relations have been obtained also for hydrocarbons with a different structure, differing in the number of methyl groups in the molecule; some of these are indicated below:



The increased viscosity of aromatic hydrocarbons with methyl groups in the benzene rings is due to increased intermolecular interaction (a relatively smaller molecular volume and a higher heat of evaporation). On hydrogenation, such hydrocarbons give rise to cyclanes, the viscosity of which is lower rather than higher than that of the initial aromatic hydrocarbons.

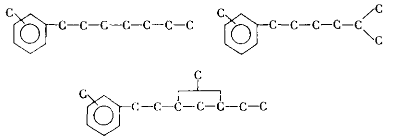
Table 5. Physicochemical characteristics of aromatic hydrocarbons.

Formula	Structure	ρ_4^{20}	n_D^{20}	Molecular volume, ml	Heat of evaporation, kcal mole^{-1}		Viscosity, cP	
					50° C	0° C	50° C	0° C
C_8H_{10}		0.8670	1.4959	122.5	9.70	10.35	0.48	0.87
C_8H_{10}		0.8802	1.5055	120.6	10.05	10.63	0.56	1.06
C_9H_{12}		0.8620	1.4920	139.5	10.65	11.18	0.58	1.18
C_9H_{12}		0.8758	1.5048	137.2	11.06	11.64	0.72	1.32
C_9H_{12}		0.8944	1.5139	134.6	11.31	11.86	0.82	1.82
$C_{10}H_{14}$		0.8601	1.4898	155.9	11.67	12.29	0.68	—
$C_{10}H_{14}$		0.8904	1.5130	150.7	12.77	13.35	0.82	1.86

Thus the decrease of viscosity on hydrogenation of petroleum fractions indicates primarily the presence in these fractions of considerable amounts of methyl-substituted aromatic hydrocarbons (including polycyclic condensed aromatic hydrocarbons). The cause of this characteristic of methyl-substituted aromatic hydrocarbons is unknown and requires separate examination. Here one can only note that the phenomenon of hyperconjugation has been observed for molecules containing methyl groups linked to the benzene ring, which may be reflected also in certain features of their physicochemical properties.

The conclusion reached concerning the structure of aromatic hydrocarbons in petroleum has been confirmed also by certain data obtained in direct studies on petroleum hydrocarbons. For example, C_{10} benzene homologues with methyl groups predominate among the aromatic hydrocarbons of Romashkino petroleum. On passing to higher petroleum fractions, the benzene homologues may contain also higher alkyl groups. According to non-Soviet investigators, hydrocarbons containing methyl groups and one larger alkyl group, do indeed predominate in the alkylbenzenes in petroleum[33].

Thus aromatic hydrocarbons, the alkylbenzenes in the light gas oil from American petroleum boiling in the range 230–305°C (from the Ponca deposit), have been investigated[33]. The light gas oil constituted 70% of the petroleum and the aromatic hydrocarbons isolated constituted 19.6% of the light gas oil. Adsorption chromatography on silica gel, adsorption on molecular sieves, and gas–liquid chromatography were used to isolate and separate the hydrocarbons; low-voltage mass-spectrometry and NMR were employed to determine the structure of the "average" molecule. It was established that the $C_{13}-C_{15}$ alkylbenzenes in the light gas oil consist mainly of di- and trisubstituted derivatives. The disubstituted alkylbenzenes usually contain one methyl group and one long C_7 or C_8 alkyl group in the 1,3- and 1,2-positions. The typical dialkylbenzenes can be represented as follows:



Two possible locations of the methyl group in the alkyl chain are indicated in the last formula.

A similar study of aromatic hydrocarbons containing a single benzene ring, isolated from the heavy gas oil and the light oil distillate (305–405°C) of the same petroleum, showed that these distillates contain approximately 75% of $C_{24}-C_{26}$ alkylbenzene with a single long alkyl group and several, sometimes three or four, methyl groups; some of these alkylbenzenes can also contain ethyl groups[34]. It is interesting to note that optically active $C_{25}-C_{26}$ hydrocarbons of the type of tetra- or penta-cyclanobenzenes with $[\alpha]_D^{25} = 6$ were detected in the same distillates.

Systematic research on petroleum hydrocarbons carried out in accordance with the programme of the American Petroleum Institute Project 6 permitted a number of conclusions concerning the hydrocarbon composition of different types of petroleum. Particular mention should be made of the conclusion that the relative quantitative contents of hydrocarbons within the limits of each type of hydrocarbons (straight-chain paraffins, branched paraffins, alkylcyclopentanes, alkylcyclohexanes, and alkylbenzenes) are approximately the same in different types of petroleum. Certain specific instances of this general conclusion have already been noted.

We shall now consider the possible cause of the above similarity of the compositions of different types of petroleum, namely whether this generalisation is applicable only to petrol fractions, whether it can be extended also to hydrocarbons with higher molecular weights, and whether it is valid for petroleums of sharply different ages.

It was noted a comparatively long time ago that petroleum consists of an equilibrium mixture of hydrocarbons formed as a result of various catalytic reactions occurring, for example, under the influence of aluminosilicates (natural clays) at certain temperatures near 150–250°C. Thus Frost[79] and Obryadchikov[80] established for the first time that the contents of cyclohexane and methylcyclopentane in a wide variety of petroleums corresponded to their equilibrium concentrations at temperatures in the range ~150° to 300°C.

The relative equilibrium concentrations of cyclohexane and methylcyclopentane (the K_e values) at different temperatures between 150° and 300°C are as follows:

T, °C	K_e
150	1.38
200	0.89
250	0.63
300	0.48

Approximately the same relations are observed also for the contents of both hydrocarbons in different types of petroleum. The knowledge of the temperatures in the formation of petroleum with allowance for the possible transformations of hydrocarbons (or the initial compounds) under the influence of natural catalysts of the aluminosilicate type seemingly might have accounted for the differences between the chemical compositions of different types of petroleum and might have led to the discovery of new possibilities for the investigation of the chemical composition of petroleum itself. Having established the equilibrium proportions of the hydrocarbons within the limits of the particular group at a given temperature, for example at 200°C, and having determined the thermodynamically most stable structures of the hydrocarbons, it might be possible to predict beforehand their contents and proportions in petroleum; this would be particularly useful in the determination of the contents in petroleum of the structural and steric isomers of different types of hydrocarbons.

There are a number of publications on the stereochemistry and relative stabilities of hydrocarbons[46,64,81,82]. The stereochemistry and equilibrium proportions (relative stabilities) of a series of C_7-C_9 alkylcyclopentanes, C_8-C_{12} alkylcyclohexanes, various C_8-C_{10} bicyclanes, $C_{11}-C_{12}$ alkyldecalins, and $C_{11}-C_{13}$ alkyladamantanes have now been investigated. The conformational characteristics of alkanes and cyclanes are being widely studied.

The results obtained are undoubtedly valuable for the characterisation of certain types of hydrocarbons and for their determination in petroleum. For example, in many instances it has indeed been found that the thermodynamically most stable bicyclanes predominate in petroleum.

The study of the relative stabilities of the isomeric forms of methylbicyclo[3,2,1]octanes and methylbicyclo-[2,2,1]octanes in synthetic model hydrocarbons[83] permitted the subsequent identification of nine methylbicyclo[3,2,1]-octanes and methylbicyclo[2,2,2]octanes in Soviet petroleums of different origins. It was established that, among identified hydrocarbons of the 125–150°C fraction of the Gryazevaya Sopka petroleum[84] and the 70–180°C fraction of Balakhansk petroleum[85], the most stable 1-methylbicyclo[3,2,1]octane is present in the largest amount, while the contents in the petroleums of the relatively less stable 2,3- and 6-substituted methylbicyclo[3,2,1]octanes are smaller. There are other examples of this kind.

Thus the above type of research on hydrocarbons, based on the determination of the equilibrium proportions of hydrocarbons and their relative thermodynamic stabilities at specific temperatures, yields valuable evidence for subsequent direct studies on petroleum hydrocarbons.

At the same time one must note that the limits of the applicability of this approach to the investigation of petroleum hydrocarbons are still not clear. It is not known which types of hydrocarbons are present in petroleum in equilibrium proportions corresponding to a specific temperature. Nor can the temperature limits corresponding to the formation of petroleum hydrocarbons be regarded as rigorously established. The thermodynamic stability of hydrocarbons depends to a large extent on temperature.

Presumably petroleum contains three groups of hydrocarbons. The first includes biogenic hydrocarbons which retain the structure of the initial natural products, for example, isoprenanes, steranes, triterpanes, and other still unknown hydrocarbons, the proportions of which may not, of course, correspond to equilibrium. They are determined by the contents of the natural products in the initial material from which petroleum originated. The hydrocarbons whose proportions correspond to equilibrium (at a specific temperature) may be included in the second group; the third group consists of hydrocarbons formed as a result of a number of transformations which do not retain the initial structure and whose composition does not correspond to equilibrium for one reason or another, which has not as yet been elucidated. One must bear in mind that the proportions of hydrocarbons might have altered also as a result of secondary processes (adsorption on rocks, particularly during the migration of petroleum, etc.).

Further research on biogenic petroleum hydrocarbons and the determination of the types of hydrocarbons whose proportions may correspond to equilibrium is necessary; this requires in its turn further far-reaching investigation of the hydrocarbon composition of petroleum as a whole. Such research will make it possible also to obtain more refined data on one of the most important problems in the geochemistry of petroleum—the problem of the temperatures at which petroleum was formed.

The discussion of these aspects of the hydrocarbon composition of petroleum frequently involved certain problems which have some bearing on the origin of petroleum. It is becoming increasingly necessary that investigators concerned with the study of the chemical composition of petroleum should examine new data on its composition from the standpoint of general modern ideas about its origin. The most important generalisations will probably be made on these lines.

The present review has dealt only with certain problems associated with the investigation of petroleum hydrocarbons and petroleum fractions. The extremely important questions in the field of petroleum chemistry, such as the investigation of the chemical composition of the oil fractions and lubricating oils, the study of high-molecular-weight compounds (including hydrocarbons) in petroleum, and others require separate consideration.

Heteroatomic Components of Petroleum

G.D.Gal'pern

The state of the problem of the isolation, separation, and characterisation of the heteroatomic compounds of petroleum is examined and current data on the chromatographic and mass-spectrometric characteristics of organosulphur compounds in petroleum and petroleum products are surveyed. The results obtained in studies on the composition and structures of sulphides and thiophens in distillates and residual petroleum fractions are listed and the fundamental data on the oxidation of middle petroleum fraction sulphides to sulphoxides and sulphones and on the pathways followed in their further chemical transformation are compiled. Certain aspects of the utilisation of petroleum sulphides and sulphoxides in the national economy are considered. The bibliography includes 210 references.

CONTENTS

I. INTRODUCTION

Modern experimental techniques have made it possible to compile information about the characteristics of the composition of complex natural formations such as petroleum and bitumens. The hydrocarbons contained in such substances have been investigated in detail. Fine instrumental analytical methods for the investigation of the compositions, structures, and properties of organic compounds and their multicomponent mixtures have been developing vigorously during the last 5–10 years. Intensive investigation of the heteroatomic components of petroleum and bitumens has been particularly characteristic of this period.

The interest in heteroatomic compounds (HAC) of petroleum is due to a number of causes: the fraction of petroleums rich in HAC has increased sharply in the world production and processing of petroleum; in the manufacture of fuel and lubricating oil, the majority of HAC constitute a harmful admixture hindering the processing of the raw material and lowering the quality of the commercial products; the HAC are responsible for the formation and stabilisation of water–petroleum emulsions on the way from the borehole to the refinery; the study of the HAC helps to approach more closely the solution of the problems of the origin of petroleum and its transformations underground and the solution of the associated problem of the distribution of petroleums of particular quality in the deposits. In other words, the knowledge of the HAC constitutes a basis for the geochemical prediction of the available raw material resources for the petrochemical processing of petroleum. Such processing has been tending to replace the production of fuel and lubricating oil at an increasing rate. The value of the petroleum HAC is also of considerable interest for fundamental science. The chemical composition and structure of the majority of the petroleum HAC were unknown. The determination of the relation between the HAC and the petroleum hydrocarbons, on the one hand, and the parent material of petroleum, on the other, is one of the most interesting problems of modern biogeochemistry.

An attempt will be made below to describe briefly certain results of studies in the past five years and, in relation to specific problems, the last ten years (from 1966 to 1976). One should note that this period has been characterised by a still unduly analytical approach to the solution of the problem of the composition of petroleum. The following factors require constant attention: the complex combination of the acid–base and oxidation–reduction properties of petroleum hydrocarbons; the characteristic donor–acceptor interactions of the HAC with condensed aromatic hydrocarbons; the problem of the colloidal, supermolecular structure of petroleum and the role of the HAC in its changes; the involvement of charge-transfer complex and clathrate compound formation in the organisation of short-range order leading to structure formation in petroleums, which has not been considered hitherto in any way at all.

II. METHODS FOR THE ISOLATION OF HETEROATOMIC COMPOUNDS FROM PETROLEUM AND PETROLEUM PRODUCTS

Crude petroleum is characterised primarily by its elemental composition and the limits of its boiling point range corresponding to the distribution of the components with respect to their molecular weights. The elemental compositions of all petroleums are distinguished by the predominance of carbon and hydrogen, which are the main constituents not only of hydrocarbons but also of all heteroatomic compounds in petroleum. The latter are in most instances monofunctional; a more detailed study led to the discovery of the presence in petroleums of a large number of bi- and tri-functional compounds but at negligibly low concentrations. The content of carbon in petroleum is in most cases restricted to the range 80 to 87%, of hydrogen to 11–14%, of sulphur to 0.01–0.1% (up to 8% in sulphur-containing and high sulphur petroleums), and of nitrogen to 0.04–0.6% (unique petroleums with an increased nitrogen content are known). The data on the oxygen content are in most instances insufficiently accurate, since they have frequently not been obtained by direct analysis but by difference (the errors in the determination of all the remaining elements naturally accumulate under these conditions in the calculated oxygen content); nevertheless, one can assume that the oxygen content varies in the range 0.2–7.0%, i.e. is of the same order of magnitude as the sulphur content and an order of magnitude higher than the nitrogen content. The overall content of all the remaining elements in petroleums is usually less than 1%. Most of the residue consists of vanadium derivatives.

The simplest and oldest method for the resolution of petroleums into fractions is based on their boiling points. To a first approximation, this corresponds to the distribution of the components with respect to their molecular weights in view of the validity of the expression $T \simeq aM^b$, where T is the boiling point (on the Kelvin scale) and a and b are constants[1,2]. In most cases b differs little from 2, i.e. $T \simeq a\sqrt{M}$; a varies within wide limits (from 36 to 48 for hydrocarbons), being correlated with the particular homologous series to which the compound belongs (with the value of x in the formula $C_nH_{2n} \pm x$ proposed by Mendeleev[3]) and with the characteristics of the heteroatoms present. When petroleum or petroleum products are distilled with the aid of relatively inefficient fractionating devices (still widely used to determine the standard characteristics of commercial products), the distribution of the components with respect to their melting points in the multicomponent fractions collected is nearly Gaussian[4].

An increase in the efficiency of fractionation entails a marked decrease of the number of compounds included in the fractions collected and in the limit leads to the isolation of individual compounds; this rules out a statistical approach to the characterisation of narrow fractions. The latter is shown particularly clearly in attempts to extend to narrow fractions the statistical methods for the analysis of composition, particularly those proposed by Waterman et al.[5] for commercial petroleum products and broad petroleum fractions. Nevertheless there is no doubt that fractionation to give comparatively broad fractions is at present useful for a preliminary resolution of petroleum and petroleum products. It is useful to set limits to the fractions collected on the basis of the structural transitions of the components, for example from alkanes to monocyclic compounds, from monocyclic to bicyclic compounds, and from the latter to polycyclic compounds.

The employment of highly efficient chromatographic devices and of mass spectrometry in the next separation stage permits the recommendation that one abandons the preliminary separation of test materials by fractionation into extremely narrow fractions, which is still used. The collossal multiplicity of the components of the middle and high petroleum fractions requires the application of the methods of group and structural-group analysis, including functional analysis, and not individual analytical techniques. In many spectroscopic, refractometric, and other physical methods for structural-group analysis, one uses the atomic or bond increments (frequencies, intensities, refractions, dispersions, etc.) obtained by averaging the data for a multiplicity of individual compounds of different structures. Naturally, the application of these increments to compounds with restricted compositions without due allowance for their characteristics may lead to an increase of error in the determination of the composition. We shall return to this problem below when modern chromatographic mass-spectrometric methods for the analysis of petroleum distillates are considered.
