# Proton Transfer Reactions in the Excited Electronic States of Aromatic Molecules

I.Yu.Martynov, A.B.Demyashkevich, B.M.Uzhinov, and M.G.Kuz'min

Proton transfer reactions involving electronically excited aromatic molecules are examined and the methods for the determination of the acidities of aromatic molecules in various electronic excited states are discussed and compared. The proton phototransfer reactions in protic and aprotic solvents and in the solid phase as well as intramolecular proton phototransfer are considered separately. Particular attention is devoted to the degradation of the electronic excitation energy in proton phototransfer reactions.
The bibliography includes 186 references.

## I. INTRODUCTION

Considerable advances have been achieved during the last two decades in studies on the chemical reactions of electronically excited molecules. Many important characteristics of the reactions occurring in excited electronic states have been elucidated[1,2]. Photoexcitation of molecules leads to a significant change of their electronic structure and reactivity. Among the reactions of excited molecules, the acid–base processes involving the addition or elimination of a proton are of particular interest. Proton phototransfer is the simplest example of a heterolytic reaction and is extremely convenient for the investigation of the general characteristics of the reactions of electronically excited molecules. Phototransfer reactions are used in lasers and masers[3,4] and in photochromic materials[5,6].

Two types of proton transfer reactions are known. Proton transfer via a system of hydrogen bonds (between two heteroatoms) proceeds both in the ground and in the excited electronic states almost without activation energy and with very high rate constants—up to $10^{10}$–$10^{11}$ litre $mole^{-1}$ $s^{-1}$. In the absence of a hydrogen bond (when at least one of the reactants is a CH acid or a C base), a considerable activation energy is characteristic of the proton transfer reactions and the rate constants are less

than $10^7$ litre mole$^{-1}$ s$^{-1}$. The mechanisms of these two types of proton transfer reactions are significantly different[7]. In the excited electronic states, proton transfer via a system of hydrogen bonds usually takes place with retention of the electronic excitation (adiabatically). In proton phototransfer reactions involving CH acids and C bases, electronic excitation is lost. This review is devoted to reactions involving the phototransfer of a proton via a system of hydrogen bonds. The acid–base properties of electronically excited organic molecules, proton transfer reactions in liquid and solid solutions, and processes involving the degradation of the electronic excitation energy in proton phototransfer are considered.

## II. THE ACID–BASE PROPERTIES OF THE EXCITED ELECTRONIC STATES

When an organic molecule absorbs light and passes to an excited state, the electron density is redistributed. In particular, in molecules containing an N, O, or S heteroatom, the density of the lone electron pair at the heteroatom increases or decreases, which causes a change in the acid–base properties of the organic molecule.

The change in acid–base properties occurring on photoexcitation was observed comparatively long ago. As early as 1931, Weber[8] observed a change in the fluorescence spectrum of 1-naphthylamine-4-sulphonate as the acidity of the solution was altered, although the absorption spectrum remained unchanged. Förster[9-11] attributed this phenomenon to a change in the acid–base properties of the molecules in the excited state. Later, the problem of the acid–base properties of electronically excited molecules and of proton phototransfer was investigated in detail by Weller[12-14]. Terenin and Karyakin observed proton phototransfer in solid layers in 1947[15]. The p$K$ values corresponding to the excited states of numerous compounds have now been determined and are listed in Table 1.

The p$K$ of the excited states are determined by various spectroscopic methods. Some of these will now be briefly considered.

1. The method based on the so called Förster cycle[10] can be called the thermodynamic method. The attainment of protolytic equilibrium in the excited state is not necessary in this method; it is sufficient to know the spectroscopic characteristics of the starting materials and the final products of the photoprotolytic dissociation.

By considering the diagram in Fig. 1, where $\Delta H$ and $\Delta H^*$ are the enthalpies of dissociation in the ground and excited states respectively and $\Delta E_{AH}$ and $\Delta E_{A^-}$ are the differences between the energies of the two states of the undissociated and dissociated forms respectively, one can write

$$\Delta H - \Delta H^* = \Delta E_{AH} - \Delta E_{A^-}. \quad (1)$$

Assuming further that the entropies of protolytic dissociation in the ground and excited states are equal, we obtain

$$\ln \frac{K^*}{K} = \frac{\Delta E_{AH} - \Delta E_{A^-}}{RT}, \quad (2)$$

where $K$ and $K^*$ are the equilibrium constants for protolytic dissociation in the ground and excited states respectively. If the energy difference is expressed in terms of the difference in wavenumbers ($\Delta\nu$, cm$^{-1}$) and the numerical value of $R$ is substituted, then we have at room temperature ($T$ = 298 K)

$$pK = pK^* + 2.1 \cdot 10^{-3} \Delta\nu. \quad (3)$$

**Table 1.** The acid dissociation constants of organic compounds in various electronic states in aqueous solutions.

*The acidities of related compounds are also quoted in the relevant paper.

**The acidities determined by other methods are also quoted in the relevant paper.

***$pK$ was determined from data on the variation of the rate constants for the destruction of triplet states with the acidity of the medium.

****The method of determination is not indicated.

There are literature data for the acidity constants of naphthols [111], hydroxyquinolines [36,39,40,61,65,67,74,88,93], 8-mercaptoquinoline [69], aminoquinolines [108], nitroquinolines [43], aminoanthracenes [109], nitrobenzene [70], azo- and azoxy-benzenes [33], 5,6-diazaphenanthrene [89], indolizidine [37], lumiflavin [63], thionine [54,71,80], warfarin [106], riboflavin [107], azures [54], fluoroscein and dichlorofluorescein [41], purines [46], and many other compounds [110,112-115].

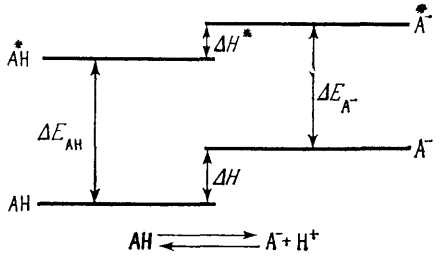

Figure 1. A simplified energy level diagram for acid dissociation in the ground and excited electronic states.

In this equation $\Delta\nu$ is determined experimentally. It is noteworthy that, first, the above equation is applicable only when the entropies of protolytic dissociation in the ground and excited states are equal. The discrepancy between the values of $pK^*$ measured by this method and the values obtained by other procedures is sometimes attributed to the failure of precisely this condition [16]. Secondly, $\Delta\nu$ refers to purely electronic transitions between the zero vibrational sublevels of the corresponding electronic levels (0–0 transition). Since it is difficult to determine the frequency of the 0–0 transition (and hence also its shifts) for compounds in solutions, one usually measures the shift of the maxima in the absorption spectra of the acid and basic forms (method 1a) or in the fluorescence spectra of these forms (method 1b). The average shift in the absorption and fluorescence spectra (method 1c) is also frequently used. This procedure can be applied to determine the $pK$ of triplet states. In this case, the shift of the short-wavelength maximum in the phosphorescence spectrum is determined experimentally assuming it to be the shift of the frequency of the 0–0 transition (method 1d).

2. The method based on the measurement of the intensity or quantum yields of the fluorescence under steady-state conditions has been developed in detail by Weller [12]. Consider the mechanism of the photoprotolytic dissociation of an acid AH:

$$\begin{array}{ccc} A^*H & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & A^- + H^+ \\ h\nu \uparrow \; k_f \downarrow \; k_d & & k_f' \downarrow \; k_d' \\ AH & & A^- \end{array} \qquad (4)$$

Using the method of steady-states, the following expressions can be obtained for this mechanism:

$$\frac{\varphi}{\varphi_0} = \frac{1 + k_{-1}\tau_0'[H^+]}{1 + k_{-1}\tau_0'[H^+] + k_1\tau_0}, \qquad (5)$$

$$\frac{\varphi\,\varphi_0'}{\varphi'\varphi_0} = \frac{1}{k_1\tau_0} + \frac{k_{-1}\tau_0'}{k_1\tau_0}[H^+], \qquad (6)$$

where $\varphi$ is the quantum yield of the fluorescence of the undissociated form for certain specific pH values. $\varphi'$ the quantum yield of the fluorescence of the dissociated form at the same pH values, $\varphi_0$ the quantum yield of the fluorescence of the undissociated form in the absence of the protolytic reaction, $\varphi_0'$ the quantum yield of the fluorescence of the dissociated form in an alkaline solution, $k_1$ and $k_{-1}$ are the rate constants for the forward and reverse reactions, $k_f$ and $k_f'$ the rate constants for the processes involved in the fluorescence of the undissociated and dissociated forms, $k_d$ and $k_d'$ the rate constants for the monomolecular non-radiative deactivation processes for the undissociated and dissociated forms, and $\tau_0 = 1/(k_0 + k_d)$ and $\tau_0' = 1/(k_f' + k_d')$ the decay times of the fluorescence of the undissociated and dissociated forms respectively.

Having plotted $\varphi\varphi_0'/\varphi'\varphi_0$ against $[H_3O^+]$, it is possible to obtain the rate constants $k_1$ and $k_{-1}$ as well as the photoprotolytic dissociation equilibrium constant $K^* = k_1/k_{-1}$ (method 2a). A necessary condition for the applicability of method 2a is the establishment (at least partially) of the acid–base equilibrium in the excited state. In certain cases, it is necessary to allow for the contribution of the deviation from the steady state to the kinetics of the protolytic dissociation. Eqn. (6) then assumes the form

$$W\frac{\varphi\,\varphi_0'}{\varphi'\varphi_0} - (1 - W) = \frac{1}{k_1\tau_0} + \frac{k_{-1}\tau_0'}{k_1\tau_0}[H^+], \qquad (7)$$

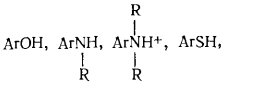
where $1 - W$ is the fraction of molecules reacting immediately after excitation before the establishment of the steady state. $W$ can be calculated from the changes in the relative fluorescence quantum yields as a function of the

pH of the solution by the method of successive approximations, provided that the corresponding diffusion coefficients are known[17].

The method in which the pH of the solution at the point of inflection in the plot of the relative fluorescence quantum yield against pH is adopted as p$K^*$ (method 2b) is sometimes used. However, it has been shown[18,19] that this method frequently does not yield the true value of p$K^*$. According to Eqn. (5), the pH at the point of inflection ($pH_{\frac{1}{2}}$) in the $\varphi/\varphi_0$–pH plot is†

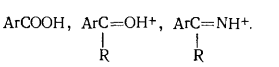
$$pH_{1/2} = \lg \frac{k_{-1}\tau_0'}{|1 + k_1\tau_0|}. \quad (8)$$

When $k_1\tau_0 \gg 1$, we have in this case



$$pH_{1/2} = pK^* + \lg \frac{\tau_0'}{\tau_0}. \quad (9)$$

Thus $pH_{\frac{1}{2}} \simeq pK^*$, provided that $\tau_0 \simeq \tau_0'$, but in this case it is better to use the more accurate method 2a. Method 2b is used when one of the forms (AH or $A^-$) does not fluoresce, but under these conditions the error is particularly large. Suppose that $A^-$ does not fluoresce. This implies that $\varphi_0' < 10^{-4}$ and $\tau_0' < 10^{-12}$ s and if $\tau_0 = 10^{-8}$ s, then $pH_{\frac{1}{2}} < pK^* - 4$. The point of inflection method is used to determine the p$K$ values for triplet molecules, since during the lifetime of the triple state there is sufficient time for the establishment of the protolytic equilibrium. The pH at the point of inflection in the plot of the intensity of the triplet–triplet absorption (method 2c) or phosphorescence (method 2d) against the pH of the solution is adopted as the value of p$K(T)$.

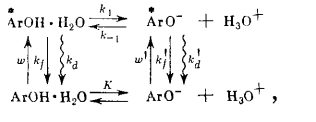


Measurements of the p$K^*$ for aromatic hydroxy-compounds led to the conclusion[20] that methods 2b and 1c usually yield similar results, which do not agree with the results obtained by method 1a, the difference being outside the limits of experimental error. It is assumed that the difference is caused by the relaxation of the solvent molecules during the lifetime of the excited molecule. The frequencies of the 0–0 transitions in the absorption and fluoresence spectra will then differ. This is confirmed by measurements of the p$K^*$ in solid solutions[20], where solvent relaxation is hindered. In this case, all three methods yield similar results.

The difference between p$K$ values for the ground and excited states can reach several orders of magnitude. According to the charge-transfer theory[21], such a jump in acidity is a consequence of the mixing of the configuration of the corresponding electronically excited state with the possible configuration of the charge-transfer (CT) state, which has a higher energy. The degree of mixing is greater the smaller the difference between the energies of the two states, so that $\Delta pK\,(S_0 - S_1) > \Delta pK\,(S_0 - T)$. However, when this theory is used, one cannot explain the similarity of the p$K$ values for the ground and triplet states found experimentally. The resonance theory predicts[22] that the relative contribution of the CT structure compared with that of the biradical structure should be greater in the $S_1$ state than in the triplet state. This theory readily explains small changes in the p$K^*$ values for the singlet states of aromatic carboxylic acids on the grounds that these compounds have only one resonance structure incorporating the C=O bond. It has also been shown theoretically[23,31,32] that acidity can both increase and decrease on photoexcitation.

Examination of Table 1 shows that the acidity of excited singlet states increases for compounds in which the dissociated proton is in the $\alpha$-position:

and decreases for compounds where the dissociated proton is in the $\beta$-position:



The basicity of amines of the aniline type decreases in the singlet excited state, while that of amines of the acridine type increases. A similar tendency has been observed for the triplet state, but is less pronounced.

Many interesting results may be obtained using the Hammett equations. It has been noted for phenol derivatives, 2,4-dinitrophenylhydrazones, and other benzene derivatives[24-28] that there is a linear relation between $\Delta\nu$ (in the absorption spectrum) and the $\sigma$ constant for the substituent (in the ground state). Hence it follows[16] that, since the variation in the p$K$ for the ground states of these compounds obeys the Hammett equation, the p$K^*$ should also obey this equation. Such correlation has been obtained for a series of *meta*- and *para*-substituted phenols[29]. The change in $\rho$ for these compounds relative to the ground state indicates[16] a change in the electronic interaction in the excited state.

For many compounds, the p$K^*$ of the deuterated form is smaller than the value of the non-deuterated form[30].

## III. PROTON PHOTOTRANSFER REACTIONS IN PROTIC SOLVENTS

Proton phototransfer reactions were first discovered and investigated in aqueous solutions. Förster[10,11] investigated similar reactions for solutions of hydroxy-derivatives of pyrene and naphthalene in water. The sharp increase in the acidity of these compounds on excitation leads to their dissociation during the lifetime of the excited state with formation of the excited ions of the conjugate base and the hydronium ion. These systems were investigated in detail by Weller[47,97,98,102,116], who studied the fluorescence spectra of many aromatic hydroxy-compounds, aromatic amines, and heterocyclic bases over a wide pH range. In many cases, the equilibrium in the excited state is not established completely owing to the competition of radiative and non-radiative deactivation processes involving the excited molecules. A typical curve for the pH dependence of the fluorescence of the dissociated and undissociated forms is illustrated in Fig. 2 (for 2-naphthol). The general mechanism of all dark and photochemical processes occurring in aqueous solutions of hydroxy-derivatives of aromatic compounds may be formulated as follows:

(10)

where $w$ and $w'$ are the rates of light absorption by the undissociated molecules and ions respectively. The variation of the relative fluorescence quantum yields of the dissociated and undissociated forms with hydrogen ion

†At the point of inflection, $\varphi/\varphi_0$ is equal to half the sum of the relative quantum yields of the AH fluorescence in acid and alkaline media.

concentration is described by Eqns. (5) and (6). A similar variation of the relative fluorescence quantum yields of the protonated and non-protonated forms with hydroxide ion concentration has been observed for bases whose proton-accepting properties are more marked in the excited state than in the ground state (for example, in the case of acridine).

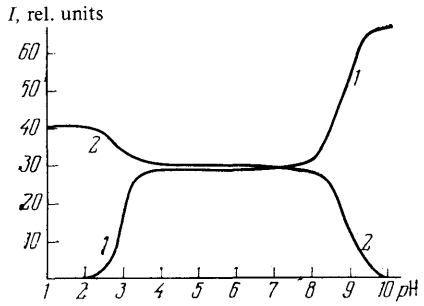


Figure 2. pH dependence of the fluorescence intensity ($I$) of the dissociated (curve *1*) and undissociated (curve *2*) forms of 2-naphthol in aqueous solution [176].

We shall consider in greater detail the 2-napthol–water system. The rate of protolytic dissociation of excited 2-napthol is fairly low compared with the rates of fluorescence and non-radiative deactivation and the majority of the excited 2-napthol molecules are deactivated without dissociating. In the pH range 3–8, the equilibrium in the excited state of this system is therefore not fully established. The activation energy for the dissociation of excited 2-napthol molecules is 16.8 kJ $mol^{-1}$. The rate-limiting stage in the proton transfer in this system is probably the reorientation of the water molecules of the solvation shell, which requires an activation energy. The rate of the reverse reaction is probably limited by diffusion. In the dissociation of excited 2-napthol, an appreciable kinetic isotope effect is observed [103]. The dissociation rate constants are $5.29 \times 10^7$ and $1.3 \times 10^7$ $s^{-1}$ in $H_2O$ and $D_2O$ respectively, while the corresponding rate constants for the reverse reactions are $5.5 \times 10^{10}$ and $3.5 \times 10^{10}$ litre $mol^{-1}$ $s^{-1}$. The influence of isotope substitution is significantly greater for the forward reaction than for the reverse reaction, where the effect can be to a large extent accounted for by the difference between the diffusion coefficients of the ions in $H_2O$ and $D_2O$. It is still not clear whether the decreased rate constant for the dissociation of excited 2-napthol in $D_2O$ is associated with an increase in the activation energy owing to the smaller vibrational energy of the zero level of the O–D bond compared with the O–H bond or with the decrease of the pre-exponential factor. The influence of isotope substitution on the protolytic dissociation equilibrium constants of excited aromatic hydroxy-compounds has been investigated [30].

The proton-accepting properties of water as well as its ability to give up a proton are fairly weak, so that the stronger bases and acids present in solution may compete with water in the reaction with excited proton donors and acceptors:

$$Ar^*OH + B \underset{k_A}{\overset{k_B}{\rightleftarrows}} Ar^*O^- + BH^+. \qquad (11)$$

The variation of the fluorescence quantum yields of the protonated and non-protonated forms with hydrogen ion (or hydroxide ion) concentration and with the concentration of the added base (or acid) can be described as follows [174]:

$$\frac{\varphi}{\varphi_0} = \left(1 + \frac{k_1\tau_0 + k_B[B]\tau_0}{1 + k_{-1}\tau_0'[H_3O^+] + k_A[BH^+]\tau_0'}\right)^{-1}, \qquad (12)$$

$$\frac{\varphi'}{\varphi_0'} = \left(1 + \frac{1 + k_{-1}\tau_0[H_3O^+] + k_A[BH^+]\tau_0'}{k_1\tau_0 + k_B[B]\tau_0}\right)^{-1}. \qquad (13)$$

*Excited molecule.
**(1) The rate constant for a pseudounimolecular reaction ($s^{-1}$); (2) the rate constant for a bimolecular reaction (litre $mol^{-1}$ $s^{-1}$).
[a] DHN = Dyhydroxynaphthalene.

Table 2 lists the rate constants for proton phototransfer in protic solvents determined by different investigators. It shows that the rate constants for the proton phototransfer reactions involving oppositely charged ions are of the order of $10^{10}$–$10^{11}$ litre $mole^{-1}$ $s^{-1}$ and depend only slightly on the

chemical nature of the reacting ions. This is evidence in support of the view that the rates of such reactions are diffusion limited. The slight differences between the rate constants are probably caused by the differences between the diffusion coefficients and steric factors.

The rate constants for the dissociation of excited hydroxy-derivatives of aromatic compounds have a wide range of values and depend on the nature of the hydroxy-compound. Weller [122] and Derkacheva [86] noted a linear relation between log $k_1$ and $pK_a^*$ for a series of hydroxy- and dihydroxy-derivatives of naphthalene. The rate-limiting step in these reactions is apparently the actual proton transfer to the polar solvent accompanied by the dielectric relaxation of the latter. The water molecule is a weak proton acceptor and the dissociation of excited aromatic compounds in aqueous solutions proceeds exclusively by virtue of the high polarity of water and the specific solvation of the ions formed. The absence of any appreciable dissociation of excited 2-naphthol molecules in absolute ethanol [123], which is less polar than water, may serve as a confirmation of this hypothesis. Compounds which are more acid, such as excited ammonium derivatives of pyrene, dissociate also in alcoholic solutions [96]. In a study of the dissociation of compounds whose acidity changes in the excited state within the limits of four orders of magnitude (in methanol, ethanol, 1-propanol, and 1-butanol), Weller [96] showed that the ionisation rate constants are almost independent of the nature of the aromatic compound and depend only on temperature and the nature of the solvent. This is direct proof that the rate-limiting stage of proton phototransfer in such systems is the reorientation of the polar solvent molecules. The reactions of excited aromatic hydroxy-compounds with proton acceptors, which are much more powerful than water and alcohols, namely carboxylate anions, proceed at much higher rates than dissociation and their rates are probably limited by diffusion. The rate constants for the reactions of excited 2-naphthol with these bases are almost independent of the basicity of the anions, which varies over a factor of ten, and are equal to $(2.5 - 3.0) \times 10^9$ litre mole$^{-1}$ s$^{-1}$. Proton phototransfer from excited 2-naphthol to the acetate ion proceeds also in alcoholic solutions [119].

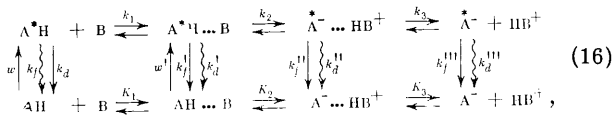
The study of the proton phototransfer reaction in protic solvents involves a large class of protolytic reactions, ranging from fairly slow, whose rate is limited by the reorientation of the polar solvent molecules, requiring an activation energy, to rapid reactions, whose rate is limited by diffusion. On photoexcitation, certain compounds dissociate so rapidly that the fluoresence of the undissociated molecules in neutral aqueous solutions is not observed and only the dissociated form fluoresces. As an example, one may quote the 2-naphthylammonium cation [94,124] and 1-naphthol in aqueous solutions [47,86]. The absence of the fluorescence of these compounds in conjunction with the usual emission rate constants (approximately $10^8$ s$^{-1}$) shows that the rate constant for the dissociation of the excited molecules $k \geqslant 10^{11}$ s$^{-1}$.

The high rate constant for proton phototransfer in principle enables this process to compete successfully with the deactivation reactions of the highest excited states and other relaxation processes. Analysing the kinetics of the onset of the fluorescence of the naphthoxide ion following the excitation of 2-naphthol in aqueous solution, Ofran and Feitelson [118] observed that a proportion of the excited 2-naphthol molecules, namely 5%, are dissociated during a period less than 1 ns, i.e. the rate of dissociation of some of the molecules is much higher than that of the others. Since the quantum yield in the formation of excited 2-naphthoxide ions is independent of the wavelength of the exciting light, the rate-limiting stage of such rapid dissociation is probably the rearrangement of the solvent molecules in the solvation shell. Consequently two processes were observed for 2-naphthol—rapid dissociation in the non-relaxed state and fairly slow dissociation in the state corresponding to thermal equilibrium.

In studies on the possibility of photoprotolytic reactions in the higher excited states, Hochstrasser [147] and Shablya [148] showed that the fluorescence quantum yields of the acridinium cation are different on excitation to the first and higher singlet states. The difference disappears when the fluorescence of the acridinium cation is quenched by hydrochloric acid, but persists on quenching by potassium chloride. In order to account for this phenomenon, it has been suggested [147,148] that, on excitation of the acridinium cation to the first ($S_1$) and higher ($S_2$) singlet states, the following equilibria occur:

$$S_1\ C_{13}H_9^*NH^+ \rightleftarrows C_{13}^*H_9N + H^+; \quad (14)$$

$$S_2\ C_{13}H_9^*NH^+ \rightleftarrows C_{13}^*H_9N + H^+. \quad (15)$$



On excitation to the highest singlet states, the fluorescence quantum yield of the protonated form should then be smaller than for excitation to the $S_1$ state in consequence of dissociation and should increase when this process is suppressed, i.e. at a fairly high concentration of $H^+$ ions the quantum yields should be equal on excitation to different electronic states if the main deactivation process of the $S_2$ state is the internal transition $S_2 \rightarrow S_1$. However, the authors of the present review have shown [149] that the equalisation of the fluorescence quantum yields is observed only simultaneously with the quenching of the fluorescence and is not observed when acids such as perchloric, formic, and acetic are used. Furthermore, the equalisation of the fluorescence quantum yields on excitation of different electronic states is observed in systems where acid–base interaction is ruled out, for example on quenching the fluorescence of 2-naphthylamine by ethyl bromide in ethanol. The observed phenomena are probably associated with a change in the probabilities of the intercombination transitions from the highest singlet states to the highest triplet states and not with the shift of the protolytic equilibrium in the highest excited states.

Thus proton phototransfer in protic solvents (water, alcohols) proceeds via a protolytic mechanism with formation of solvated ions as the reaction products. The rate constants for such reactions are in the range $10^7$ to $10^{11}$ s$^{-1}$. In most cases, the proton phototransfer proceeds in the excited singlet state corresponding to thermal equilibrium. However, in some instances rapid proton transfer occurs in the non-relaxed state. The proton phototransfer reactions may be accompanied by non-radiative deactivation of the excited molecules. This phenomenon is examined below.

## IV. PROTON PHOTOTRANSFER REACTIONS IN APROTIC SOLVENTS

The interaction of aromatic hydroxy- and amino-compounds with acids and bases in the ground electronic state in aprotic solvents results in the formation of hydrogen-bonded complexes and ion pairs in which the ions are or are not separated by solvent molecules (depending on the strength of the acid and base and the

polarity of the solvent) [170]. This is manifested clearly in the infrared and near ultraviolet absorption spectra [125,126]. As in the ground state, in the excited state there is a possibility of the formation of excited hydrogen-bonded complexes, excited ion pairs, and excited solvated ions. The general mechanism of the processes occurring in the ground and excited states in aprotic solvents can be represented as follows:

(16)

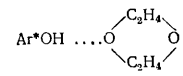
where $k_f$, $k'_f$, $k''_f$, and $k'''_f$ are the fluorescence rate constants, $k_d$, $k'_d$, $k''_d$, and $k'''_d$ are the rate constants for the non-radiative deactivation of the free form of the fluorescent species, the excited hydrogen-bonded complex, the excited ion pair, and the excited ion respectively, and $K_1$, $K_2$, and $K_3$ are the equilibrium constants for the formation of the hydrogen-bonded complex, the ion pair, and the ion in the ground electronic state respectively. If the base B is fairly weak, proton transfer in the excited hydrogen-bonded complex does not occur and a new complex formation equilibrium is established in many cases during the lifetime of the excited state.

The fluorescence spectra of the hydrogen-bonded complexes differ insignificantly from those of the free molecules (the shift of the maximum is of the order of 500 $cm^{-1}$). The fluorescence of hydrogen-bonded complexes was first observed by Mataga et al. for complexes of 2-naphthol with methyl acetate, ethyl acetate, n-butyl acetate, and ethyl chloroacetate in hexane [127]. When the excited hydrogen-bonded complex fluoresces, it is possible to determine the complex-formation equilibrium constant in the excited state from the fluorescence data (Table 3). Mataga et al. [173] derived the following equation for the concentration dependence of the fluoroscence intensity subject to the conditions that equilibrium is established in the excited state, that there are no induced deactivation processes, and that the fluorescence spectra of the free form and the complex are identical:

$$\frac{1-I_0/I}{[B]} = -K^* + \alpha K^* I_0/I, \qquad (17)$$

where $\alpha$ is the ratio of the fluorescence quantum yields of the hydrogen-bonded complex and the free molecule. In those cases where the excited hydrogen-bonded complex does not fluoresce, it is possible to determine only the rate constant for the quenching of the free molecules. It is then convenient to use the formula taking into account the attainment of equilibrium in the ground state:

$$\frac{\varphi_0/\varphi}{1+K[B]\,\varepsilon_1/\varepsilon} = 1 + k_1\tau_0[B]\ , \qquad (18)$$



where $\epsilon$ and $\epsilon_1$ are the extinction coefficients of the free form and the hydrogen-bonded complex at the wavelength of the exciting light. A similar situation is observed in the interaction of naphthols and 3-hydroxypyrene with pyridine and $\alpha$-chloropyridine. Weller [122] identified the rate constants for the dynamic quenching of the fluorescence of these compounds by nitrogen-containing heterocycles with the rate constants for the formation of hydrogen-bonded complexes between the excited molecules of the hydroxy-compounds and those of the bases. This is confirmed by the finding that pyridine does not quench the fluorescence of 2-methoxynaphthalene. The quenching effect of pyridine on the fluorescence of 2-naphthol depends significantly on the solvating capacity and polarity of the solvent [120]. The reverse dissociation reaction of the excited hydrogen-bonded complex is usually neglected. The complex formation equilibrium constant in the ground state is as a rule of the order of $10^2$ litre $mol^{-1}$ and increases by 1–2 orders of magnitude on photoexcitation. Since the rate constant for the formation of the hydrogen-bonded complex does not exceed $10^{10}$ litre $mol^{-1}$ $s^{-1}$, the rate constant for the reverse reaction is of the order of $10^6$ $s^{-1}$, i.e. dissociation cannot compete with the radiative and non-radiative deactivation reactions of the excited hydrogen-bonded complex.

Table 3. The equilibrium constants for the formation of hydrogen-bonded complexes in the ground (K) and excited (K*) states.

| Proton-donating molecule | Proton-accepting molecule | Solvent | $K$, litre $mol^{-1}$ | $K^*$, litre $mol^{-1}$ | Refs. |

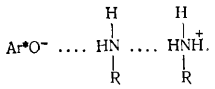
Strong bases such as aliphatic amines interact with excited aromatic hydroxy-compounds, the process involving proton transfer from the excited molecule to the base. This is manifested experimentally by the anomalously large shift of the fluorescence maximum of the proton transfer product relative to the fluorescence maximum in the spectra of hydrogen-bonded complexes. In 1962 Mataga et al. attributed this long-wavelength maximum to the fluorescence of the excited ion pair in which the counterions are joined by a hydrogen bond [171]. Similar phenomena involving an anomalous fluorescence shift have been described by 2-naphthol–aliphatic amine, 3-hydroxy-pyrene–aliphatic amine, 1-naphthol–aliphatic amine, and aromatic aza-compound–carboxylic acid systems [117,123,130–132,172].



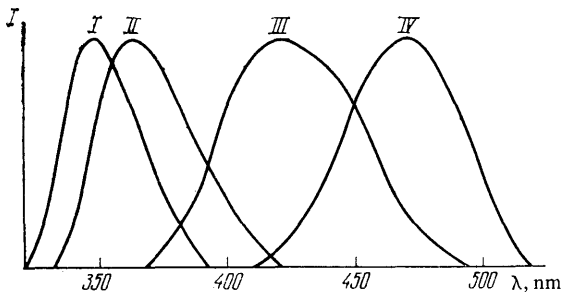
The excited ion pair can be formed in two ways: by the reaction of the excited fluorescent molecules with the base (dynamic pathway) and on excitation of the hydrogen-bonded complexes if the latter are already formed in the ground state (the static pathway). Comparison of the positions of the fluorescence maxima of the photoproduct, the initial excited molecule, and its conjugated base (acid) permits the identification of the proton phototransfer products. In a study of the dependence of the position of the maxima in the fluorescence spectra of 2-naphthol and 3-hydroxypyrene in various solvents (methylcyclohexane, dioxan, triethylamine, and n-butylamine), Weller [130] showed that the fluorescent species are the hydrogen-bonded complex

in dioxan, the contact hydrogen-bonded ion pair

$$Ar^*O^- \ldots HN^+R_3$$

in triethylamine, and the excited ion pair, in which the counterions are separated by hydrogen bonds with a solvent molecule,

in n-butylamine. Nakamizo[117] attributed the long-wavelength band in the fluorescence spectra of the complexes of benzoquinolines with acetic and trichloroacetic acids to emission by the protonated cation of the heterocycle, since the long-wavelength fluorescence spectrum coincided with the fluorescence spectrum of the cation in aqueous solution. In the 2-naphthol–diethylamine system in various solvents, the authors of the review observed the formation of an excited hydrogen-bonded complex, an excited ion pair, and an excited ion (Fig. 3)[123,134,145]. In a study of the temperature variation of the fluorescence spectra of the same system in methylcyclohexane, Krasheninnikov and Shablya[133] found that, when the temperature is reduced, bands with maxima at 365, 392, and 410 nm appear successively; these were assigned to the excited hydrogen-bonded complex, the excited contact ion pair, and the excited naphthoxide ion respectively. The lifetime of the excited ion pairs is in many cases shorter than the lifetime of the excited ions. This difference has been used as a method for the identification of the proton phototransfer products[134].



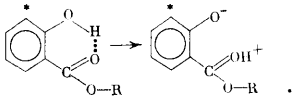


**Figure 3.** The fluorescence spectra of 2-naphthol in hexane (*I*), the hydrogen-bonded complex of 2-naphthol with triethylamine in hexane (II), the 2-naphthol–triethylamine ion pair in toluene (III), and the naphthoxide ion in dimethylformamide (IV).

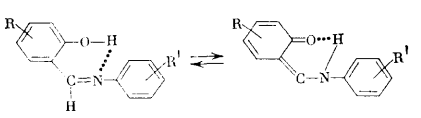
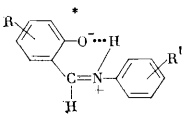
The nature of the proton phototransfer product depends to a considerable degree on the solvent. For example, in aromatic solvents (benzene, toluene, and *o*-chlorotoluene) the interaction of excited 2-naphthol and 3-hydroxypyrene molecules with triethylamine and diethylamine leads to the formation of excited ion pairs[123,130]. A different situation is observed in cyclohexane solutions[123]. When excited 2-naphthol interacts with diethylamine at low concentrations of the latter, an excited hydrogen-bonded complex is formed, an increase of the concentration of the amine results in marked quenching of the fluorescence, and a new fluorescence band, which has been attributed to the fluorescence of the ion pair, appears only at very high concentrations. When excited 2-naphthol interacts with triethylamine, a broad fluorescence spectrum is observed and is regarded[130] as resulting from the superposition of the fluorescence spectra of the hydrogen-bonded complex and the ion pair, which are in equilibrium. The shift of the equilibrium towards the formation of the ion pair in aromatic hydrocarbons is evidence that these solvents stabilise the ion pair to a greater extent, despite the fact that their dielectric constants hardly differ from those of aliphatic hydrocarbons. The polarisation of the $\pi$-electron system of the aromatic solvent, leading to partial delocalisation of the charges of the ion pair, probably also has a stabilising influence.

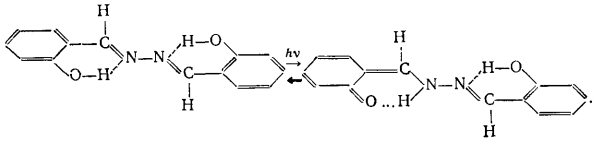


## V. INTRAMOLECULAR PROTON PHOTOTRANSFER REACTIONS

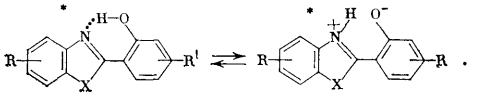
Proton phototransfer can occur not only between two separate molecules of an acid and a base but also between the parts of a single molecule joined by a hydrogen bond. These reactions are observed both in liquid solutions and in the solid phase. The first intramolecular proton phototransfer reaction, involving salicylic acid and its esters, was observed in 1955 by Weller, who subsequently investigated this phenomenon in detail[122,130,138,139]. On excitation, proton transfer occurs in these systems from the hydroxy-group to the carbonyl group with formation of an excited product:



The fluorescence spectra of salicylic acid and its esters consist of two bands—a short-wavelength band corresponding to the emission by the excited initial molecule and the long-wavelength band corresponding to the emission by the form with proton transfer. It is assumed that equilibrium between the two forms is fully established in the excited state. Estimates showed that the energy barrier between the two forms in the excited state of methyl salicylate does not exceed 0.12 kcal mole$^{-1}$. The enthalpy of the reversible interconversion of the two forms is very sensitive to the nature of the substituent in the aromatic ring. The loss of electronic excitation by the form with proton transfer is accompanied by the rapid reverse proton transfer and the regeneration of the initial compound.

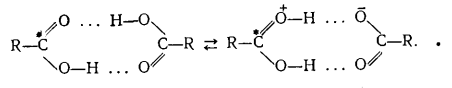


Intramolecular proton phototransfer has been observed in the hydrogen-bonded complex of 2-hydroxy-3-naphthoic acid and pyridine. When this complex is excited, a proton is transferred from the hydroxy-group to the carboxy-oxygen[140-142]. The proton phototransfer reaction occurring with retention of electronic excitation in azomethines with an *ortho*-hydroxy-group in the aldehyde ring has been investigated in detail by Knyazhanskii et al.[186] In solutions of these compounds, there is a tautomeric equilibrium between the benzenoid and quinonoid forms, the equilibrium constant depending on the polarity and proton-donating properties of the solvent:

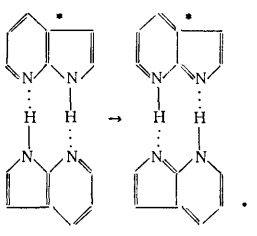


Photoexcitation of the benzenoid form leads to proton phototransfer with formation of an excited ionic form:

which is responsible for the luminescence of the system. A similar intramolecular proton transfer reaction in the salicylaldehyde molecule has been observed by Fassler et al.[6]:



Williams and Heller examined proton phototransfer in 2-hydroxy-derivatives of benzoxazoles, benzothiazoles and benzimidazoles[167]:



The majority of investigators believe that the form with proton transfer is dipolar and not quinonoid, but the problem has not been finally elucidated.

Proton transfer in dimers can be regarded by convention as intramolecular transfer Hochstrasser[135] observed an appreciable bathochromic shift of the fluorescence of the 1-naphthoic acid dimer in a methylcyclohexane solution at 77 K relative to room temperature. This shift was attributed to the formation of an ion pair as a result of proton transfer in the dimer owing to the sharp increase of the basicity of the carbonyl group:

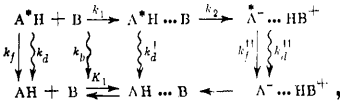
Solutions of 7-azaindole in solvents incapable of forming hydrogen bonds exhibit two emission bands. Their relative intensities depend on the 7-azaindole concentration, temperature, and the excitation wavelength[136]. It has been suggested that the long-wavelength fluorescence band is due to the emission by the excited tautomeric form of the dimer with double proton transfer via the mechanism

## VI. PROTON PHOTOTRANSFER IN THE SOLID PHASE

Bimolecular processes requiring the migration of the reactants are inhibited in the solid state. Cases of proton phototransfer within hydrogen-bonded complexes[131,132] in 1-naphthol–aliphatic amine systems have been noted. According to the authors, proton phototransfer within the complex is very rapid and leads to the formation of an ion pair in the excited singlet state, which is manifested by the fact that a band, identical with that in the fluorescence spectrum of the naphthoxide ion, appears in the emission spectrum of this system. The phosphorescence spectra of the systems then coincide with the phosphorescence spectrum of 1-naphthol, which shows that the reverse proton transfer takes place after the intercombination transition in the triplet state of the ion pair.

Interesting results were obtained by Terenin and coworkers in studies on the reversible proton phototransfer reactions in frozen solutions of acridine derivatives[145,146]. When 3,6-diaminoacridinium, 3-aminoacridinium, Acridine Orange, and trypaflavinium cations are irradiated with light, the cations dissociate in tetrahydrofuran and toluene at 77 K with formation of the free bases. This photochemical reaction is reversible on raising the temperature. A study of the dependence of the steady-state concentration of the ionic form and of the base on light intensity led the authors to the conclusion that the photochemical reaction proceeds in both directions and that photodeprotonation of the cation is a two-photon process and occurs on excitation to one of the highest triplet states; the reverse reaction, involving the regeneration of the ionic form, is a one-photon process. The quantum yields of both the forward and reverse reactions are low.

The proton phototransfer at 77 K in solid layers obtained by the sublimation of aminoacridines together with various organic acids has been investigated in fair detail. In these systems, protonated forms of the aminoacridines are formed in the ground state, their photolysis resulting in the elimination of a proton and the formation of the base. In this case, the reaction has a one-quantum mechanism[148].



## VII. DEGRADATION OF THE ELECTRONIC EXCITATION ENERGY IN PROTON PHOTOTRANSFER REACTIONS

The deactivation of the excited molecules, associated with the acid–base interaction, was observed for the first time by Mataga et al. in 1957[177] and by Feitelson in 1964[42]. Photochemical acid–base reactions, leading to isotope exchange in C acids and bases, proceed with loss of electronic excitation and lead to the formation of products in the ground state. Induced non-radiative deactivation, competing with the isotope exchange reaction and leading to the loss of excitation without the formation of products, is also observed[151].

For heteroatomic acids and bases, proton phototransfer proceeds in many cases adiabatically, i.e. with retention of electronic excitation. However, in these reactions too non-radiative deactivation of the excited molecules, induced by the acid–base interaction, is observed. Since the proton transfer process involves many stages, non-radiative deactivation can occur at different stages of the reaction. Firstly, the deactivation can proceed when the molecules of the acid and base interact in the step involving the formation of an excited hydrogen-bonded complex. Secondly, there is a possibility of deactivation in the proton transfer stage, where the excited hydrogen-bonded complex is converted into an excited pair. Finally, there is a possibility of the deactivation of the excited ion pair owing to the interaction of the counterions. We shall consider each of the above deactivation pathways in greater detail.

The kinetic mechanism of the proton phototransfer reaction, taking into account the deactivation processes,

is of the following form for systems where the reverse reactions may be neglected[134]:

(19)

where $k_q$ is the rate constant for the induced non-radiative deactivation in the stage involving the formation of the excited hydrogen-bonded complex. On steady-state excitation at the isosbestic point, the dependence of the quantum yields and the fluorescence quenching times for the initial compound and the proton phototransfer product on the reactant (acid or base) concentration can be expressed as follows taking into account complex formation in the ground state:

$$\frac{\varphi_0}{\varphi}\frac{1}{1+K_1[B]} = 1+(k_1+k_q)\tau_0[B], \tag{20}$$

$$\frac{\tau_0}{\tau} = 1+(k_1+k_q)\tau_0[B], \tag{21}$$

$$\frac{\varphi_0\varphi''}{\varphi[B]} = \varphi_1''\frac{\varphi_0}{\varphi}\frac{K_1}{1+K_1[B]} + \varphi_1''k_1\tau_0, \tag{22}$$

$$\frac{\varphi_0}{\varphi}\left(1-\frac{\varphi''}{\varphi_1''}\right) = 1+k_q\tau_0[B], \tag{23}$$

$$\frac{\varphi_1''\tau_0}{\varphi_0\tau_0''} = \frac{k_f''}{k_f}\frac{k_2}{k_2+k_d'}, \tag{24}$$

where $\varphi_0$ and $\varphi$ are the fluorescence quantum yields of the initial compound in the absence and presence of the reactant, $\varphi''$ is the fluorescence quantum yield of the photochemical reaction product, $\varphi_1''$ the fluorescence quantum yield of the photochemical reaction product extrapolated to infinite concentration of the reactant where the entire initial compound is in the ground state in the form of the hydrogen-bonded complex, $k_2/(k_2 + k'_d)$ a quantity characterising the efficiency of the adiabatic proton transfer within the complex, $\tau_0$ and $\tau$ are the lifetimes of the excited initial compound in the absence and presence of the quenching agent, and $\tau_0''$ is the lifetime of the excited product of the photochemical reaction (ion pair). The authors of the present review have shown[134] that, in the 2-naphthol–aliphatic amine systems in polar aprotic solvents (dimethylformamide and acetonitrile), the induced non-radiative deactivation of the excited 2-naphthol molecules by the amine molecules in the stage involving the formation of the excited hydrogen-bonded complex competes to a large extent with the adiabatic reaction [the rate constant $k_q$ for non-radiative deactivation is of the order of $10^9$ litre mol$^{-1}$ s$^{-1}$ (Table 4)]. In solvents of low polarity (benzene, toluene, and dichloroethane), induced non-radiative deactivation was not observed at this stage. In polar solvents, diethylamine and triethylamine also quench the fluorescence of 2-methoxynaphthalene (which is incapable of forming hydrogen bonds with amines), which suggested a donor–acceptor mechanism of the induced non-radiative deactivation.

A study of proton phototransfer from 2-naphthol to various bases in protic solvents showed[119] that the ratio of the rate constants for the reaction and the induced deactivation depends on the type of base‡. Thus the rate constant for the induced non-radiative deactivation in the 2-naphthol–sodium acetate system is negligibly small compared with the rate constant for the adiabatic proton phototransfer. If triethylamine and dimethylhydrazine are used as the bases, the rate constants for proton transfer are comparable to the rate constants for the induced non-radiative deactivation. In the system with potassium benzoate and dimethylaniline, whose molecules contain an aromatic ring, only the quenching of the fluorescence of the neutral form of 2-naphthol is observed. The absence of the fluorescence of the naphthoxide ion in such cases is evidence that the non-radiative deactivation process predominates over the adiabatic proton transfer. It is noteworthy that potassium benzoate and dimethylaniline quench the fluorescence of not only 2-naphthol but also of 2-methoxynaphthalene, the rate constant for the quenching of the fluorescence of 2-methoxynaphthalene by potassium benzoate being close to the corresponding constant for 2-naphthol.

Table 4. The rate constants for the formation of excited ion pairs and ions ($k_1$) and for the non-radiative deactivation ($k_q$) of 2-naphthol in the presence of various bases[119,162].

| Base | Solvent | $10^{-8}(k_1+k_q)$, litre mole$^{-1}$ s$^{-1}$ | $k_1$, litre mole$^{-1}$ s$^{-1}$ | $10^{-8}k_q$, litre mole$^{-1}$ s$^{-1}$ |
|---|---|---|---|---|
| Triethylamine | Benzene | 20±2 | 20±4 | <4 |
| Diethylamine | Benzene | 41±4 | 41±8 | <8 |
| Triethylamine | Toluene | 23±2 | 23±2 | <2 |
| Diethylamine | Toluene | 34±3 | 34±8 | <8 |
| Piperidine | Toluene | 40±6 | 40±6 | <6 |
| Triethylamine | Dichloroethane | 46±5 | 46±10 | <10 |
| Triethylamine | Acetonitrile | 11±1 | 1.6±0.6 | 9±3 |
| Diethylamine | Acetonitrile | 12±1 | 3.0±0.7 | 9±3 |
| Piperidine | Acetonitrile | 19±2 | 7±2 | 13±4 |
| Triethylamine | Dimethylformamide | 3.3±0.3 | 1.0±0.1 | 2.2±0.2 |
| Triethylamine | Ethanol | 2.0±0.1 | 0.8±0.1 | 1.2±0.1 |
| Dimethylhydrazine | Ethanol | 6.0±0.6 | 2.8±0.3 | 3.2±0.3 |
| *NN*-Dimethylaniline | Ethanol | 44±4 | <0.4 | 44±4 |
| Potassium benzoate | Methanol | 19.5±2.0 | <0.2 | 19.5±2.0 |
| Sodium acetate | Ethanol | 5.0±0.5 | 5.0±0.5 | <0.5 |

In the above systems, excited 2-naphthol molecules behave both as the acid (proton donor) and the electron acceptor. The donor–acceptor interaction can lead to the deactivation of excited molecules[154]. The relative rate constants for the adiabatic proton transfer and the deactivation depend on the relative basicity of the base and on its ionisation potential (its electron-donating properties). On passing from triethylamine ($I$ = 7.8 eV) and dimethylhydrazine ($I$ = 7.75 eV) to dimethylaniline ($I$ = 7.3 eV), the proton transfer rate constant decreases and the deactivation rate constant increases. Similarly, the reaction

‡In protic solvents, where the acid and base form hydrogen-bonded complexes with the solvent, it is impossible to separate experimentally the deactivation processes at various stages, so that the deactivation rate constants determined from the equation

$$\frac{\varphi_0}{\varphi}\left(1-\frac{\varphi''}{\varphi_0''}\right) = 1+\left[k_q + k_1\frac{k_d'}{k_2+k_d'}\right][B]\tau_0 \tag{25}$$

may refer to a combination of processes of different types: deactivation at the stage involving the formation of the excited complex and in the proton transfer step itself.

with the benzoate ion leads to the deactivation of excited 2-naphthol molecules, in contrast to the reaction with the acetate ion, which proceeds adiabatically and leads to proton transfer (the ionisation potentials of acetic and benzoic acids are 10.7 and 8.5 eV respectively). Thus, non-radiative deactivation at the stage involving the formation of the excited hydrogen-bonded complex in the above systems apparently proceeds as a result of the donor–acceptor interaction of the components and competes with the reaction proper.

The quenching of the fluorescence as a result of the formation of hydrogen-bonded complexes has been observed by Cooke and Solomon in a study of the interaction of excited 1- and 2-methoxynaphthalenes with benzoic acid [156]. The introduction of a compound capable of forming a hydrogen bond with benzoic acid, for example, dioxan, reduces the efficiency of the quenching and, at high dioxan concentrations, the quenching vanishes altogether. It is of interest that only monomers and linear (but not cyclic) benzoic acid dimers can quench the fluorescence of methoxynaphthalenes.

Table 5. The relative quantum yields for the formation of excited ion pairs on excitation of the hydrogen-bonded complexes of 2-naphthol with aliphatic amines [134].

| Solvent | Triethylamine | Diethylamine | Piperidine | Benzylamine | t-Butylamine |
|---|---|---|---|---|---|
| Toluene | 1.0 | 0.8±0.1 | 0.6±0.1 | 0.4±0.1 | 0.6±0.1 |
| Dichloroethane | 1.0 | 0.8±0.1 | 0.8±0.1 | — | — |

A number of experimental data, which are treated as proof of the occurrence of non-radiative deactivation in the proton transfer step itself, have been obtained recently. In the excitation of hydrogen-bonded complexes of 2-naphthol with aliphatic amines in aprotic solvents of low polarity, the quantum yield in the formation of the excited ion pair is in many instances less than unity [134] (Table 5). This shows that the degradation of the electronic excitation energy can occur directly in the proton transfer step itself and not as a result of subsequent or competing electron transfer processes.

Förster showed [124] that the excitation of the 2-naphthylammonium cation in aqueous sulphuric acid solutions to the fluorescence of 2-naphthylamine, which is a result of proton transfer to the solvent. At sulphuric acid concentrations where the fluorescence of both forms is observed, the overall fluorescence quantum yield is very low (0.002). The fluorescence quantum yields of 2-naphthylamine in the $H_2SO_4$–$H_2O$ and $D_2SO_4$–$D_2O$ systems at low acid concentrations approach a common limit of 0.26. Both values decrease with increase of acid concentration, but the quantum yield in the deuteriated system decreases much more slowly. In the range of acid concentrations where the fluorescence of the cation may be observed, the fluorescence quantum yield in the deuteriated system is much higher than in the non-deuteriated system. With increase of acidity, the fluorescence quantum yields of the cation increase in both systems and approach one another. In the deuteriated system, the equalisation of the fluorescence quantum yields of the cation and the molecular base occurs at a somewhat lower acid concentration than in the non-deuteriated system. Förster [124] believes that the proton transfer from the excited cation to the solvent makes possible non-radiative deactivation, which is not observed either for the neutral molecule or the cation separately.

However, there are other explanations of the above experimental facts. Schulman and Liedke [143] suggest the existence of at least one non-emitting intermediate complex. This may be a stoichiometric intermediate complex of the naphthylammonium ion and one water molecule. Such a complex may be virtually non-fluorescent owing to the intense internal transition to the ground state. Förster [124] believed that the deactivation could be also caused by the protonation of the aromatic ring of 2-naphthylamine in the singlet state. The excited amine is more sensitive to electrophilic attack by the proton than the cation. The rate of this process should increase with increased acidity of the solution and with increase of the fraction of the neutral amine obtained in the excited state.

Deactivation processes in excited ion pairs have been observed in 2-naphthol–aliphatic amine systems. In particular, the deactivation is manifested by a decreased lifetime of the excited ion pairs compared with the 2-naphthoxide ion in the same solvent and by the marked dependence of the fluorescence quantum yields and the lifetimes of the excited ion pairs on temperature [133,134,161]. In those cases where the molecules of the polar protic solvent quench the fluorescence of the aromatic acid or base, it is difficult to isolate the stage in which the electronic energy is degraded. It has been observed that excited 1-naphthol [162] and indole and its derivatives [178] are effectively quenched by water molecules. In both cases, a decrease of solution temperature and deuteriation of the solvent lead to an appreciable decrease in the rate constant for the non-radiative deactivation. The fluorescence quantum yield and the lifetime of the excited 1-naphthol molecules in aqueous solution increase in the presence of an electrolyte (guanidinium chloride) and a non-electrolyte (sucrose) at high concentrations (of the order of several mole litre$^{-1}$). [169] A similar influence of added salts on the fluorescence of organic compounds has been found for sodium 1-naphthol-4-sulphonate and the ionised forms of indole and its derivatives [179,180]. The authors explain this effect by a decrease in the activity of water when its molecules are bound in the solvation shells of the added salts. The mechanism of the quenching of the fluorescence by water molecules has not been completely elucidated. It is suggested that, when the excited molecule of an aromatic acid or base interacts, there is a possibility of the formation of forms with charge transfer (complete or partial) due to proton or electron transfer [179]. The quenching of the fluorescence of organic molecules by water is probably a general phenomenon.

The study of the temperature variation of the lifetimes of excited ion pairs led to the conclusion that the rate constant for non-radiative deactivation $k''_d$ [see Eqn. (19)] is the sum of two terms, of which the first ($k''_{d_1}$) depends only slightly on temperature and is comparable to the rate constant for the non-radiative deactivation of the 2-naphthoxide ion, while the second component, of the type $k_T = k''_{d_2} \exp(-E/RT)$, is determined by the interaction of the counterions and depends markedly on the nature of the amine and the solvent (Table 6).

Two possible mechanisms of such deactivation have been proposed. In the first, each cycle of the reversible proton transfer in the ion pair is accompanied by the deactivation of some of the molecules [161]. In this case the measured activation energy (of the order of 5–10 kcal

mole$^{-1}$) should correspond approximately to $\Delta H^*$ for the reversible reaction

$$A^*H \ldots B \rightleftarrows \dot{A}^- \ldots\ldots HB^+,$$

and the pre-exponential factor for the deactivation rate constant is equal to the product of the proton transfer rate constant and the probability of the degradation of the energy in the excited hydrogen-bonded complex. The decrease of the activation energy for the quenching processes in ion pairs and the decrease of the pre-exponential factor following the replacement of hydrogen by deuterium are evidence in support of this model. According to another model, the electronic excitation energy is degraded by the donor–acceptor interaction of the counterions in the excited ion pair [133,161]. In this case, the activated quenching mechanism may be associated with the fact that the counterions must overcome an energy barrier (possibly the dissociation of the $-O^-\ldots H-\overset{+}{N}\lessgtr$ hydrogen bond is necessary) in order to achieve a configuration ensuring the maximum probability of rapid electron transfer. The activation energy for the electronic excitation energy degradation processes can then include the dissociation energy of the hydrogen bond between the ions. Such energy degradation in the products of the proton phototransfer reaction leads to the usual quenching via the electron transfer mechanism.

Table 6. The kinetic characteristics of the deactivation processes in excited ion pairs formed by the 2-naphthoxide anion with alkylammonium ions [182].

| Cation | Solvent | lg $k_T$ (20° C) | $E_{act}$, kcal mole$^{-1}$ | lg $k_{d_s}$ |
|---|---|---|---|---|
| $(C_2H_5)_3\overset{+}{N}H$ | Toluene | 8.9±0.1 | 6.4±0.5 | 13.6±0.5 |
| | Triethylamine | 8.7±0.1 | 5.2±0.5 | 12.5±0.5 |
| | Tetrahydrofuran | 7.5±0.2 | 4.7±0.7 | 11.0±1.0 |
| | Butyronitrile | 8.0±0.1 | 5.0±0.5 | 11.7±0.5 |
| $(C_2H_5)_2\overset{+}{N}H_2$ | Toluene | 8.7±0.1 | 10.0±1.0 | 16.0±1.0 |
| | Diethylamine | 8.4±0.1 | 9.3±0.7 | 15.0±1.0 |
| | Tetrahydrofuran | 7.9±0.2 | 6.3±0.5 | 12.5±1.0 |
| $(C_2H_5)_2\overset{+}{N}D_2$ | Toluene | 8.2±0.1 | 6.6±1.0 | 13.0±1.0 |
| | Deuterated diethylamine | 7.4±0.2 | — | — |
| $(CH_2)_5\overset{+}{N}H_2$ | Toluene | 8.6±0.1 | 10.0±1.0 | 16.0±1.0 |
| \|————\| | Tetrahydrofuran | 7.9±0.2 | 6.7±0.5 | 13.0±0.5 |
| $C_6H_5CH_2\overset{+}{N}H_3$ | Toluene | 8.2±0.1 | 8.0±1.6 | 14.0±1.0 |

| t-$C_4H_9\overset{+}{N}H_3$ | Toluene | 7.9±0.2 | 6.5±1.0 | 12.0±1.0 |
| t-$C_4H_9\overset{+}{N}H_3$ | Tetrahydrofuran | 8.3±0.1 | 4.0±0.8 | — |

A similar deactivation mechanism, including proton transfer to the hydrogen-bonded complex followed by the donor–acceptor interaction of the counterions, one of which is excited, has been proposed by Ermolaev and coworkers [157,159,182] to explain the complete absence of the fluorescence and phosphorescence of the hydrogen-bonded complexes where both the proton donor and acceptor possess a $\pi$-electron system directly linked to the acid and basic functional groups. The hydrogen-bonded complexes of aromatic hydroxy-derivatives with aromatic heterocycles are examples of such systems [120,122,164,183]. It is suggested that, in the excited hydrogen-bonded complex, there is a fairly high probability of the formation of species with proton transfer, which exhibit electron-donating and electron-accepting properties favourable for electron transfer from the anion to the cation when one of them is in the excited state and the partners have a conjugated $\pi$-electron system. Electron transfer results in the formation of a pair of radicals, which, being unable to move apart in the time available, recombine with formation of a hydrogen-bonded complex in a non-excited state. Proton transfer in the complex is much slower ($10^{-12}$ s) than electron transfer ($10^{-15}$ s). Furthermore, proton transfer is retarded by a potential barrier, whose presence is due to a small difference between the acid–base properties of the partners in the complex, so that it is quite likely that proton transfer is the rate-limiting stage in the quenching process. Apparently these stages are not significantly separated during their occurrence, so that it is impossible to isolate one from the other.

The transfer of a proton and an electron is equivalent to the transfer of a hydrogen atom. In a study of the interaction of 2-naphthol with pyridine in cyclohexane solution by flash photolysis, it was shown [128] that the excitation of the hydrogen-bonded complex did not lead to the formation of any intermediate products, while the reaction of free 2-naphthol molecules in both the first singlet state and the triplet state led to the formation of naphthoxy-radicals, i.e. the fluorescence is quenched via the abstraction of a hydrogen atom from 2-naphthol by pyridine. A similar mechanism of the quenching of fluorescence by the transfer of a hydrogen atom in hydrogen-bonded complexes has been proposed for the benzacridine–phenol system [158]. Mataga and coworkers [184] showed by laser photolysis that, apart from the formation of the excited ion, in the carbazole–triethylamine system in acetonitrile there is a competing process involving the abstraction of a hydrogen atom and the formation of the carbazyl radical. However, the quenching of the carbazole fluorescence by pyridine is not accompanied by the appearance of any unstable intermediate products.

A study of the quenching process in hydrogen-bonded complexes at low temperatures permitted certain conclusions concerning the rate-limiting deactivation stage [159]. When the temperature is reduced from 77 to 4K, the quenching of the fluorescence in 2-naphthol–pyridine and carbazole–pyridine complexes in frozen toluene solutions is found to be diminished. The rate-limiting stage of the deactivation process in such complexes is apparently proton transfer from the acid to the base (pyridine) by tunnelling.

All the processes considered above refer to the singlet excited state. The study of the deactivation processes in the triplet state is complicated by the fact that the latter is formed from the singlet state as a result of an intercombination transition. All the deactivation processes leading to the quenching of the singlet state can therefore decrease the quantum yield of the triplet state. However, this difficulty may be overcome if the triplet state is populated by means of a triplet–triplet energy transfer. Using the method of the triplet–triplet energy transfer from the toluene glassy matrix to the luminescent compound investigated, it has been shown [164] that the phosphorescences of carbazole, 2-naphthol, pyrazine, benzophenone, and anthraquinone are quenched by pyridine and phenol. In contrast to the latter, triethylamine does not quench the phosphorescence of carbazole and 2-naphthol. In those cases where the system components do not form a hydrogen bond and the functional groups forming a hydrogen bond

with the $\pi$-systems of the aromatic molecules are not conjugated, there is no quenching of the phosphorescence and hence no deactivation of the triplet state.

When processes involving the deactivation of the singlet excited state in proton phototransfer reactions are examined, it is of interest to consider the problem of which process (internal conversion or intercombination transition) is influenced to a greater extent by the acid–base interaction§. It has been stated that proton transfer within 2-naphthol–aliphatic amine complexes [162] increases the degree of internal conversion.

Non-radiative degradation of the electronic excitation energy has also been observed in intramolecular proton transfer reactions in salicylate esters [185]. This is manifested by a sharp increase of the intensity of the fluorescence of the species with proton transfer as the temperature is reduced. The absence of any influence by isotopic substitution on the kinetic characteristics of the deactivation processes is evidence that the latter are not associated with the proton phototransfer reaction. This is the essential difference between the mechanisms of the degradation of the electronic excitation energy in intramolecular and intermolecular proton transfers.

The available data are insufficient to decide whether the deactivation processes in one of the species involved in interconversion play a dominant role or whether deactivation proceeds with a high efficiency in both species.

# The Mechanism of the Adsorption of Sulphur Dioxide on Carbonaceous Adsorbents

S.A.Anurov, N.V.Kel'tsev, V.I.Smola, and N.S.Torocheshnikov

The most important literature data concerning the mechanism of the adsorption of $SO_2$ and the influence of oxygen and water vapour on the latter are described systematically and analysed. The possible types of interaction between the components of the gaseous mixture and the surface of the carbonaceous adsorbent are discussed.
The bibliography includes 112 references.

## I. INTRODUCTION

During the last 10–15 years, increasing attention has been devoted to active search for new adsorbents in many world scientific centres. The reason for this is, on the one hand, the ease of their preparation as a result of favourable thermodynamic and kinetic factors governing adsorbent–adsorbate systems, and, on the other hand, their importance and the wide variety of their practical applications. The vigorous development of such research is to a large extent associated with the fact that it is directed to the solution of one of the most urgent problems in the development of modern society—the protection of the environment, in particular the elimination of sulphur oxides from gases.

The tendency towards an increase in the amount of waste sulphur oxides is manifested from year to year in connection with the expansion of the manufacture of heavy non-ferrous metals and sulphuric acid, the increase in the output of electric power stations operating on sulphur-containing fuels, etc. Thus the $SO_2$ waste (and the predicted amount of such waste) discharged into the atmosphere in the USA is characterised by the following data (million tonnes)[1]:

| 1966 | 1970 | 1980 | 1990 | 2000 |
|---|---|---|---|---|
| 28.6 | 36.6 | 61.0 | 86.5 | 126.0 |

The development of new methods for the extraction of sulphur dioxide from gases led to the appearance of carbonaceous and silicon-containing adsorbents, adsorbents based on metal compounds, and various ion-exchange resins. Many of these adsorbents have a high thermal stability, chemical resistance, effective characteristics as regards deformation and strength, etc.

The method for the elimination of sulphur dioxide from gaseous mixtures by means of various carbonaceous adsorbents has developed extensively at the present time. The extraction of $SO_2$ by carbonaceous adsorbents has attracted the attention of specialists by its relative simplicity, the ease of preparation of the adsorbents on an industrial scale, and the wide range of particle sizes and types of adsorbents. The elimination of $SO_2$ from gases by carbonaceous adsorbents is one of the procedures undergoing industrial tests. Studies on the applications of carbonaceous adsorbents for the sorption of $SO_2$ have been very numerous; a wide variety of methods and starting materials have been used for their preparation. Nevertheless, despite the different nature and types of these adsorbents, the adsorption of sulphur dioxide on them may involve the same process.

Studies in recent years have been characterised by a growth of interest in the mechanism of the sorption of $SO_2$ on various carbonaceous adsorbents and by a more far-reaching investigation of the properties of the latter. The number of studies on these lines has been increasing every year. However, the published data, scattered throughout numerous articles and journals, have not so far been reviewed systematically and analysed. In the present review, an attempt is made to fill the existing gap.

The review does not claim to cover the available data fully. Attention is concentrated on the mechanism of the adsorption of $SO_2$ and on the influence of various factors on this process.

## II. GENERAL CHARACTERISTICS OF THE SORPTION OF THE COMPONENTS OF THE GASEOUS MIXTURE

The experimental data accumulated hitherto concerning the adsorption of $SO_2$ from gaseous mixtures by carbonaceous adsorbents have shown that the sorption process has many features which depend on the chemical composition of the gas to be purified. However, despite this, it is always possible to isolate a large group of typical primary or secondary reactions occurring when a gaseous mixture is passed through a layer of a carbonaceous adsorbent. One should also note that the general characteristics do not rule out the occurrence of specific individual elementary reactions of the components of the gaseous mixture.

The primary adsorption processes consist mainly in the sorption of the components of the gas stream via fundamental mechanisms[2,3] of the following types:

$$SO_2 \rightleftarrows SO_2^*\ , \qquad (1)$$

$$H_2O \rightleftarrows H_2O^*\ , \qquad (2)$$

$$^1/_2O_2 \rightleftarrows O^*\ , \qquad (3)$$

where an asterisk denotes the sorbed state of the component.

Because of the occurrence of the three fundamental types of the primary interaction of the components of the gaseous mixture with the carbonaceous sorbent, the process involving the elimination of the desired component (sulphur dioxide) proceeds in two ways—via the primary

reaction (1) and via secondary interconversions of the sorption products[4,5]:

$$SO_2^* + H_2O^* \rightleftarrows H_2SO_3^* \quad , \tag{4}$$

$$H_2SO_3^* + O^* \rightleftarrows H_2SO_4^* \quad , \tag{5}$$

$$H_2SO_4^* + n\,H_2O^* \rightleftarrows (H_2SO_4 \cdot nH_2O)^* \quad . \tag{6}$$

It is frequently very difficult to determine the contribution of the adsorption step to the technological process. This is because modern technical procedures permit a reliable and fairly simple identification of only ionised products in the solid state (conductimetric, ESR, infrared spectroscopic, and other methods). As a rule, the role of the adsorbed product in the sorption process must be inferred from indirect data. However, there have been recently many studies where the formation of secondary compounds and their role in various sorption processes were analysed.

The adsorption capacity and catalytic properties of activated charcoals are known to depend not only on the specific surface but also on the nature of the distribution of pores with respect to their effective radii[6-8] and also on the chemical structure of the surface layer[9,10]. Dubinin's studies[11,12] showed that the activated charcoal is a conglomerate of irregularly joined hexagonal graphite prisms. During the preparation and activation of the charcoal, some of the rings are disrupted and ring residues, consisting of one or two carbon atoms, accumulate on the surface. Such atoms have unused valencies and form surface oxides on coming into contact with oxygen. The formation of surface oxides has been observed in numerous investigations[13-16]. It is also noteworthy that many investigators claim the existence of two types of surface oxides—acidic and basic oxides[17-19].

Davtyan and coworkers[20,21] carried out a series of experiments in which they showed that surface oxides are formed on contact with oxygen (and water). They believe that these oxides do not constitute a separate, independent phase but are bound directly to the crystal lattice of the adsorbent. These surface compounds are formed because the energy liberated as a result of oxidation is insufficient for the removal of the oxide molecule from the surface. Reactions (4)–(6) proceed as follows. Sulphur dioxide molecules in the sorbed state interact with the initial adsorbent–oxygen or adsorbent–hydroxyl surface compound, which results in the formation of an activated surface complex having a definite chemical reactivity. If the energy of the system is sufficient for the removal of a species from the surface, the final product of the reaction

$$(H_2SO_4 \cdot n\,H_2O)^* \rightarrow H_2SO_4 + n\,H_2O \tag{7}$$

is formed directly via the activated surface complex. In certain studies, the formation of sulphuric acid is regarded as the primary stage of the gas purification process and it is suggested that the acid is formed before its sorption by the carbonaceous adsorbent[22,23]. We believe that such a process can occur only in the purification of the residual gases in the manufacture of sulphuric acid, containing a sulphuric acid mist[24].

The role of surface oxides in the sorption of $SO_2$ by carbonaceous adsorbents is probably really considerable[25,26]. However, analysis of numerous investigations shows (without going into the details of the mechanism of the primary step involving the sorption of the components of the gaseous mixture and of secondary processes) that the conventional subdivision of the extraction of $SO_2$ from industrial gases by sorption into two groups of processes [reactions (1)–(3) and (4)–(6)] is probably legitimate. One should bear in mind that, under certain conditions, reaction (4) is favoured over reaction (6).

In considering typical reactions of the second group [reactions (4)–(6)], the authors usually distinguish two temperature ranges in each of which a characteristic reaction takes place[27,28]. At low temperatures (up to approximately 200°C), sulphurous acid decomposes to $SO_2$ and water vapour via the reaction

$$H_2SO_3^* \rightarrow SO_2 + H_2O \quad . \tag{8}$$

This reaction is characteristic of the purification of gases which do not contain oxygen. However, under real conditions, an oxygen-free gaseous mixture is hardly ever encountered.

At temperatures above 200°C (approximately 350–450°C), the decomposition of the adsorbed sulphuric acid is most probable:

$$2H_2SO_4^* + C \rightarrow 2SO_2 + 2H_2O + CO_2 \quad , \tag{9}$$

as a result of which the adsorbent reduces the acid to sulphur dioxide with formation of carbon dioxide.

Reactions (8) and (9) were investigated in detail by Dratwa[29]. The experiments were performed using model gases with the following compositions:

I. $SO_2 + N_2$ ,

II. $SO_2 + N_2 + O_2$ ,

III. $SO_2 + N_2 + O_2 + H_2O$ ,

IV. $SO_2 + N_2 + H_2O$ .

The concentration of nitrogen was kept constant and the concentrations of the remaining components of the gaseous mixtures were 5 vol.% $SO_2$, 10 vol.% $O_2$, and 18 vol.% $H_2O$. $SO_2$ was adsorbed at 110–120°C and the regeneration temperature was kept in the range 400–450°C. The results of these studies are presented in Fig. 1.

In the experiments on the $SO_2 + N_2$ (I) model gas, there is only physical adsorption of $SO_2$ by the activated charcoal. In the regeneration of the spent activated charcoal, the presence of $SO_2$ in the desorbed gas is detected over the entire temperature range from 20° to 200°C and the rate of evolution of $SO_2$ increases rapidly after heating the adsorbent above 100°C. The evolution of carbon dioxide is observed only in the temperature range which is not characteristic of the desorption of physically adsorbed $SO_2$.

The results of these experiments with the oxygen-containing model gas (II) are analogous to those analysed above. Here too an increase of temperature during adsorption is insignificant and $SO_2$ is mainly desorbed in the range between room temperature and 200°C. A considerable amount of $CO_2$ is formed together with $SO_2$. It follows from these data that sulphuric acid is not formed in the adsorption of $SO_2$ by carbonaceous adsorbents from an oxygen-containing gas.

In order to investigate the conditions under which $SO_2$ is vigorously oxidised to sulphuric acid, an experiment was performed on the model gas (III), which contains water vapour in addition to $SO_2$ and oxygen. Here an appreciable increase of temperature is observed following the adsorption of $SO_2$. The $SO_2$ content in the desorbed gas increases with increase of regeneration temperature: the evolution of $SO_2$ is initially observed above the adsorption temperature and is accompanied by the formation of a large amount of $CO_2$. These results (the high heat of the phase transition in the adsorption of $SO_2$, the shift of the temperature curve for the desorption of $SO_2$, and the vigorous formation of $CO_2$) can be explained by the fact that the simultaneous presence of oxygen and water vapour promotes the conversion of $SO_2$ into sulphuric acid.

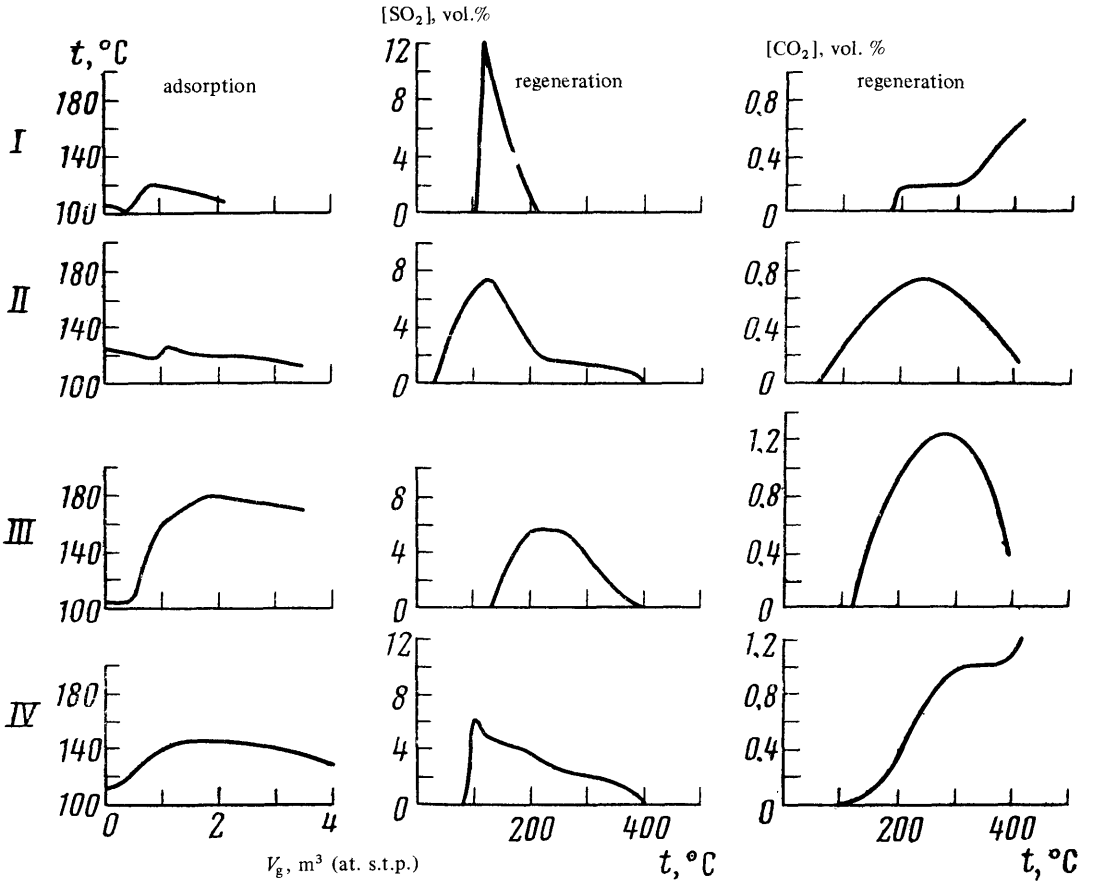

Figure 1. The influence of the composition of the initial gaseous mixture on the adsorption of sulphur dioxide and the regeneration of activated charcoal[29]; $V_g$ ($m^3$ at s.t.p.)—amount of purified gas passed through the layer of adsorbent; $t$ (°C)—regeneration temperature; $[SO_2]$ and $[CO_2]$ (vol.%)—concentrations of the components in the desorbed gas: I)–IV) model gases of different compositions.

In order to discover which reaction takes place in the presence of water vapour but in the absence of oxygen from the gases, the model gas (IV) was used. Here an appreciable increase of temperature was noted in the adsorption process and an extended $SO_2$ desorption curve (Fig. 1). Consequently in this case too there is extensive oxidation of $SO_2$ to sulphuric acid, probably by surface oxides. Similar results were obtained also in later studies[30].

The above classification of the reactions is naturally extremely arbitrary and in specific instances there is a possibility of particular departures from the proposed mechanism. Thus it has been stated[31] that the following reaction is possible in the adsorption of $SO_2$:

$$3SO_2^* \rightarrow S^* + 2SO_3^* \ . \qquad (10)$$

However, its occurrence is extremely doubtful.

One may note that the determination of the exact limits of the temperature ranges corresponding to the occurrence of the adsorption-catalytic processes is not only difficult but also controversial if one is dealing with specified carbonaceous adsorbents. Even for a particular type of activated charcoal, the temperature ranges where given sorption processes occur may be displaced as a function of the nature and amount of various impurities, the history of the active centres, etc.

It is noteworthy that, according to some data[32], free radicals are present on the surface of carbonaceous adsorbents. In the sorption of oxygen by an activated charcoal containing free radicals, the electrons of the latter become localised at oxygen molecules. These electronic states are stable, the corresponding species are rapidly chemisorbed and then activate the oxygen molecules[33,34]. Such a process on the surface of a carbonaceous adsorbent leads to the formation of the radical-ion $O_2$.[35] The occurrence of this stage may be represented by the reaction[36]:

$$R{\equiv}C^- + O_2 \rightarrow RCO_2^- \rightarrow R{\equiv}C \ldots O_2^- \ . \qquad (11)$$

If sulphur dioxide molecules appear on the surface of the charcoal, the following reactions may take place:

$$R{\equiv}C \ldots O_2^- + SO_2 \rightarrow R{\equiv}CO \ldots OSO_2 \ , \qquad (12)$$

$$R{\equiv}CO \ldots OSO_2 \rightarrow R{\equiv}C{-}O{-} + SO_3 \ , \qquad (13)$$

$$R{\equiv}C{-}O^- + SO_2 \rightarrow R{\equiv}C{-}O{-}SO_2 \ . \qquad (14)$$

It is noteworthy that, although the operation of this $SO_2$ sorption mechanism has been questioned by many specialists, the available experimental data are apparently consistent with this interpretation of the primary reactions.

The form of the bond between $SO_2$ and the surface of the carbonaceous material can have a marked influence on the primary $SO_2$ sorption processes. According to the hypotheses put forward by a number of investigators, two types of bond are formed between $SO_2$ and the carbon surface: a weak bond, which dissociates on slight heating in a stream of an inert gas ($a_I$) and a strong bond, the dissociation of which requires an increase of temperature (up to 300°C) as for surface oxides ($a_{II}$). Furthermore, these reactions are considerably influenced by the interaction of the surface with $SO_2$ and water vapour and by the ability of sulphur atoms to form hydrogen bonds[37,38].

We shall now consider the occurrence of the sorption processes from the theoretical standpoint based on the occurrence of reactions (1)–(3). The extent of adsorption of $SO_2$ on the activated charcoal obeys satisfactorily the Langmuir equation[30,31,39]:

$$a = \frac{a_m P}{P + b}, \tag{15}$$

where $a_m$ is the degree of adsorption of $SO_2$ at equilibrium, $P$ the partial pressure of $SO_2$, and $b$ a constant, which depends on temperature and which can be calculated from the Arrhenius equation:

$$b = b_0 e^{-\frac{E^*}{RT}}, \tag{16}$$

where $E^*$ is the heat of adsorption.

If it is assumed that $P \ll o$, Eqn. (16) can be replaced by Henry's law [Eqn. (17)], i.e. the degree of adsorption of $SO_2$ is directly proportional to its partial pressure:

$$a = \frac{a_m}{b} P. \tag{17}$$

$SO_2$ is oxidised to $SO_3$ on the surface of the activated charcoal and sulphuric acid is formed at a rate which is determined by the equation

$$\frac{d[H_2SO_4]}{dt} = k_I [SO_2^*] [O^*]^{0,5} [H_2O^*] - k_{II} [H_2SO_4^*], \tag{18}$$

where $k_I$ and $k_{II}$ are the rate constants for the forward and reverse reactions. The sulphuric acid formed on the surface fills internal pores, which enables the surface of the charcoal to participate in the oxidation process again. Thus the reverse reaction may be neglected in the adsorption of $SO_2$.[29]

We obtain from Eqns. (17) and (18)

$$\frac{d[H_2SO_4]}{dt} = k_I \frac{a_m a_{m_1} \sqrt{a_{m_2}}}{b\ b_1\ \sqrt{b_2}} P\ P_1\ P_2^{0,5}, \tag{19}$$

where the subscripts 1 and 2 refer to water and oxygen respectively.

During sorption, the values of $a_m$, $a_{m_1}$, and $a_{m_2}$ are constant when the partial pressures of sulphur dioxide, water vapour, and oxygen are constant; the rate of formation of sulphuric acid in the catalytic region is likewise constant. The rate constant for the reaction is

$$k_I = k_{0I} e^{-\frac{E_{act}}{RT}}, \tag{20}$$

where $E_{act}$ is the activation energy for the chemical reaction on the surface of the charcoal.

Having substituted in Eqn. (19) the adsorption rate constants defined by Eqn. (16), we obtain

$$\frac{d[H_2SO_4]}{dt} = {}'A e^{-\frac{E^*}{RT}}; \tag{21}$$

and the apparent activation energy $E^*$ for the overall reaction now consists of the activation energy for the entire adsorption process and of the activation energy for the chemical reaction:

$$E^* = E^* + E_1^* + {}^1/_2 E_2^* - E_{act}. \tag{22}$$

When $(E^* + E_1^* + \frac{1}{2}E_2^*) > E_{act}$, the experimental data agree in this case with the calculated results[4] (Fig. 2). Data were obtained for two different types of activated charcoal: BKTs (continuous lines) and BKA (dashed lines). In the former case, the adsorbent particle size was varied for a constant contact time of 12 s and in the latter case the contact time was varied. The logarithm of the rate of adsorption of $SO_2$ ($cm^3\ kg^{-1}\ min^{-1}$) for constant $SO_2$, water vapour, and oxygen concentrations in the gaseous mixture is proportional to the reciprocal of temperature, in agreement with Eqn. (21). The apparent activation energy is 22 kcal $mole^{-1}$ for the BKTs charcoal and 14.6 kcal $mole^{-1}$ for the BKA charcoal. To a first approximation, $E^*$ is comparable to the heat of adsorption.

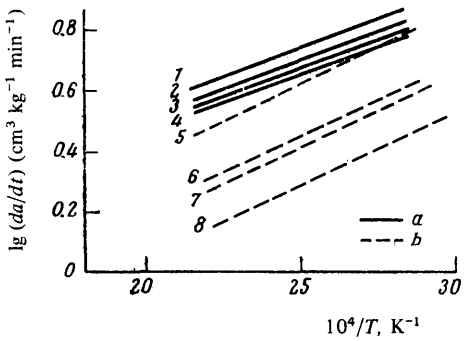

**Figure 2.** Temperature variation of the rate of adsorption of $SO_2$ on different activated charcoals in terms of the Arrhenius equation[4]: *a*) BKTs activated charcoal [particle size (mm): 1) 0.5–1.0; 2) 1–2; 3) 2–3; 4) 4–5]; *b*) BKA activated charcoal (particle size 2–3 mm). Contact time between the solid and gas phases (s): 1)–4) 12; 5) 5.4; 6) 8.6; 7) 13.0; 8) 22.0.

Measurements have been made[40] of the heat of adsorption of $SO_2$ on the "Aussig" coarsely porous charcoal at very low sulphur dioxide concentrations. The authors established that the minimum heat of adsorption is close to the heat of condensation of $SO_2$ (6.32 kcal $mole^{-1}$) and the maximum heat is 8.5 kcal $mole^{-1}$. The heat of adsorption of $SO_2$ on a finely porous activated charcoal reaches 10 kcal $mole^{-1}$.[41] However, the heats of adsorption of $SO_2$ on carbonaceous sorbents (coke, semicoke, and others) are lower than for activated charcoals, amounting to 6.5–8.0 kcal $mole^{-1}$.[42]

It is noteworthy that the heat of sorption of $SO_2$ on activated charcoal from a gaseous mixture containing oxygen and water vapour is much higher, reaching 14–16 kcal $mole^{-1}$.[43]

## III. THE INFLUENCE OF OXYGEN

Real technological and ventilation gases as a rule contain oxygen[44,45]. Studies have shown that sulphur dioxide is in this case oxidised to the trioxide on the surface of carbonaceous adsorbents. In the presence of moisture, sulphur trioxide forms sulphuric acid [reactions (4)–(6)].

Thus the presence of oxygen and moisture must influence the mechanism of the process and hence its equilibrium and kinetic characteristics. The influence of oxygen on the sorption process was observed in the very first experiments designed to investigate the elimination of $SO_2$ from gases by an activated charcoal. However, systematic studies on these lines were undertaken only recently.

In 1956 Davtyan et al.[46] investigated the effect of oxygen in the gas phase in the adsorption of $SO_2$ on surfaces of different chemical types (adsorption from a mixture of $SO_2$ and $O_2$ in proportions of 2 : 1). The adsorbents investigated can be arranged in the following sequence in terms of their catalytic activity at low temperatures:

$$\text{activated charcoal} > V_2O_5 > \text{graphite} > Cr_2O_3 > Fe_2O_3.$$

It follows from Eqn. (19) that the rate of oxidation of $SO_2$ to sulphuric acid is proportional to the square root of the oxygen partial pressure. Under industrial conditions, the addition of oxygen to the gaseous mixture increases the degree of adsorption of $SO_2$[47] and the degree of purification of the gases[29] (Fig. 3). Here too $SO_2$ is apparently oxidised to sulphuric acid.

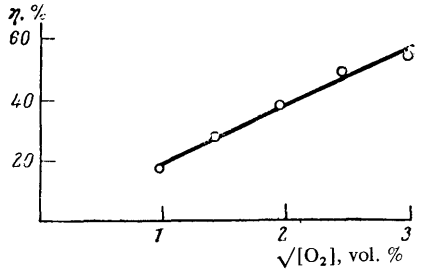

**Figure 3.** Variation of the degree of purification of the gases ($\eta$, %) with the initial concentration of oxygen in the gaseous mixture[29].

At very low (5%) and very high (95%) oxygen partial pressures, a smaller amount of sulphuric acid is obtained than in the case where the oxygen and sulphur dioxide partial pressures are equal (50%) for a given oxidation time[21]. However, the authors note that the amount of oxidised product can reach a limiting value after a specific time interval whatever the oxygen partial pressure. The formation of the limiting amount of the oxidised product on the charcoal is slow, which can be evidently accounted for by the rôle of diffusion in micropores. Only part of the adsorbed sulphur dioxide is then oxidised. On this basis, the authors conclude that "oxides" weakly bound to the charcoal surface and involved in equilibrium with the oxygen in the gas phase take part in the catalytic $SO_2$ oxidation process; these catalytically active "oxides" are readily removed by evacuation for 1 h at 20°C.[48] They consist of chemisorbed oxygen with a low activation energy and occupying about 10% of the entire surface of the charcoal[49,50]. Apart from these "oxides", weakly bound to the activated charcoal surface, Davtyan and Tkach[21] believe that none of the individual surface oxides of the charcoal are involved in the catalytic oxidation of sulphur dioxide.

A similar view has been developed also in other investigations[51,52] in the discussion of the adsorption of $SO_2$ by an activated charcoal from a nitrogen–oxygen–sulphur dioxide mixture. However, in this case the $SO_2$ concentration did not exceed 4 vol.% and the yield of the oxidised product, i.e. sulphur trioxide, was 50% of the adsorbed $SO_2$; the dynamic capacity of the charcoal proved to be 250 mg $g^{-1}$.

The sorption of $SO_2$ from a dry gas on activated SKT charcoal at 26°C consists of two processes: physical adsorption (77%) and chemisorption (23%).[53] With increase of temperature to 150°C, the amount of $SO_2$ chemisorbed from the dry gas hardly changes. This confirms yet again the hypothesis of the presence of a limited and constant number of active centres on the surface of the charcoal.

One should note that the degree of oxidation of $SO_2$ on carbonaceous adsorbents with a low surface activity (semicoke, coke, etc.) is insignificant[5]. The degree of oxidation of $SO_2$ on the semicoke obtained from brown coal at the pyrolysis temperature (650°C) is 10–12, 5–6, 3–4, and 2–3 wt.% of the total amount of adsorbed $SO_2$ at 25°, 75°, 100°, and 150°C respectively. The degree of adsorption of $SO_2$ (its equilibrium concentration in the gas–air mixture is 3 vol.%) is 148, 52, 48, and 26 mg $g^{-1}$ at the temperatures stated.

It is noteworthy that, despite the different surface activities of activated charcoal and semicoke, the rate of acid formation increases in both cases during the first 10 min and is then stabilised[5,46] (Fig. 4). This can probably be explained by the identical mechanism of the interaction of $SO_2$ with the carbon surface.

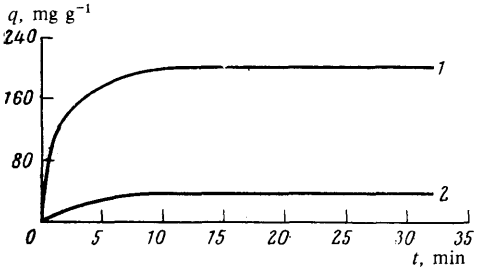

**Figure 4.** Kinetic curves for the increase in the weight of sulphuric acid on activated charcoal (curve *1*) and brown coal semicoke (curve *2*) in the adsorption of $SO_2$ from a gas–air mixture[5,46] at 20°C.

It has been claimed[23,29] that the oxidation of $SO_2$ on a carbon surface, for example on activated coke, is possible only in the presence of water vapour. The reaction

$$SO_2^{\bullet} + {}^1/_2O_2^{\bullet} + H_2O \rightarrow H_2SO_4^{\bullet} \qquad (23)$$

then occurs.

This view is adhered to also in other investigations[54,55], where the adsorption of $SO_2$ on carbonaceous adsorbents with a low surface activity was likewise investigated. The

degree of oxidation of $SO_2$ on semicoke at an adsorption temperature of 100°C for a moist gaseous mixture containing 2, 5, 10, and 15 vol.% of water vapour is 4–5, 5–6, 7–8, and 10–11%.[5] The degree of oxidation is higher in all cases for the moist gas than for the dry gas.

According to some workers[54-59], the oxidation of $SO_2$ on a carbon surface proceeds in the temperature range 20–120°C, while on heating the saturated adsorbent in a stream of inert gas above 220°C, sulphuric acid is reduced by carbon in the adsorbent via reaction (9) with regeneration of $SO_2$ and renewal of the carbon surface. However, this evidence has been disproved by subsequent investigations of the adsorption of $SO_2$ in the temperature range 50–300°C.[60] The spent charcoal was regenerated at temperatures up to 950°C. The authors noted the sorption of $SO_2$ up to 300°C, but physical adsorption of $SO_2$ was not observed at 250° and 300°C (Table 1).

Table 1. Variation of the degree of adsorption of $SO_2$ at different temperatures[60] (charcoal regeneration temperature 950°C).

| Adsorption temp., °C | Degree of sorption of $SO_2$, mg $g^{-1}$ | | |
|---|---|---|---|
| | overall | chemisorption | physical adsorption |

*Regeneration temperature 650°C
**Regeneration temperature 500°C

We may note that the amount of chemisorbed $SO_2$ at temperatures in the range 50–300°C changes insignificantly. In the regeneration of the charcoal in the temperature range 650–950°C, particles of elemental sulphur were observed on the cold surfaces of the column. Hence the authors concluded that, in the adsorption of $SO_2$ at 50–300°C, the chemisorbed sulphur dioxide is converted into elemental sulphur in the regeneration stage.

Chemical analysis of the regenerated charcoal showed that the adsorbent still contains a considerable amount of sulphur (0.68–2.03 wt.%). On this basis, one may conclude that the restoration of the initial adsorption capacity of the charcoal cannot be attributed to its liberation from sulphur. In this case, there is surface migration of sulphur from the initial adsorption centres and the formation of new centres as a result of the evolution of CO and $CO_2$ (observed in the regeneration of the charcoal).

The decrease of the $SO_2$ content in the desorbed gas during the regeneration of the charcoal can be explained by the following reactions[61]:

$$SO_2 + C \rightarrow CO_2 + {}^1/_2S_2 \quad , \tag{24}$$

$$CO_2 + C \rightarrow 2CO \quad . \tag{25}$$

The appearance of CO as a product at 250–300°C (and naturally also up to 700°C, since the adsorbent is sintered above this temperature) cannot be attributed solely to these reactions, since the rate of reaction (25) is insignificant under these conditions[62]. It is more likely that an oxygen-exchange reaction takes place between $SO_2$ and the charcoal, analogous to the well known reaction between $CO_2$ and charcoal[63]. In this case, an intermediate oxygen complex is formed and may be desorbed in the form of CO or converted into a more stable oxygen compound[13,64,65].

The only oxygen compound found at 300°C is CO; $CO_2$ was detected together with CO only at 600–650°C. In contrast to this, when carbon interacts with oxygen, the ratio of CO and $CO_2$ increases with temperature[2,66].

The combustion of carbon is known to yield CO and $CO_2$ from intermediate oxygen complexes with the carbonyl and lactone structures respectively[67,68]. It has been shown by infrared absorption spectroscopy[69,70] that these structures arise when carbon interacts with oxygen at room temperature. During vacuum heat treatment up to a higher temperature, a large amount of $CO_2$ is formed and the concentration of the complexes with the lactone structure decreases faster than that of the complexes with the carbonyl structure. It was observed[69,70] that CO appeared initially at 150°C in the regeneration of the charcoal after the adsorption of $SO_2$; there were no traces of CO up to 500°C. The sulphur content in the charcoal increased with increase of the number of adsorption–desorption cycles. The authors therefore suggested that the presence of sulphur on the surface of charcoal affects either the relative accessibility of peripheral regions, which can give rise to the carbonyl or lactone structures, or the relative thermal stabilities of these complexes after their formation.

Furthermore, $CO_2$ can be evolved also when the reaction

$$SO_2 + 2CO \rightarrow 2CO_2 + {}^1/_2S_2 \tag{26}$$

takes place[61]. Stagy et al.[60] investigated this reaction at 550°, 500°, and 350°C. A gaseous mixture containing 0.5 vol.% $SO_2$ and 2 vol.% CO in a stream of helium passed through a layer of the adsorbent; the experimental results are presented in Table 2.

Table 2. Material balance in the $SO_2$–C (1) and $SO_2$–CO–C (2) systems*.

| Temp., °C | $10^5 c_1$, mole $min^{-1}$ | | Duration of expt., min | $10^5 c_2$, mole $min^{-1}$ | | | |
|---|---|---|---|---|---|---|---|

* $c_1$ and $c_2$ are the $SO_2$, CO, $CO_2$, and COS concentrations in systems (1) and (2) respectively.

Comparison of the results obtained for the above two systems ($SO_2$–activated charcoal and $SO_2$–CO–activated charcoal) shows that the presence of CO appreciably altered the mechanism of the formation of elemental sulphur. It follows from Table 2 that the absence of a loss of carbon from the activated charcoal is characteristic of the $SO_2$–CO–C system. In the $SO_2$–C system at 600°C,

more than 50% of the oxygen bound in $SO_2$ was still retained in the layer of activated charcoal. However, in the $SO_2$–CO–C system at 550°C oxygen was essentially not retained. Evidently the presence of CO fully suppressed the formation of the oxygen complex on the surface of the activated charcoal.

At 550°C, the ratio of CO and $SO_2$ was approximately 2, confirming the occurrence of reaction (26). However, when the temperature was reduced to 350°C, the ratio of CO and $SO_2$ rose to 2.8 and 75% of the total sulphur was detected in the form of carbonyl sulphide. Thus carbon monoxide reacted under these conditions with the sulphur–oxygen surface complex.

Despite the apparent simplicity of the mechanism described above for the reaction of $SO_2$ on a carbon surface during adsorption and desorption, there are data throwing doubt on its validity. There exist different views concerning the details of the process. Some workers observed the oxidation of $SO_2$ during adsorption on a dry adsorbent from a dry gas[38,46], while others assumed that the oxidation is possible only in the presence of water[2,16]. According to one group of investigators[22], all the adsorption centres are catalytically active in the reactions, while others[23] believe that only some are active.

Furthermore, there exist experimental data which cannot be accounted for at all in terms of this mechanism. This applies to the amount of carbon dioxide appearing in the desorption of $SO_2$ via reaction (9). According to Dratwa et al.,[4] its amount is 80–120% relative to the stoichiometric composition based on reaction (9). The increase of the amount of $CO_2$ can be explained by the desorption of part of the surface carbon oxides. On the other hand, the decrease of the amount of $CO_2$ relative to stoichiometry can be attributed only to the fact that not all the chemisorbed $SO_2$ is oxidised to $SO_3$ at a temperature in excess of 220°C, where $SO_2$ is formed from $SO_3$ via reaction (9) according to the mechanism described: in fact ordinary desorption of strongly bound sulphur dioxides takes place to some extent.

The presence of oxygen in the gas causes not only a change in the nature of the process but also leads to a decrease of the overall rate of adsorption. This can be clearly seen in Fig. 5 from a comparison of the kinetic curves characterising the rate of adsorption of $SO_2$ by SKT-2 charcoal grains at an initial concentration of 1 vol. %, at 20°C, and for different amounts of oxygen in the inert gas (nitrogen).[30]

## IV. THE INFLUENCE OF WATER

The influence of water on the sorption properties of activated charcoals can be manifested both in the gas phase and directly in the adsorbent itself. The sorption of water vapour by the activated charcoal or the desorption of water from the latter not only accompany the sorption of other vapours and gases but, as a rule, constitute an important factor, determining the kinetics (and hence also the dynamics) of the adsorption. It has been shown in a number of studies[73–76] that the equilibrium capacity of the activated charcoal with respect to sulphur dioxide depends to a large extent on the moisture content in the system.

The moisture present in the activated charcoal grains constitutes an intermediate diffusion medium in which the volatile component is transferred between the gas phase and the solid substance of the activated charcoal. Consequently the gas–activated charcoal system consists of three phases in the presence of moisture; the equilibrium compositions of the phases and the kinetics of the interphase exchange are determined by the content and nature of the water in the activated charcoal.

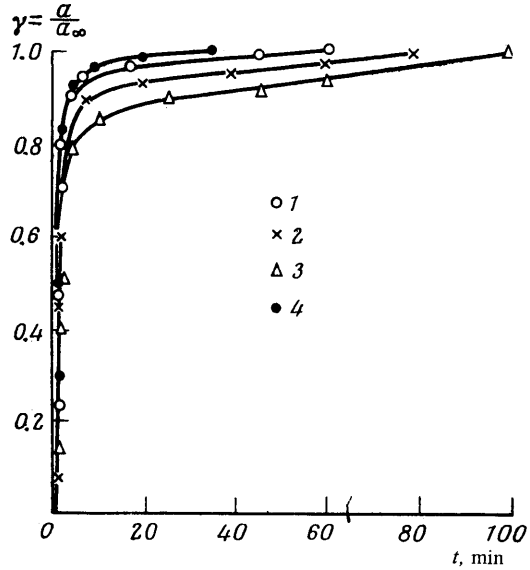

**Figure 5.** The influence of the oxygen content on the kinetics of the adsorption of $SO_2$ by SKT-2 charcoal[30]; initial $SO_2$ concentration 1 vol.%; temperature 20°C; oxygen content in the gaseous mixture (vol.%): 1) 3; 2) 5; 3) 15; 4) no oxygen.

The influence of the moisture content in the activated charcoal on the sorption of $SO_2$ was noted for the first time in 1917 in a study of the sorption properties of wood charcoal[77]. It was found that the overall sorption of $SO_2$ by the moist charcoal greatly exceeds the value for the dry charcoal. Somewhat later a similar effect was observed also for activated charcoals obtained from different starting materials, for example coconut, sugar, etc.[78] In the 1950s and 1960s, several patents were issued abroad for a method of synthesis of sulphuric acid using moist charcoal[79–88]. Widely known methods for the elimination of sulphur dioxide from industrial gases, such as the Lurgi[89–92], Hitachi[93,94], and West-Vaco[95,96] methods, are based on this principle.

The influence of charcoal saturated beforehand with moisture on the adsorption of $SO_2$ has been investigated comprehensively. It has been established that moisture has a significant effect on the nature and shape of the isotherm (Fig. 6), particularly at low partial pressures of sulphur dioxide in the gaseous mixture[48]. The degree of adsorption of $SO_2$ increases sharply with increase of the moisture content in the charcoal. Furthermore, it has been found that the amount of sulphuric acid obtained initially increases almost linearly with increase of the moisture content in the charcoal, reaches a maximum only in the presence of a moisture content of 300 mg $g^{-1}$, and then decreases sharply (Fig. 7).[48] The descending branch of the curve corresponds to saturation of the adsorbent

micropores with water. Similar effects were observed also on other activated charcoals for different initial $SO_2$ concentrations[19].

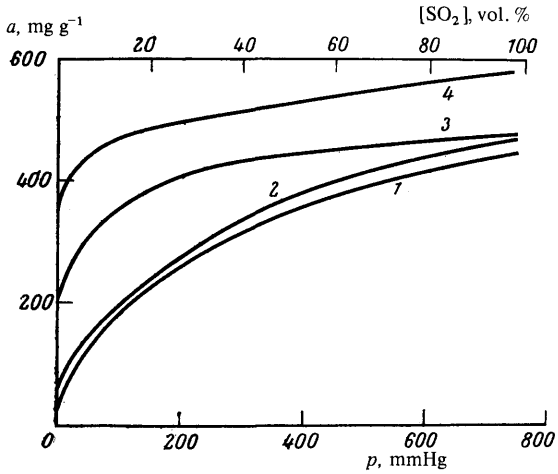

**Figure 6.** $SO_2$ adsorption isotherm at room temperature on activated charcoals with different moisture contents[48] (mg $H_2O$ per gram): 1) 0; 2) 1.98; 3) 13; 4) 19.6.

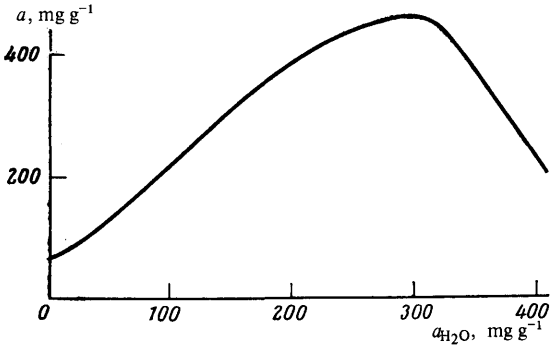

**Figure 7.** Variation of the degree of sorption of $SO_2$ at 20°C on activated charcoal with the amount of moisture adsorbed beforehand[48].

It has been suggested[37] that there are two types of interaction between $SO_2$ molecules and the carbonaceous adsorbent. The first is due to a weak bond between them, which may be broken on heating the adsorbent in a stream of an inert gas up to 100°C. This interaction makes a contribution $a_I$ to the overall degree of adsorption. The second interaction is characterised by a strong bond, which is not dissociated up to 200°C. It makes a contribution $a_{II}$ to the total sorption of $SO_2$. This hypothesis was also confirmed in a study of the adsorption of $SO_2$ on activated charcoal from a moist gas (Fig. 8).[97] With increase of the concentration of water vapour in the gas, $a_I$ diminishes, while $a_{II}$ passes through a maximum. The diametrically opposite effects of water vapour on $a_I$ and $a_{II}$ indicate the presence on the charcoal surface of adsorption centres of two types, involved in different kinds of surface interactions during the adsorption of sulphur dioxide and water vapour.

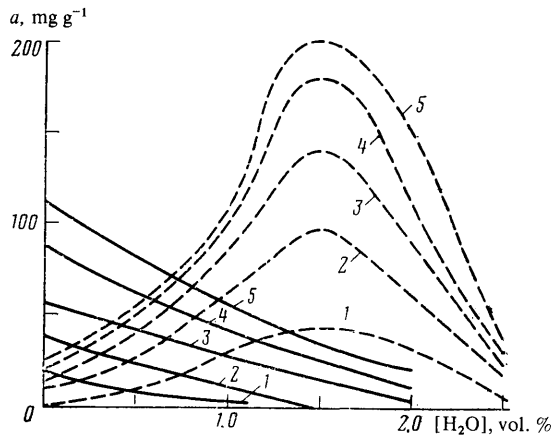

**Figure 8.** Variation of the degree of sorption of $SO_2$ [$a_I$ (continuous lines) and $a_{II}$ (dashed lines)] on SKT-2 charcoal with the concentration of water vapour at 25°C for different $SO_2$ concentrations[97] (vol.%): 1) 0.2; 2) 0.5; 3) 0.8; 4) 1.2; 5) 1.6.

Analysis of the experimental data leads to the following conclusions. The primary active centres in the adsorption of water on carbonaceous adsorbents are known to be oxygen complexes formed on the charcoal as a result of its activation. In the absence of such complexes, there is virtually no adsorption of water on the charcoal[11-16,98]. It is also known that oxygen complexes on the surface of charcoal serve as adsorption centres for sulphur dioxide too[19-23,46,48-53,99]. Under these conditions, the adsorption of $SO_2$ on active oxygen complexes is mainly in the nature of physical adsorption[40,43,100,101].

The water molecules adsorbed on the oxygen centres of the charcoal surface at water vapour pressures close to 0.5 of the saturation pressure are associated with one another via hydrogen bonding, which results in the coverage of the charcoal surface by isolated patches of condensed phase. The hydrogen atoms in the adsorbed water molecule, which are capable of forming hydrogen bonds, then serve as new adsorption centres and fresh portions of water are adsorbed by them. As a result, the number of adsorption centres in the given range of water vapour pressures increases sharply[97]. This mechanism is in fact used to account for the characteristic concave form of the water vapour adsorption isotherms on carbonaceous adsorbents with a sharp rise in the region of vapour pressures greater than 0.5 of the saturation pressure[98,102].

Sulphur is one of the elements capable of association via hydrogen bonding[103-105]. Thus the addition of $SO_2$ to the charcoal surface may proceed via the hydrogen of the adsorbed water. Since both water and sulphur dioxide molecules have strong dipoles, the strength of the bond formed may be greater than in the adsorption of $SO_2$ on silica gel via hydrogen bonding with the surface hydroxyls[106-109].

Thus the adsorption centres of the first type in the adsorption of $SO_2$ on charcoal from moist air are the oxygen complexes on the adsorbent surface. The adsorption centres of the second type in the adsorption of $SO_2$ from a moist gas are the protons of the adsorbed water molecules (hydrogen bonds). The above mechanism has been recently confirmed[97,110,111].

In the industrial synthesis of sulphuric acid, it is important to achieve the complete oxidation of $SO_2$ on carbonaceous adsorbents. Thus it has been stated[55] that, in order to attain the required degree of oxidation of $SO_2$ to $SO_3$, the contact time between the gas and the charcoal must be 10–20 s if the adsorbent temperature is maintained at the same time in the range 65–80°C; below 60°C, the reaction is strongly retarded. The concentration of the sulphuric acid obtained does not exceed 20% when the purified gas and water flow directly through the layer of adsorbent.

In a recently published study[112], carried out on a semi-industrial scale with the aim of purifying the residual gases in the manufacture of sulphuric acid, the influence of the regeneration time of the activated SKT-2 charcoal and of the amount of wash liquid on the concentration of the sulphuric acid formed was investigated (Fig. 9). In these experiments, the charcoal was wetted with the sulphuric acid solution obtained as a result of the adsorption of $SO_2$ before each adsorption–desorption cycle (apart from the first cycle, where the charcoal was wetted with water). The maximum concentration of sulphuric acid was 17% ($SO_2$ content in the gaseous mixture 0.2 vol.%, temperature 30–40°C).

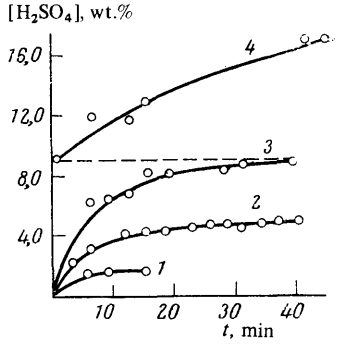

**Figure 9.** Variation of the concentration of the sulphuric acid formed with the regeneration time for dry charcoal (curve *1*), charcoal saturated with moisture after a single cycle (curve *2*), after two cycles (curve *3*), and after four cycles (curve *4*)[112]; SKT-2 charcoal; temperature 30–38°C.

There are data showing that, in the adsorption of $SO_2$, it is possible to obtain a 40% concentration of the acid[20]. However, in this case the gaseous mixture must contain 20 vol.% $SO_2$ and 80 vol.% $O_2$.

Thus the results presented above show that the sorption of sulphur dioxide by carbonaceous adsorbents is a complex physicochemical process, the rate of which and the absolute degree of adsorption of $SO_2$ depend not only on the composition of the gaseous mixture and the specific surface of the adsorbent, but also on its catalytic activity in relation to the oxidation of $SO_2$ to $SO_3$. The latter is in its turn determined by the specific properties of the adsorbent, for example, by the coverage of its surface by surface oxides, by the presence of the appropriate catalysts, and other factors.

# The Electrochemistry of the π-Complexes and Organometallic Compounds of Transition Metals

L.I.Denisovich and S.P.Gubin

The results of electrochemical studies on the oxidation-reduction reactions of the π-complexes and organometallic compounds of transition metals are surveyed and described systematically. They are compared with other physicochemical properties of compounds of this class.
The bibliography includes 272 references.

## I. INTRODUCTION

The application of electrochemical methods (classical polarography, potentiometry, voltamperometry, chronopotentiometry, etc.) in the study of the oxidation-reduction reactions of the π-complexes and organometallic compounds of transition metals yields quantitative information about one of the most important properties of these compounds—their capacity to give up and accept electrons. The undoubted advantage of electrochemical methods is that they make it possible to investigate the distribution of electron density in the molecule and the relative positions of the highest occupied and lowest vacant orbitals for a number of compounds with similar structures. Such information is important for the complicated molecules of the π-complexes and organometallic compounds of transition metals with their unusual type of bonding, for which quantum-chemical calculations are still very laborious and require considerable computer time. It is useful to survey data obtained in electrochemical studies on compounds of this class, since the above properties of the complexes may be of interest for many electrochemists and chemists working on organometallic compounds. The results of the electrochemical study of the π-complexes are particularly significant for the chemistry of these compounds, since they characterise the state and behaviour of the molecules in solutions, i.e. under the conditions where the majority of chemical reactions are carried out.

The results of electrochemical studies are grouped in the present review in terms of types of complexes investigated, since the electrochemical reactions of complexes of the same type as a rule proceed via the same mechanism. Particular attention has been devoted to the problem of the location of the electronic changes in the electrochemical reactions of the complexes. Depending on the relative contribution of the ligand molecular orbital and the metal atomic orbital to the molecular orbital of the complex, it is useful to distinguish three types of location of the electronic changes in the π-complexes and organometallic compounds of transition metals: (1) in the molecular orbital of the complex to which the atomic orbital of the metal makes the main contribution; (2) in the molecular orbital of the complex to which the molecular orbital of the ligand makes the main contribution; (3) in the antibonding orbital of the localised metal–ligand σ-bond. The principal procedures used to solve the problem of the location of the electronic changes in the complexes have already been formulated in a review[1]. In many cases the properties of charged species (radical-cations and radical-anions), formed as a result of the electrochemical reactions of the complexes, have also been discussed.

Brief information concerning the electrochemical behaviour of individual representatives of the π-complexes and organometallic compounds of transition metals may be found in a number of reviews[2-4]. However, a full discussion of studies on the electrochemistry of such π-complexes and organometallic compounds has not so far been published. The present review does not include the results of electrochemical studies on the coordination compounds of transition metals and transition metal complexes with donor–acceptor ligands without at least one metal–carbon bond [for example $M(PR_3)_n$]; however, in these cases, references are given wherever necessary to the most important studies in this field. The review covers the literature up to 1975 inclusive.

## II. ELECTROCHEMICAL BEHAVIOUR OF SANDWICH COMPLEXES

A characteristic feature of neutral complexes of this type is that the metal is enclosed in a stable hydrocarbon shell and that its direct contact with solvent molecules or the electrode is hindered.

### 1. Dicyclopentadienyl and Bisarene Complexes

Reactions involving a change in the formal oxidation state of the metal atom are characteristic of π-complexes of the sandwich type (dicyclopentadienyl and bisarene complexes). The neutral compounds $(\pi\text{-}C_5H_5)_2M$ and $(\pi\text{-}C_6H_6)_2M$ as a rule undergo reversible one-electron oxidation at the electrode with formation of the corresponding cations $[(\pi\text{-}C_5H_5)_2M]^+$ and $[(\pi\text{-}C_6H_6)_2M]^+$. These reactions have been investigated in greatest detail in relation to dicyclo-

pentadienyl compounds and, particularly, ferrocene†. The ferrocene–ferrocenium cation pair is one of the most reversible oxidation-reduction systems under homogeneous conditions. Electron exchange between the oxidised and reduced forms in this system is of the outer-sphere type and proceeds at a high rate, greatly exceeding the rate of electron exchange in rapidly exchanging systems such as, for example, $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$.[7] This means that[8,9], in the transition from the reduced to the oxidised form, there should be no significant changes in the coordination spheres and in the geometry of the complex. Indeed, X-ray diffraction studies have shown that the ferrocenium cation, like ferrocene itself, has a sandwich structure with analogous bond lengths and valence angles. Quantum-chemical calculations on ferrocene[10] and the ferrocenium cation[11,12] as well as experimental data obtained from the photoelectronic spectra of ferrocene[13,14], from magnetic susceptibility measurements[14], and from the ESR spectra of the ferrocenium cation[16,17] have shown that the highest occupied molecular orbital of ferrocene, from which an electron is removed on oxidation, is the weakly bound orbital of the $e_{2g}$ type formed mainly by the $3d$ orbitals of iron ($d_{xy}$, $d_{x^2-y^2}$).

It has been shown by classical polarography at platinum[18–23] and dropping mercury electrodes[21–25] (in aprotic[22,23,26] and protic[21,25,27] media), chronopotentiometry[28–30], oscillographic and a.c. polarography[31–33], and potentiometry[34,35], using for each method standard criteria of the reversibility of the electrochemical reactions, that the electrode reactions involving the oxidation of ferrocene and the reduction of ferrocenium consist in the reversible transfer of a single electron‡. However, it has been observed that the electrode reaction of ferrocene in many organic solvents may be complicated by the subsequent chemical reaction (overall *EC* mechanism) due to the instability of the resulting ferrocenium cation in these solvents[37,39].

The electrochemical behaviour of heavier ferrocene analogues—ruthenocene and osmocene—differs by a number of characteristic features. Ruthenocene undergoes irreversible electrochemical oxidation at a platinum electrode[23,29,40] with abstraction of two electrons. The most probable product is $[(C_5H_5)_2Ru]^{2+}$; however, it has not been possible to isolate salts of this cation owing to their instability§. The oxidation of osmocene at a platinum electrode involves the stepwise abstraction of two electrons[23,29]. The electrochemically irreversible removal of the first electron leads to the formation of a singly-charged cation, which has been isolated in the form of the salt $(C_5H_5)_2OsBF_4$. The observed differences in the behaviour of ferrocene ruthenocene, and osmocene are probably caused by the differences in their electronic structures¶. In conformity with the higher Lewis basicity of ruthenocene and osmocene compared with ferrocene[23], the former two compounds give rise to waves at the dropping mercury electrode (DME) due to the reactions of these metallocenes with the mercury anode[23,41]†:

$$2(C_5H_5)_2M + Hg \rightleftarrows [(C_5H_5)_2M]_2Hg^{2+} + 2e \quad ;$$
$$M = Ru, Os .$$

The electronic changes at the metal atom take place also in the oxidation-reduction reactions of cobaltocene ($d^9$) and nickelocene ($d^{10}$). The reversible ($k_S = 0.98$ cm $s^{-1}$)[43] one-electron oxidation of cobaltocene[25,43–45] and its derivatives[46,47] to the cobaltocenium cation proceeds very readily. Because of this, it is more convenient to employ as the depolariser in electrochemical studies the stable cobaltocenium cation rather than the neutral cobaltocene. The cation gives rise to a cathodic wave, whose half-wave potential $E_{1/2}$ coincides with $E_{1/2}$ for its anodic wave. It has been found that the bisindenylcobalt cation is reduced much more readily[44,48] than the cobaltocenium cation, as has been observed for bisindenyliron complexes[49].

The one-electron reversible oxidation of nickelocene in aprotic[50] and protic[21,51,52] media leads to the formation of the nickelocenium cation. It has been observed by voltamperometry that the cation undergoes further oxidation to $[(C_5H_5)_2Ni]^{2+}$, which reacts extremely readily with nucleophiles[53,54].

The available information about the electrochemical behaviour of the dicyclopentadienyl complexes of other metals is limited. It has been shown that[55,56] $[(C_5H_5)_2V]^{2+}$ combines with a single electron and is reversibly reduced to $[(C_5H_5)_2V]^+$, which has two unpaired electrons. Two reduction waves were obtained on the polarogram of $[(C_5H_5)_2Nb]^+$, while $[(C_5H_5)_2Ta]^{3+}$ does not undergo polarographic reduction. In an aqueous alcoholic medium, $[(C_5H_5)_2Rh]^+$ gives rise to a cathodic wave, while $[(C_5H_5)_2.Ir]^+$ is not reduced under these conditions[51,52]. The electrochemical reduction of the dicyclopentadienylvanadium complexes with chelating ligands L of different types has been investigated in greater detail. It has been shown[57–59] that the reduction at a mercury electrode proceeds via the *EC* mechanism:

$$[(C_5H_5)_2V^{IV}L]^+ + e \rightleftarrows [(C_5H_5)_2V^{III}L]^0 \quad ;$$
$$[(C_5H_5)_2V^{III}L]^0 \xrightarrow{k} [(C_5H_5)_2V^{III}] + L \quad .$$

The electrochemical behaviour of sandwich bisarene complexes has been studied in relation to bisbenzenechromium ($d^6$). It has been shown[26,60–62] that it is readily oxidised to the cation $[(\pi\text{-}C_6H_6)_2Cr]^+$ ($d^5$). The electrode reaction is reversible under all the conditions investigated (aprotic medium[26,44,60,63,64] or protic medium[61,62,65–73]). There is a possibility of further oxidation of $[(\pi\text{-}C_6H_6)_2Cr]^+$ at a platinum electrode[74]:

$$[(\pi\text{-}C_6H_6)_2Cr]^+ - 2e \rightarrow Cr^{3+} + 2C_6H_6 \quad .$$

† A brief description of the electrochemical properties of the ferrocene–ferrocenium cation system as well as other biscyclopentadienyl compounds can be found in a number of reviews on the chemistry of metallocenes[5,6].

‡ However, there is a brief communication[36], unsupported by sound evidence, concerning the equilibrium $[(C_5H_5)_2Fe]_2^+ \rightleftharpoons (C_5H_5)_2Fe + [(C_5H_5)_2Fe]^+$ and the electrochemical irreversibility of the $(C_5H_5)_2Fe/[(C_5H_5)_2Fe]^+$ system.

§ The chemical oxidation of ruthenocene by $FeCl_3$ or $Br_2$ leads to the formation of the stable salts $[(C_5H_5)_2RuCl].FeCl_4$ and $[(C_5H_5)_2RuBr]Br_3$. The introduction of halogens into the inner coordination sphere apparently stabilises the +4 formal oxidation state of ruthenocene[23].

¶ It has been stated[13] that the ionisation energies of the highest occupied orbitals of ruthenocene and osmocene are similar (7.25 and 7.23 eV) and that the energies of the orbitals of the $e_{2g}$ and $a_{1g}$ types in ruthenocene are much smaller (0.18 eV) than in ferrocene (0.35 eV). The highest occupied orbital in osmocene is apparently the $a_{1g}$ orbital (and not $e_{2g}$ as in ferrocene).

† It was suggested initially[42] that ruthenocene and osmocene are oxidised to the corresponding cations at the DME.

Polarograms of $[(\pi\text{-}C_6H_6)_2Cr]^+$ at the dropping mercury electrode in aqueous solutions frequently exhibit adsorption prewaves associated with the low solubility of the reduced form of the complex, namely $(C_6H_6)_2Cr$.[66,70-73] Measurements of the electrocapillary curves for the cation $[(\pi\text{-}C_6H_6)_2Cr]^+$ showed that the reduction proceeds in the adsorbed layer[71]. The area occupied by a single cation $[(C_2H_5C_6H_5)_2Cr]^+$ is 19.2 Å$^2$.[72] The diffusion coefficients of $[(C_6H_6)_2Cr]^+I^-$ have been measured in various media[44,61]. The differences between the half-wave potentials $E_{1/2}$ for the reduction of two structurally similar non-coordinated ligands ($C_6H_6$ and $C_6H_5-C_6H_5$) and their complexes with a chromium atom have been used to estimate the relative contribution of the atomic orbital of the metal and the molecular orbitals of the ligands to the molecular orbital of the bisarene complex, where electronic changes occur during the oxidation-reduction reaction[65]. The coefficient $C_2^2$ for the mixing of the atomic orbital of the metal and the molecular orbital of the ligand in the molecular orbital of the complex in which electronic changes take place during the oxidation-reduction process was calculated from the formula

$$(E^1_{1/2} - E^2_{1/2})_{\text{complex}} = C_2^2 (E^2_{1/2} - E^1_{1/2})_{\text{ligand}} .$$

It was found to be 0.15, which implies that the contribution of the ligand orbital to the molecular orbital of the complex where electronic changes take place during the oxidation of bisbenzenechromium is not more than 15% and this orbital is therefore mainly the atomic orbital of chromium.

The electrochemical properties of the bisarene complexes of other Group VIB metals have been inadequately investigated owing to their low stability. It has been noted that the reversible oxidation of $(\pi\text{-}C_6H_6)_2Mo$ proceeds with somewhat greater difficulty ($E_{1/2} = -0.71$ V) than that of $(\pi\text{-}C_6H_6)_2Cr$ ($E_{1/2} = -0.80$ V).[62] Although the available data are clearly insufficient, they nevertheless indicate that the abstraction of an electron from sandwich compounds of transition metals becomes more difficult on going from downwards in isostructural and isoelectronic series of the Periodic System.

It has been shown that the bisareneiron complexes, which exist in the form of dications, and their heteroanalogue bisthiopheniron are reduced in two stages[75]:

$$[\pi\text{-}L_2Fe]^{2+} + e \rightleftarrows [\pi\text{-}L_2Fe]^+ \rightarrow [\pi\text{-}L_2Fe] .$$

(L = tetramethylthiophen, mesitylene, and hexamethylbenzene).

Sandwich compounds with two different ligands possess electrochemical properties similar to those of their homoligand analogues. Reversible one-electron reactions at the electrode, proceeding with a change in electron density mainly in the metal atom, are also characteristic of these substances. A study of the polarographic behaviour of the cations $[\pi\text{-}C_5H_5Fe\text{-}\pi\text{-arene}]^+$ (arene = $C_6H_6$, biphenyl, naphthalene, anthracene, or phenanthrene) in an aprotic medium has shown[76,78] that the product of the reversible one-electron reduction is a neutral complex of formally univalent iron. The complexes of other metals have been little investigated. It is known only that the reduction of $[\pi\text{-}C_5H_5CrC_7H_7]^+$ in an aprotic medium also proceeds reversibly with addition of one electron[79], while the reversible one-electron oxidation of $\pi\text{-}C_5H_5VC_7H_7\text{-}\pi$ leads to the formation of the unstable cation $[\pi\text{-}C_5H_5.VC_7H_7]^+$.[80,81]

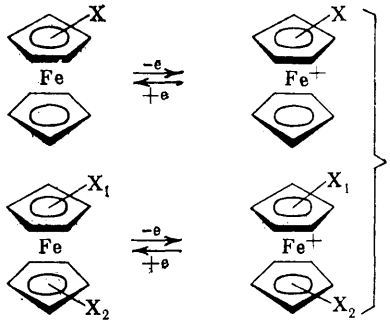
## 2. Sandwich π-Complexes and Their Cations as Standard Oxidation-reduction Systems

The $(C_5H_5)_2Fe/[(C_5H_5)_2Fe]^+$ and $(C_5H_5)_2Co/[(C_5H_5)_2Co]^+$ systems have been suggested[82-87] and widely used (see the relevant references in the papers by Duschek and Gutmann[88] and Coetzee and Campion[89]) as standards to which the potentials measured in various media are referred. Their use as standard systems is based on Strehlow's hypothesis that the free energies of solvation of the above metallocenes and their cations are the same in different solvents. The above redox pairs have considerable advantages over familiar systems such as $Rb/Rb^+$ and $Cs/Cs^+$. Metallocenium cations are even larger than heavy alkali metal ions and the charged atom is located between two cyclopentadienyl rings, which hinders their solvation. However, subsequent studied showed[31,38,89] that the wide-scale employment of the $(C_5H_5)_2Fe/[(C_5H_5)_2.Fe]^+$ system as a standard is hindered by a number of limitations. It has been found that, owing to the specific interaction of $[(C_5H_5)_2Fe]^+$ with water, the hypothesis that $\Delta G_{(C_5H_5)_2Fe} = \Delta G_{(C_5H_5)_2Fe^+}$ does not hold in water and water-organic solvent mixtures as well as formamide. Furthermore, owing to the instability of $[(C_5H_5)_2Fe]^+$ in organic solvents, the $(C_5H_5)_2Fe/[(C_5H_5)_2Fe]^+$ system does not yield satisfactory results in potentiometric measurements in the majority of organic solvents. Thus the ferrocene–ferrocenium cation system is not an ideal standard system and its employment is possible only in relatively similar organic solvents in polarographic and voltamperometric measurements. The $(C_5H_5)_2Co/[(C_5H_5)_2.Co]^+$ system is probably likewise not ideal owing to its negative standard potential (for example, −0.98 V in acetonitrile). According to Gutmann and coworkers[90,91] the larger radius of $[(C_6H_6)_2Cr]^+$ compared with that of $[(C_5H_5)_2M]^+$ and the absence of specific interactions with water make the $(C_6H_6)_2Cr/[(C_6H_6)_2Cr]^+$ system more promising for these purposes than the two previous ones.

## 3. An Electrode Reversible with Respect to the Ferrocenium Cation

The high rate of electron exchange between the oxidised and reduced forms of the ferrocene–ferrocenium cation system as well as the virtual insolubility of ferrocene and its derivatives in aqueous solutions made it possible to devise an electrode reversible with respect to ferrocenium cations[92] derived from both unsubstituted ferrocene and its derivatives[93]. In the study of the properties of the ferrocene–ferrocenium electrode, the following galvanic cells were used:

$$\text{Pt} \mid \underline{\text{Fe}(C_5H_5)(C_5H_4R)}, \ \text{Fe}(C_5H_4R)(C_5H_5)^+X^- \mid \underline{\text{KCl}}, \ \underline{Hg_2Cl_2} \mid \text{Hg}.$$

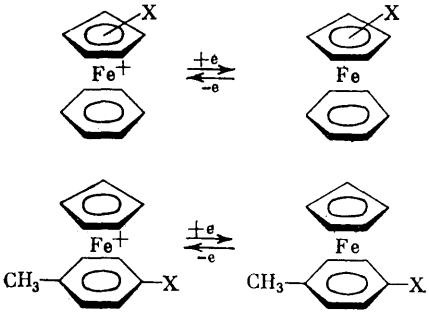


The ferrocene–ferrocenium electrode has been employed to investigate the properties of the ferrocenium cation in solutions: thermodynamic stability in aqueous solutions[94], hydrolytic decomposition[95], complex formation[96,97], and determination of the heat of hydration[98,99].

A perchlorate electrode[100], retaining the perchlorate response in solutions containing oxidants and reductants, has been devised on the basis of alkylferrocenes and the corresponding alkylferrocenium perchlorates.

4. The Electronic Effects of Substituents in the Oxidation-reduction Reactions of $\pi$-Complexes of the Sandwich Type

Electrochemical methods have been used successfully to investigate the nature of the electronic influence of substituents on the reaction centre (the transition metal atom) in oxidation-reduction reactions [29,34,35,101-108]. This problem has been investigated in greatest detail in the following reaction series: monosubstituted ferrocenes [108], heteroannular disubstituted ferrocenes [108], arenecyclopentadienyliron cations with substituents in the arene or cyclopentadienyl ring [76], and bisbenzenechromium derivatives [109]. In all cases, systematic correlation analysis with different sets of substituent constants $\sigma$ showed that the best linear relation is observed when Taft's $\sigma_\pi^0$ constants are used. Furthermore, the additivity of the influence of substituents, located in different rings of the molecule, on the oxidation potential of the metal atom was demonstrated for heteroannular disubstituted ferrocenes [108] and alkyl derivatives of bisbenzene chromium [109].



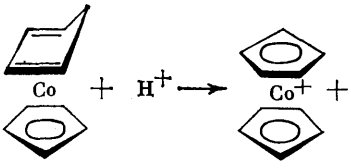
The results obtained led to the hypothesis that the nature of the influence of substituents in the above reaction series‡ differs from the influence of substituents in classical aromatic systems by the fact that there is no direct polar conjugation of the substituent with the reaction centre and that mainly the overall inductive component of the total polar influence of substituents is transmitted to both the metal atom and to the other ring. If the substituent is separated from the ferrocenyl nucleus by a methylene group ($\pi$-$C_5H_5Fe$-$\pi$-$C_5H_4$-$CH_2$-X), preventing the conjugation of X with the five-membered ring, a satisfactory linear relation is observed between $E_f^0$ and the inductive constants $\sigma_i$ of the corresponding substituents. The observed relation has been used successfully to determine the $\sigma_i$ for metallocenyl groups and other polyatomic groups [X = $\pi$-$C_5H_5FeC_5H_4$, $\pi$-$C_5H_5Fe^+$-$\pi$-$C_5H_4$, $\pi$-$C_5H_5Ru$-$\pi$-$C_5H_4$, $\pi$-$C_6H_5Cr(CO)_3$, or $\pi$-$C_6H_5Cr(CO)_3$] [1§].

$E_f^0 = (+0.50\sigma_n^0 - 0.272)$v;

‡ A similar type of influence of substituents has been found in "non-electrochemical" reaction series [110] and reflects a general property of the metal-$\pi$-ligand bond, namely its ability to transmit mainly the inductive component of the total polar influence of substituents in the direction of the metal atom and other ligands.

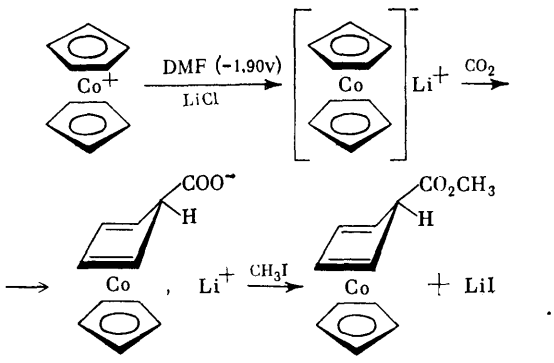
§ The oxidation-reduction potentials of the ferrocene-ferrocenium cation system have been correlated with other physicochemical parameters of ferrocene derivatives (absorption maxima in ultraviolet spectra [111], $S_N1$ solvolysis rate constants [112], etc.

$E_{1/2} = (+0.52\sigma_n^0 - 1.39)$v;



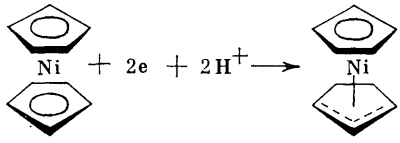
$E_{1/2} = (+0.515\sigma_n^0 - 1.42)$v.

5. Electrochemical Properties of Biferrocenyls

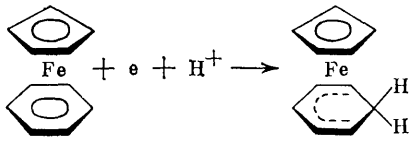


The electrochemical oxidation of biferrocenyl ($\pi$-$C_5H_5Fe$-$\pi$-$C_5H_4$)$_2$ and biferrocenylene ($\pi$-$C_5H_4Fe$-$\pi$-$C_5H_4$)$_2$ proceeds in two one-electron stages [30,113-116]. The first oxidation stage is reversible [30] and leads to a mixed valence Fe(III)-Fe(II) compound [117]. The electron transfer reaction Fe(II)*-Fe(III) $\rightleftharpoons$ Fe(III)*-Fe(II) takes place in the resulting monocation between the oxidised and neutral ferrocenyl nuclei [114,115]. The second electron is apparently abstracted irreversibly [30], which corresponds to the oxidation of the second ferrocenyl nucleus with formation of the Fe(III)-Fe(III) dication. The introduction of a bridge group between the two ferrocenyl nuclei of biferrocenyl and biferrocenylene leads to an appreciable decrease of the difference between the potentials of the first and second oxidation stages. When X = $-CH_2-CH_2-$, $-Hg-$, $-(CH_3)_2C-C(CH_3)_2-$, or $-CH=CHC_6H_4CH=CH-$, biferrocenyl is oxidised in a single two-electron stage [114]. When X = $-C\equiv C-$, the oxidation proceeds in two stages with similar values of $E_{1/2}$. [118] It has been shown that compounds with metal atoms in different oxidation states can be formed when $\pi$-arenebis-($\pi$-cyclopentadienyliron) dications are reduced at the dropping mercury electrode [119].

6. Electrochemical Reduction of Neutral $\pi$-Complexes of the Sandwich Type



Together with oxidation, electrochemical reduction reactions have been observed for neutral metallocenes (cobaltocene and nickelocene) [22]. In an aprotic medium (1,2-dimethoxyethane) [43] or in an alkaline medium at pH > 11, [47] cobaltocene undergoes reversible electrochemical reduction ($k_S$ = 0.3 cm s$^{-1}$, $E_{1/2}$ = -1.89 V) ($n$ = 1) to the previously unknown anion ($\pi$-$C_5H_5$)$_2$Co$^-$ containing the cobalt atom in the formal +1 oxidation state. In a more acidic medium (pH < 8) or acetonitrile, the anion formed reacts with a proton of the solvent, forming $\pi$-$C_5H_5Co$-$\pi$-$C_5H_6$. [120] A decrease of pH to 0-1 results in an increase of the height of the reduction wave owing to the catalytic evolution of hydrogen [120]:



The high reactivity of $(\pi\text{-}C_5H_5)_2Co^-$ has been used in electrochemical syntheses [121]:

The anion $[(C_5H_5)_2Co]^-$ completes the series of cobalt complex $[(C_5H_5)_2Co]^+$ $(d^8)$, $(C_5H_5)_2Co$ $(d^9)$, and $[(C_5H_5)_2Co]^-$ $(d^{10})$ isoelectronic with the analogous nickel compounds: $[(C_5H_5)_2Ni]^{2+}$ $(d^8)$, $[(C_5H_5)_2Ni]^+$ $(d^9)$, and $(C_5H_5)_2Ni$ $(d^{10})$. A cathodic wave is also observed on the polarogram of neutral nickelocene. By analogy with chemical reduction, it is suggested [22] that in this case the reduction proceeds via the ligand in accordance with the following mechanism:

A reaction via the ligand has also been suggested in the reduction of neutral $\pi\text{-}C_5H_5Fe\text{-}\pi\text{-}C_6H_6$: [76]

## 7. Electrochemical Properties of Dicarbollyl $\pi$-Complexes

Like the dicyclopentadienyl compounds, the dicarbollyl complexes of transition metals, having the general formulae $(\pi\text{-}B_9C_2H_{11})_2M$ and $(\pi\text{-}B_9C_2H_{11})M(\pi\text{-}C_5H_5)$ [122] and the sandwich structure, undergo oxidation-reduction reactions, which lead to a change in the formal oxidation state of the metal atom. The study of the electrochemical behaviour of the dicarbollyl complexes of iron [123], cobalt [123-125], nickel [53,123,124,126,127], palladium [126,128], gold, and copper [128] showed that, in contrast to the $\pi$-cyclopentadienyl ligand, the $\pi$-dicarbollyl ligand stabilises the metal in both the highest and lowest oxidation states. Thus a series of electrochemically reversible one-electron transitions have been observed for the dicarbollyl complexes of cobalt, nickel, and palladium:

$$Co^{IV} \underset{+1.57\ V}{\rightleftharpoons} Co^{III} \underset{-1.36\ V}{\rightleftharpoons} Co^{II} \underset{-2.24\ V}{\rightleftharpoons} Co^{I} \quad ;$$

$$Ni^{IV} \underset{+0.18\ V}{\rightleftharpoons} Ni^{III} \underset{-0.56\ V}{\rightleftharpoons} Ni^{II} \underset{-2.10\ V}{\rightleftharpoons} Ni^{I} \quad ;$$

$$Pd^{IV} \underset{-0.47\ V}{\rightleftharpoons} Pd^{III} \underset{-0.71\ V}{\rightleftharpoons} Pd^{II} \quad .$$

It is interesting that isomeric dicarbollyl complexes, differing in the positions of the carbon atoms in the plane with the metal atom, have half-wave potentials $E_{1/2}$ differing by a very large amount (up to 0.5 V).

As for the ferrocene–ferrocenium cation system, the rate constants for electron transfer between the oxidised and reduced forms, namely $[(B_9C_2H_{11})_2Fe]^{2-}$ and $[(B_9C_2H_{11}).Fe(C_5H_5)]^-$, are high [129]. Owing to the large bulk of the dicarbollyl ligand, an arrangement of molecules in the transition states of these compounds of the "sitting on top" type is unlikely. One can therefore assume that, in both dicarbollyl complexes and in the ferrocene–ferrocenium system, the molecules in the transition state are arranged "side by side". It is useful to express the data described in Section II in terms of a scheme (see Table below) including only electrochemically reversible oxidation-reduction systems.

## III. ELECTROCHEMICAL REACTIONS OF THE FUNCTIONAL GROUPS OF THE LIGAND BOUND IN THE $\pi$-COMPLEX

Apart from the electrochemical reactions involving the metal atom, fairly numerous reactions with participation of the functional groups of the ligand bound in the $\pi$-complex are known. The study of these reactions proved fruitful from the standpoint of the quantitative estimation of the electronic influence of metallocenes as substituents and in the study of the problem of the influence of coordination on the reactivity of ligands bound in $\pi$-complexes.

The numbers of electrons around the metal atom.

Cp = cyclopentadienyl

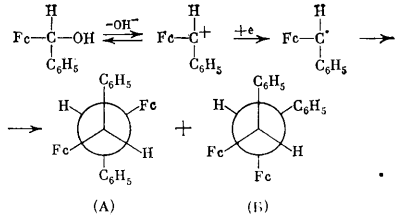
The electrochemical reactions of the functional groups in the coordinated ligand proceed mainly via mechanisms similar to those which have been established for the analogous substituents in aromatic rings. In accordance with its electronic properties, the metal-containing group alters only the potential of the electrochemical reaction of the substituent, which permits conclusions concerning the electronic effects of the metal-containing group. The polarographic reduction of acyl derivatives of $\pi$-complexes has been investigated in greatest detail. It has been demonstrated [130-132] that the mechanism of the polarographic reduction of the acetyl derivatives of ferrocene [$(\pi$-$C_5H_5)Mn(CO)_3$ and $\pi$-$C_6H_6Cr(CO)_3$] and benzene in a protic medium are identical. The results led to the conclusion that the ferrocenyl group is more electropositive than $C_6H_5$ and is close to pyrrole on the electron affinity scale, while $(CO)_3MnC_5H_4$- and $(CO)_3CrC_6H_5$- are more electronegative than phenyl. The results of the polarographic reduction of $(CO)_3Cr(C_6H_5COCH_3)$ in an aprotic medium lead to the analogous conclusion about the electronic properties of the $C_6H_5Cr(CO)_3$ groups [133].

The $\sigma$ constants ($\sigma_p$, $\sigma_m$, $\sigma_p^0$, and $\sigma_m^0$), characterising quantitatively the electronic influence of ferrocenyl as a substituent, have been calculated [134] on the basis of the correlation between the half-wave potentials $E_{1/2}$ for the reversible one-electron reduction of the C=C bond in the chalcones $C_5H_5FeC_5H_4CH{=}CHCOC_6H_4X$ (*m*, *p*), $C_5H_5FeC_5H_4$.$COCH{=}CHC_6H_4X$ (*m*, *p*), $C_6H_5CH{=}CHCOC_6H_4X$ (*m*, *p*), and $C_6H_5COCH{=}CHC_6H_4X$ (X = $OCH_3$, $CH_3$, F, Cl, Br, or $CNC_5H_4FeC_6H_5$). It was first shown [130,135-139] that ferrocenyl-containing chalcones are reduced in the same way as aromatic chalcones. The polarographic reduction of ferrocenyl aldehydes [139,140] and of nitrogen-containing derivatives of acetylferrocenes of the type $C_5H_5FeC_5H_4CR{=}NA$ [135] also proceed analogously to the reduction of the corresponding benzene derivatives. In conformity with the electron-donating properties of the ferrocenyl group, the half-wave potentials $E_{1/2}$ for these derivatives are displaced towards negative potentials.

It has been established for the quinone complexes of rhodium and iridium [141] that the polarographic reduction of the coordinated quinones proceeds with greater difficulty than that of the free quinones. The half-wave potentials $E_{1/2}$ for the first reversible one-electron quinone waves are displaced towards more negative values by 0.9, 1.1, 0.6, and 0.3 V as a result of the coordination to the $RhC_5H_5$-$\pi$, $IrC_5H_5$-$\pi$, $RhC_9H_7$-$\pi$-indenyl, and Rh(acac) groups respectively. The ligands combined with the metal atom have been arranged in a series in terms of their donating capacity on the basis of the results obtained: $\pi$-$C_5H_5 > \pi$-$C_9H_7 >$ acac.

In a few instances, the application of electrochemical methods made it possible to demonstrate the formation of previously unknown functional derivatives of $\pi$-complexes. Thus the use of cyclic voltamperometry and of a rotating disc electrode with a ring showed [132-144] that the reduction of $C_5H_5FeC_5H_4NO_2$ at an amalgamated gold electrode in an alkaline medium proceeds via the intermediate formation of radical-anions. The reduction of the radical anion leads to the formation of previously unknown ferrocenylhydroxylamine:

$$C_5H_5FeC_5H_4NO_2 + e \rightleftarrows C_5H_5FeC_5H_4NO_2^{\cdot-} \quad ;$$



$$C_5H_5FeC_5H_4NO^{\cdot-} + 3e + 3H_2O \rightarrow C_5H_5FeC_5H_4NHOH + 4OH^- \quad .$$

In contrast to $C_6H_5NHOH$, ferrocenylhydroxylamine is extremely unstable and disappears as a result of a disproportionation reaction:

$$C_5H_5FeC_5H_4NHOH + [C_5H_5FeC_5H_4NH_2OH]^+ \rightarrow$$
$$\rightarrow C_5H_5FeC_5H_4NH_2 + Fe^{2+} + C_5H_5^{\cdot} + C_5H_4NO^- + H_2O + H^+ \quad .$$

Electrochemical methods are used fairly widely for the generation of radical-anions. It has been shown that the electrolysis of a number of ferrocene derivatives (benzoyl, *p*-nitrophenyl, cyano-, nitro-, and other derivatives) [145] and of the benzoyl derivative of cyclopentadienylmanganese tricarbonyl [146] leads to radical-anions, which give rise to ESR signals. The study of the distribution of the unpaired spin density in these species showed [145] that, when both the $C_6H_5$ group and the ferrocenyl group are present in the same molecule, the unpaired spin density is delocalised to a larger extent over the $C_6H_5$ group than over the ferrocenyl group.

The electrochemical reduction of a number of other ferrocene derivatives has also been investigated [147,148]. Thus electrolysis of ferrocenylmethanol, which is involved in an equilibrium with the ferrocenylcarbonium ion in an acid medium, proceeds via a one-electron mechanism with formation of a free radical (Fc = ferrocenyl):

The radical then dimerises with formation of the stereoisomers (A) and (B). [147] In this section, it is also appropriate to quote data on the polarographic studies of the mercury derivatives $R_2Hg$ and RHgX [R = ferrocenyl, $(CO)_3MnC_5H_4$, or $(CO)_3ReC_5H_4$], which are reduced similarly to the compounds $R_2^1Hg$ and R'HgX (R' = alkyl or aryl) [149]:

$$\left.\begin{array}{l} R_2Hg + 2e \rightarrow Hg^0 + 2R^- \xrightarrow{+2H^+} 2RH\ (R = C_5H_5FeC_5H_4)\ ; \\ RHgX + e \rightarrow RHg^{\cdot} \\ RHg^{\cdot} + e \rightarrow Hg^0 + R^- \xrightarrow{H^+} RH \end{array}\right\} (R = C_5H_5FeC_5H_4-,\ \text{or}\ (CO)_5MC_5H_4;\ M = Mn \text{ or } Re)$$

A linear correlation is observed between $E_{1/2}$ and $pK_a$(RH): $E_{1/2} = (-0.07pK_a + 0.16)$ (V); $r = 0.966$. The $pK_a$ values for ferrocene ($pK_a = 39$) and $(CO)_3MC_5H_5$ ($pK_a = 31$ for M = Mn and $pK_a = 30$ for M = Re) as CH acids were estimated from this relation [149-151].

## IV. ELECTROCHEMICAL REACTIONS OF METAL CARBONYLS AND THEIR DERIVATIVES

The electrochemical behaviour of metal carbonyl complexes containing n-donor ligands bound in $\pi$- and $\sigma$-complexes is extremely varied, primarily due to the differences between their electronic structures.

### 1. Metal Carbonyls

In contrast to chemical reduction, which has been investigated in fair detail (see, for example, Kaska [152]), the electrochemistry of metal carbonyls has been inadequately studied. It has been shown [26] that in dimethoxyethane singly-charged metal carbonyls $M(CO)_n$ (M = Fe, $n = 5$; M = V, $n = 6$; M = Ni, $n = 4$) combine as a rule with one electron and the process is electrochemically irreversible. $Fe(CO)_5$ and $Ni(CO)_4$ form short-lived paramagnetic species giving rise to ESR signals; however, the nature of these species is obscure. In a protic medium ($C_2H_5OH-H_2O$), $Fe(CO_5)$ is reduced with addition

of two electrons and the dissociation of the M–CO bond[153]. As in the initial compound, in the product $Fe(CO)_4^{2-}$ an 18-electron shell is formed around the metal atom. The polarographic reduction of $M(CO)_6$ (M = Cr, Mo, or W) in aprotic solvents proceeds via the following irreversible electrochemical mechanism[26,154,155]:

$$M(CO)_6 + e \rightarrow [M(CO)_6]^{\mp} \xrightarrow{-CO} [M(CO)_5]^{\mp} \rightarrow \frac{1}{2}[M_2(CO)_{10}]^{2-} .$$

The one-electron reversible voltamperometric oxidation of $Cr(CO)_6$ at platinum and gold electrodes ($E_{a.p.}$ = +1.44 V relative to the $Ag/Ag^+$ electrode) leads to the formation of the 17-electron cation $Cr(CO)_6^+$, which gives rise to a broad signal in the ESR spectrum[154,156]. At higher anodic potentials, a further electron is removed with formation of the unstable species $Cr(CO)_6^{2+}$. The oxidation of $Mo(CO)_6$, $W(CO)_6$, and $Fe(CO)_5$ is electrochemically irreversible and involves the abstraction of two electrons. Dinuclear carbonyls containing the M–M bond are reduced at dropping mercury[26,157,158] and platinum electrodes[159,160] with dissociation of the M–M bond and the formation of 18-electron anions of the metal carbonyls (see below for further details).

The reduction of trinuclear $Fe_3(CO)_{12}$ proceeds with addition of one electron[26]; the reaction products are unknown.

## 2. Metal Carbonyl Complexes with n-Donor Ligands

(a) Oxidation. Compounds having the general formula $L_nM(CO)_m$ (L = amines, phosphines, isonitriles, or carbenes¶ and M = Cr, Mo, or W) are oxidised at a platinum electrode in methylene chloride with the loss of one electron and the formation of the corresponding cations[161–164]; the process is electrochemically reversible. The cations $[Mn(CO)_6 - n(CNR)_n]^+$ and $[Cr(NO)_2(CNR)_5]^+$ are oxidised to the dications, which are capable of further oxidation[165–167]. The half-wave potentials $E_{1/2}$ depend on the electronic properties of the ligand L, the number of CO groups, and the nature of the metal atom. The successive weakening of the $\pi$-acceptor properties of L, accompanied by the corresponding increase of the $\sigma$-donor capacity, leads to a shift of $E_{1/2}$ towards lower positive potentials. A similar result is obtained when $n$ in $[(RNC)_nM(CO)_{6-n}]$ is diminished, which is associated with the gradual substitution of the strong $\pi$-acceptor ligand CO by the less effective CNR. It has been shown for $Cr(CO)_5L$ (the L species are different phosphines) that there is a linear correlation between the values of $E_{1/2}$ for the oxidation of the complex and the ionisation potential of the free ligand L. It has been established[162] that the ease of abstraction of the electron from $[(RNC)_nM(CO)_{6-n}]$ diminishes in the sequence Cr > W > Mo.

The observed relations lead to the conclusion that both the atomic orbital of the metal and the molecular orbital of the ligand L contribute to the molecular orbital from which the electron is removed on oxidation. Studies on the ESR and Mössbauer spectra of the radical-cations generated on oxidation of the complexes CoL(CO)(NO), where L = $o$-phenanthroline or 2,2′-bipyridyl, in dimethoxyethane at a mercury electrode[168] have confirmed this view and have shown that the spin density is located in the molecular orbital to which predominantly $s$-type metal orbitals contribute together with the ligand orbitals. However, quantum-chemical calculations on molecules of the type $Cr(CO)_5L$ (L = $NH_3$, $PH_3$, or $PMe_3$) have shown, in contrast to electrochemical data, that the ligand orbitals do not contribute significantly to the highest occupied orbital of the complex, comprising mainly the $3d$(Cr), $2p$(C), and $2s$(O) orbitals. According to Lloyd et al.[163], this contradiction can be resolved if it is supposed that L has a long-range or indirect influence on the energy of the highest occupied orbital of the complex without a change in the relative contributions of the atomic orbitals.

The electrochemical oxidation of complexes with chelating diphosphine ligands, namely $M(CO)_2(DPE)_2$ and $M(CO)_2(DPM)_2$, where M = Mn, Cr, Mo, or W, DPE = $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ and DPM = $(C_6H_5)_2PCH_2P(C_6H_5)_2$, proceeds with the successive elimination of two electrons and the formation of cations and dications respectively; the stereochemistry of the electrochemical reactions has been investigated[169,170]. The available information concerning the oxidation of other complexes with $n$-donor ligands is limited. It has been shown, for example, that the oxidation of $M(CO)_3$(triarsine)† in a $C_2H_5OH-C_6H_6$ mixture at mercury and platinum electrodes proceeds with the elimination of two electrons and the formation of a dication[171]. In this section, it is also appropriate to mention the oxidation of the carbonyl hydride complexes $M(H)(CO)L_3$ (M = Rh or Ir and L = $PPh_3$).[172] The reversible oxidation of $Ir(H)(CO)L_3$ in acetonitrile at a platinum electrode leads to the formation of a fairly stable cation containing the metal in the unusual +2 oxidation state:

$$Ir(H)(CO)L_3 \rightleftarrows Ir(H)(CO)L_3^+ .$$

The oxidation of $Rh(H)(CO)L_3$ is irreversible. Owing to the instability of the Rh–H bond, the cation formed reacts further via the following mechanism:

$$Rh(H)(CO)L_3^+ \rightarrow M(CO)L_3^+ + {}^1/_2H_2 .$$

(b) Reduction. Octahedral chromium, molybdenum, and tungsten complexes $L_1M(CO)_5$ ($L_1$ = pyridine or quinoline) and $L_2M(CO)_4$ ($L_2$ = ethylenediamine or 2,2′-bipyridyl) and the tetrahedral cobalt and iron complexes $L_2Co(CO)(NO)$ and $L_2Fe(NO)_2$ ($L_2$ = $o$-phenanthroline or 2,2′-bipyridyl) are as a rule reduced in two electrochemically reversible one-electron stages with formation of radical-anions and dianions[60,168,173]. The reduction proceeds at less negative potentials than the reduction of the non-coordinated ligand L and in the case of the chromium, molybdenum, and tungsten complexes also at less negative potentials than the corresponding unsubstituted metal carbonyl. The radical-anions formed give rise to an ESR signal and exhibit an enhanced chemical stability compared with the radical-anions of the non-coordinated ligand. It has been concluded[168,173] on the basis of the similarity of the hyperfine splitting constants for the ESR spectra of the radical-anions of the complexes and the non-coordinated ligands that the electron occupies on reduction the antibonding $\pi$-orbital of the ligand L; the infrared spectra of the radical-anions showed that the addition of the electron does not lead to a change in the symmetry of the molecule. The absence of an ESR signal from the spectrum of the dianion showed that it exists in the singlet state. Analysis of the ESR, infrared, Mössbauer, and NMR spectra of the radical-anions and dianions led to a conclusion concerning the distribution of spin and charge densities in these species (for a more detailed treatment, see below).

¶ The M–C bond is present in carbenes.

† Triarsine = methylbis-(3-propyldimethyl)arsine.

The reduction of cobalt carbonyl nitrosyl complexes $Co(NO)(CO)L_{n-3}$ ($L = EPh_3$; E = P, As, or Sb) and iron carbonyl nitrosyl complexes $Fe(NO)_2(CO)_nL_{n-2}$ ($L = PPh_3$) (the formal degree of oxidation of the metal in the complexes is −1) in acetonitrile at the DME has been investigated[174-177]. Brief information concerning the electrochemical behaviour of other substituted carbonyl compounds can be found in a number of reports[26,60,179,180]. The reduction proceeds as a rule irreversibly and the reaction products have not been identified. The reduction of metal carbonyl compounds with an M—M bond and bridging phosphorus- and sulphur-containing ligands is discussed below.

## 3. Complexes Containing Hydrocarbon Ligands Bound in π-Complexes

(a) Complexes with two-electron ligands. The reduction reactions of the bipyramidal complexes (olefin)$Fe(CO)_4$ and carbonyl complexes with *n*-donor ligands (see the previous section) have much in common. The electrochemically reversible addition of one-electron to (olefin)$Fe(CO)_4$ leads to fairly stable radical-anions, where the unpaired electron is located in the antibonding π*-orbital of the olefin ligand[26,60,178]; the distribution of spin and charge densities in the radical-anions formed has been investigated by ESR, infrared spectroscopy, and Mössbauer spectroscopy (see below).

The cationic olefin complexes of platinum $[Pt(NH_3)_2.(RCH{=}CH_2)Cl]ClO_4$ (R = H, $CH_3$, $CH_2OH$, or $C_6H_5$) have been reduced at the dropping mercury electrode[181]. It was found that these complexes are reduced more readily than the initial amine complex $[Pt(NH_3)_3Cl]^+$.

(b) Complexes with three-electron π-allyl ligands. The electrochemical behaviour of π-allyl complexes $(\pi\text{-}C_3H_5MX)_2$ of platinum group metals, where the formal oxidation state of the metal is +2, is determined by the well known ease of reduction of these metal ions $M^{2+}$ and of their chloride complexes. $Pd^{2+}$ and $Pt^{2+}$ ions ions are reduced even with metallic mercury without the application of a potential difference[182,183]. The study of the reduction of $(\pi\text{-}C_3H_5PdX)_2$ (X = halogen) at the DME showed[183-186] that these compounds react with the mercury of the electrode:

$$(\pi\text{-}C_3H_5PdX)_2 + Hg \rightarrow Pd^0 + 2C_3H_5HgX \quad .$$

The waves observed on the polarogram correspond to the reduction of $C_3H_5HgX$. The diffusional nature of the waves shows that the preceding chemical reaction of the π-allyl complexes of palladium with mercury proceeds so fast that its rate does not affect the electrode reduction of $C_3H_5HgX$. The results suggest that the coordination of $Pd^{2+}$ to the π-allyl ligand has little influence on the capacity of $Pd^{2+}$ for reduction.

The electrochemical reduction of $\pi\text{-}(C_3H_5M)(CO)_3X$ (M = Fe or Ru) leads to the dissociation of the M—X bond (see Section V). $\pi\text{-}C_3H_5Fe(CO)_2NO$ and $\pi\text{-}C_3H_5Co(CO)_3$, which do not contain π-bonds, behave differently. The addition of two electrons leads to the dissociation of the π-bond between the allyl ligand and the metal atom[187,188]:

$$\pi\text{-}C_3H_5Fe(CO)_2NO + 2e \rightarrow [Fe(CO)_2NO]^- + C_3H_5^- \xrightarrow{+H^+} CH_2{=}CH{-}CH_3 \quad ;$$

$$\pi\text{-}C_3H_5Co(CO)_3 + 2e \rightarrow Co(CO)_3^- + C_3H_5^- \xrightarrow{H^+} C_3H_6 \quad .$$

(c) Complexes with four-electron ligands. The polarographic reduction of $(\pi\text{-diene})Fe(CO)_3$ at the dropping mercury electrode in aprotic media proceeds via the successive addition of two electrons, as was observed for the free diene ligand[189]. The first electrochemically reversible stage leads to the formation of a radical-anion, which gives rise to an ESR signal in the case of complexes with cyclic dienes[190]. In view of the identity of the polarographic characteristics of $(\pi\text{-diene})Fe(CO)_3$ and the free dienes, it was concluded that the electronic changes occurring on reduction of the complexes are localised in the antibonding π*-orbital of the diene ligand.

(d) Complexes with five-electron ligands. The electrochemical properties of monocyclopentadienylmetal carbonyls have been inadequately investigated. It has been shown[26,60,149] that $\pi\text{-}C_5H_5M(CO)_3$ (M = Mn or Re) and some of their derivatives are reduced at the DME, but the number of electrons added and the reaction products are unknown. The complexes $\pi\text{-}C_5H_5V(CO)_4$, $\pi\text{-}C_5H_5Co(CO)_2$, $\pi\text{-}C_5H_5W(CO)_2NO$, and $\pi\text{-}C_5H_5NiNO$ are reduced with addition of one electron, but the formation of a short-lived anion has been demonstrated only for the last two compounds[191].

The addition of one electron to the cationic complexes $[\pi\text{-}C_5H_5Fe(CO)_2L]^+$ ($L = CO$ or $PPh_3$) apparently leads to the formation of the dimer $[\pi\text{-}C_5H_5Fe(CO)_2]_2$, the reduction of which gives rise to the second wave on the polarograms[60].

The one-electron oxidation of cyclopentadienylmanganese and cyclopentadienylrhenium tricarbonyls at a platinum electrode proceeds with much greater difficulty than, for example, the reduction of ferrocene under analogous conditions; cyclopentadienylrhenium tricarbonyl is oxidised at more positive potentials than cyclopentadienylmanganese tricarbonyl[192]. The replacement of carbonyl groups by the more strongly electron-donating phosphine ligands leads to a significant cathodic shift of the oxidation potentials and to an increase of the stability of the cation formed[193]:

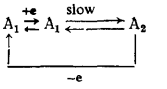
$$\pi\text{-}C_5H_5M(CO)_2L \underset{+e}{\overset{-e}{\rightleftarrows}} [\pi\text{-}C_5H_5M(CO)_2L]^+ (M{=}Mn \text{ or } Re;\ L{=}PR_3) \quad .$$

The cationic nitrosyl complexes $[\pi\text{-}C_5H_5Mn(NO)LL']^+$ (L and L′ are Lewis bases such as $PR_3$ and amines) are oxidised to the dications[194]. The change in $E_{1/2}$ reflects the change in the π-acceptor properties of the Lewis bases as ligands.

The polarographic behaviour of π-cyclopentadienylmetal complexes with chelating ligands has been investigated in greater detail. It has been found that π-cyclopentadienyldithiolenemetal complexes are as a rule reduced reversibly in dimethoxyethane (with the addition of one electron and the formation of radical-anions, which give rise to an ESR signal[26,60,179]. The half-wave potentials $E_{1/2}$ of $\pi\text{-}C_5H_5MS_2C_4F_6$ depend on the nature of the metal atom and increase in the sequence Fe < Co < Ni (from left to right in Mendeleev's Table) and in the cobalt subgroup Co < Rh < Ir (from above downwards (see also McCleverty[195]). The anionic complexes $[\pi\text{-}C_5H_5MS_4C_4(CN)_4]^-$ (M = Ti, Mo, or W) are oxidised to neutral species at a platinum electrode in $CH_2Cl_2$ solution[196].

A detailed study of π-cyclopentadienylnitrosyldithiolenemanganese complexes showed that those with 1,2-dithiolenes are capable of reversible oxidation and reduction to radical-cations and radical-anions respectively. The complexes of 1,1-dithiolenes are capable of one-electron reduction only, while dithiocarbamates and thioxanthates

are capable of one-electron oxidation [194,196-198]. The paramagnetic species have been characterised by their ESR spectra.



(e) Arenemetal carbonyl complexes. It follows from chemical data‡ that ($\pi$-arene)$Cr(CO)_3$ complexes are oxidised with greater difficulty than ($\pi$-arene)$_2$.Cr. Indeed, the complexes ($\pi$-$C_6H_5X$)$Cr(CO)_3$ are oxidised at a platinum electrode in $CH_2Cl_2$ in two electrochemically reversible stages at fairly considerable positive potentials [199,200]. The values of $E_{1/2}$ for the first waves are sensitive to the nature of the substituent in the benzene ring (X = alkyl or $NR_2$). A linear relation has been observed between $E_{1/2}$ for the first wave of ($\pi$-$C_6H_5X$)Cr.$(CO)_3$, on the one hand, and the $E_{1/2}$ and the ionisation potentials of the non-coordinated ligand $C_6H_5X$, on the other, the half-wave potentials $E_{1/2}$ of the complexes being less sensitive to structural changes in the arene bound in the complex than the $E_{1/2}$ of the free ligand. There is also a linear relation between $E_{1/2}$ for the first wave and the ionisation potentials of the complexes. The observed relations indicate the involvement of the orbitals of the arene ligand in the highest occupied molecular orbital from which the electron is removed on oxidation. The problem of the degree of involvement of the metal orbitals in this molecular orbital remains obscure [cf. the above discussion of the oxidation of $LM(CO)_5$].

The half-wave potential $E_{1/2}$ for the oxidation of the $\pi$-cycloheptatriene complex ($\pi$-$C_7H_8$)$Cr(CO)_3$ is close to $E_{1/2}$ for its isomer ($\pi$-$C_6H_5CH_3$)$Cr(CO)_3$. It has been found that the *exo*- and *endo*-isomers of $RC_7H_7Cr(CO)_3$ (R = Ph or CN) differ significantly (by approximately 70 mV) in their capacities for oxidation [200]. The reversible one-electron oxidation of ($\pi$-$C_6Me_{6-n}H$)$Cr(CO)_2$(PhC≡CPh) to the corresponding cations proceeds at potentials lower by 0.8 V than for ($\pi$-arene)$Cr(CO)_3$, which reflects the more pronounced $\sigma$-donor and weaker $\pi$-acceptor properties of the acetylene ligand compared with CO. [201]

The polarographic reduction of ($\pi$-$C_6H_6$)$Cr(CO)_3$ proceeds in a single two-electron stage with formation of a dianion [26,202]. The intermediate formation of the radical-anion has been demonstrated by electrolysis at a controlled potential. The polarograms of ($\pi$-arene)$Cr(CO)_3$ (arene = diphenyl or naphthalene) as well as those of the non-coordinated aromatic hydrocarbons show one-electron reversible waves corresponding to the reduction to the radical-anions. As in the reduction of metal carbonyl complexes with $\pi$-olefinic and $n$-donor ligands, the electron apparently occupies in this case the antibonding $\pi^*$-orbital of the aromatic hydrocarbon ligand. The observed shift of the $E_{1/2}$ for the complexes relative to the $E_{1/2}$ for the free ligands towards more positive potentials by 600–700 mV is consistent with the available data [199] showing a decrease of electron density in the aromatic ring on coordination to the $Cr(CO)_3$ group.

It has been noted that the reduction of the cationic arene complexes $[1,3,5\text{-}(CH_3)_3C_6H_3Mn(CO)_3]^+$ and the cycloheptatrienyl complexes $[\pi\text{-}C_7H_7Cr(CO)_3]^+$ and $[(\pi\text{-}C_7H_6OMe)Cr.(CO)_3]^+$ proceeds readily [26,200], but the nature of the process and the reaction products have not been investigated in detail.

(f) Complexes obtained on interaction of acetylenes with metal carbonyls. The complexes obtained when acetylenes react with metal carbonyls contain $\pi$-linked organic ligands of various types; cyclobutadiene, cyclopentadiene, quinone, tropone, and other ligands, containing as a rule several metal atoms and carbonyl groups. Many of these compounds undergo reversible electrochemical reduction at the dropping mercury electrode with formation of radical-anions and then dianions [190]. The stability of the radical-anions varies within wide limits. Studies of the individual radical-anions showed that, despite the electrochemical reversibility of the process demonstrated by triangular voltamperometry, the half-wave potentials $E_{1/2}$ for their oxidation do not agree with the half-wave potentials for the reduction of the initial complex. The electrochemical oxidation of the radical-anions nevertheless restores the initial state. The authors believe that the discrepancy between $E_{1/2}$(ox) and $E_{1/2}$(red) is due to the slow change in the structure of the radical-anion§:

The foregoing data are of interest from the standpoint of the investigation of the properties of organometallic radical-anions.

## 4. General Conclusions Concerning the Electrochemical Reactions of Metal Carbonyls and Their Derivatives

The results of electrochemical studies on the majority of metal carbonyl complexes with $\pi$-linked or $n$-donor ligands have shown that these undergo both oxidation and reduction reactions. The reduction processes have been investigated in greater detail. The reversible stepwise addition of two electrons leads to the formation of radical-anions and then dianions. The agreement of the hyperfine splitting constants for the radical-anions of the complexes and the non-coordinated ligands shows that the electron is located in the antibonding $\pi^*$-orbital of the ligand. The absence of splitting by the nitrogen of the NO group in the radical-anions $L_2Co(NO)CO$ and $L_2Fe(NO)_2$ (see subsection 2 above) shows that the spin density of the unpaired electrons belonging to $L_2$ is not transmitted via the metal atom to the other ligands. The infrared spectra of the radical-anions confirmed this conclusion and, together with the NMR spectra of the dianions, showed that a major proportion of the charge density in the radical-anion and the dianion is concentrated in the $M(CO)_n$ group. Thus, in contrast to organic compounds, the distribution of spin and charge densities in the radical-anions of the complexes may not be the same. While the spin density is concentrated at the ligand L, the charge density is largely concentrated at the metal atom and the carbonyl groups. The study of the Mössbauer spectra of the radical-anions of iron-containing complexes showed that charge transfer proceeds via $\sigma$-bonds [203].

It is noteworthy that, compared with their reduction, the electrochemical oxidation of the complexes has been inadequately investigated. There are virtually no data for the kinetics of the electrochemical processes.

## V. ELECTROCHEMICAL REACTIONS OF COMPLEXES CONTAINING $\sigma$-BONDS

Together with the complexes examined in the previous sections, studies have been made on a large number of compounds containing $\sigma$-bonds of different types: M–M,

‡ See A.R. Siedle, J.Amer.Chem.Soc., 97, 5931 (1975).

§ The nature of the rearrangement is so far obscure.

M–halogen, and M–C. It has been shown that, as a rule, these compounds are reduced or oxidised with participation of the σ-bond, while π- and donor–acceptor bonds are electrochemically inactive.

## 1. METAL COMPLEXES WITH AN M–M σ-BOND

Compared with compounds containing M–X and M–C σ-bonds, complexes with an M–M bond have a wide variety of structures, as a result of which various types of electrochemical reactions are characteristic of these substances.

### Electrochemical Reactions Involving the Dissociation of the M–M σ-Bond

(a) Homodimetallic compounds. Complexes of this type are reduced polarographically in a single irreversible two-electron stage with dissociation of the M–M σ-bond and formation of an 18-electron metal carbonyl anion [157,158,204,205]:

$$L_nM{-}ML_n + 2e \rightarrow 2[L_nM]^- \quad ;$$

$L_nM = C_5H_5M(CO)_3$, (M = Cr, Mo or W), $(CO)_5M$, (M = Mn or Re); $C_5H_5M(CO)_2$, (M = Fe or Ru), $(CO)_4Co$ or $C_5H_5NiCO$ .

It has been shown [206] that the anions $M(CO)_5^-$ (M = Mn or Re) enter into the following chemical reaction under the conditions of electrolysis:

$$M(CO)_5^- + M_2(CO)_{10} \rightarrow [M_3(CO)_{14}]^- + CO \ .$$

The reduction of complexes of Group VI–VIII metals becomes more difficult on moving from above downwards in the Periodic Table. For $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$, this is satisfactorily consistent with the higher Re–Re bond energy ($\Delta H$ = 2.22 eV) compared with the Mn–Mn bond energy ($\Delta H$ = 0.96 eV). [207] It has been stated [157] that in the remaining compounds the bond energy also increases with increasing atomic number down the Group in the Periodic System. In those cases where the M–M bond energy is low, as happens for $[\pi\text{-}C_3H_5Fe(CO)_3]_2$, dissociation with formation of a monomeric radical takes place at room temperature when the solution is diluted [208] and the polarographed solution contains radical species, which are reduced at the electrode [209]. For other homodimetallic compounds, the dissociation energy is not sufficiently small to enable the detection of paramagnetic species in the solution, but it has been shown for $Mn_2(CO)_{10}$ [210] that many reactions may proceed via the initial homolytic dissociation of the M–M bond. One can therefore suppose that, in the polarographic reduction of compounds with an M–M bond, there is also homolytic dissociation of the reduced bond with formation of a pair of radicals having a half-filled orbital to which the electron is transferred.

The electrochemically irreversible oxidation of homodimetallic compounds at a platinum electrode also proceeds with the dissociation of the M–M bond [156,211,212]

$$[\pi\text{-}C_5H_5Fe(CO)_2]_2 - 2e \xrightarrow{L} [\pi\text{-}C_5H_5Fe(CO)_2L]^+ \quad ;$$

L = $CH_3CN$, acetone, $Cl^-$, or S$(C_2H_5)_2$ .

$$Mn_2(CO)_{10} - 2e \rightarrow 2Mn(CO)_5^+ \xrightarrow{CH_3CN} 2(CO)_5Mn{-}N{\equiv}\overset{+}{C}{-}CH_3 \ .$$

(b) Heterodimetallic compounds ($L_nM{-}M'R_3$). The majority of compounds of this class [$L_nM$ = $C_5H_5M(CO)_3$ (M = Cr, Mo, or W), $(CO)_5M$ (M = Mn or Re), $C_5H_5Fe(CO)_2$, or $(CO)_4Co$; M′ = Sn or Pb; R = $CH_3$ or $C_6H_5$] are reduced polarographically with addition of one electron at potentials intermediate between the reduction potentials of the related homodimetallic compounds [157]. The addition of one electron results in the formation of an anion of the homodimetallic compound, which is reduced at less negative potentials to a radical, which dimerises at the limiting current potentials for the first wave with formation of a homodimetallic compound, identifiable by the appearance of the corresponding wave on the polarogram. The polarographic reduction of $\pi\text{-}C_5H_5FeCO.(SiCl_3)H$ and $\pi\text{-}C_5H_5Fe(CO)_2SiCl_3$ has also been investigated [213].

(c) Polymetallic compounds. Symmetrical mercury derivatives containing two M–Hg bonds are reduced polarographically in a single two-electron irreversible stage with dissociation of the M–Hg bonds and formation of a pair of metal carbonyl anions [157,158,204,205]:

$$L_nM{-}Hg{-}ML_n + 2e \rightarrow 2[L_nM]^- + Hg \quad ;$$

$L_nM = C_5H_5M(CO)_3$, (M = Cr, Mo, or W), $C_5H_5Fe(CO)_2$; or $(CO)_5Mn$ .

The reduction proceeds at more positive potentials than the reduction of the corresponding $(L_nM)_2$. Owing to the non-equivalence of the Hg–Cl and M–Hg bonds, the asymmetric mercury derivatives M–Hg–Cl are reduced in two stages. The first wave is of the one-electron type and corresponds to the dissociation of the Hg–Cl bond. The mercury radical formed dimerises at the limiting current potentials for the first wave with formation of the compound $(L_nM)_2Hg$, which is reduced in the second stage.

The trimetallic complexes $[\pi\text{-}C_5H_5(CO)_3Mo]_2Sn(CH_3)_2$ and $[\pi\text{-}C_5H_5(CO)_2Fe]_2Sn(CH_3)_2$ are reduced in a single two-electron irreversible stage with dissociation of the Mo–Sn and Fe–Sn bonds and formation of the metal carbonyl anion [157]. The complexes $[\pi\text{-}C_5H_5Mo(CO)_3]_2Sn[Fe(CO)_2.C_5H_5\text{-}\pi]_2$, containing four metal–metal bonds, are reduced in several stages, each of which corresponds to the rupture of one of the M–M bonds [157].

(d) The nucleophilic properties of the metal-containing anions $[L_nM]^-$. It follows from the foregoing that the reduction of homo-, hetero-, and poly-metallic compounds results as a rule in the formation of the metal carbonyl anions $[L_nM]^-$. The nucleophilicity of the $[L_nM]^-$ anion is a parameter which determines quantitatively its reactivity in relation to electrophiles. The study of the electrochemical behaviour of these anions permitted the determination of their nucleophilic properties [214]. It has been found that the anions $[L_nM]^-$ give rise to distinct oxidation waves at a platinum electrode; the variation of the current with the $[L_nM]^-$ concentration is linear. Polarographic study of the kinetics of the reaction of $[L_nM]^-$ with alkyl halides RX showed that the reaction is described by the equation for second-order kinetics. The rate constants $k_2'$, adjusted to conform to $k_2$ for the anion $[(CO)_4CO]^-$, have been adopted as a measure of the nucleophilicity of $[L_nM]^-$.

It has been established that the nucleophilicity of $[L_nM]^-$ varies in parallel with $E_{1/2}$ for its oxidation. Thus the possibility of one-electron transfer from $[L_nM]^-$ to the substrate (Sub),

$$[L_nM]^- + Sub \rightarrow [L_nM]^{\cdot} + Sub^{\cdot -}$$
$$\downarrow$$
$$^1/_2L_nM{-}ML_n \ ,$$

is related to $E_{1/2}$ for the oxidation of $[L_nM]^-$ and hence to its nucleophilicity. The problem of the relation between

$E_{1/2}$ for the oxidation of $[L_nM]^-$ and $E_{1/2}$ for the reduction of the substrate and of the possibility of one-electron transfer reactions between them has been examined[215].

The determination of $E_{1/2}$ for the reduction of compounds with an M–M bond and for the oxidation of $[L_nM]^-$ and the quantitative determination of the nucleophilicity of the latter made it possible to establish the fundamental characteristics of the formation of complexes with an M–M bond in the following reactions[216,217]:

$$[L_nM]^- + L_nM'-X \rightarrow L_nM-M'L_n + X^- \quad ;$$
$$[L_nM]^- + L_nM-M'L_n \rightarrow L_nM-ML_n + [L_nM']^- \quad .$$

A linear correlation has also been observed between $E_{1/2}$ for the oxidation of $[L_nM]^-$ and $E_{1/2}$ for the reduction of the hydrides $L_nM-H$ formed when proton donors are added to $[L_nM]^-$.[218]

Electrochemical Reactions Occurring Without the Dissociation of the M–M Bond

(a) Clusters. Clusters containing triangular or polyhedral fragments made up of the metal atoms and the M–M bond are capable of electrochemical oxidation and reduction, the structure of the cluster being retained. The reduction proceeds in a single reversible one-electron stage with formation of paramagnetic radical-anions[60,157]. The stepwise oxidation of $[\pi\text{-}C_5H_5FeCO]_4$ and $[\pi\text{-}C_5H_5FeS]_4$ in acetonitrile at a platinum electrode leads to a series of oxidation states[219,220]. The complex monocations are paramagnetic:

$$[Fe_4]^{2+} \overset{+1.08V}{\rightleftarrows} [Fe_4]^{+} \overset{+0.32V}{\rightleftarrows} [Fe_4]^{0} \overset{-1.30V}{\rightleftarrows} [Fe_4]^{-} \quad .$$

(b) Metal carbonyl complexes with phosphorus- and sulphur-containing bridge ligands. The compounds $[(CO)_4ME(CH_3)_2]_2$ (M = Cr, Mo, or W; E = P or As) and $[Mn(CO)_3SPh]_2$ and $[(CO)_3.ME(CH_3)_2]_2$ (M = Fe or Ru; E = As or P) are reduced to the dianions in a single electrochemically reversible stage[157,179]. The interaction of solutions of the dianions with the initial compounds as a rule leads to the formation of coloured solutions of the radical-anions, which give rise to an ESR signal. A detailed study of $[(CO)_3MP.(CH_3)_2]_2$ (M = Fe or Ru) showed[180] that, on passing from the neutral compound to the radical-anion, the molecular structure is retained, but, on further conversion into the dianion, the molecular geometry is altered. It is assumed[180] that the addition of two electrons to the molecular orbital incorporating the metal orbitals leads to an increase of the charge on the metal and hence to the repulsion of the metal atoms from one another and to an increase of the Fe–Fe distance. This in its turn leads to a decrease of the P–P distance. It has been shown by NMR that, compared with the initial molecule, the frequency of the inversion of the bridge groups in the dianion increases.

The oxidation of the diphosphineiron carbonyl complex $\{[\pi\text{-}C_5H_5Fe(CO)_2]_2Ph_2P(CH_3)_nPPh_2\}$ ($n$ = 2 or 3) also does not lead to the dissociation of the M–M bond[221,222]. The elimination of the first electron proceeds reversibly both electrochemically and chemically and leads to the formation of a cation containing a one-electron M–M bond. The removal of the second electron is electrochemically irreversible and results in the formation of a short-lived dication, which then reacts via the following mechanism:

$$\{[(\pi\text{-}C_5H_5)\,Fe\,(CO)I_2\,Ph_2PCH_2CH_2PPh_2\}^{2+} \longrightarrow$$
$$\xrightarrow{k_1} [(\pi\text{-}C_5H_5)\,Fe\,(CO)_2\,Ph_2PCH_2CH_2PPh_2]^{+} + Fe^{2+}$$
$$\xrightarrow[(Solv\,=\,solvent)]{k_2,\ 2Solv} \{[(\pi\text{-}C_5H_5)\,Fe\,(CO)\,Solv]_2\,Ph_2PCH_2CH_2PPh_2\}^{2+} \quad .$$

In contrast to the complexes examined, in neutral compounds with sulphur-containing bridge ligands $[\pi\text{-}C_5H_5.MLSR]_2$ (M = Mn or Mo and L = NO; M = Fe and L = CO) and $[\pi\text{-}C_5H_5MSR]_2$ (M = Co or Ni), there is no M–M bond. However, in the cation formed after reversible one-electron oxidation, the formation of a one-electron M–M bond is postulated[194,223]. The considerable decrease of the M–M distance in the cation (the Fe–Fe distance is 2.93 Å) compared with the neutral compound (3.39 Å) leads to the same conclusion. It is believed that oxidation to the dication can result in a further contraction of the molecule and the formation of a two-electron M–M bond.

2. METAL COMPLEXES WITH A METAL–HALOGEN σ-BOND

Depending on the structure of the complexes, the reduction proceeds in one two-electron or one-electron stage. The irreversible addition of one electron results in the dissociation of the metal–halogen bond and the formation of 17-electron organometallic radicals, the stability of which varies within wide limits[60,173,204,205,209,224]:

$$L_nM-Hal + e \rightarrow [L_nM]^{\cdot} + Hal^- \quad .$$

The gradual transition from one- to two-electron reduction of the M–X bond has been observed in $\pi\text{-}C_5H_5W(CO)_3X$. While the first wave for the iodide is of the one-electron type, the polarograms of the bromide and chloride showed a single two-electron wave[205]:

$$L_nM-Hal + 2e \rightarrow [L_nM]^- + Hal^- \quad .$$

The compounds $(CO)_5M-Hal$ (M = Mn or Re) are reduced via a similar mechanism[158]. The appearance of a two-electron wave in the reduction of the M–Hal bond is associated with the fact that the potential at which there is a possibility of the transfer of the first electron from the electrode is displaced to an increasing extent towards negative values and approaches the reduction potential of the dimers of the symmetrical mercury compounds, which are the products of the stabilisation of the unstable organometallic radicals formed on transfer of the first electron.

The observed sequence based on the decrease in the ease of reduction of the metal–halogen σ bond in both one-electron and two-electron reduction is the opposite of the sequence of the electronegativities of the halogens, which determine the polarity of this bond. The increase of the polarity of the Fe–Hal bond in $\pi\text{-}C_3H_5Fe(CO)_3Hal$ on passing from the iodide to the chloride has been confirmed by Mössbauer spectra[225]. The observed sequence based on the decrease of the ease of reduction of the metal–halogen bond agrees with the sequence based on the variation of the halfwave potentials $E_{1/2}$ for the reduction of the C–Hal bond[226] in alkyl halides. A radical reduction mechanism is postulated in this case and the decrease of the ease of reduction in the sequence C–I > C–Br > C–Cl is explained by the increase of the strength of the C–Hal bond. Presumably, a similar explanation is applicable

also to the reduction of the transition metal–halogen bond. Thus, in contrast to the simplest inorganic halides, the metal–halogen bond in the carbonyl complexes of transition metals is distinctly covalent and exhibits a tendency towards a predominantly homolytic rather than heterolytic dissociation.

The electrochemical oxidation of complexes with a metal–halogen σ bond has been hardly investigated. It is only known that the voltamperometric oxidation of the halogenopentacarbonylmetallate anions $[(CO)_5MHal]^-$ (M = Cr, Mo or W) takes place in two one-electron reversible stages with formation of an uncharged complex and a cation respectively [227].

## Electrochemical Behaviour of Cyclopentadienyl Complexes of Titanium and Zirconium Containing Metal–Halogen σ-Bonds

The enhanced interest in the electrochemical reduction of dicyclopentadienyl compounds of titanium is due to the fact that the system incorporating $(\pi\text{-}C_5H_5)_2TiCl_2$ and reducing agents are catalysts of the Ziegler type and are also capable of the active fixation of molecular nitrogen.

It has been shown that, in an aprotic medium (dimethylformamide, acetonitrile, dimethoxyethane, and tetrahydrofuran), $(\pi\text{-}C_5H_5)_2TiCl_5$ is reduced at the dropping mercury electrode in two stages with subsequent cleavage of the Ti–Cl bonds [60,228,233]. The first wave on the polarogram corresponds to the reversible transfer of a single electron with formation of a titanium(III) compound:

$$(\pi\text{-}C_5H_5)_2TiCl_2 + e \rightleftarrows (\pi\text{-}C_5H_5)_2TiCl + Cl^- \quad .$$

The compound $(\pi\text{-}C_5H_5)_2TiCl$ gives rise to an ESR signal [60, 229]; its subsequent reduction proceeds irreversibly with the apparent formation of titanocene:

$$(\pi\text{-}C_5H_5)_2TiCl + e \rightarrow [(\pi\text{-}C_5H_5)_2Ti]_n + Cl^- \quad .$$

The reduction of $(\pi\text{-}C_5H_5)_2TiX_2$ (X = F, Br, or I) proceeds via analogous mechanisms. The difference between $E_{1/2}$ for the first X = Cl, Br, or I waves is small, while $(\pi\text{-}C_5H_5)_2TiF_2$ is reduced at much more negative potentials [229]. The reduction of $(\pi\text{-}C_5H_5)_2Ti(R)Cl$ [R = $CH_3$, $C_6H_5$, $C_5F_5$, or $OTiCl(C_5H_5\text{-}\pi)$] also begins with the one-electron cleavage of the TiCl bond and the formation of $(\pi\text{-}C_5H_5)_2TiR$. [232] A study [229] has shown that the reduction of $\pi\text{-}C_5H_5TiCl_3$ proceeds in three stages with successive dissociation of Ti–Cl σ-bonds.

In a protic medium, $(\pi\text{-}C_5H_5)_2TiCl_2$ is readily hydrolysed to $(\pi\text{-}C_5H_5)_2TiOH^+$, which is then reduced at the dropping mercury electrode:

$$(\pi\text{-}C_5H_5)_2TiOH^+ + e + H^+ \rightarrow [(\pi\text{-}C_5H_5)_2Ti]^+ + H_2O \quad .$$

The half-wave potentials have also been found for the reduction of $(\pi\text{-}C_5H_5)_2TiCl_2$ in other solvents (ethylenediamine [234], morpholine [235], phenylphosphonic dichloride [236], and dimethyl sulphoxide [237]) and for the reduction of $(\pi\text{-}C_5H_5)_2TiBr_2$ in formamide [44].

The reduction of $(\pi\text{-}C_5H_5)_2ZrCl_2$ in an aprotic medium likewise proceeds in two stages, but has more negative potentials. The product of the addition of the first electron does not give rise to an ESR signal, evidently because of dimerisation and the formation of the M–M bond [60]:

$$(\pi\text{-}C_5H_5)_2ZrCl_2 + e \rightarrow (\pi\text{-}C_5H_5)_2\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{Zr}}\!\!-\!\!\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{Zr}}(C_5H_5\text{-}\pi)_2 \quad .$$

In an aqueous medium with $NaClO_4$ as the supporting electrolyte, the reduction of $(\pi\text{-}C_5H_5)_2ZrCl_2$ is not observed, because its reduction potential lies outside the limits of the discharge of the supporting electrolyte [51,55].

## Transition Metal Complexes with a Metal–Carbon σ-Bond

Transition metal compounds with a metal–carbon σ-bond are as a rule reduced at more negative potentials than the complexes with metal–halogen and metal–metal σ-bonds. Depending on the structure of the complex, the reduction proceeds via different mechanisms. Octahedral iron, tungsten, manganese, and rhenium complexes are reduced irreversibly at the dropping mercury electrode in an aprotic medium (acetonitrile) in a single two-electron stage with dissociation of the metal–carbon σ-bond [158,205, 238].

$$\pi\text{-}C_5H_5(CO)_2Fe\text{—}R + 2e \rightarrow [\pi\text{-}C_5H_5(CO)_2Fe]^- + R^- \xrightarrow{H^+} RH \quad .$$

The reaction products are the metal carbonyl anion and the carbanion $R^-$. The latter is stabilised with formation of RH, evidently on interaction with the solvent or with the traces of water in the solvent¶. The structure of the group R has a significant influence on the values of $E_{1/2}$, displacing them towards more negative potentials with increase of the basicity of $R^-$. A satisfactory linear correlation is observed between the $E_{1/2}$ for the reduction of the Fe–C bond and the values of $pK_a(RH)$ in the series of compounds $\pi\text{-}C_5H_5(CO)_2FeR$: $E_{1/2} = -0.03\ pK_a - 0.81$ (V); $r = 0.994$†. It has been suggested that the observed correlation be used for the determination of new values of $pK_a$ [151] for C–H acids whose acidity is unknown.

The replacement of one carbonyl group in $\pi\text{-}C_5H_5(CO)_2\text{.}FeC_6H_4X$ by a phosphorus-containing ligand L leads to a change in the reduction mechanism [238,240]. In this case, the first stage involves the addition of one electron. Simultaneously with electron transfer, the M–C bond is dissociated. The values of $E_{1/2}$ for the first wave were used to estimate the influence of substituents on the transition state in the electrode reaction [238]. The best linear correlation is observed between $E_{1/2}$ and the values of $\sigma_n^0$ for the substituents X ($r = 0.873$; $\rho = +0.19$ V). Consequently, the polar influence of substituents is slight, in good agreement with the hypothesis of the homolytic dissociation of the M–C bond during reduction.

The reduction of the organometallic derivative $(\pi\text{-}C_5H_5)_2\text{.}TiR_2$ (R = $CH_2\text{–}C\text{–}CH$, with $B_{10}H_{10}$) proceeds in two irreversible one-electron stages with subsequent dissociation of Ti–C σ-bonds. When R = $CH_3$ or $C_6H_5$, a single one-electron wave is observed on the polarogram [241].

The polarographic reduction of $RCOM(CO)_5$—the acyl derivatives of manganese and rhenium carbonyls—has also been investigated [158].

¶ According to Vlček [239], a proton is split off from the solvent in the solvation shell of the depolariser molecule and the R–H bond is formed in the activated complex.

† A similar relation has also been observed in the polarographic reduction of symmetrical organomercury compounds and organomercury salts (see, for example, Denisovich and Gubin [149,150]).

Organometallic Derivatives of Planar Chelate Complexes of Cobalt

The oxidation-reduction reactions of σ-organocobalt derivatives of corrin complexes (natural organometallic compounds related to the vitamin $B_{12}$ series) and of their simpler analogues are of considerable interest. Electrochemical studies have shown that, under certain conditions, the cleavage of the Co–C bond during their reduction or oxidation is preceded by rapid electron transfer. This is also important for the understanding of biochemical processes involving vitamin $B_{12}$. The availability of a series of model organocobalt chelates makes it possible to determine the role of chelating ligands and of the organic group in the mechanism of the reductive cleavage of the Co–C σ-bond. The polarographic behaviour of the organometallic complexes of cobalt having the general formula $[RCo^{III}(chel)L]$ and $\{RCo^{III}[(do)(doh)pn]L\}^+$, where R is a hydrocarbon group, L a Lewis base (in the simplest case a solvent molecule), and chel and [(do)(doh)pn] are the equatorial chelating dianion and the monoanion respectively‡, has been investigated in greatest detail [242–245]. The reduction of these complexes proceeds with greater difficulty than that of the corresponding chelates without Co–C bonds [244], but much more easily than, for example, the reduction of organomercury compounds with the same groups R. Polarographic cyclic voltamperometric and electrolytic studies at a controlled potential have shown that the reduction at the dropping mercury electrode proceeds in accordance with the following mechanisms:

$$[RCo^{III}(chel)L] \underset{-e}{\overset{+e}{\rightleftarrows}} [RCo^{II}(chel)L]^- \underset{-e}{\overset{+e}{\rightleftarrows}} [RCo^{I}(chel)L]^{2-} ;$$

$$\{RCo^{III}[(do)(doh)ph]L\}^+ \underset{-e}{\overset{+e}{\rightleftarrows}} \{RCo^{II}[(do)(doh)ph]L\}^0 \underset{-e}{\overset{+e}{\rightleftarrows}} \{RCo^{I}[(do)(doh)ph]L\}^- .$$

The above mechanisms show that the reduction is electrochemically reversible and does not therefore require an appreciable activation energy for electron transfer. The values of $E_{1/2}$ for the first reduction stage ($Co^{III} \rightarrow Co^{II}$) of complexes of the same type depend on R. It has been found [243–246] that the values of $E_{1/2}$ vary linearly with the $pK_a$ for the corresponding RH, i.e. the electron affinity of the organometallic chelate depends on the stability of $R^-$, and the orbital to which the electron is transferred on reduction is therefore the antibonding orbital of the Co–C bond. The electron-donating capacity of the equatorial ligands influences the electron affinity of the complexes investigated [243–246]. The dependence of $E_{1/2}$ on the nature of the equatorial ligand shows that the energy of the antibonding orbital of the Co–C bond increases in the sequence from [(do)(doh)pn] to salen and bae. The stability of the intermediate and final products depends to a large extent on the nature of R. Thus the one-electron reduction of $[C_6H_5Co^{III}(salen)L]$ leads to the formation of a potential carbanion, while the products of the reductive cleavage of $[CH_3Co(salen)L]^-$ are a cobalt(I) complex and $CH_3^{\cdot}$: [246]

$$[C_6H_5Co^{II}(salen)L]^- \xrightarrow{H^+} C_6H_6 + [Co^{II}(salen)L] ;$$

$$[CH_3Co^{II}(salen)L]^- \rightarrow CH_3^{\cdot} + [Co^{I}(salen)L]^- .$$

The differences in the behaviour of these complexes are explained by the changes in the lowest vacant molecular orbital of the complex where the electron is accepted on transition from $[C_6H_5Co(salen)L]$ to $[CH_3Co(salen)L]$, namely in the case of powerful donors (R = $CH_3$) the lowest free orbital may be a metal orbital of the $d_{xy}$ type.

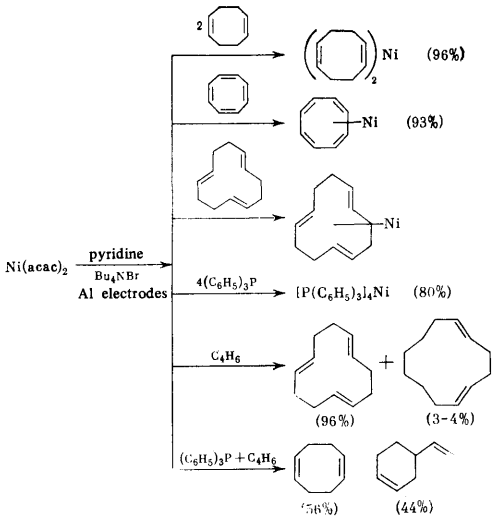
The ability of organometallic chelates to behave as donors of the methyl group is greatly enhanced on their reduction. Thus $\{CH_3Co^{I}[(do)(doh)pn]L\}^-$ behaves as a methylating agent in relation to the initial compound even under electrolysis conditions:

$$RCo^{I}[(do)(doh)pn]\}^- + \{RCo^{III}[(do)(doh)pn]\}^+ \rightarrow$$
$$\rightarrow \{R_2Co^{III}[(do)(doh)pn]\} + \{Co^{I}[(do)(doh)pn]\} .$$

The reversible one-electron oxidation of cobalt(III) organic chelates in the series [RCo(salen)] and $[RCo(Dh)_2]$ (Dh is the dianion of a 1,2-dioxime) has also been observed at a platinum electrode in acetonitrile with formation of labile cobalt(IV) compounds which readily transfer the σ-linked organic group to nucleophiles [247].

The polarographic behaviour of alkylcobalamins, glucopyranosylcobalamin, and 5′-deoxynucleoside analogues of the cobamide coenzyme in an aqueous medium has been investigated [248]. The great complexity of the polarographic reduction of $RCo(Dh)_2$ compared with organocobalt chelates of other series is also noteworthy [248–250].

## VI. ELECTROCHEMICAL SYNTHESIS OF π-COMPLEXES OF TRANSITION METALS AND OF COMPLEX ORGANOMETALLIC CATALYSTS

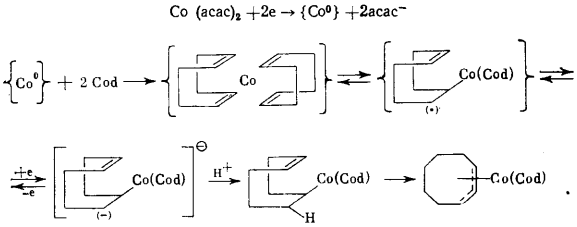


The polarographic study of the behaviour of transition metal π-complexes and of the corresponding non-coordinated ligands at electrodes leads to the possibility of selecting conditions for the electrochemical synthesis of transition metal π-complexes [251,252]. As a rule, the starting compounds for the electrochemical synthesis of transition metal complexes are chelate complexes of the same metals or their salts. Electrolysis is carried out using an organic compound, which subsequently behaves as the π-ligand for the complex to be formed, in the presence of electron-donating molecules [pyridine, DMF, $P(C_6H_5)_3$, etc.] capable of stabilising a low oxidation state of the metal. Thus, transition metal carbonyls have been synthesised from acetylacetonates and carbon monoxide [253, 254]. The electrolysis was carried out at a stainless steel cathode in anhydrous pyridine containing 1–5% $Bu_4NBr$; the anode was metallic aluminium. The carbon monoxide pressure was varied within wide limits, whereupon the following processes take place at the electrodes:

$$\text{Cathode: } M(acac)_n + XCO + ne \rightarrow M(CO)_x ;$$
$$\text{Anode: } Al \rightarrow Al^{3+} + 3e .$$

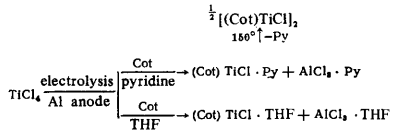
The carbonylation of $CrCl_3(Py)_3$ in pyridine at 85 °C and a carbon monoxide pressure of 60 atm leads to the formation of $Cr(CO)_6$ in 85% yield [255]. The reduction of $Fe(acac)_3$ at a mercury cathode in the presence of $P(C_6H_5)_3$ and 1,3-dienes leads to the formation of $FeP(C_6H_5)_3$ (diene)

‡ The following notation has been adopted for various chelating dianions: salen = *NN′*-ethylenebis(7,7′-dimethylsalicylideneaminate); bae = *NN′*-ethylene bis(acetylacetone iminate) [*NN′*-ethylenebis(1-methylethylideaminate)]; saloph = *NN′*-*o*-phenylenebis(salicylideneaminate); [(do)(doh)pn] = monoanion of 1,3-diacetylmonoxime-iminodiacetylmonoximatoiminopropane.

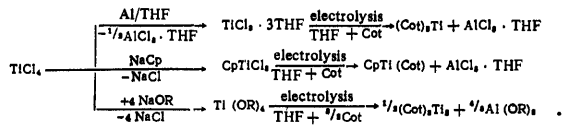


(diene = buta-1,3-diene or isoprene)[256]. Olefin complexes of nickel have also been obtained by a similar procedure[257]:

The last two rows of the above scheme show that the complexes of zero-valent nickel synthesised electrochemically catalyse the oligomerisation of butadiene. The electrochemical preparation of butadiene oligomerisation and polymerisation catalysts containing zero-valent nickel and cobalt has been investigated in greater detail in other studies[258-262]. It has been shown that the conversion of butadiene and the composition of the products formed are influenced by the nature of the initial nickel and cobalt compounds, the nature of the solvent, and the potential at which the electrolysis is carried out. Similarly electrolysis at a platinum electrode of a solution containing $Py_4Ni(ClO_4)_2$ or $NiCl_2$ and butadiene involves the tetramerisation of butadiene[263], but this reaction is not catalytic. The electrochemical synthesis of previously unknown $(Ph_3P)_4Rh(O)$ has also been described[264].



The following mechanism has been proposed for the electrochemical synthesis of cobalt complexes of cyclo-octa-1,5-diene (Cod) at aluminium electrodes[265]:



$$Co(acac)_2 + 2e \rightarrow \{Co^0\} + 2acac^-$$

The intermediate biscyclo-octa-1,5-dienecobalt is subsequently reduced to an anionic complex, which reacts with a proton, forming $\pi$-cyclo-octenylcyclo-octadienecobalt.

The electrochemical preparation of cobalt complexes of acyclic 1,3-dienes $(\pi\text{-}C_4H_6)Co(\pi\text{-}C_4H_6R)L$, where L = $P(C_6H_5)_3$ or $P(C_4H_9)_3$, by the reduction of $CoCl_2$ at a mercury cathode in the presence of buta-1,3-diene and L has been described[266].

Another approach to the electrochemical synthesis of $\pi$-complexes is based on the involvement of the electrode material in the electrode reaction. Ferrocene has been obtained in this way from $C_5H_5Tl$ at an iron anode in 94.6% yield[268]:

$$\text{Anode: } 2C_5H_5Tl + Fe \rightarrow (C_5H_5)_2Fe + 2Tl^+ + 2e \ ;$$

$$\text{Cathode: } 2C_5H_5Tl + 2e \rightarrow 2Tl^0 + 2C_5H_5^- \ .$$

A method for the preparation of cyclopentadienylmanganese carbonyl compounds, based on the anodic dissolution of manganese, has been patented[269,270]. Similarly, in the electrolysis of solutions of indenylsodium and fluorenylsodium in THF or diglyme, the manganese anode dissolves with formation of di-indenylmanganese and difluorenylmanganese[271]. When a current is passed between two copper electrodes in a methanol solution of $Cu(BF_4)_2$ and cyclo-octa-1,5-diene, the copper undergoes anodic dissolution with formation of bis(cyclo-octa-1,5-diene)copper tetrafluoroborate:

$$Cu + n\,(Cod) + BF_4^- \rightarrow Cu\,(Cod)_n\,BF_4 + e \ .$$

At the same time copper(II) is reduced at the cathode to copper(I) and the subsequent reaction of copper(I) with Cod likewise leads to the formation of $Cu(Cod)_nBF_4$:[272]

$$Cu^{2+} + n\,(Cod) + BF_4^- + e \rightarrow Cu\,(Cod)_n\,BF_4 \ .$$

---o0o---

In conclusion, one should note that, together with the undoubted advances in electrochemical research on transition metal $\pi$-complexes, there are a number of branches of this field which have so far been inadequately investigated and whose study is likely to be rewarding: (1) investigation of the mechanisms of electrode processes involving $\pi$-complexes; (2) investigation of the properties of the intermediate species and the final products of the electrochemical reactions of $\pi$-complexes; (3) the study of the relation between electrochemical data and the chemical and physical properties of $\pi$-complexes (acid–base properties, reactivity in relation to electrophiles and nucleophiles, ionisation potentials, electron affinities, quantum-chemical data, etc.); (4) electrochemical synthesis of $\pi$-complexes and complex organometallic catalysts.

# Rearrangements in Sulphoxides and Sulphones Induced by Electron Impact

R.A.Khmel'nitskii and Yu.A.Efremov

The survey covers processes involving the isomerisation of molecular ions and the rearrangement of ionic fragments during the initial stages of the dissociative ionisation of sulphoxides and sulphones on electron bombardment. Characteristic ions are formed by skeletal rearrangements, in particular by migration of an alkyl or an aryl group from the sulphur to an oxygen atom. The relative statistical weight of a particular structure of a molecular ion is the main factor determining subsequent competitive decomposition paths of the primary ionic fragments. A list of 82 references is included.

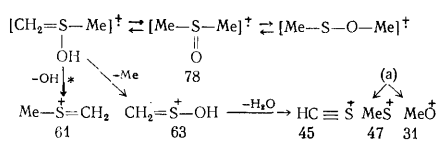
## I. INTRODUCTION

Migrations of groups on electron impact, with the formation of new bonds—so called skeletal rearrangements—make the interpretation of mass spectra substantially more difficult, since they cannot be predicted *a priori* with sufficient certainty. On the other hand, the rearranged ions, whose activation energy of formation is low, often corresponds to the most intense peaks in the mass spectra, and can therefore be most effectively used to identify compounds and establish their structure.

Several reviews have appeared on rearrangements involving aliphatic and aromatic sulphoxides and sulphones[1-5]. They reflect the variety of such processes characterising the behaviour of sulphur-containing organic compounds under electron bombardment—migration of an alkyl or an aryl group from the sulphur atom to an oxygen atom in aliphatic or aromatic sulphoxides and sulphones to form a sulphenic or a sulphinic ester, migration of a hydrogen atom to an oxygen atom in aliphatic sulphoxides and sulphones, and finally reactions involving formation of new bonds accompanied by detachment of neutral molecules, of the type $(ABC)^+ \rightarrow (AC)^+ + B$.



In the present Review we shall summarise the large amount of new work that has appeared on skeletal rearrangements in aliphatic and aromatic sulphoxides and sulphones. Discussion of the mechanisms is based on the application of high-resolution mass spectrometry and isotopic labelling.

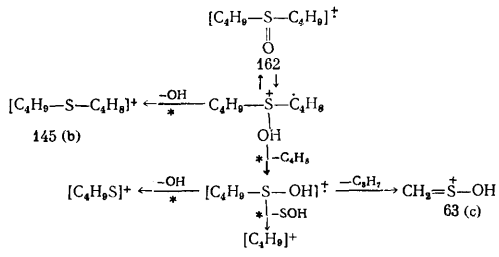
## II. ALIPHATIC SULPHOXIDES

The breakdown of aliphatic sulphoxides involves the formation of weak peaks of rearranged ions due to loss by the molecular ion of a hydroxy-group or a neutral alkene. These processes are accompanied by migration of hydrogen to the oxygen atom.

Several studies have been made of the behaviour of symmetrical dialkyl sulphoxides[6-11]. The first member of the series—dimethyl sulphoxide—is unable, of course, to eliminate an alkene on electron impact, but its mass spectrum reveals the occurrence of other rearrangements: together with the formation of $[M - OH]^+$ and $[M - CH_3]^+$ ions (where $M$ is the molecular ion), due to successive or simultaneous cleavage of the sulphur–oxygen or a sulphur–carbon bond accompanied by migration of an alkyl hydrogen atom to the oxygen atom, approximately equally intense peaks of $CH_3S^+$ and $CH_3O^+$ ions are observed[9] in the mass spectrum of dimethyl sulphoxide. From this it was concluded that the molecular ion isomerised into the structure (a)†, and this was followed by cleavage of the sulphur–oxygen bond (Scheme 1)†. Detachment of a methyl radical leads to formation of the maximum peak (of mass 63) in the spectrum. The high probability of elimination of a hydroxyl from the molecular ion of dimethyl sulphoxide is due to formation of sulphonium ions $R\overset{+}{S}=C\langle$.[10] The spectrum of dimethyl sulphoxide contains also weak peaks corresponding to rearranged hydrocarbon ions $[M - SOH]_n^+$, where $n = 0-3$.

Scheme 1

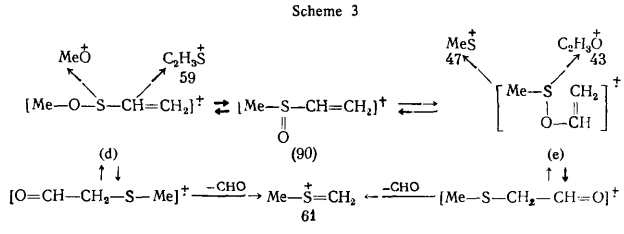
The dissociative ionisation of higher dialkyl sulphoxides



($R$ = n-$C_3H_7$, n-$C_4H_9$, iso-$C_4H_9$) is accompanied by elimination of R associated with migration of a hydrogen atom to the charged fragment. This process corresponds formally to detachment of a neutral alkene. Detailed study of deuterated di-n-butyl sulphoxide has shown[11] that the migration of hydrogen is non-specific. The location of

†Here and subsequently the numerals accompanying ionic formulae indicate $m/e$ values, and asterisks denote metastable ions.

the migrating hydrogen atom probably determines the probability of successive or simultaneous loss of hydroxyl, cleavage of a carbon–sulphur bond, or other process (e.g. McLafferty rearrangement). Indeed, fission of a carbon–sulphur bond in an aliphatic sulphoxide hardly takes place without migration of hydrogen. Even in dimethyl sulphoxide such migration is probably involved in removal of a methyl group[11]. Formation of the new carbon–hydrogen bond is accompanied by single-stage detachment of a hydroxy-radical with formation of fragment (b) of mass 145 (Scheme 2).



Scheme 2

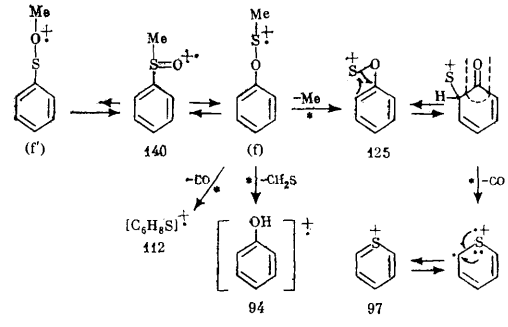
Another common feature of the mass spectra of these compounds is a characteristic peak due to ions of mass 63 (ion c). Study of deuterated compounds indicates that this fragment contains an $\alpha$-methylene group and a hydrogen atom that has migrated[11]. The dissociative ionisation of dibutyl sulphoxide exhibits all the characteristic modes of breakdown of dialkyl sulphoxides (Scheme 2). It is interesting that migration to oxygen of a hydrogen atom more remote from the oxygen atom may occur partly also through a McLafferty rearrangement. Randomisation of hydrogen is then completely absent from these compounds[11].

It was suggested[1] that an unsaturated migrating group in an unsymmetrical sulphoxide should facilitate rearrangement, resulting in relatively intense ion peaks due to $[M - SO]^+$, $[M - SOH]^+$ and $[M - SOH_3]^+$.[6] The peaks in the mass spectrum of methyl vinyl sulphoxide[12] due to ionic fragments of masses 31, 43, 47, and 59—$[CH_3O]^+$, $[C_2H_3O]^+$, $[CH_3S]^+$, and $[C_2H_3S]^+$ respectively—also indicate isomerisation of molecular ions of the sulphoxide into the sulphenates (d) and (e) followed by cleavage of the sulphur–oxygen bond. The maximum peak in the spectrum, corresponding to ions of mass 61, however, results from rearrangement of the isomerised molecular ion. This may involve either migration of two methyl hydrogen atoms to the vinyl group of the ion (d) followed by rupture of the sulphur–oxygen bond, or rearrangement of the ion (e) (Scheme 3).

Scheme 3

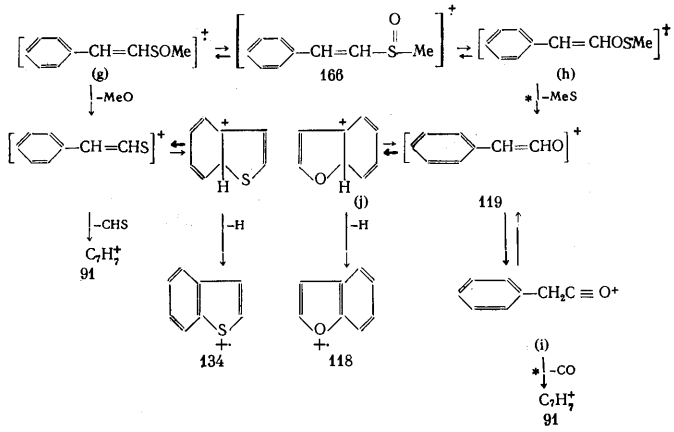
The spectra of unsymmetrical compounds, such as n-butyl methyl, ethyl, propyl, and isopropyl sulphoxides, show that, when unbranched alkyl groups are present, a small alkyl is eliminated preferentially, with migration of a hydrogen atom to the oxygen; in $\alpha$-branched systems this effect is ill defined[11].

## III. AROMATIC SULPHOXIDES



The mass spectra of aromatic sulphoxides, in contrast to those of the aliphatic compounds, containing weak peaks of rearranged ions, are characterised by intense peaks due to ions that may result from isomerisation of the molecular ion. Alternative migration of one of the groups from the sulphur atom to oxygen is observed in the dissociative ionisation of alkyl aryl or unsymmetrical diaryl sulphoxides. This indicates that the molecular ion can exist in at least three forms[1]:

Reversible O → S migration of allyl and benzyl with formation of a sulphoxide has been demonstrated[13] on heat-treatment of the sulphenate. However, phenyl sulphoxides probably do not undergo S → O migration on thermolysis[14].



The elimination of carbon monoxide in the dissociative ionisation of aromatic sulphoxides[8] indicates unambiguously formation of a carbon–oxygen bond by isomerisation of the molecular ion or of ionic fragments appearing in the first stage of breakdown. Thus the mass spectrum of methyl phenyl sulphoxide shows that the molecular ion and the ion $[M - CH_3]^+$ of mass 125 lose carbon monoxide. In addition, the molecular ion eliminates a $CH_2S$ group with formation of an ion of mass 94 $[C_6H_6O]^+$ (perhaps having the phenol structure), a process which is confirmed by a metastable peak. The molecular ion of methyl phenyl sulphoxide can be regarded as represented mainly by structure (f) (Scheme 4).

Scheme 4

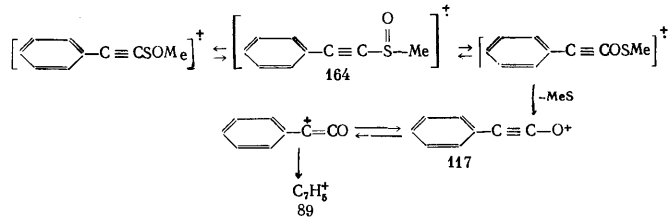
However, these workers[8] do not detect the $CH_3O^+$ ion, which would have indicated isomerisation of the molecular ion involving migration of the alkyl group from the sulphur to the oxygen atom (f′). Such isomerisation has been observed with methyl styryl and phenethynyl sulphoxides[15–17], when alternative formation of the intermediate structures (g) and (h) takes place (Scheme 5) with preferential migration of the styryl or the alkyl group from the sulphur to the oxygen atom. Decomposition of these ions (g) and (h) yields the characteristic ionic fragments. Thus the mass spectrum of methyl styryl sulphoxide indicates elimination of a methoxy-group from the former ion, although no metastable ions were observed for this purpose. Study of deuterated derivatives of methyl styryl sulphoxide confirmed the above observation[15].

Scheme 5

Migration of the styryl group from sulphur to oxygen can be traced by the detachment of a methylthio-radical from the isomerised molecular ion of structure (h) and the appearance of the peak of the corresponding metastable ion. One of the main pathways along which the resulting ion of mass 119 breaks down involves migration of a hydrogen atom to the $\alpha$-carbon atom relative to the ring with formation of the phenylacylium ion (i) followed by elimination of carbon monoxide (Scheme 5).

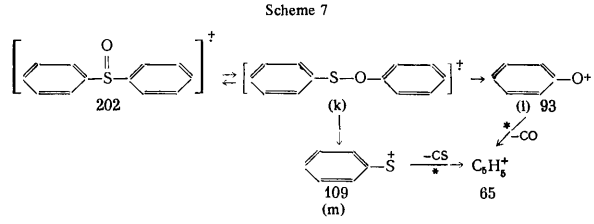
Another mode of breakdown of the ion of mass 119 involves [15-17] electrophilic attack on the benzene ring by the positively charged oxygen atom to form the protonated benzofuran ion (j), from which the hydrogen atom splits off to give the pseudomolecular benzofuran ion of mass 118. Electrophilic attack induced by electron impact is made not only by oxygen [18] but also by sulphur [7], as shown by formation of a pseudomolecular benzothiophen ion of mass 134 when structure (g) breaks down.

Appearance of the tropylium ion of mass 91 probably has a lower activation energy [4] than that of the benzofuran ion. With ionising electrons of low energy the process $119^+ \rightarrow 91^+$ still occurs, but the ion of mass 118 disappears.



The molecular ion of methyl styryl sulphoxide also loses carbonyl (and/or formyl) and hydroxyl. Examination of deuterium-labelled compounds has established that the carbon atom present in the formyl radical had probably been attached to the sulphinyl group, whereas the hydroxyl hydrogen atom may have belonged either to the phenyl ring or to the alkyl group, which is confirmed by the mass spectra of the compounds

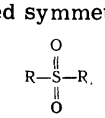
where R = $CH_3$, $C_2H_5$, $C_6H_5$.



The presence of a second phenyl group in the styryl system greatly facilitates the sulphoxide–sulphenate rearrangement. High-resolution mass-spectrometric data and results for labelled compounds showed that elimination of the sulphinyl group from the molecular ions occurred neither with methyl styryl nor with methyl phenethynyl sulphoxide (Scheme 6), the latter of which is characterised by preferential migration of the acetylenic group with its *sp*-hybridised carbon atom from sulphur to oxygen. Successive detachment of a methylthio-group and of carbonyl gives the $[C_7H_5]^+$ ion of mass 89.

Scheme 6

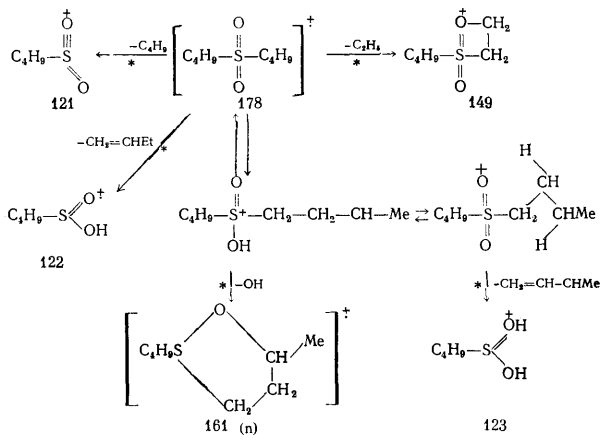
Formation of a carbon–oxygen bond and elimination of carbon monoxide do not occur on electron bombardment of alkyl aryl sulphoxides having a long alkyl chain [19] and of $\beta$-keto-sulphoxides [20], owing to sulphenate isomerisation of the molecular ion. These compounds are characterised not only by rupture of $\alpha$- and $\beta$-bonds relative to the aromatic ring but also by the McLafferty rearrangement, which involves a six-membered transition state. This specific rearrangement occurs even with ionising electrons of very low energy. Elimination of the sulphinyl group from the molecular ion, which takes place with diphenyl [7], dibenzyl [21,22], and di-*p*-tolyl [8] sulphoxides, was not observed.



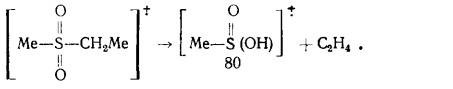
Scheme 7

Some evidence of the isomerisation of molecular ions of diphenyl sulphoxides into sulphenates (k) can be obtained from an examination of the mass spectra of diphenyl sulphoxide. Cleavage of the sulphur–oxygen bond causes the appearance of ions of mass 93 and 109—$[C_6H_5O]^+$ (*l*) and $[C_6H_5S]^+$ (*m*)—(Scheme 7). The metastable peaks indicate that elimination of carbonyl and thiocarbonyl groups leads in each case to an ion of mass 65 $[C_6H_5]^+$. In the mass spectra of higher homologues the fragments (*l*) and (*m*) are formed directly from the molecular ion (Scheme 7). The elementary composition of the fragments is confirmed by the high-resolution spectra [7]. Another feature of the above diaryl sulphoxides is the elimination of carbon monoxide and a hydrogen atom from the molecular ion, as well as the presence of the intense rearranged ion $[M - SO]^+$.

## IV. ALIPHATIC SULPHONES

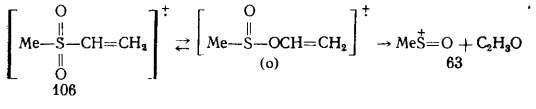


Aliphatic sulphones behave like the sulphoxides towards electrons. With the exception of dimethyl sulphone the mass spectra of saturated symmetrical dialkyl sulphones



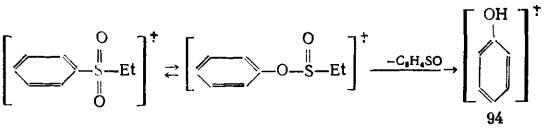
(R = $C_2H_5$, n-$C_3H_7$, n-$C_4H_9$, n-$C_5H_{11}$, n-$C_6H_{13}$, n-$C_7H_{15}$) contain intense peaks of hydrocarbon ions. Formation of rearranged ionic fragments $[RSO_2H_n]^+$, where $n = 0-2$, is characteristic of aliphatic sulphones [7,8,11,23]. The dissociative ionisation of dibutyl sulphone exhibits all the typical features of the breakdown of saturated dialkyl

sulphones due not only to rupture of a carbon–sulphur bond but also to $\gamma$-cleavage with migration of one or two hydrogen atoms to the oxygen atoms. The use of deuterium-labelled compounds has shown[11] that oxygen, together with the $\gamma$-hydrogen atom migrating to it, is detached from the molecular ion as a result of a McLafferty rearrangement with formation of the cyclic ionic fragment (n) of mass 161 (Scheme 8). It is interesting that the probability that an alkyl group will split off, with double migration of hydrogen to the charged ionic fragment, increases with the length of the alkyl chain[8].



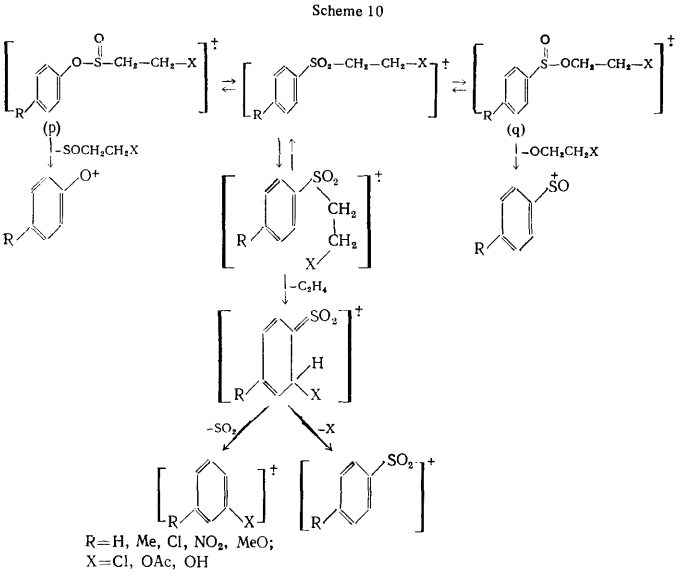
Scheme 8

Study of the mass spectra of unsymmetrical aliphatic sulphones—e.g. ethyl methyl and butyl methyl, ethyl, n-propyl, and isopropyl—shows[11] that the larger group is more easily removed from unbranched compounds, whereas cleavage of the secondary carbon–sulphur bond predominates in $\alpha$-branched systems. Furthermore, hydrocarbon fragments do not appear from the breakdown of ethyl methyl sulphone, as with dimethyl sulphone. In this case the rearrangement caused by migration of a hydrogen atom to oxygen leads to formation of an ion of mass 80:



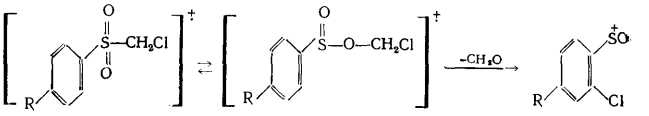
An unsaturated group present in an unsymmetrical sulphone migrates from the sulphur atom to oxygen. Thus the mass spectrum of methyl vinyl sulphone contains an intense peak of the $CH_3SO^+$ ion formed as a result of S → O migration of the vinyl group followed by fission of the sulphur–oxygen bond in the intermediate structure (o):

## V. AROMATIC SULPHONES



The spectra of mixed alkyl aryl sulphones $C_6H_5.SO_2.R$ (where R = $CH_3$, $C_2H_5$, iso-$C_3H_7$, cyclo-$C_3H_7$, n-$C_4H_9$, n-$C_6H_{13}$) exhibit the S → O migration of phenyl also observed with sulphoxides[8,24–26]. For example, the molecular ion of ethyl phenyl sulphone eliminates $C_2H_4SO$ in a single stage with formation of the $[C_6H_6O]^+$ ion of mass 94. This mode of decomposition has been proved by high-resolution mass spectrometry and by the study of deuterium-labelled specimens (Scheme 9).

Scheme 9

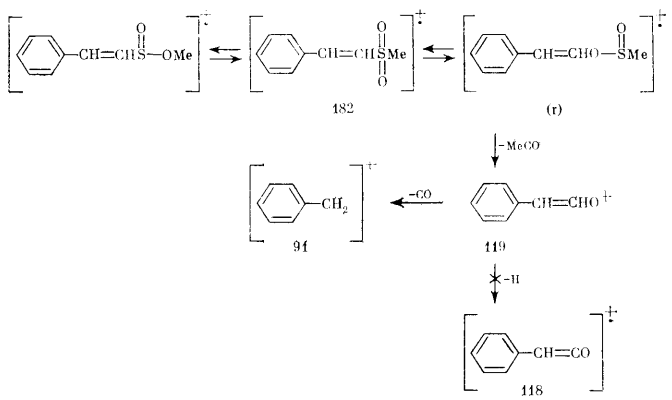


A $\beta$-substituent X present in an aryl ethyl sulphone may migrate to the aromatic ring[27–31]. However, the ions $[M - C_2H_4.X]^+$ and $[M - C_2H_4.SO_2]^+$, formed by the McLafferty arrangement, do not represent the chief mode of decomposition. The most intense peaks in the mass spectra of substituted aryl ethyl sulphones correspond to the ions $[M - OCH_2CH_2X]^+$ and $[M - SOCH_2CH_2X]^+$, which can be formed only by isomerisation of the molecular ion followed by rupture of the sulphur–oxygen bond in the intermediate structures (p) and (q) (Scheme 10).

Scheme 10

Furthermore, a substituent in the aromatic ring may influence migration of the aryl group from the sulphur atom to oxygen[25–32]. Thus the electron-accepting *p*-nitro-group hinders S → O migration of the aryl in the dissociative ionisation of 2-chloroethyl *p*-nitrophenyl sulphone, whereas the electron-donating methoxy-group (in 2-chloroethyl *p*-methoxyphenyl sulphone) facilitates such migration.

Although unsaturation in the migrating group is regarded as a factor increasing the probability of rearrangement, investigation of substituted aryl chloromethyl sulphones shows[28] that migration of the alkyl competes successfully with that of the aryl. The appearance of $[RC_6H_4SO]^+$ ions in the mass spectra of these compounds is due to formation of an alkyl–oxygen bond in the transition state with subsequent elimination of the neutral species $CH_2O$ and migration of the chlorine atom to an *ortho*-position relative to the sulphur atom:



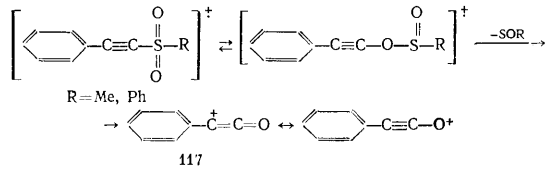
where R = $CH_3O$, $CH_3$, H, Cl, Br, $NO_2$. When the chlorine atom is replaced by hydrogen, such rearrangement is not observed, but an $SOCH_2$ group is eliminated with formation of an ion having the structure of the corresponding phenol.

Evidence of S → O migration of the aryl is lacking for benzenesulphonyl chlorides and their derivatives[27,33,34]. These compounds undergo rearrangement with formation of the $[M - SO_2Cl]^+$ ion. The *ortho*-effect is responsible for the absence of this ion peak in *o*-nitrobenzenesulphonyl chloride, which undergoes initial abstraction of a nitroso-group from the molecular ion followed by elimination of a chlorine radical.

Aryl vinyl sulphones behave similarly to aryl ethyl sulphones. Isomerisation of their molecular ions involves migration of the vinyl in preference to the phenyl group[30]. The peak due to $[M - OCH:CH_2]^+$ ions produced by rupture of the sulphur–oxygen bond is the most intense in the mass spectra of these compounds.

A substituent in the aromatic ring influences not only the migrating power of the phenyl group but also the less significant mode of decomposition involving detachment of a neutral sulphonyl group from the molecular ion. Thus, although the $[M - SO_2]^+$ ion peak is absent from the spectrum of *p*-nitrophenyl vinyl sulphone, it becomes the most intense in the spectrum of the methoxy-derivative, which is evidence of the influence of the electron-donating power of a ring substituent on the probability of elimination.

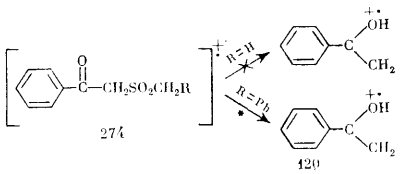
Scheme 11



Styryl sulphones show similar competition between the S → O migration of alkyl or styryl[17]. Thus in the decomposition of methyl styryl sulphone on interaction with electrons the preferential migration of styryl from sulphur to oxygen followed by abstraction of a $CH_3SO$ radical from the intermediate structure (r) promotes formation of a carbon–oxygen bond and elimination of carbon monoxide from the fragment of mass 119 (Scheme 11). The loss of hydrogen by the ionic fragment of mass 119 observed with methyl styryl sulphoxides is completely absent from the mass spectrum of the sulphone. The process $119^+ \rightarrow 118^+$ probably requires more energy than does $119^+ \rightarrow 91^+$ (Scheme 11). Elimination of hydrogen from the $[M - CH_3SO]^+$ ion and removal of carbonyl or formyl from the molecular ion are absent also from the mass spectra of higher homologues of methyl styryl sulphone.

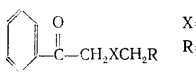
In view of the above, the lack of competition between the S → O migration of the groups in phenyl styryl sulphone is extremely curious. The mass spectrum indicates unambiguously migration of the styryl group and absence of migration of phenyl[17].

Loss of the sulphonyl group as a result of a rearrangement of the type $[ABC]^+ \rightarrow [AC]^+ + B$ also exhibits a lower probability than the removal of sulphinyl from methyl styryl sulphoxide.



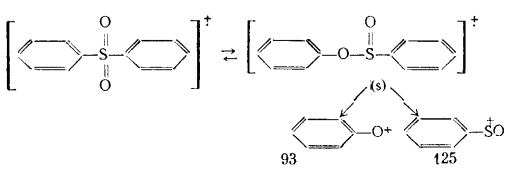
The dissociative ionisation of methyl or phenyl phenethynyl sulphone reveals peculiar behaviour of the acetylenic group, which alone migrates from sulphur to oxygen, while the methyl or phenyl group plays almost no part in the process (Scheme 12).

Scheme 12



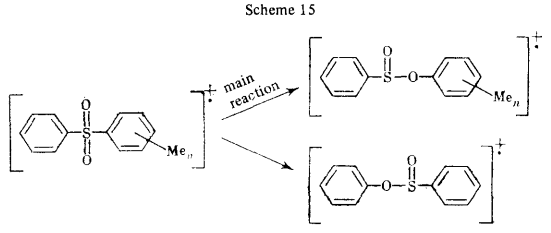
The stability of the neutral species expelled from the molecular ion is responsible for the McLafferty rearrangement[20,22], which has an important role in the formation of the characteristic ions. Indeed, with a keto-sulphone [20] such rearrangement is not followed by elimination of a simple sulphine. In the case of the phenyl derivative, however, such a sulphine may be stabilised, since the spectrum contains a peak at mass 120 corresponding to the $[M - SO_2CHR]^+$ ion, which is confirmed by a metastable transition (Scheme 13).

Scheme 13



Investigation of the series of compounds [20]

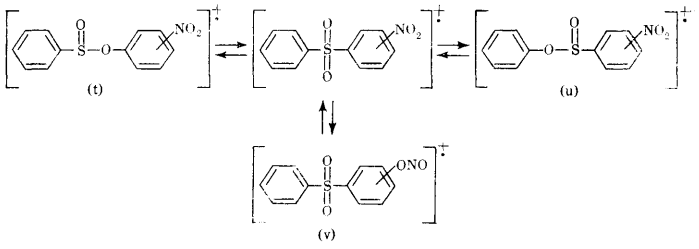
revealed that increase in the stability of the neutral fragment XCHR with R = $C_6H_5$ is accompanied by intensification of the peak of the rearranged ion $[M - XCHR]^+$ in comparison with that obtained with R = H.



A peculiarity of the dissociative ionisation of diphenyl sulphones is the equally probable S → O migration of aryl with formation of an intermediate aryl arenesulphinate (s). Whereas benzophenone and diphenylmethane are characterised by the formation of ions undergoing rearrangement with detachment of the bridging group, together with one or two hydrogen atoms that have migrated, resulting in formation of an ion of biphenylene structure[35], this process is less strongly developed with diphenyl sulphone, for which the main reaction involves cleavage of the sulphur–oxygen bond in (s) with formation of an intense peak of mass 125 [22] (Scheme 14).

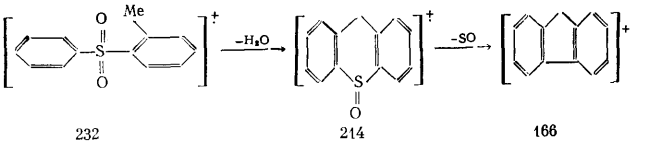
Scheme 14

The introduction of different substituents into the aromatic rings leads to competition in migration of the aryl groups with preferential formation of ionic fragments containing a substituted or an unsubstituted phenyl. The tendency to migrate increases with the number of electron-donating methyl groups [26]. It was suggested [26] that the electron deficit is localised mainly in the non-bonded orbital of the oxygen, so that the phenyl ring better able to function as an electron donor would be more likely to migrate [26,36] (Scheme 15).



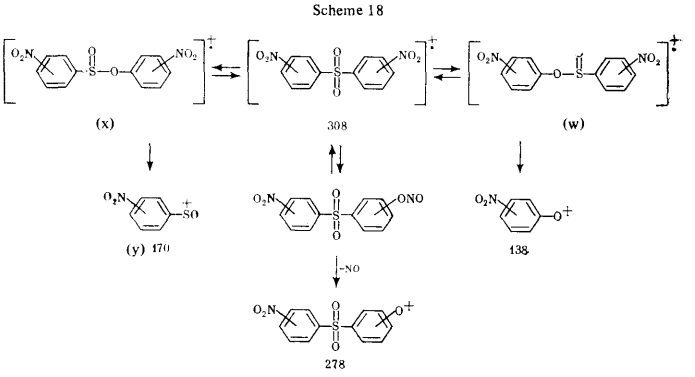
Scheme 15

However, study of a series of *para*-substituted diphenyl sulphones has shown that both electron-donating and electron-accepting substituents are able to increase the migratory power of an aromatic ring [37]. Since an electron-donating group has a considerably stronger stabilising influence on $[ArO]^+$ than on $[ArSO]^+$ ions, the increased migratory power of such a group can be attributed to the stability of the resulting ion. On the other hand, electron-accepting substituents obviously facilitate bond rupture, since they diminish the stability of the positively charged species. If the change in energy of bond rupture exceeds the change in stability of the resulting ion, the migratory power of the aromatic ring containing the electron-accepting group may exhibit an apparent increase [37].



The intensity ratio of the $[ArSO]^+$ and $[ArO]^+$ ion peaks varies within wide limits depending on the type and position of a substituent in the aromatic ring, which indicates competition in formation of intermediate sulphinate structures by migration of a ring from sulphur to oxygen. Thus for the isomeric nitrophenyl phenyl sulphones the probability of formation of the intermediate structure (t) decreases in the sequence *para* > *meta* > *ortho*, whereas the structure (u) is most characteristic of the *ortho*-isomer and less typical of the *para*- and *meta*-compounds [38] (Scheme 16).

Scheme 16

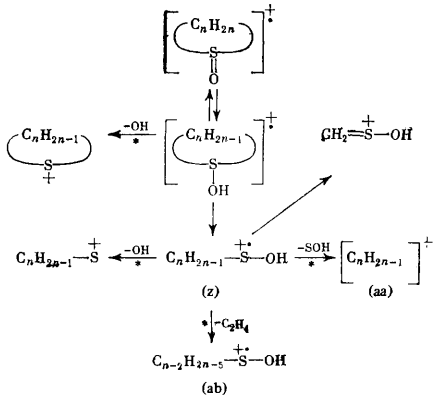


The possibility of nitro-nitrate isomerisation of the molecular ions must be taken into account when considering the dissociative ionisation of nitro-substituted aromatic sulphones [39]. In the case of nitrodiphenyl sulphones it leads to the formation of ions (v) whose subsequent breakdown with elimination of a nitroso-group results in the appearance of characteristic $[M - NO]^+$ ions. The probability of nitro-nitrate isomerisation is doubled in the case of the *ortho*-isomer, owing to the presence of an *ortho*-effect. Such an effect is apparent also in the decomposition of phenyl *o*-tolyl sulphone, where it causes the formation of characteristic $[M - H_2O]^+$ and $[M - OH]^+$ ions, which then eliminate the sulphinyl group [26] (Scheme 17). Elimination of hydrogen atoms from the *o*-methyl group was confirmed by a study of deuterated compounds. The relative intensities of the ion peaks formed by the detachment of $SO_2$, $SO_2H$, and $SO_2CH_3$ from the molecular ion also depend on the position of the substituent in the aromatic ring [26].

Scheme 17

With 2,4-dinitrophenyl phenyl sulphone migration of the unsubstituted aromatic ring from sulphur to oxygen is preferred [38]. The probability of such isomerisation increases with decrease in the energy of the ionising electrons, and the $[ArO]^+$ ion becomes the main peak in the spectrum.

Scheme 18



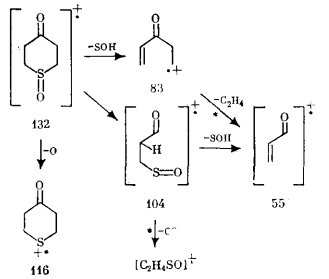
When both rings in a diphenyl sulphone are substituted [40], cleavage of the sulphur–oxygen bond in the ions (w) and (x) formed by migration of either aromatic ring from sulphur to oxygen leads to preferential formation of $[Ar'SO]^+$ ions of mass 170 (y) in relation to $[Ar'O]^+$ ions [40] (Scheme 18). Depending on the positions of substituents in the aromatic ring relative to the sulphonyl group the ion (y), corresponding to the maximum peak in the spectrum of all the isomers other than 2,4'-dinitrodiphenyl sulphone, increases in intensity relative to the total ion current in the sequence of isomers *ortho* < *meta* < *para*.

## VI. CYCLIC SULPHOXIDES

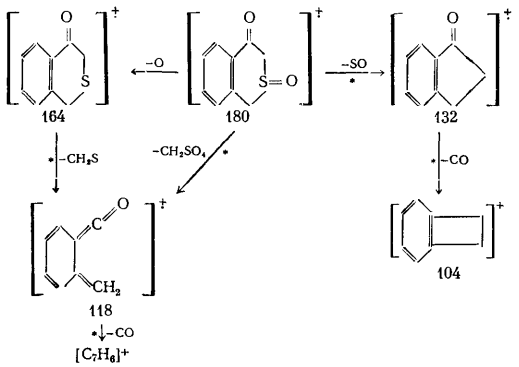
The mass spectra of sulphoxides and sulphones containing the sulphur atom in a saturated or partly saturated ring system had not been studied in such great detail as those of the aliphatic and aromatic compounds. The behaviour of saturated cyclic compounds such as thietan, thiolan, thian, and thiepan *S*-oxides is similar to that of aliphatic sulphoxides subjected to electron bombardment [11]. The general pattern is shown in Scheme 19. Migration of a hydrogen atom to the oxygen atom followed by cleavage of a carbon–sulphur bond is responsible for the appearance of the ion $[R-S-OH]^+$ (z). The fact that this bond forms part of the ring impedes direct detection of the migration of hydrogen atoms involved in the process. The character

of the migration can be determined only after loss of the SOH group, i.e. after the process (z) → (aa). Rupture of the carbon–sulphur bond may be followed by removal of ethylene comprising $\alpha$- and $\beta$-methylene groups—process (z) → (ab)—which increases the difficulty of establishing the mechanism of decomposition.

Scheme 19



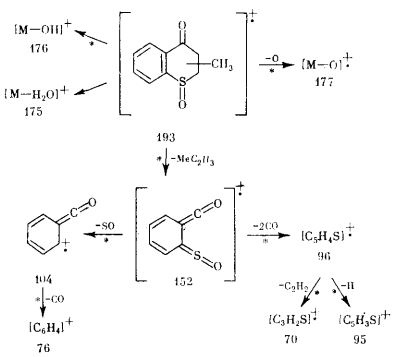
The mass spectra of deuterated sulphoxides [11] indicate that the migration of hydrogen involved in the cleavage of a carbon–sulphur bond (loss of SOH) is effected by a McLafferty rearrangement. The elimination of a hydroxyl is less important than thietan, thiolan, and thian-1-oxides, but leads to intense peaks in the mass spectrum of thiepan 1-oxide, whereas the probability of elimination of the SOH group increases as the ring becomes smaller. This effect is attributed [41] to the difference in the distance of closest approach of the sulphinyl oxygen atom to $\beta$- and $\gamma$-hydrogen atoms.



The pattern of decomposition is greatly changed by introduction of a 4-keto-group into thian 1-oxide [42], when it involved mainly loss of ethylene as a result of a retrodiene reaction. This indicates that the presence of an $sp^2$-hybridised carbon atom attached to sulphur in the cyclic sulphoxides promotes rearrangement, whereas a specifically introduced carbonyl group causes retrodiene decomposition. For example, application of the concept of charge localisation to the dissociative ionisation of 4-oxothian 1-oxide suggests preferential elimination of an alkene from the molecular ion, which is evident in formation of the corresponding metastable ion. Subsequent detachment of the group SOH from the $[M - \text{Alkene}]^+$ ion tends to produce the maximum peak in the spectrum at mass 55 [Scheme 20]. From the low intensity of the $[M - \text{SOH}]^+$ ion peak it may be supposed that this mode of decomposition is less favourable, while the weak ion peak at mass 116, formed as a result of removal of an oxygen atom from the molecular ion, indicates the improbability of this process. The elimination of hydroxyl from the molecular ion, observed with aliphatic and caromatic sulphoxides [8], is found also in the spectrum of the present compound.

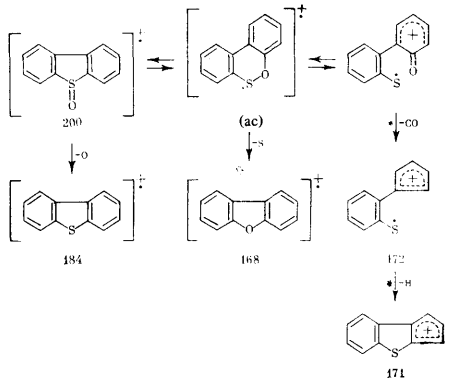
Competition between retrodiene decomposition and elimination of a sulphinyl or sulphonyl group has been detected among compounds of the thiachromanone series [43]. Accompanying elimination of an oxygen atom, a hydroxy-group, or a water molecule from the molecular ion, the chief mode of breakdown of 4-oxothiaisochroman 2-oxide involves initial loss with formation of the maximum ion $[M - \text{SO}]^+$. Subsequent detachment of carbon monoxide yields an ion of mass 104 having a benzocyclobutene structure. Scheme 21 is confirmed by the metastable peaks observed in the mass spectrum. Retrodiene decomposition, which is less probable in this case, involves abstraction of a $CH_2SO$ group and is also accompanied by a metastable transition.

Scheme 20



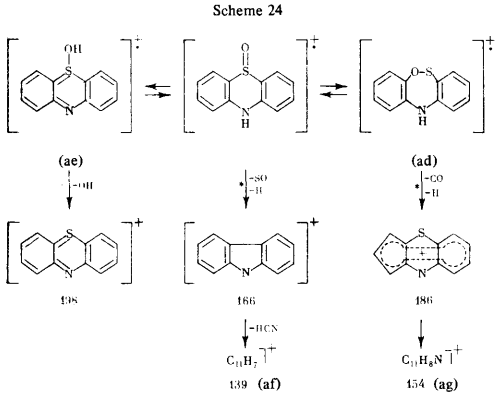
Scheme 21

Thiachromanone and its methyl derivatives undergo breakdown mainly by a retrodiene reaction involving loss of $CH_3C_2H_3$ with formation of a maximum ion peak at mass 152. The ion then loses sulphur monoxide to give an ion peak at mass 104 (Scheme 22). Direct detachment of a sulphinyl group from the molecular ion is secondary in character.



Scheme 22

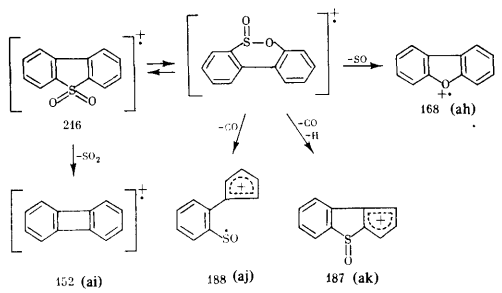
It is noteworthy that, although sulphur is attached to two $sp^2$-hybridised carbon atoms in oxothiachroman oxides, rearrangement of the molecular ion into a sulphenate on electron bombardment, which is characteristic of unsaturated cyclic compounds, could not be demonstrated [43]. Thus dibenzothiophen S-oxide breaks down [44] with formation of the dibenzothiophen cation of



mass 184. This is accompanied by detachment of CO or CO + H from the molecular ion. This can be explained by the rearrangement noted with open-chain sulphoxides[8]. Appearance of the intermediate ion (ac) as a consequence of the rearrangement is confirmed by a weak peak of mass 168, corresponding to the dibenzofuran cation (Scheme 23).

Scheme 23

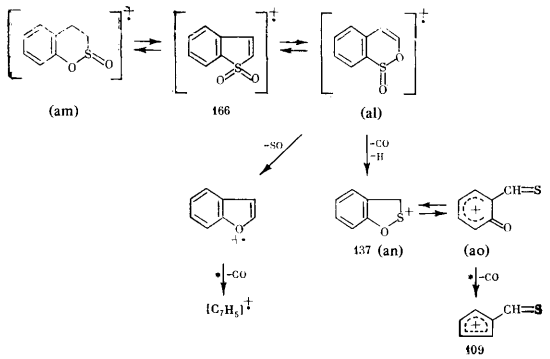
Detachment of a sulphinyl group in a single stage is not observed with compounds containing two heteroatoms in the middle ring[44], where the sulphoxide oxygen is involved in formation of the $[M - CO - H]^+$ ion, but the ring oxygen atom is involved in a subsequent stage of fragmentation. The dissociative ionisation of phenothiazine 5-oxide is remarkable in a mode of decomposition, accompanying those mentioned above, in which the middle ring expands to seven members (ad).[45] It is also noteworthy that hydroxyl is removed from the molecular ion (ae) following transannular redistribution of hydrogen (Scheme 24). The ions (af) and (ag) are extremely stable: the former is met in almost all mass spectra of dibenzo-derivatives of heterocyclic compounds; and the latter is always present when one or two heteroatoms in a six-membered ring are attached to hydrogen.



Scheme 24

## VII. CYCLIC SULPHONES

Cyclic sulphones are characterised by rearrangements involving isomerisation of the molecular ion. For example, the main processes in the initial breakdown of dibenzothiophen [*S*-dioxide] include the loss of sulphinyl and carbonyl groups[8,46,47], probably as a result of isomerisation of the molecular ion into a sulphinic ester similarly to alkyl aryl and diaryl sulphones[26]. The dibenzofuran ring system (ah) is formed considerably more readily than is the four-membered cyclobutadiene ring of biphenylene (ai). Elimination of carbonyl and formyl groups from the molecular ion produces the ions (aj) and (ak) respectively (Scheme 25).

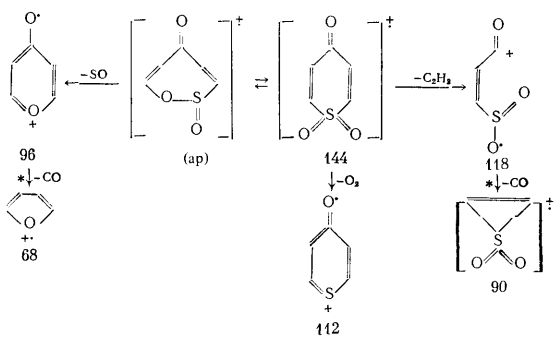


Scheme 25

When a heteroatom has been introduced into the ring—thiaxanthen, oxothiaxanthen, phenothiazine, thianthren, and phenoxathiin *S*-dioxides—decomposition involves preferential elimination of sulphur dioxide[44,45,48]. In the ensuing stages carbon monoxide is removed, which is evidence of formation of a carbon–oxygen bond by isomerisation of the molecular ion into a cyclic sulphinate.

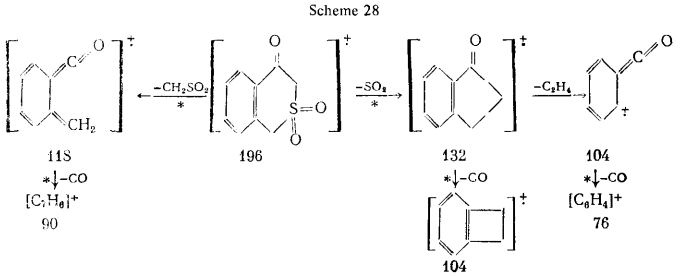
The mode of decomposition is greatly affected by change in the structure of the cyclic sulphone. In this respect the mass spectrum of dihydronaphthobenzothiophen *S*-dioxide is quite remarkable[49], containing an intense peak of $[M - SO_2]^+$ ions but without the elimination of carbonyl and sulphinyl groups resulting from isomerisation of the molecular ion into a sulphinic ester. Yet benzothiophen 1-dioxide[44,50,51] isomerises with preferential formation of the intermediate structure (al), not (am). Subsequent elimination of SO and CO + H groups from the ion (al) leads to the formation of characteristic ions, the latter of which can be represented by the two tautomers (an) and (ao) (Scheme 26). Investigation of deuterated compounds established the initial elimination of CO + D, which was confirmed by the corresponding metastable peak: i.e. the rearrangement involves a hydrogen atom in an $\alpha$-position with respect to the sulphur atom[50].

Scheme 26



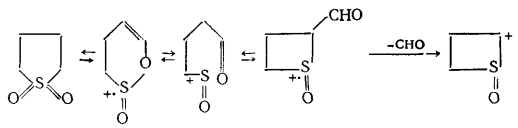
The most probable process with phenylated and chlorinated benzothiophen 1,1-dioxides is the elimination of $COC_6H_5$ and COCl from the isomerised molecular ion[52]. Nevertheless, dihydrobenzothiophen 1,1-dioxide after isomerisation breaks down in a different way, with elimination of sulphinyl and hydroxymethyl groups from the molecular ion.

The saturated cyclic compounds rearrange and decompose[45] similarly to aliphatic sulphones[8]. The dissociative ionisation of thiolan, thian, and thiepan 1,1-dioxides is accompanied by migration of a hydrogen atom with preferential detachment of sulphonyl and sulphino-groups as a result of rupture of a carbon–sulphur bond[11]. If a carbonyl groups is introduced into the six-membered ring, e.g. at position 4, the pattern of dissociative ionisation changes fundamentally[45], to resemble the scheme of decomposition of substituted five- and six-membered sultams[53]. A characteristic reaction in the decomposition of the above compounds is the detachment of sulphur dioxide not from the molecular ion but from the ionic fragments $[M - C_2H_4]^+$ and $[M - CO]^+$ respectively.



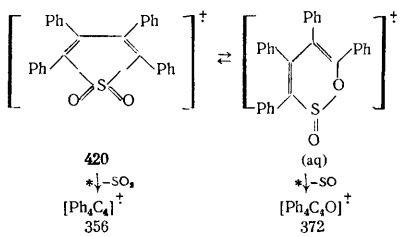
If the ring contains unsaturated bonds, the molecular ions of cyclic sulphones isomerise similarly to aryl sulphones[29]. Thus the dissociative ionisation of thiapyrone 1,1-dioxide [42] involves the intermediate ion (ap), from which sulphinyl is removed. However, the principal mode of decomposition includes preferential elimination of acetylene from the molecular ion. This takes place by a mechanism of retrodiene breakdown with subsequent formation of a carbon–oxygen bond and loss of carbon monoxide (Scheme 27).

Scheme 27



Change in the size of ring in a cyclic sulphone does not affect the mode of decomposition. This was revealed in a study of thiepin 1,1-dioxide and its dihydro-derivative[44,54]. The characteristic $[M - CHO]^+$ ion peak indicates sulphone–sulphinate rearrangement of these compounds.

Scheme 28

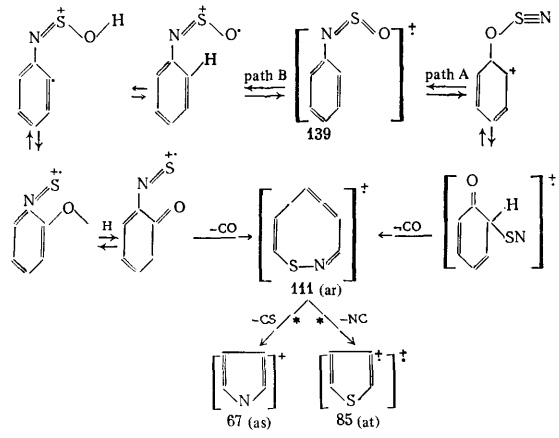


Nevertheless, although sulphur is combined with an $sp^2$-hybridised carbon atom in such compounds as thiachromanone dioxide, the molecular ion does not isomerise into a sulphinic ester[43] before decomposition begins. For example, 4-oxothiaisochroman 2,2-dioxide breaks down mainly with elimination of sulphur dioxide from the molecular ion. Retrodiene decomposition with the detachment of $CH_2SO_2$ is of secondary importance (Scheme 28). The most probable process for 4-oxothiachroman 1,1-dioxide, however, involves detachment of ethylene with subsequent elimination of sulphur dioxide. Direct removal of a sulphonyl group from the molecular ion is far less probable. Introduction of a methyl substituent into a thiachromanone does not in principle change the mode of decomposition, which involves a retrodiene reaction resulting in elimination of a $C_3H_6$ group.

Scheme 29

It is interesting that the mass spectrum of sulpholan contains peaks due to ions formed by direct detachment of SO, $HSO_2$, and $CH_3SO_2$ groups from the molecular ion. Cleavage of a carbon–sulphur bond with retention of charge on the carbon fragment is highly probable in the decomposition of this compound[55]. Nevertheless, the presence of unsaturated bonds promotes isomerisation of the molecular ion of sulpholan into a sulphinic ester with subsequent elimination of a COH group (Scheme 29). The molecular ions of mono- and di-substituted sulpholans do not undergo sulphone–sulphite isomerisation on decomposition[55], whereas tetraphenylthiophen 1,1-dioxide readily loses a sulphinyl group from the isomerised molecular ion[56,57] formed as a result of sulphur–oxygen migration of a ring carbon atom (Scheme 30).

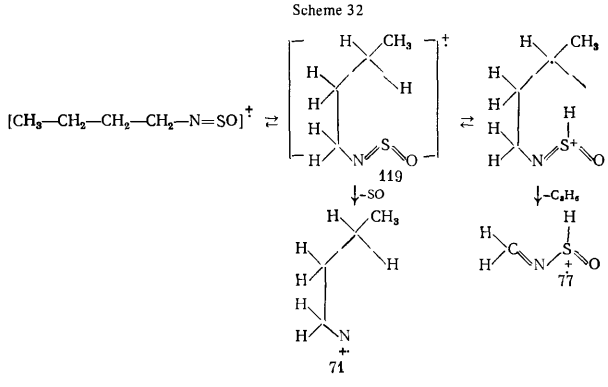
Scheme 30



It must be added that complicated cyclic keto-sulphones, which readily lose sulphur dioxide from the molecular ion, do not undergo sulphone–sulphite isomerisation[58,59].

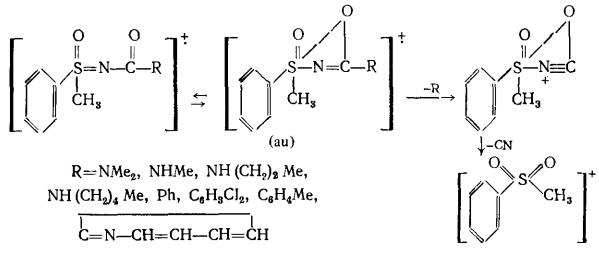
## VIII. NITROGEN-CONTAINING SULPHOXIDES AND SULPHONES

### Sulphinylanilines



The chief modes of decomposition of arylsulphinylanilines result in formation of a carbon–oxygen bond, and ions are formed even with ionising electrons of low energies. Such rearrangement should take place either with migration of the aromatic ring to the oxygen atom followed by movement of the SN group to position 2 (path A) [60] or with migration of an *ortho*-hydrogen atom from the ring to the oxygen atom followed by regrouping of the hydroxy-group in the aromatic ring (path B)[61]. In the former case the $C_{(1)}$ atom is lost, and the latter case the $C_{(2)}$ atom (Scheme 31). Study of a 1-$^{13}$C-sulphinylaniline has shown[65] that the $C_{(2)}$ atom, not $C_{(1)}$, is lost when carbon dioxide is eliminated. The $[M - CO]^+$ ion (ar) may be a cyclic ion, which then breaks down with removal of CS and HCN groups to form structures (as) and (at) respectively[62].

Scheme 31

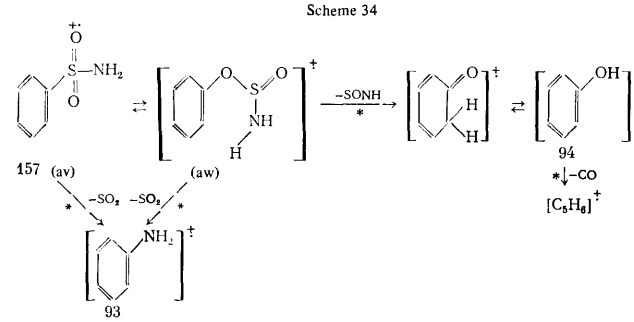


Substituted sulphinylanilines may also undergo rearrangement. The spectrum of *m*-methoxy-sulphinylaniline, for example, reveals well defined rearranged ions, whereas the mass spectra of the *ortho*- and *para*-isomers are devoid of corresponding peaks[63].

Scheme 32

Scheme 33

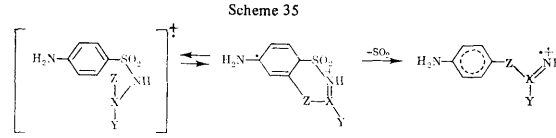
The decomposition of alkylsulphinylanilines[63-65], however, involves a McLafferty rearrangement, in which the hydrogen atom attached to the $\gamma$-carbon atom migrates to the sulphur atom, after which an ionic fragment of mass 77 is formed (Scheme 32). A second important mode of dissociative ionisation is formation of the $[M - SO]^+$ ion. When the $\alpha$- or $\beta$-carbon atom is substituted, however, simple rupture of a carbon–carbon or carbon–nitrogen bond is correspondingly more probable than a McLafferty rearrangement.



## Sulphoximines

The principal decomposition pathway of *N*-substituted sulphoximines is characterised by the appearance of $[M - R]^+$ and $[M - CH_3]^+$ ion peaks. The observed formation of a sulphone ion $[C_6H_5SO_2CH_3]^+$ is due to breakdown of the $[M - R]^+$ ion and is responsible for establishment of a bond between the carbonyl oxygen atoms and the sulphur atom in the transition state[66] (Scheme 33).

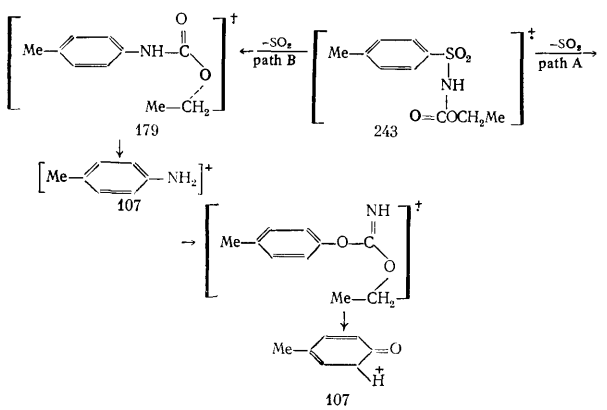
## Sulphonamides



Available data on the decomposition of sulphonamides reveal a tendency to rearrangement with removal of sulphur dioxide. Thus the mass spectrum of benzenesulphonamide and its derivatives shows well defined skeletally rearranged ions resulting from the formation of carbon–oxygen and carbon–nitrogen bonds. Two rearrangements of $(M - SO_2)$ and $(M - SONH)$ take place[36,37,67,68]. The migration of phenyl from the sulphur to an oxygen atom promotes formation of an intermediate structure (aw), from which an ion of phenolic type can then be formed (Scheme 34). The ion of the aniline radical $[M - SO_2]^+$ can probably be formed from (av) or (aw). It is noteworthy that elimination of carbon monoxide from the molecular ion is not observed in the case of sulphonamides[69].

Scheme 34

The nature of the alkyl substituent in secondary sulphonamides affects the behaviour of the compounds on electron impact. The main process is $\beta$-rupture relative to the nitrogen atom; skeletally rearranged ions are absent. When alkyl is replaced by amino the main process becomes formation of $[M - NH_2 - O_2]^+$ ions, whereas sulphonamides containing two substituents undergo fission at the nitrogen–sulphur bond with the charge retained on the nitrogen-containing fragment. Skeletally rearranged ions are represented by weak peaks. The mass spectrum contains no ion corresponding to formation of a carbon–oxygen bond.

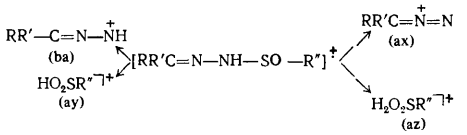


Scheme 35

The probability of the loss of sulphur dioxide increases considerably with the basicity of the substituting group in sulphonamides. With steric factors taken into account, the general direction of decomposition can be represented by Scheme 35. The behaviour of sulphonamide derivatives is explained by the influence of strongly electrophilic substituents, which create a partial positive charge and favour rearrangement with elimination of sulphur dioxide[70,71].

Evident skeletal rearrangements, associated with the appearance of $[M - SO_2]^+$ ions, are in turn characteristic also of sulphonylureas [72,73] and sulphonylcarbamates [74] containing primary, secondary, and tertiary alkyl substituents. The combination of high-resolution mass spectrometry with use of labelled compounds has established the occurrence of two decomposition processes involving rearrangement with elimination of sulphur dioxide from the molecular ion. With both groups of compounds the main process includes preferential formation of an aryl–oxygen bond (path A) and to a lesser extent an aryl–nitrogen bond (path B) followed by breakdown of the $[M - SO_2]^+$ ion with a McLafferty rearrangement. An example is the decomposition of an alkyl *N*-toluenesulphonylcarbamate (Scheme 36). The probability of decomposition of a sulphonylcarbamate by path B can be increased by strengthening the nucleophilic character of the *N*-methylated derivative or by the steric effect of the methyl substituent.

Scheme 36

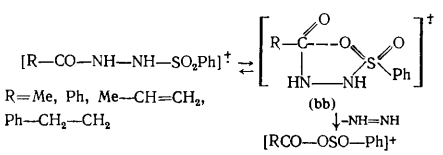


It is interesting that the spectrum of t-butyl *N*-*p*-methoxybenzenesulphonylcarbamate does not contain the $[M - SO_2]^+$ ion. The most probable decomposition involves elimination of carbon dioxide accompanied by a methyl radical. This was explained [74] by the influence on the relative stability of the aryl–sulphur and alkyl–oxygen bonds of the factors responsible for the direction of decomposition. In primary and secondary alkyl derivatives of sulphonylcarbamates the aryl–sulphur bond is weakest, so that decomposition along path B (Scheme 36) predominates. Introduction of a t-alkyl group results in some strengthening of the alkyl–oxygen bond. Yet introduction of an *N*-methyl substituent lowers the strength of the aryl–sulphur bond. This unusual change in stability of the two types of bond on the introduction of a methyl substituent is difficult to interpret in terms of the inductive effect alone, since steric factors cannot be ignored. Interaction of methyl with the sulphonyl group and the aromatic ring lengthens the aryl–sulphur bond sufficiently to neutralise the effect of the t-alkyl on the alkyl–oxygen bond. The relative stability of the former bond can be changed also by introducing various *para*-substituents into the benzene ring: electron-donating substituents will strengthen the aryl–sulphur bond in comparison with unsubstituted rings, whereas electron-accepting substituents will tend to weaken the bond [71].

## Sulphonylhydrazones, Sulphonylhydrazines, and Sulphonyl Azides

Elimination of relatively stable neutral species from ions $[ABC]^+ \rightarrow [A-C]^+ + B$ is most characteristic of sulphonylhydrazones [74]. Four ionic species are produced when the molecular ion decomposes with rupture of the nitrogen–sulphur bond. Fragments (ay) and (az) are formed with migration of hydrogen. The ion (az), into which two hydrogen atoms have migrated, is converted into (ay) when the compound contains an alkyl group with hydrogen attached to the $\alpha$-carbon atom (Scheme 37).

Scheme 37

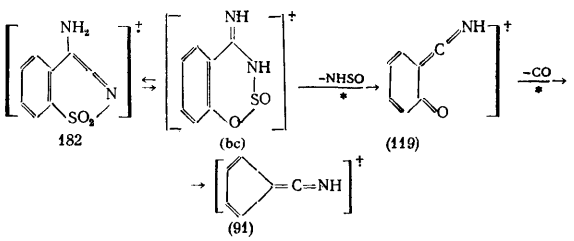


Aromatic sulphonylhydrazones (R = $C_6H_5$, R′ = H) decompose with elimination of molecular nitrogen from the ion (ax), whereas the ion (ba) rearranges with removal of a nitrile molecule from the middle of the chain.

The mass spectra of aliphatic sulphonylhydrazones indicate formation of (ba) in preference to (ax), (ay), and (az). The decomposition sequence is greatly dependent on the type and size of the aliphatic groups.

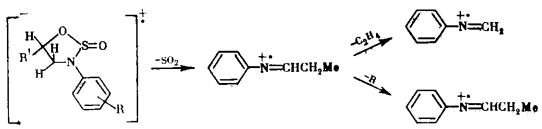
The decomposition of *N*-acyl-*N*′-*p*-toluenesulphonylhydrazines [74,75] also involves a rearrangement $[ABC]^+ \rightarrow [AC]^+ \rightarrow B^2$ with elimination of a di-imide molecule from the molecular ion, perhaps via an intermediate cyclic structure (bb) (Scheme 38).

Scheme 38



Skeletal rearrangements with elimination of sulphur dioxide from the molecular ion do not occur with sulphonyl azides [76,77]. Detachment of an azide radical is inconsistent with the photochemical behaviour, which involved elimination of nitrogen [75].

## Benzisothiazoles and Thiazolidines



Benzisothiazole derivatives [78] on dissociative ionisation undergo rearrangement with formation of an intermediate structure (bc). For example, an investigation of 3-aminobenzisothiazole 1,1-dioxide labelled with deuterium in the amino-group confirmed the occurrence of decomposition in conformity with Scheme 39.

Scheme 39

*ortho*-Alkylated derivatives undergo rupture with migration of two hydrogen atoms and loss of an alkyl group followed by elimination of sulphur dioxide from the ionic fragment.

Scheme 40

Higher homologues are characterised by decomposition with McLafferty rearrangement, but *N*-substituted compounds by elimination of an alkylamine from the molecular ion. Direct detachment of sulphur dioxide is improbable. Yet various oxathiazolidines [79,80] undergo rearrangement with removal of sulphur dioxide (Scheme 40). The probability of formation of an $[M - SO_2]^+$ ion varies with the nature and the position of the substituent. Thus with chloro-derivatives this is the most intense peak in the mass spectrum of the *ortho*-isomer, whereas with the methyl derivatives the $[M - SO_2]^+$ ion peak has approximately the same intensity for all the isomers. Its subsequent decomposition can take place in two ways, with elimination of ethylene or of the ring substituent.

The chief mode of decomposition of oxothiazolidine having a t-butyl substituent in the ring [81] involves loss of a methyl radical preceding elimination of sulphur dioxide, whereas introduction of a chloromethyl substituent into the oxathiazolidine ring [82] suppresses the rearrangement associated with the elimination. With such a compound sulphur dioxide and a chlorine radical are detached in a single stage.

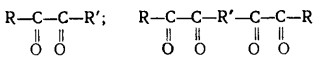
# Mono- and Bis-α-diketones and Related Polymers

E.S.Krongauz



Published information on the methods of preparation and the reactions of mono- and bis-α-diketone is reviewed. Special attention is paid to use of the latter to obtain heat-resistant and thermostable polymers, in particular polyphenylquinoxalines. A list of 201 references is included.

CONTENTS

I. Introduction 59
II. Methods of preparation of α-diketones 59
III. Reactions of α-dicarbonyl compounds 64
IV. Bis-α-dicarbonyl compounds in the preparation of heterocyclic polymers 67

## I. INTRODUCTION

The past decade has witnessed appreciable heightening of interest in mono- and bis-α-dicarbonyl compounds of general types

(where R and R′ represent aliphatic or aromatic groups), which are finding ever wider application in organic synthesis in virtue of their high reactivity. Such compounds provide a basis for obtaining aliphatic, aromatic, and heterocyclic products, whether of low or high molecular weight, possessing several valuable properties. Previous reviews[1-3] have paid insufficient attention to methods for the preparation of α-diketones, and have completely disregarded their chemical reactions and practical application. The present Review aims to fill this gap, paying special attention to methods of preparation that have already found or may find application in obtaining bis-α-dicarbonyl compounds, and also to the use of the latter in the synthesis of thermostable high polymers. Although compounds containing α-diketone groupings are mainly considered, methods of obtaining α-keto-aldehydes and polymers based on them are also included.

## II. METHODS OF PREPARATION OF α-DIKETONES

Existing methods for preparing α-diketones can be separated into the following main groups—(1) oxidation of acyloins, (2) oxidation of α-methylene-carbonyl compounds, (3) oxidation of compounds containing carbon–carbon multiple bonds, and (4) other methods.

### 1. Oxidation of Acyloins

The first observations indicating that benzoin could be oxidised by nitric acid to benzil were made more than a century ago by Zinin[4]. Since then the reaction conditions and the oxidising agents have been varied. The most widely used oxidants have been copper(II) salts, applied in the presence of regenerating agents (air, ammonium nitrate): e.g.[5]

$$RCH(OH)COR' + 2\,Cu(OAc)_2 \rightarrow RCOCOR' + 2\,CuOAc + 2\,AcOH\ ,$$
$$2\,CuOAc + NH_4NO_3 + AcOH \rightarrow 2\,Cu(OAc)_2 + NH_4NO_2 + H_2O\ ,$$
$$NH_4NO_2 \xrightarrow{H^+} N_2 + 2H_2O\ .$$

Acetic acid not only acts as solvent but also favours decomposition of the ammonium nitrite formed in the regeneration of copper(II). The yield of α-diketones is often nearly theoretical. This reaction is specific to acyloins, for benzaldehyde, benzhydrol, and mandelic acid are not oxidised under these conditions[5].

Table 1. Characteristics of α-diketones from acyloins.

| α-Diketone | Yield, % | M.p., °C | Ref. |
|---|---|---|---|
| (*a*) Oxidation by $Cu^{II}$ sulphate in pyridine | | | |
| Benzil | 86-97 | 94.5 | 6 |
| *o*-Methoxybenzil | 60 | 71-72 | 7 |

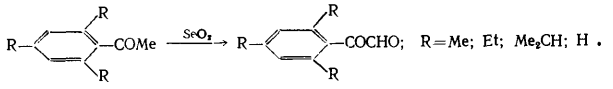
*Boiling points given (*p*, mmHg).

Table 1 gives some data on α-diketones obtained by oxidising acyloins with salts of bivalent copper[5-17]. Salts of tervalent iron can also be used for this purpose[10,18-20].

## 2. Oxidation of α-Methylene-carbonyl Compounds

In 1932 Riley et al.[21] first showed that selenium dioxide is a specific reagent for oxidising a methylene-carbonyl group to dicarbonyl. Since then the dioxide has been widely used for obtaining α-dicarbonyl compounds from aliphatic or aliphatic–aromatic aldehydes and ketones under mild conditions. In contrast to chromic acid, potassium permanganate, and other reagents that oxidise primarily the carbonyl group, selenium dioxide acts on a methyl or methylene group attached to various activating groups—alkene, alkyne, aldehyde, ketone, carboxyl, ester, amide, anhydride, nitrile, or an aromatic ring—where the degree of activation varies within wide limits[22-28]. Oxidation can be accomplished either in the absence of a solvent or in various organic solvents not oxidised by selenium dioxide—in alcohol, acetic anhydride or acid, or dioxan[29].

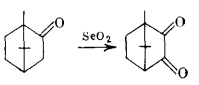


Oxidation occurs most simply with carbonyl compounds $RCH_2COR'$ having one active position, when high yields of α-dicarbonyl products are obtained. For example, acetaldehyde gives a 90% yield of glyoxal[21,29]:

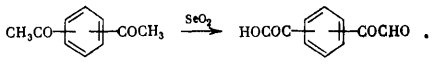
$$CH_3CHO \xrightarrow{SeO_2} CHOCHO .$$

Propionaldehyde and butyraldehyde form methyl- and ethyl-glyoxal respectively; phenylacetaldehyde is converted into phenylglyoxal; etc.[29] The rate of oxidation of aliphatic aldehydes decreases with increase in their molecular weight[30]. α-Keto-aldehydes or α-diketones are the main products of the oxidation of ketones by selenium dioxide[21,22,30-46]. Thus acetone is converted into methylglyoxal in 60% yield[21], and acetophenone into phenylglyoxal in 50% yield[21,47]. α-Diketones are obtained in high yields when various substituted benzyl phenyl ketones are oxidised with selenium dioxide; for example, deoxybenzoin and its derivatives containing various unoxidisable substituents in the ring are converted into theoretical yields of benzils[29,48]:

$$ArCCH_2Ar' \xrightarrow[96-100\%]{SeO_2} Ar{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}Ar' .$$



Here the methylene group is doubly activated, and the steric conditions do not favour secondary aldol condensation. 2,4,6-Trialkylacetophenones are oxidised without steric hindrance to the corresponding glyoxals[49-51]:

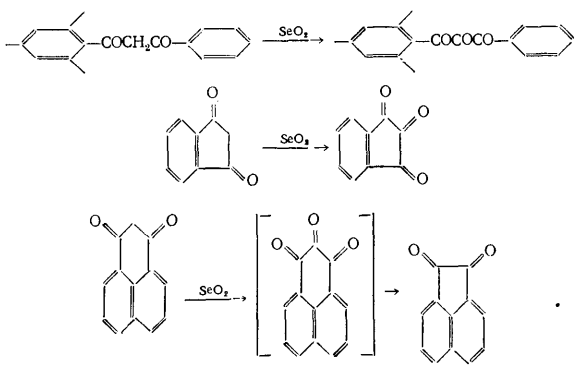


It is interesting that a higher yield of phenylglyoxal is obtained by the oxidation of acetophenone than by that of phenylacetaldehyde, which is probably due to the liability of the latter to undergo aldol condensation[3]. The oxidation of ω-bromoacetophenone in methanol gives an 80% yield of methyl phenylglyoxylate[52]:

$$PhCOCH_2Br \xrightarrow[MeOH]{SeO_2} PhC(O)C(O)OMe .$$

Non-aromatic systems, having only one position open to attack, give high yields of α-diketones when oxidised. For example, camphor is converted into camphorquinone in 90% yield[53], and α-santene forms the corresponding dione in quantitative yield[55]. Several bicyclic compounds containing a methylene-carbonyl grouping also give α-diketones[53,56]:

Nor does the presence of two equivalent α-methylene-carbonyl functions in the molecule present special difficulties in oxidation. Thus *p*- and *m*-diacetylbenzene are oxidised to the corresponding diglyoxals[57,58]:



This reaction formed the basis for the later development of general methods for preparing diglyoxals of type $CHOCOArCOCHO.2H_2O$ [59-64] (Table 2) and bis-α-diketones of general formula $Ar'COCOArCOCOAr'$ [65-80] (Table 3, No. 1–9 and 15–25).

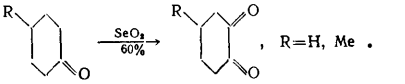


Table 2. Aromatic bisglyoxals[59-64].

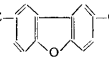
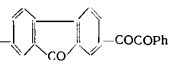
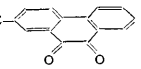
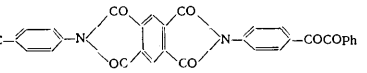
| No. | Compound | M.p., °C (decomp.) |
|---|---|---|
| 1 | HOCOC–Ar–COCOH·2H₂O | 162—164 |
| 2 | HOCOC–Ar–Ar–COCOH·2H₂O | 162—166 |
| 3 | HOCOH–(Ar)₃–COCOH·2H₂O | 211—214 |
| 4 | HOCOC–Ar–O–Ar–COCOH·2H₂O | 141—143 |
| 5 | HOCOC–(Ar–O–)₂Ar–COCOH·2H₂O | 157—160 |
| 6 | HOCOC–(Ar–O–)₃Ar–COCOH·2H₂O | 154—156.5 |
| 7 | (H₂O·HOCOC–Ar–O–Ar–)ₓ | 178—180 |
| 8 | HOCOC–Ar–SO₂–Ar–COCOH·2H₂O | 138—139 |
| 9 | HOCOH–Ar–S–Ar–COCOH·2H₂O | 100—100.5 |
| 10 | HOCOC–Ar–COCOH·2H₂O | 110—111 |

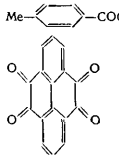
Several systems containing β-diketone groups can be oxidised to 1,2,3-triones[54,56]:

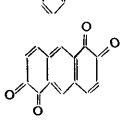












Oxidation by means of selenium dioxide presents no difficulties also with symmetrical systems containing two equivalent groups separated by an activating centre. For example, cyclohexanone and 4-methylcyclohexanone are oxidised to cyclohexane-1,2-dione and 4-methylcyclohexane-1,2-dione respectively[21,81]:

1,2-Diones are formed more slowly from cyclopentanone and cycloheptanone than from cyclohexanones, and cyclooctanone does not give diones at all[42]. Alicyclic ketones

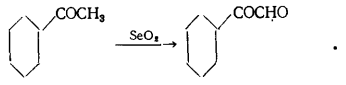
(cyclohexanone and the isomeric methylcyclohexanones) are oxidised by selenium dioxide more rapidly than are aromatic and aliphatic ketones containing the same number of carbon atoms. 4-Methylcyclohexanone is oxidised most rapidly, and the 2-methyl isomer the most slowly[42,81].

It is often observed that only one of two or more oxidisable groups is predominantly oxidised. Thus the doubly activated methylene group in pentane-2,4-dione is oxidised to give a 29% yield of the final product, which indicates the simultaneous occurrence of side-reactions:



$$CH_3COCH_2COCH_2 \xrightarrow{SeO_2} CH_3COCOCOCH_3 .$$

*trans*-2-Decalone (which enolises at the 3 position) forms the 2,3-dione in 60–65% yield[46]:

3-Keto-steroids are oxidised by selenium dioxide to the corresponding 2,3-diones[46].

Under comparable conditions the oxidation of α-methyl groups by selenium dioxide is more vigorous than that of α-methylene. Thus cyclohexyl methyl ketone gives a 59% yield of cyclohexylglyoxal:

More butane-1,2-dione than butane-2,3-dione is formed by the oxidation of butan-2-one[21]:

$$CH_3COCH_2CH_3 \xrightarrow{SeO_2} \underset{(17\%)}{CH_3CH_2COCHO} + \underset{(1\%)}{CH_3COCOCH_3} .$$

The reason for such behaviour is still obscure. It may be supposed that steric factors play an important part, as well as secondary processes involving further oxidation, polymerisation, etc. of the products. The rates of oxidation of aldehydes and ketones by selenium dioxide depend on their structure and the reaction conditions. The rate falls with increase in the molecular weight of aldehydes and of straight-chain alkyl methyl, dialkyl, and alkyl phenyl ketones, as well as in the presence of secondary and tertiary groups in the α-position with respect to the carbonyl[82]. Alkyl methyl ketones are oxidised more rapidly than are straight-chain aldehydes containing the same number of carbon atoms[30]. Ketones of general formula $C_6H_5[CH_2]_nCOCH_3$ with $n$ and even number are oxidised more slowly by selenium dioxide than are ketones containing an odd number of methylene groups[3]. The nature of the substituent influences the rate of oxidation of substituted acetophenones: thus the rate constants for oxidation by selenium dioxide of the compounds $RC_6H_4COCH_3$ in 75% acetic acid decrease according as R represents[3]

$$p\text{-I} > p\text{-M} > \text{H} > p\text{-MO} > p\text{-Cl} > p\text{-Br} > m\text{-}NO_2 .$$

The rate constant of the oxidation of ketones by selenium dioxide depends also on the solvent: it is lower in alcohols than in acetic acid, which is related to the formation of complexes between ketones and alcohols. The oxidation of ketones by selenium dioxide is catalysed by acids[3].

## MECHANISM OF OXIDATION BY SELENIUM DIOXIDE

Although the oxidation of aldehydes and ketones by selenium dioxide has been the subject of many detailed studies, its mechanism cannot be regarded as fully established.

The first kinetic data on this reaction in 75% acetic acid, obtained from gravimetric determinations of the precipitate of colloidal selenium, were published by

Mel'nikov et al.[3] These workers stablished the second order, and noted that the reaction was controlled by enolisation of the ketonic group by means of a hydrogen atom from the $\alpha$-carbon atom, since ketones incapable of enolisation are not oxidised by selenium dioxide.

Later Duke[83] suggested the third order for this reaction, regarding formation of an intermediate reactive complex as the rate-determining stage:

$$RCOCH_2R' + SeO_2 - H^+ \xrightarrow{\text{slow}} \left[ \begin{matrix} R-C-CH_2R' \\ \| \\ O \rightarrow SeO \\ \quad\quad \backslash OH \end{matrix} \right]^+ .$$

The most careful investigation was made by Corey and Schaefer[29], although doubt was cast on their results by Waters et al.[84] Deoxybenzoin was chosen for investigation, having only one possible oxidisable position and forming benzil in theoretical yield:

$$PhCOCH_2Ph \xrightarrow{SeO_2} PhCOCOPh + Se + H_2O.$$

The introduction of various substituents into the aryl groups revealed their electronic influence on the oxidation. Kinetic measurements were made by titrating the unchanged selenous acid in 70% acetic acid over a wide range of substrate and selenium dioxide concentrations. The results indicated the third order in conformity with the equation

$$-d[SeO_2]/dt = k[SeO_2] \cdot [PhCOCH_2Ph] \cdot [H^+] .$$

Electron-donating groups in the benzyl component and electron-accepting substituents in the benzoyl group increased the reaction velocity. The easier oxidation of benzyl methyl ketone than of acetone indicated that the course of the reaction was not affected by steric hindrance at the carbonyl group. On the other hand, steric hindrance at the $\alpha$-methylene group explains why the rate of oxidation of phenyl 2,4,6-trimethylbenzyl ketone is around 10% of that of benzyl methyl ketone. Benzoin is not an intermediate product, since it is oxidised at one-twentieth of the rate of oxidation of deoxybenzoin. The reaction is initiated by bases (alkali-metal acetates), is insensitive to radical initiators and inhibitors, and hence cannot be described in terms of a radical-chain mechanism.

On the basis of the above results the following mechanism was suggested[29] for the oxidation of deoxybenzoin by selenium dioxide:

$$ArCOCH_2Ar' + HSeO_3^+ + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\quad\quad | \\ \quad OSeO_2H}{ArC=CHAr'} + H_2O + H_3O^+ \rightarrow$$

$$\rightarrow ArCO-\underset{\quad\quad | \\ \quad OSeOH}{CH}-Ar' \rightarrow ArCOCOAr' .$$

This is analogous to acid-catalysed enolisation, and has closely similar Hammett constants. According to the above mechanism unsymmetrical ketones should be oxidised on the side on which they are enolised in an acid. Thus *trans*-2-decalone will be enolised and oxidised at the 3 position. However, there are exceptions: as remarked earlier, the oxidation of ethyl methyl ketone yields 17% of ethylglyoxal and only 1% of biacetyl, although enolisation should take place at the methylene group[21]. The low yield of butane-2,3-dione can be attributed to its degradation by secondary reactions after it has been formed. The selenous ester of the enol may be assumed to rearrange more rapidly than biacetyl is formed from it.

Since benzoin is not an intermediate product in the oxidation of deoxybenzoin, it may be concluded that the formation of benzil is more rapid than is solvolysis of the intermediate product to benzoin. This conclusion is not entirely consistent with results obtained by Schaefer and Horvath[85] in a study of the behaviour of analogous intermediate products in the oxidation of alkenes. However, the difference can be attributed to the circumstance that, whereas solvolysis of intermediate products in the oxidation of alkenes yields resonance-stabilised cations, solvolysis of intermediate products in the oxidation of deoxybenzoins is always accompanied by the appearance of a positive charge on the carbon atom adjacent to the positive end of the carbonyl dipole. The $\alpha$-hydrogen atom is then acidic owing to the contiguity of the carbonyl, and is more liable to direct abstraction under the influence of bases:

$$Ar-\underset{\quad\quad \| \\ \quad O}{C}-\underset{H}{C}(-O-Se-OH)-Ar' \xrightarrow{B^-} ArCOCOAr' + H_2O + Se .$$

Formation of the selenous ester of the enol was regarded[29] as the rate-determining stage. An attempt was made to use the suggested mechanism to explain the formation from certain ketonic systems of $\alpha\beta$-unsaturated compounds instead of the expected $\alpha$-diketones, as well as the greater rapidity of the oxidation of aldehydes and ketones than of the aldol condensation, but the latter is still not entirely clear.

### 3. Oxidation of Compounds containing Carbon–Carbon Multiple Bonds

Compounds of transition metals, because of their stability and adequate selectivity towards different functional groups and also unsaturated bonds, occupy an important place among the oxidising agents used in organic chemistry[86]. The principal oxidant used for a triple bond C≡C is potassium permanganate in neutral or weakly acid medium, when the main undegraded products of the oxidation of alkynes are $\alpha$-diketones and $\alpha\beta$-unsaturated alcohols[87]. The oxidation of acetylenic bonds by potassium permanganate has recently been successfully applied to the preparation of bis-$\alpha$-diketones, previously obtained by oxidising the corresponding deoxybenzoins with selenium dioxide (Table 3, No. 3–7 and 10–12):[76,88,89]

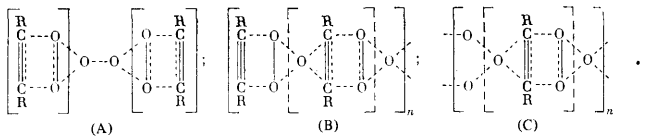
$$Ph{\equiv}C-Ar-C{\equiv}CPh \xrightarrow{KMnO_4} PhC(=O)-C(=O)-Ar-C(=O)-C(=O)-Ph$$

(Ar = arylene). Potassium permanganate in acetic anhydride has been used to obtain $\alpha$-diketones from cycloalkenes of the type[90]

$$(CH_2)_{10}\begin{matrix} CH \\ \| \\ CH \end{matrix} \rightarrow (CH_2)_{10}\begin{matrix} C=O \\ | \\ C=O \end{matrix} + (CH_2)_{10}\begin{matrix} C=O \\ | \\ CHOAc \end{matrix} + (CH_2)_{10}\begin{matrix} COOH \\ | \\ COOH \end{matrix} .$$

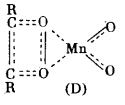
However, this method was unsuitable for the preparation of $\alpha$-diketones from small rings (below cyclo-octene). The explanation proffered was that reaction takes place only when the carbonyl groups in the expected $\alpha$-diketone are incapable of cisoid orientation. This oxidising system is advantageous because many organic compounds dissolve in acetic anhydride. In several cases, however, dimethoxyethane alone or added to acetic anhydride is recommended as solvent[90].

Numerous attempts have been made to use other oxidants, but convenient preparations of $\alpha$-diketones have not resulted. Oxidation by organic peroxy-acids yields various products depending on the conditions and the acid



used[91]. Thus trifluoroperacetic acid converts diphenylacetylene into benzil and benzoic acid, the latter obviously a product of further oxidation of the benzil:

$$PhC{\equiv}CPh \xrightarrow[Na_2HPO_4,\ CH_2Cl_2]{2CF_3CO_3H} \underset{(76\%)}{PhCOCOPh} + \underset{(17\%)}{PhCOOH}\ .$$



More highly oxidised products—finally a mixture of carboxylic acids or their esters—are obtained by the action of perbenzoic, peracetic, and trifluoroperacetic acids on penylacetylene, involving cleavage of the triple bond[92]. One reason suggested was the intermediate formation of [1,3-dioxabicyclo[1,1,0]butanes:]

$$R{-}C{\equiv}C{-}R' \rightarrow \left[R{-}C\begin{matrix}O\\ \diagup\\ \diagdown\\ O\end{matrix}C{-}R'\right] \rightarrow RC{-}C{-}R' + RCOOH + R'COOH\ .$$

Oxidation of a carbon–carbon triple bond has been accomplished by means of selenium dioxide in the presence of catalytic quantities of sulphuric acid[93], thallium trinitrate[94], ozone[95,96], tetracarbonylnickel in the presence of alkyl halides[97], bromosuccinimide in anhydrous dimethyl sulphoxide (e.g. No. 26 in Table 3), [98,99] oxides of nitrogen[100], and ruthenium tetraoxide[101]. In spite of good yields of α-diketones, however, these oxidants have not found wide application for preparative purposes.

Molecular aspects of mechanisms of the oxidation of acetylenic compounds to α-diketones by singlet oxygen, ozone, and potassium permanganate in neutral or weakly alkaline media have been discussed[102]. The oxidation is assumed to involve intermediate formation of dioxetans without the involvement of "ene", free-radical, or ionic processes, since traces of peroxides or products of an "ene" reaction are not detected when singlet oxygen is used. Ozonisation also involves formation and decomposition of a dioxetan as molecular intermediate transition complex (A), whose breakdown is accompanied by rapid evolution of singlet oxygen. The complex (A) may undergo rearrangement into the thermodynamically more stable complexes (B) and (C), which also decompose into monomeric ozonides and singlet oxygen. Oxidation by potassium permanganate (pH 7) involves intermediate formation of the complex

which then breaks down into the α-diketone, singlet oxygen, and manganese dioxide.

## 4. Other Methods of Preparation of α-Diketones

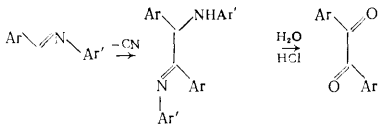
To complete the account mention must be made of a few other methods of obtaining α-diketones, which have not become widely used. Thus they can be obtained from monoximes or isonitroso-ketones, formed by the action of nitrous acid on ketones $RCOCH_2R'$; as well as via dioximes, which are produced by replacing the nitrous acid by an alkyl nitrite, hydroxylamine, or an aromatic nitroso-compound[103]. Condensation of isonitroso-ketones with diazo-compounds has been used to obtain several aryl methyl α-diketones[1]:

$$MeCOC\begin{matrix}H\\ \diagdown\\ NOH\end{matrix} \xrightarrow{ArN_2Cl} \left[MeCOC\begin{matrix}N:N\cdot Ar\\ \diagdown\\ NOH\end{matrix}\right] \rightarrow MeCOC\begin{matrix}Ar\\ \diagdown\\ NOH\end{matrix} \rightarrow MeCOCOAr\ .$$

α-Diketones can be prepared by the action of organomagnesium compounds on vinylidenoxanilide[1]:

$$\begin{matrix}O{=}C{-}N\\ |\\ O{=}C{-}N\end{matrix}\begin{matrix}Ph\\ \diagdown\\ C{=}CH_2\\ \diagup\\ Ph\end{matrix} \xrightarrow{2\,MeMgI} MeCOCOMe\ .$$

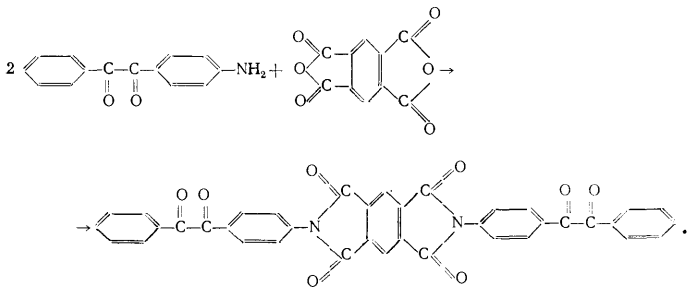
αβ-Unsaturated monoketones (e.g. vinyl ketones) will yield α-diketones by the series of reactions[1]



$$RCOCH{=}CHR' \xrightarrow{Br_2} RCOCHBrCHBrR' \xrightarrow{-HBr} RCOCBr{=}CHR' \xrightarrow{+\text{piperidine}} \rightarrow RCOCBr(NC_5H_{10})CH_2R' \xrightarrow{-HBr} RCOC(NC_5H_{10}){=}CHR' \xrightarrow{+H_2O} RCOC(OH){=}CHR' \xrightarrow{-H_2O} RCOCOR'.$$

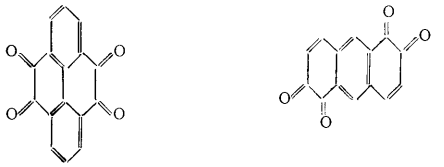
Several α-diketones can be obtained by the Friedel–Crafts condensation of phenyl ethers, e.g. anisole, with oxalyl chloride[104]:

$$2\,MeOC_6H_5 + ClOC{-}COCl \xrightarrow[CS_2]{AlCl_3} \underset{(90\%)}{4\text{-}MeOC_6H_4COCOC_6H_4OMe\text{-}4'}\ .$$



In most cases, however, the ethers are insufficiently reactive, and the oxalyl chloride decomposes under the influence of the aluminium chloride before it can react with the ether.

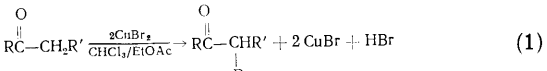
A convenient method published recently involves oxidative dimerisation of several aromatic aldimines in the presence of the cyanide ion, followed by hydrolysis of the α-diketimines formed as intermediates[105]:



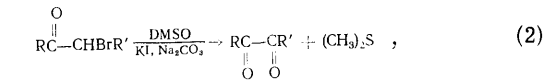
The reaction is usually conducted in dimethyl sulphoxide or dimethylformamide at room temperature, when the yield of α-diketones reaches 85–95%.

Bis-α-diketones containing imide rings (Table 3, No.13 and 14) have been prepared by an original route consisting in the action of *p*-aminobenzil on the dianhydride of a tetracarboxylic acid[70,106]. In the case of pyromellitic dianhydride the reaction can be written

The di-*o*-quinones used in the synthesis of ladder polyphenylquinoxalines—4,5,9,10-tetrahydro-4,5,9,10-tetraoxopyrene (I) and 1,2,5,6-tetrahydro-1,2,5,6-tetraoxoanthracene (II)



I II



(Table 3, No. 27 and 28)—are obtained by special methods. The first step in the preparation of (I) is oxidation by ozone of pyrene to 5-formylphenanthrene-4-carboxylic acid, which on treatment with phenylhydrazine followed by reduction is converted into 4-amino-5-hydroxypyrene, and this is oxidised to the 4,5-quinone. The most difficult step is the further oxidation of this diketone to the diquinone, conducted in acetic acid by means of aqueous chromium trioxide. After crystallisation from nitrobenzene the total yield of (I) does not exceed 15%.[107]

The second di-*o*-quinone (II) is obtained by treating anthracene-2,6-diol with a solution of zinc chloride and sodium nitrite. Subsequent reduction of the resulting 1,5-dioxime with sodium dithionite forms 1,5-diaminoanthracene-2,6-diol, whose oxidation with sodium dichromate in dilute sulphuric acid gives the 1,2,5,6-tetraketone (II) in a total yield of 3% (after crystallisation from dioxan)[108].

A two-stage preparation of α-diketones from α-methylene-ketones involves intermediate formation of α-bromoketones, which are then oxidised with dimethyl sulphoxide in the presence of iodide ions[109]:

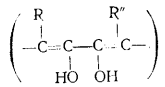
(1)

(2)

where R and R′ = Alk or Ar. The total yield of α-diketones reaches 65–92%.

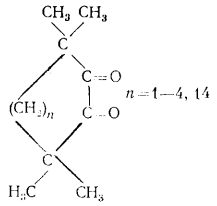
## III. REACTIONS OF α-DICARBONYL COMPOUNDS

The simultaneous presence of two carbonyl groups ensures that α-diones are able to undergo not only all the reactions of simple aldehydes and ketones but also reactions leading to the formation of heterocyclic systems. Either one or both carbonyl groups may react depending on the conditions[110].



The contiguity of the two carbonyl groups is responsible for the colour of α-diketones. These compounds may exist either in the diketonic form

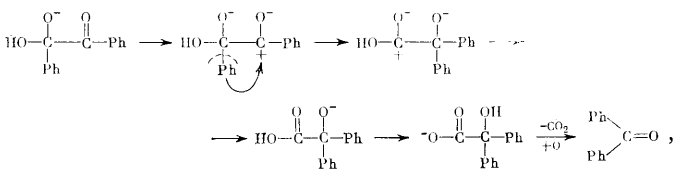
in the monoenolic form



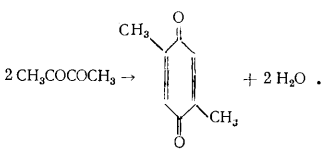
or in the dienolic form

depending on several factors, primarily the nature of substituents adjacent to the carbonyl groups. Thus acyclic α-diketones (e.g. butane-2,3-dione) are true diketones and possess a yellow colour: cyclic α-diketones are usually colourless and react typically tautomerically, forming both monoximes and dioximes[111]. When enolisation is sterically hindered, as e.g. in camphorquinone, cyclic diketones also have a yellow colour.

Investigation on a series of α-substituted diketones have shown that the ultraviolet spectra of all the compounds contain two maxima, at 219–269 and 391–421 nm, which are assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ electron transitions respectively. The position of the second maximum depends on the nature of the substituent governing the spatial arrangement of the carbonyl groups. The same factors determine absorption by the carbonyl groups in the infrared spectra[112].



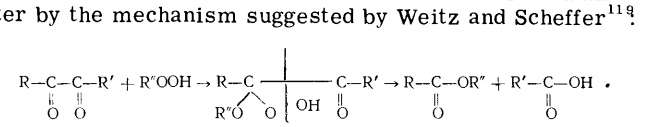
Study of the influence of steric configuration on the ultraviolet spectra of α-diketones of the type



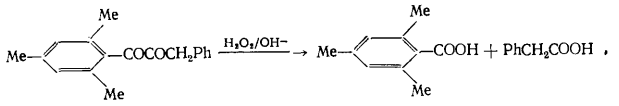
has shown that the position of absorption bands at the longer wavelengths correlates with the relative steric orientation of the carbonyl groups, which is supported by inspection of molecular models. The position of the bands varies with the angle between the planes of the carbonyl groups: a band moves to shorter wavelengths with increase in the angle from 0 to 90°, and moves back to longer wavelengths with further increase in the angle (>90°).[113]

### 1. Action of Alkalis

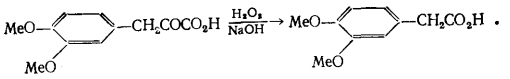
Under the influence of alkalis α-diketones tend to undergo a so called benzil rearrangement. This has been studied in greatest detail on and named after benzil itself. The benzil rearrangment compares formally with the pinacol rearrangement



where the benzil molecule is written in hydrated form. Butane-2,3-dione is characterised by condensation, in the presence of an alkali, to a cyclic xyloquinone[37]:

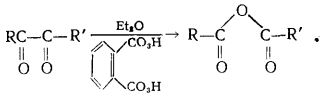


### 2. Action of Acids and Peroxides



The carbonyl–carbonyl bond undergoes cleavage when α-dicarbonyl compounds are treated with peroxy-acids or peroxides[116–118]. The first stage probably involves 1,2- or 1,4-addition of hydroxy-groups to the system with formation of an unsymmetrical product, subsequent cleavage of which (e.g. in the case of ethyl hydroperoxide) yields either two acid molecules or a mixture of an acid and an ester by the mechanism suggested by Weitz and Scheffer[119].

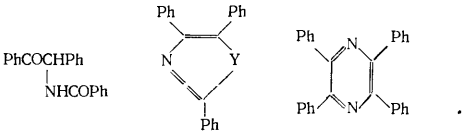
Alkaline hydrogen peroxide also splits α-dicarbonyl compounds to give high yields of the corresponding carboxylic acids[120,121]:



α-Keto-acids are readily decarbonylated under these conditions[122]:

Complicated mixtures are obtained by the action of a hydroxamic acid in the presence of concentrated sulphuric acid. The example of benzil shows that this reaction also involves bond rupture between the two carbonyls. The main product, N-benzoyl-N'-phenylurea, is then accompanied by 5-anilinotetrazole, 5-amino-1-phenyltetrazole, 5-benzamido-1-phenyltetrazole, and minute quantities of benzoic acid, aniline, and other products[123].

α-Dicarbonyl compounds react rapidly with peroxyacids. The structure of the anhydrides isolated from the reaction was regarded[124] as indicating migration of an acyl group:

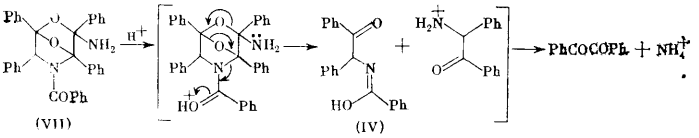


## 3. Hydrogenation

The selectivity of the hydrogenation of α-diketones is determined by the nature of the catalyst and the conditions of the reaction[125-128]. Thus reduction at a copper cathode in aqueous medium converts benzil into benzoin[125]. 1,2-Diphenylethane is formed when zinc amalgam is used as cathode in an aqueous–alcoholic solution of an acid (sulphuric) at 70–90°C.[125] The use of relatively inactive catalysts—platinum on carbon, Raney nickel, palladium on poly(methyl methacrylate)—enables hydrogenation to be arrested after 80 min, at the *meso*-1,2-diphenylethane-1,2-diol stage. Further saturation with hydrogen (for 30 h) also yields 1,2-diphenylethane[125].

When benzil is heated with sodium tetrahydroborate or lithium tetrahydroaluminate in methanol at 60°C, *meso*-1,2-diphenylethane-1,2-diol is formed[126]. Heating benzil with potassium iodide, red phosphorus, and concentrated hydrochloric acid for 15 h enabled deoxybenzoin to be isolated, together with minute quantities of 1,2,3,4-tetraphenylbutane-2,3-diol[127].

## 4. Action of Ammonia and Amines



The action of ammonia on benzil has led to the isolation of various products depending on the solvent, the temperature, and the duration of the reaction—ethyl benzoate, benzamide, N-desylbenzamide (IV), and three aromatic heterocycles—2,4,5-triphenyloxazole (Va), 2,4,5-triphenylimidazole (Vb), and tetraphenylpyrazine (VI)[129]

(IV) (V) (VI)

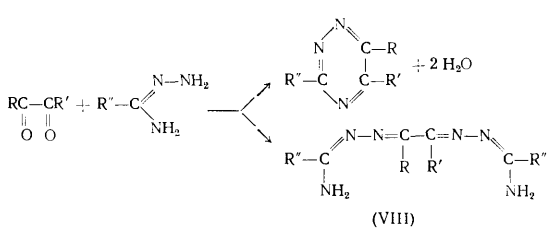
a) Y=O;
b) Y=NH

Later another product (VII), of high molecular weight and empirical formula $C_{35}H_{28}O_3N_2$, was isolated. It was regarded as formed via an intermediate complex containing three benzyl groups per ammonia molecule, whose disproportionation gave compounds (IV) and (VII). The latter was assumed to be labile, readily decomposing in the presence of acids and alkalis to form (IV), benzil, and other products[130,131]:

(VII) (IV)

α-Dicarbonyl compounds react vigorously with hydroxylamine at one or both carbonyl groups to form monoximes and dioximes[132,133]:

Alkalis abstract a water molecule from dioximes and convert them into furazans[134]:



The action of semicarbazide on α-diketones is similar: mono- or di-semicarbazones or cyclic condensation products are formed depending on the reaction conditions. With phenylhydrazine mono- or bis-phenylhydrazones are obtained also depending on the conditions[135-138]. Oxidation of the latter products (osazones) can be represented as

Several reports have appeared of the formation of Schiff bases by the action of amines on glyoxal and biacetyl[139,140]:

The reaction between α-dicarbonyl compounds and amidrazones, yielding either 1,2,4-triazines or acyclic products such as (VIII)

(VIII)

has been discussed in a review by Rusanov[141].

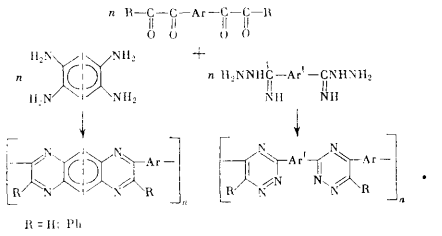
*Data for long-wavelength absorption maximum.

The reaction of greatest interest and practical importance is the quantitative cyclocondensation of $\alpha$-dicarbonyl compounds with aromatic $o$-diamines, which led to the discovery in 1884 of a new class of heterocyclic compounds—the quinoxalines[142,143]:

The chemistry of quinoxaline has been actively developed since then: diverse derivatives have been prepared, their physical and chemical properties have been studied, and possible practical applications have been examined[144].

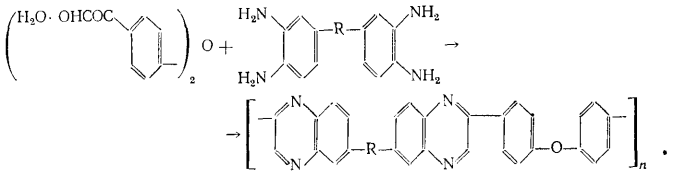
The reaction of bis-$\alpha$-dicarbonyl compounds with aromatic $o$-diamines or of $\alpha$-dicarbonyl compounds with bis-$o$-diamines yields bisquinoxalines of diverse structure (Table 4):



R=R′=H, Ph; R″=$CH_2$; O; $SO_2$; CO; S; —; Ar = arylene

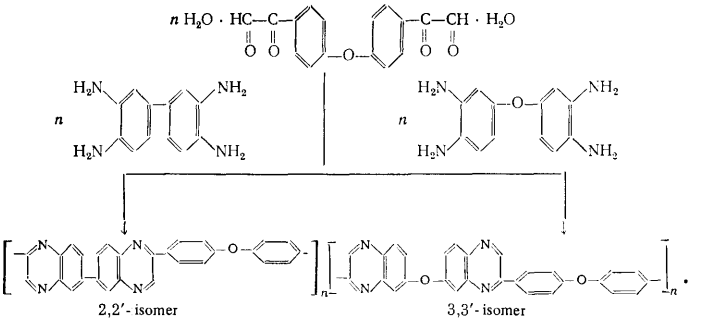
Spectral investigations show that wavelengths $\lambda_{max}$ are the same for compounds containing $p$-diphenylene ether units between unsubstituted quinoxaline rings. Replacement of these bridges by $p$-phenylene units produces a bathochromic shift in $\lambda_{max}$, which increases on passing from $p$-phenylene to $p$-biphenylylene and to $p$-terphenylylene, which is evidence of the presence of conjugation in the system. Introduction of phenyl substituents into the pyrazine ring has an analogous effect[65], which indicates that the quinoxaline and phenyl units are coplanar.

## IV. BIS-$\alpha$-DICARBONYL COMPOUNDS IN THE PREPARATION OF HETEROCYCLIC POLYMERS



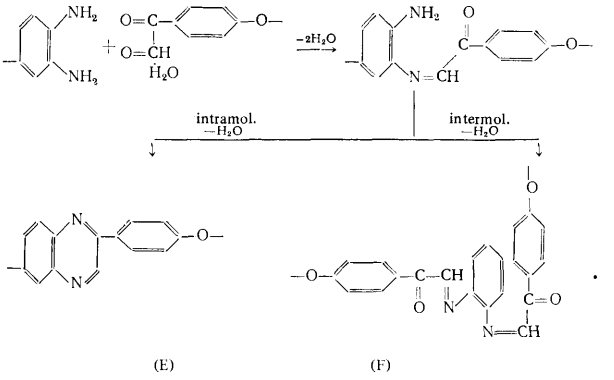
Whereas $\alpha$-dicarbonyl compounds have as yet found limited practical application only for obtaining certain quinoxaline derivatives exhibiting pharmacological activity[144], bis-$\alpha$-dicarbonyl compounds are acquiring increasing value as monomers for the synthesis of thermostable heterocyclic polymers, in particular polyquinoxalines and poly-1,2,4-triazines[145-153]:

R = H; Ph



In the opinion of Hergenrother[146] phenylated quinoxalines are among the most promising heterocyclic systems known at the present time, whose structure has the potentiality for high thermal, thermo-oxidative, and hydrolytic stability.

The route to the synthesis of polyquinoxalines was mapped out by Sorenson[147] in 1961, since when the reaction of bis-$\alpha$-dicarbonyl compounds with bis-$o$-diamines has been widely used to obtain polymers containing quinoxaline rings. To this period belong papers by Stille[59-61] and a patent[148] on the method of obtaining polyquinoxalines by the reaction of bis-$o$-phenylenediamines with aromatic bisglyoxals or their hydrates:

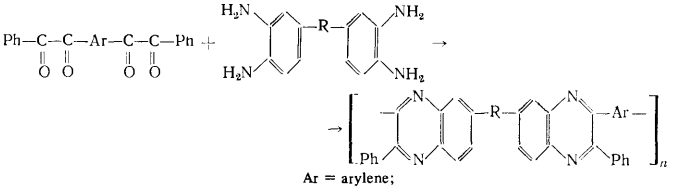


The same process for synthesising polyquinoxalines was suggested simultaneously by some French chemists[62,63,149].

The reaction of aromatic bisglyoxals with aromatic bis-$o$-diamines can obviously yield a mixture of position isomers (2,2'-, 2, 3'-, and 3,3'-polyquinoxalines), a possibility investigated by Stille et al.[59-61]. From the ultraviolet spectra of model compounds and X-ray examination of polyquinoxalines obtained from 3,3'-diaminobenzidine and $p$-diglyoxyloylbenzene dihydrate these workers concluded that the 2,2'-isomer predominated in the mixture. They considered that preferential formation of a particular isomer could be predicted from the relative nucleophilicity of the $o$-amino-groups and the relative reactivity of the aldehydic and ketonic carbonyls in the aromatic bisglyoxals. For example, the $p$-amino-groups in bis-3,4-diaminophenyl ether should be more nucleophilic than those in 3,3'-diaminobenzidine (owing to the electron-donating effect of the ethereal oxygen), which would lead to predominant formation of the 3,3'-isomer, whereas mainly the 2,2'-isomer should be formed from 3,3'-diaminobenzidine[72]. However, it seems more probable that the formation of isomers is governed by the difference in nucleophilicity of the $o$-amino-groups within the tetramine itself:

2,2'-isomer 3,3'-isomer

Intermolecular interaction of the more reactive aldehydic part of the bisglyoxal with the unreactive amino-group often leads to the formation of branched and cross-linked polyquinoxalines, having diminished resistance to oxidation owing to incompleteness of cyclisation:



(E) (F)

When the reaction between the starting materials is conducted in suspension (not in solution), the less reactive keto-group of the intermediate product is able to react intramolecularly to give the required product (E).[64,72]

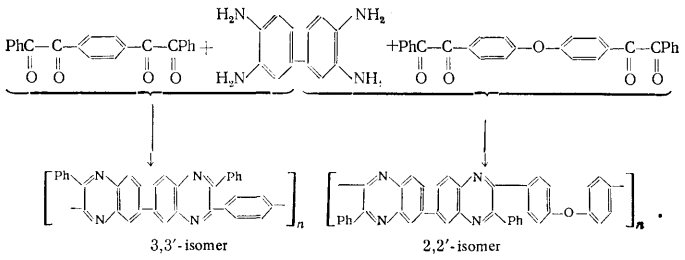


Table 5 shows that increasing the number of $p$-phenylene ether units in the polymer lowers both the softening temperature and the glass point of the polyphenylquinoxalines. The decomposition temperatures determined by dynamic thermogravimetric analysis exhibit no definite trend, but a sharp difference is evident under isothermal conditions in air at 400°C: polyquinoxalines containing $p$-phenylene links were more resistant to oxidation than those containing $p$-phenylene ether links. The former, as was to be expected, had higher softening temperatures and were less soluble in organic solvents[65].

In order to improve the thermo-oxidative stability of the pyrazine ring, which is readily oxidised at a methine group, phenylated polyquinoxalines were synthesised[69] from bis-$\alpha$-diketones instead of bisglyoxals:

Ar = arylene;
R=—, O, CO, $SO_2$, $CH_2$, S, etc.

The possibility of isomeric structures is even greater with polyphenylquinoxalines than with polyquinoxalines. The relative reactivity of the adjacent carbonyl groups in bis-$\alpha$-diketones (Table 3) is independent of steric factors, in contrast to glyoxals, but inductive and electromeric effects are more significant. For example, the reaction of 3,3′-diaminobenzidine with *p*-bisphenylglyoxyloylbenzene or with dibenzyl ether may be expected to yield the isomers[72]

The influence of isomerism on the properties of polyphenylquinoxalines will be discussed later.

The thermo-oxidative stability of phenylated polyquinoxalines was indeed considerably greater than that of their non-phenylated analogues. This is made especially clearly apparent by comparing the behaviour of the polymers under isothermal conditions. Thus the polyphenylquinoxaline obtained by the reaction of *p*-bisphenylglyoxylbenzene with 3,3′-diaminobenzidine (Table 6, No. 5) has lost only 6% of its original weight after being heated

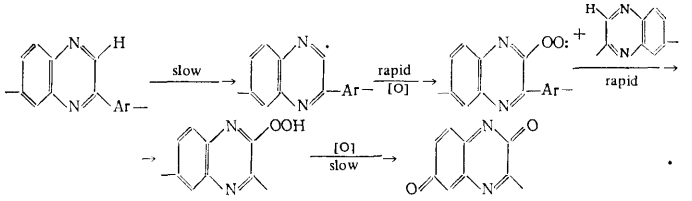
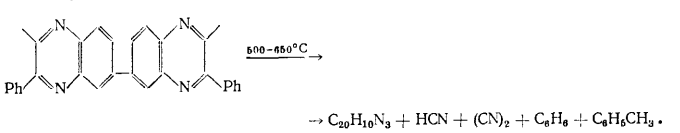
* A single bond linking aromatic rings is regarded as flexible.

in air at 400°C for 200 h, whereas the loss of weight of its unsubstituted analogue (No. 6) under the same conditions is 50%. In differential thermogravimetric analysis phenylated and non-phenylated polyquinoxalines show the same behaviour: they begin to decompose above 500°C. Polyphenylquinoxalines have the advantages of easier preparation of initial monomers and of the polymers themselves, better solubility, and ability to be converted into articles in the cyclised form. Great attention has been paid during recent years to research on the preparation and properties of polyphenylquinoxalines[66-72,150,151].



As would be expected, the introduction of ethereal oxygen into the main polymer chain produces a considerable decrease in the resistance to oxidation of polyphenylquinoxalines, accelerates the formation of volatile products, and increases their yield[150,151]. Wrasidlo[150] suggested a mechanism for the action of oxygen in which oxidation is initiated by radicals formed slowly by rupture of a carbon–oxygen bond:

The appearance of radicals is accompanied by degradation of the main chain, resulting ultimately in loss of film flexibility and strength. The phenoxy-radicals formed are rapidly converted by molecular oxygen into peroxy-radicals, whose decomposition and isomerisation liberate phenyl side-groups and yield quinonoid structures[151]

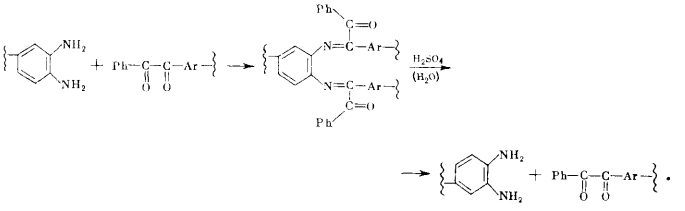


Oxidative degradation of unsubstituted polyquinoxalines proceeds differently: oxidation is initiated in the heterocycle by the action of molecular oxygen, and leads to formation of peroxy-radicals of the type[150]

These peroxy-radicals interact with a hydrogen atom of the heterocycle, to form a more stable hydroperoxy-radical. This is followed by a slow stage, which determines the rate of decomposition of the hydroperoxide and produces a resonance-stabilised quinonoid structure.

Thermo-oxidative degradation is influenced by the nature of the terminal groups[150,151,163]. In the absence of air both types of polyquinoxalines decompose between 500 and 640°C by a mechanism involving cleavage of the heterocycle[150]:

These polymers have potential uses as highly thermostable adhesives[152,153].



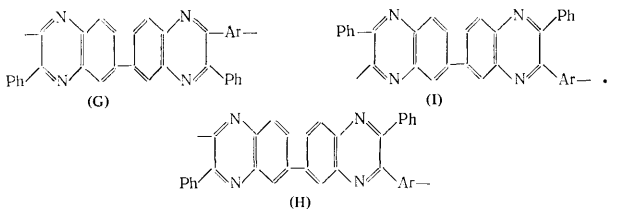
The ease of formation of polyphenylquinoxalines is extraordinary: in contrast to methods used to obtain other polyheteroarylenes, it takes place only in a single stage even at room temperature and yields completely cyclised final polymers. In no case have uncyclised intermediate products, including fragments like Schiff bases, been isolated, which evidently indicates a high degree of completeness of cyclisation. This is obviously promoted by the relatively similar nucleophilic reactivity of the *o*-amino-groups of bis-*o*-phenylenediamines and electrophilicity of the bis-$\alpha$-diketones used, and also by thermodynamic and kinetic factors favouring closure of the six-membered pyrazine ring.

Polyphenylquinoxalines have been obtained in quantitative yield both in the melt and in solution. In the former case equimolecular quantities of the tetramine and the bis-$\alpha$-diketone were heated in an inert atmosphere to 180–280°C, with the evolution of volatile products and the formation of polymers of relatively low molecular weight ($\eta_{log}$ = 0.46 dl g$^{-1}$). Polycondensation in solution involves the use of various solvents (dimethylformamide, dimethylacetamide, and *m*-cresol) over the range 10–202°C. However, polymers of high molecular weight ($\eta_{log} > 1$ dl g$^{-1}$ in sulphuric acid at 25°C) could not be obtained by boiling the initial compounds directly in dimethylformamide or in dimethylacetamide, owing to the sparing solubility of the polymers formed, which separated from the reaction mixture in the initial stages[68].

The most suitable solvent for this reaction proved to be *m*-cresol, in which polyphenylquinoxalines of high molecular weight were readily formed at room temperature (within 2–3 h); subsequent heating (boiling for 72 h) produced hardly any increase in viscosity or molecular mass of the polymers. With $\eta_{log}$ = 2.16 dl g$^{-1}$ the scattering of light gave the molecular mass $M_n$ = 247 000. *m*-Cresol probably not only is a good solvent for polyphenylquinoxalines but also catalyses their formation. This conclusion forms the basis of a method for synthesising these polymers in a cresol-free medium, e.g. a chlorinated hydrocarbon, with proton-donating compounds—methanol, acetic acid, phenols—as catalysts[154]. Reaction takes place readily and rapidly in solution at room temperature to give polymers of high molecular weight ($\eta_{log}$ = 1.5 dl g$^{-1}$).

Kinetic investigation of the formation of polyphenylquinoxalines in dilute media indicates[155] the second order for the reaction catalysed by *m*-cresol; similar results have been obtained by other workers[156]. From a study of the molecular-weight distribution and the hydrodynamic properties of dilute solutions of the polymers it was concluded that one branch point was present in ~180 ± 10 chain units[155].

Analogous conclusions were reached by Hergenrother[157], who observed gel formation during synthesis of the polymers in concentrated solutions, as well as a decrease in the viscosity of their solutions in concentrated sulphuric acid. He related this to the possibility of the formation of side-chains containing azomethine bonds, which are easily broken by the action of an acid:

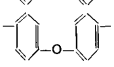


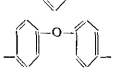
Such an explanation appears unconvincing, however, since it contradicts the good solubility of the polymers, as well

as the formation of Schiff bases usually at high temperatures[158]. It is quite possible that the branching, gel formation, and fall in viscosity mentioned by several investigators[155,157] may be due to contamination of the initial tetraketone by small amounts of impurities of functionality ≳4. This seems likely, as the method used to prepare the bis-α-diketones involved a stage of acylation in the presence of aluminium chloride, leading to formation of the required product with difficulty separable products of incomplete or excessive acetylation. Furthermore, the oxidation of deoxybenzoins by selenium dioxide may be incomplete. When bis-α-diketones obtained via diethynyl compounds are used to prepare the polymers, gel formation and the fall in viscosity of solutions in sulphuric acid are not observed[76,88,159].

Polyphenylquinoxalines are distinguished from other polyheteroarylenes in being true thermoplasts. However, their plastic properties become undesirable when the polymers are used at high temperatures (above 300°C). Numerous and varied attempts have therefore been made to overcome this defect by raising the glass point $T_{gl}$ of polyphenylquinoxalines, which usually lies below 300°C and prevents realisation of the high thermal stability inherent in the polymers.

Three main factors—molecular flexibility (mobility) of the chains, molecular symmetry, and intermolecular interaction, i.e. polar interactions and hydrogen bonds—determine the glass points of polymers. This is clearly evident from results obtained by Wrasidlo[160] and by other workers[161], who studied the molecular mobility of phenylated and non-phenylated polyquinoxalines. Position isomerism is possible with these polymers:





The probability of formation of these isomers decreases from (G) to (I), owing to the reactivity of the active groups in the initial reactants (i.e. the inductive and electromeric effects); they are all randomly distributed in the polymer chain. As a result, configurational disorder is observed, intensified by the introduction of flexible groups— O, CO, and $SO_2$— into the chain, with loss of crystallinity.

It is noteworthy that structurally similar phenylated and non-phenylated polyquinoxalines have almost the same glass points (Table 6). Wrasidlo[160] considers that the mobility responsible for the second-order transition in these polymers corresponds to movement of the main chain, since the barrier to internal rotation in them (measured by $\Delta C_p$) is extremely high owing to the effects of *ortho*-substitution and resonance, while depending little on the structure of the monomer unit. Table 6 shows that increasing the number of single bonds in the unit from two to nine (No. 1 and 21) results in a fall in the glass point from 395 to 216°C, caused mainly by the introduction of hinge groups—ether bonds, carbonyl and sulphonyl groups.

The influence of the above factors on the glass points can be traced in polyphenylquinoxalines containing various polar groups in the *para*-position of the phenyl substituent.

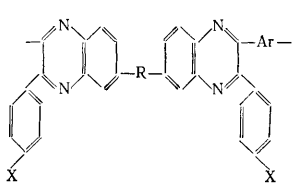
* In nitrogen at 400°C for 0.5 h.



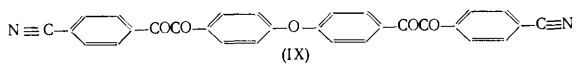


Table 7 [75] shows that such substitution has a significant effect on the glass point in comparison with polymers not containing polar groups (No. 3 and 4). With Ar = *m*-$C_6H_4$, R representing a singly bonded group, and X = $C_2H_5$, $OCH_3$, and $OC_6H_5$—i.e. groups conferring flexibility on the molecule—the glass point of the polymers falls (286, 305, and 245°C respectively—No. 8–10); with X = $C_6H_5$ (No. 11) the glass temperature rises to 326°C, but the introduction of hydroxyl (X = OH, No. 1) is accompanied by a rise to 375°C, obviously owing to the strengthening of interchain interaction by hydrogen bonding. The rise to 340°C when X = CN (No. 4) is probably due both to strengthening of polar interaction and to greater molecular symmetry, i.e. a more regular configuration of the chains and hence a more perfect conformation.

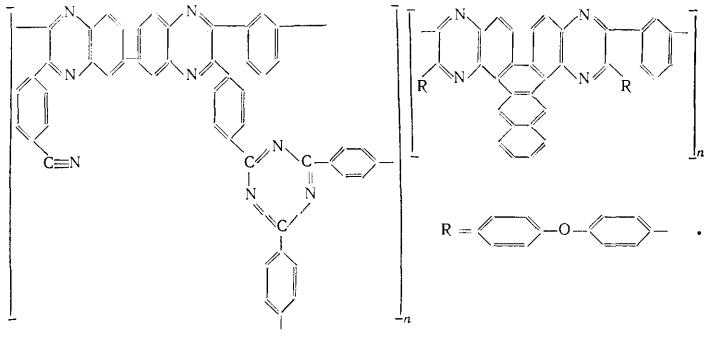
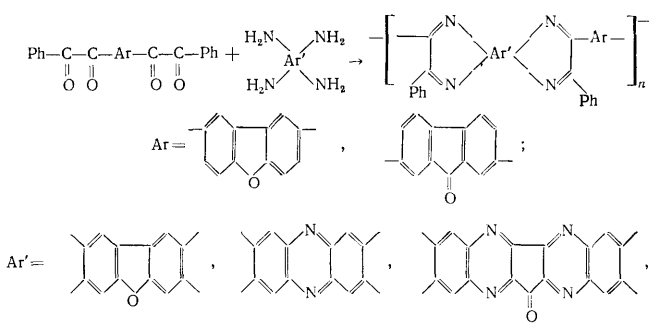
Position isomerism in polyphenylquinoxalines provides a good explanation of their solubility, amorphism, and ability to be processed in the cyclised form. However, the carbonyl groups of bis-α-diketones may differ appreciably in electrophilicity owing to non-equivalence of the inductive effects of substituents, which can in principle

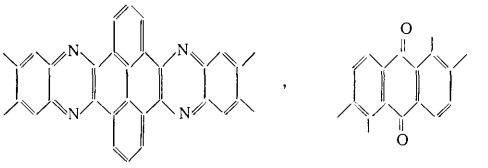
lead to preferential formation of one isomer[75]. Thus in the case of the bis-$\alpha$-diketone



(IX)

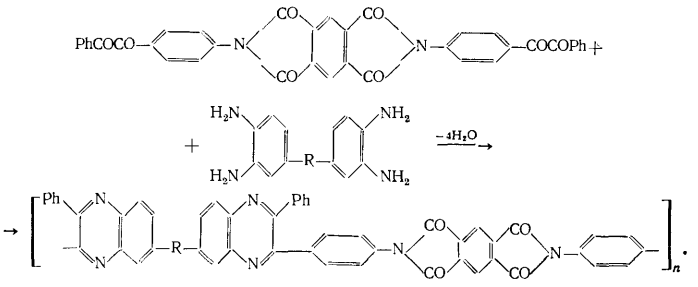


the electron-accepting effect of the cyano-group should increase the reactivity of the nearer carbonyl, whereas the ethereal oxygen atom—an electron donor with respect to the second carbonyl—would lower its reactivity, which should ultimately cause the predominance of one isomer in the polymer chain and increase the molecular symmetry[75].

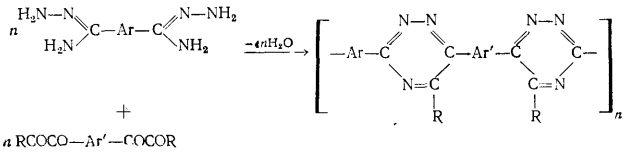


The thermal plasticity of polyphenylquinoxalines can be diminished by heat-treatment above the glass point, which is accompanied by a rise in the temperature at which the mechanical properties of the polymers are maintained. Thus heating films in helium at 400°C for 1, 4, 6, and 8 h gradually moves the temperature dependence of the modulus of elasticity to higher temperatures (the modulus begins to decrease at 316, 347, 375, and 387°C respectively). An analogous effect is achieved by heat-treatment in air, but in a shorter time, The effects are obviously due to pyrolytic cross-linking combined with oxidising processes[162,163].

Another method is available for raising the glass temperature, e.g. by introducing into the polymer functional groups—cyanato, cyano, carbonyl, phenethynyl, etc.—that on subsequent heat-treatment at moderate temperatures or treatment with simple compounds form cross-linked structures. The thermal plasticity and the solubility of the polymers are thereby lowered, and the glass point is raised considerably. In polymers containing nitrile, cyanate, and phenethynyl groups heat-treatment is accompanied by intermolecular trimerisation and formation of 1,3,5-triazine and other rings, yielding highly thermostable rigid systems of the type[75,164]

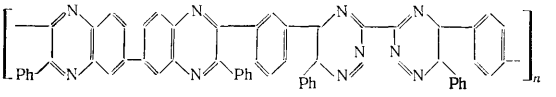


The glass point of polyphenylquinoxalines can be raised also by introducing fused rings into the amine[165] or ketone[166] component:



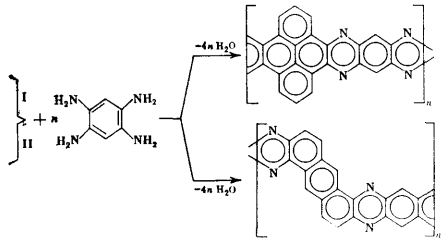
The polymers obtained from tetramines or tetraketones having high melting points possessed glass points of ~400°C and above, but exhibited loss of solubility and workability, as well as considerable impairment of their mechanical properties[165-167].

A more promising approach was the synthesis of polyphenylquinoxaline copolymers[70,168-172], in particular of polyimido-phenylquinoxalines, obtained by Augl et al.[169,170] from $\Lambda\Lambda'$-di-$p$-benzilylpyromellitimide and aromatic tetramines:



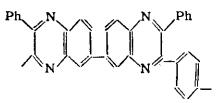
The thermal and other characteristics of the copolymers usually lie between those of the corresponding homopolymers. Table 8 lists glass points and temperatures of maximum mechanical and dielectric losses $E''$ and $\epsilon''$ for five different compositions, three of which are copolymers obtained from 3,3'-diaminobenzidine and different mixtures of $p$-bisphenylglyoxyloylbenzene and $pp'$-bisphenylglyoxyloylbenzophene.

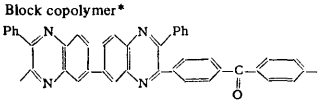
Poly-1,2,4-triazines have been obtained by reaction between bis-$\alpha$-dicarbonyl compounds and bisamidrazones of dicarboxylic acids[75,174-176]:



(where R = $C_6H_5$ and Ar, Ar' represent arylene groups). Copolymers containing quinoxaline and 1,2,4-triazine rings in the macromolecules

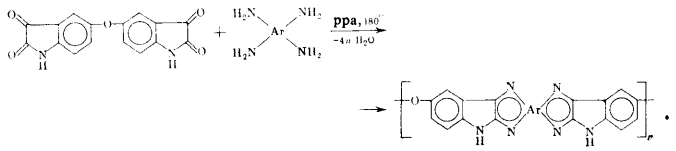
have also been prepared[157,177]. The phenylated polytriazines possess better solubility and thermal properties than do their non-phenylated analogues, but both are inferior to polyphenylquinoxalines in thermal and thermo-oxidative stability. Thus phenylated poly-2,2,4-triazines exhibit good stability in air at 260°C, whereas polyphenylquinoxalines retain their properties at 316°C for a long time (1000 h).[157]





The highest heat resistance and thermal stability are found with "ladder" polyquinoxalines, which have been obtained by the reaction of pyrene-4,5:9,10-diquinone (I)

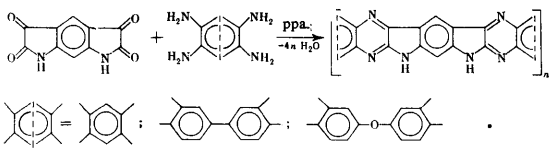
or anthracene-1,2:5,6-diquinone (II) with benzene-1,2,4,5-tetramine, naphthalene-1,2,5,6-tetramine, anthracene-1,2,5,6-tetramine, or dibenzo-5,10-dioxin-2,3,7,8-tetramine[178,179]. Completely aromatic polymers have been synthesised by the reaction of (I) or (II) with benzene-1,2,4,5-tetramine in hexamethylphosphoramide (or *m*-cresol or polyphosphoric acid) at 180°C for 120 h:



They are readily soluble in the hydrate of dichlorotetrafluoroacetone and possess viscosities $\eta_{log} \leq 2.1$ dl g$^{-1}$. Thermogravimetric analysis indicates that their degradation begins at 550°C in air and at 700°C in an inert atmosphere; they are regarded as some of the most thermostable heterocyclic polymers known at the present time[178,179].

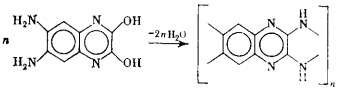
**Table 8.** Influence of structure of copolymers on transition temperatures and relaxation maxima[173].

| Polymer | Comp., %/% | $T(\Delta C_p)$, °C | $T(E''_{max})$, °C | $T(\varepsilon''_{max})$, °C |
|---|---|---|---|---|
|  | 100/0 | 372 | 385 | 435 |
| Block copolymer* | 72/25 | 352 | 369 | 415 |
| Block copolymer* | 70/50 | 344 | 352 | 408 |
| Block copolymer* | 25/75 | 330 | 346 | 391 |
|  | 0/100 | 325 | 340 | 378 |



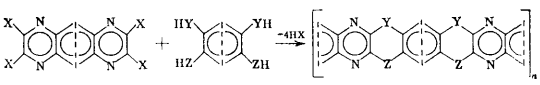
* Mean length of block determined viscosimetrically is 10–20 units[173].

A peculiar variety of this type of polymer comprises polyindoloquinoxalines, obtained by the interaction of tetramines and bi-isatins (e.g. of 5,5′-di-isatinyl ether with 3,3′-diaminobenzidine and bis-3,4-diaminophenyl ether in polyphosphoric acid at 180°C):[180–184]



These polymers begin to decompose in air at 420–500°C, dissolve in sulphuric and methanesulphonic acids, and possess comparatively low viscosities ($\eta_{log}$ = 0.1–0.4 dl g$^{-1}$).

Ladder polymers of similar structure but higher molecular weight, with $\eta_{log}$ = 0.86–0.96 dl g$^{-1}$, have been obtained by the reaction between aromatic tetramines and tetrahydro-2,3,5,6-tetraoxodipyrrolobenzene in polyphosphoric acid[185,186]:



Decomposition of these polymers began in air at 460°C, and in nitrogen at 700°C.

Marvel and his coworkers[187,188] have described ladder polymers formed from tetrasubstituted quinoxalines containing activated functional groups and polymers of graphitic structure based on tetra-aminoanthraquinone and naphthalene-1,8:4,5-bisindanedione. Thus the homocondensation of diaminodihydroxyquinoxaline in polyphosphoric acid gave a ladder polymer containing quinoxaline and dihydrophenazine rings:

Similar polymers have been synthesised by condensing tetrasubstituted bisquinoxalines or anthracenes containing like functional groups with tetramines, diamino-diols, diamino-dithiols, and tetrahydric phenols[189–197]:

X=Cl, OH, OPh; Y=Z=NH; O; Y=S, O; Z=NH

Such polymers are obtained in the melt, in a solvent of high boiling point, or in polyphosphoric acid. They contain alternating quinoxaline and dihydrophenazine, oxazine, triazine, and dioxin rings, and have comparatively good thermal characteristics (they decompose in air at ~450–550°C), but are very sparingly soluble in the usual solvents and have poor workability.

In conclusion it must be remarked that α-dicarbonyl compounds are of undoubted interest as convenient subjects for the study of molecular configuration by conformational analysis[113], electron spectroscopy[198], and photochemical methods[199]. In virtue of their great reactivity they have found application for a wide range of chemical reactions[144,200] yielding in several cases valuable products[201].

The above phenylquinoxaline polymers obtained from bis-α-diketones possess a set of valuable properties, such as ease of formation, solubility, and ability to be processed by the usual technical methods into articles having great heat resistance, theremal stability, and strength against distortion, which makes then extremely promising from practical utilisation.

# Three-stage Synthesis of "Ladder" Polyheteroarylenes

A.L.Rusanov, S.N.Leont'eva, and Ts.G.Iremashvili

Discussion of the fundamental principles of a general method for synthesising polyheteroarylenes, based on the three-stage reaction of tetrafunctional nucleophiles with tetracarboxylic acids, their derivatives, and analogues, is followed by detailed analysis of optimum procedures, principal characteristics, and fields of practical application of the main classes of "ladder" polymers—polyaroylenebenzimidazoles and related systems, polyisoindoloquinazolinediones, polyaroylene-1,2,4-triazoles, etc. A list of 280 references is included.

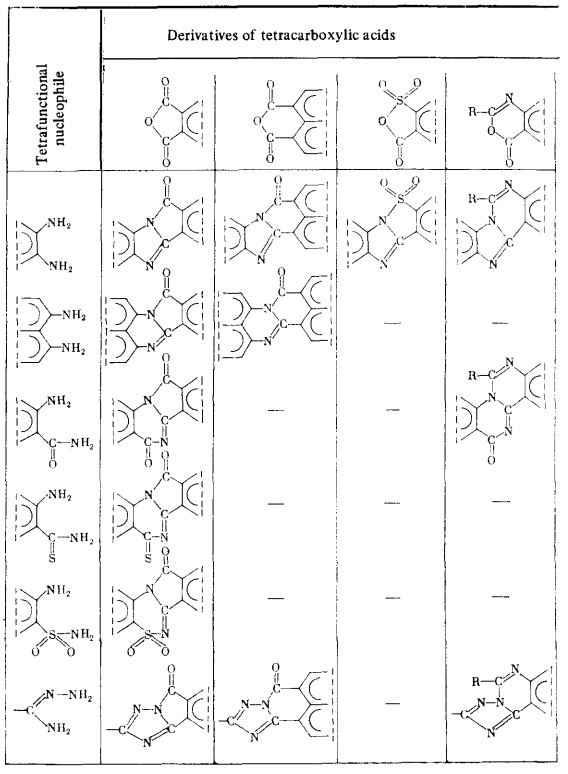
## I. INTRODUCTION

In the chemistry of synthetic polymers great attention has been paid to aromatic heterochain polymers, in particular polyheteroarylenes—polymers containing aromatic heterocycles in the main chains of the macromolecules—during the past twenty years [1-5]. The demands of new technology, requiring synthetic materials of ever increasing thermal stability, have caused the development during the past decade of an extremely interesting and peculiar field in the chemistry of polyheteroarylenes—research on "ladder" or "double-chain" polymers possessing, according to calculations by Tessler [6,7], enhanced resistance to the action of high temperatures. A completely or partly "ladder" structure is conferred on polyheteroarylenes by introducing fused aromatic heterocycles into main chains of the macromolecules [8-17].

Research in this field has yielded many polymers containing fused heterocycles in the main chains [8-17], the large majority of them obtained by one of the main methods for synthesising "ladder" structures—polyfunctional polycondensation, primarily its chief variant—polyheterocyclisation [15]. According to the Reviewers' proposed classification [18,19] the reactions involved in the synthesis of most ladder polyheteroarylenes by polyheterocyclisation can be divided into three main groups—(1) two-stage homo- or co-polymerisation of tetrafunctional monomers containing pairs in mutually *ortho*, $\alpha$, or *peri* positions; (2) two-stage reactions of aromatic dicarboxylic acids of their derivatives with aromatic diamines containing *ortho* to the amino-groups aromatic heterocycles containing labile hydrogen atoms; and (3) three-stage reactions of aromatic tetracarboxylic acids, their derivatives, or analogues with tetrafunctional nucleophilic reagents containing four amino-groups as such or as carbamoyl, hydrazide, and other residues. The last process is the most widely used for synthesising ladder polyheteroarylenes, and can be regarded as a logical extension and development of two-stage polyheterocyclisation, which is very commonly applied in the synthesis of several thermostable polyheteroarylenes [1] and is in turn a complicated variant of the synthesis of linear condensation polymers, e.g. aromatic polyamides.

The transition from the synthesis of aromatic polyamides to that of polyheteroarylenes such as polyimides [20] or polybenzimidazoles [21] in fact requires the use of one potentially tetrafunctional monomer and also an additional stage in the process, actual polycyclisation. Similarly, the transition from the synthesis of polyheteroarylenes by two-stage polyheterocyclisation to that of ladder polyheteroarylenes by three-stage polyheterocyclisation demands that both the initial compounds should be potentially tetrafunctional, as well as an additional stage in the cyclisation process [22].



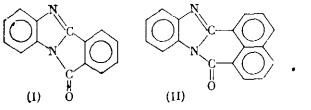
Being a more complicated variant of two-stage polyheterocyclisation, the three-stage synthesis of ladder polyheteroarylenes exhibits all the features of polycyclocondensation processes—the difficulty of selective difunctional polycondensation of potentially tetrafunctional monomers in the first stage, the complication of achieving 100% cyclisation, etc.—with the problems considerably greater than in two-stage polyheterocyclisation. The first stage in the three-stage synthesis actually involves selective polyamidation, which is more successful the greater the difference in nucleophilic reactivity between adjacent reaction centres in the tetrafunctional nucleophilic compound used, the lower the electrophilic reactivity of the acylating agent, and the lower the reaction temperature [23,24]. The nature of the solvent also has a considerable influence on the course of the process.

The tetrafunctional character of both monomers creates in several cases not only difficulties in achieving high selectivity of polyamidation but also the possibility of the formation in the first stage of polymers containing isomeric groups and thus essentially "heterounit" polymers [25]. The problem of such heterogeneity in ladder polyheteroarylenes is still more clearly evident in the second stage—polycyclisation giving polymers containing comparatively simple heterocycles *ortho* to functional substituents in aromatic rings—when the "heterounit" character of the polymers is due not only to incomplete cyclisation but also to the participation of different kinds of *ortho*-substituents, with the possible formation of at least two kinds of *ortho*-substituted polyheteroarylenes. In the third stage, finally, which usually requires more severe conditions, increase in the number and types of "foreign" units may be due to incomplete cyclisation and to secondary reactions of the heterocycles formed.

These considerations demand the most careful choice of method for the synthesis of each class of ladder polyheteroarylenes, so that in each individual case the polymers may correspond as closely as possible to the specified structure and so that their inherent properties may

be most fully realised. The three-stage synthesis of ladder polyheteroarylenes can be accomplished in different ways—(i) multistage polycyclocondensation with isolation of soluble products of the first stage, their processing into articles, and subsequent cyclisation as finished articles by gradually raising the temperature; (ii) polycyclocondensation in the melt under the conditions of the so called "Marvel reaction"[26]; or (iii) high-temperature polycyclocondensation (without isolation of intermediate polymeric structures) in solvents of high boiling point, in particular acids[27-30]. Many compounds of various classes can be used as tetrafunctional monomers in the three-stage synthesis, which is responsible for the structural diversity of the heterocycles present in the main chains of the required ladder polyheteroarylenes (see Table).

Typical monomer units and "ladder" polyheteroarylenes based on them.

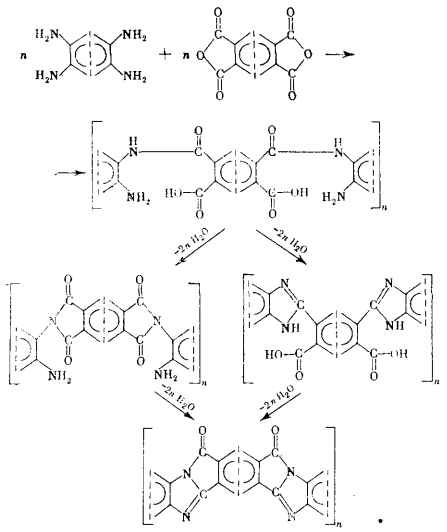


## II. POLYAROYLENEBENZIMIDAZOLES

Among the ladder polyheteroarylenes whose structural units are shown in the Table the first to attract the attention of research workers were products of the reaction of aromatic bis-*o*-diamines—also termed bis-*o*-phenylenediamines—and aromatic tetramines with aromatic tetracarboxylic acids or their derivatives.

These polymers are macromolecular compounds of the polyaroylenebenzimidazole type. The main achievements in the synthesis, processing, and application of the polymers have been summarised not only in monographs[1-5] and reviews concerned with ladder polymers as a whole[8-17] but also in several specialist reviews[31-36]. Nevertheless, many aspects of the chemistry of polyaroylenebenzimidazoles continue to be extremely controversial.

Although polyaroylenebenzimidazoles are often regarded as a single class of polyheteroarylenes, whose properties vary within narrow limits, they can be quite validly divided into two large classes—polybenzoylene- and polynaphthoylene-benzimidazoles—differing both in methods of synthesis and in properties, whose units are modelled by the compounds



An equally valid classification distinguishes polymers obtained from tetracarboxylic acids or their derivatives of high or low electrophilic reactivity. Such differences in the initial tetracarboxylic acids, connected primarily with the charges on the carbonyl carbon atoms, are responsible for significant differences not only in the course of their acylation of bis-*o*-diamines but also in the electron densities on the carbonyl carbon atoms in the terminal heterocycles, influencing the resistance to hydrolysis of the latter, the action of nucleophilic reagents, etc. The two proposed classifications coincide in considerable measure, since in general bisphthalic acids and their derivatives are considerably more strongly electrophilic than are bisnaphthalic acids and derivatives. In several cases, however, departures from the above general principles are encountered.

### 1. Polybenzoylenebenzimidazoles

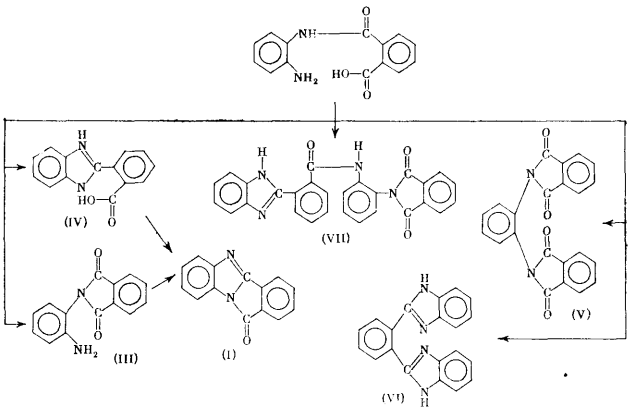
The first polyaroylenebenzimidazoles to attract the attention of investigators were polybenzoylenebenzimidazoles, known also as polyimidazopyrrolones, polybenzimidazopyrrolones, or "pyrrones"[41]. Since the initial publicity[37] attributed to these polymers extraordinarily high thermal stability, high resistance to deformation, and the ability to be processed into articles, they attracted the attention of a considerable number of research workers.

Polybenzoylenebenzimidazoles can be prepared by the interaction of aromatic bis-*o*-diamines or their salts with diesters[38-40], tetraesters[42], and also dichlorides of diesters of tetracarboxylic acids[43-45], but bisphthalic dianhydrides have found the greatest application. This reaction was conducted under conditions of "hot reactive extrusion" of the monomers[46,47], by melting the initial compounds together[48], under conditions of high-temperature polycondensation in solution in an organic solvent—nitrobenzene[49], phenol[50], or an amide solvent[49-51]—or in polyphosphoric acid[50,52-59], and also under conditions of low-temperature polycondensation at the interface[60] and in solution followed by cyclisation of the resulting initial polymers. In most cases dipolar aprotic solvents are used in the reactions of aromatic bis-*o*-diamines with

tetracarboxylic dianhydrides, when the poly-*N*-*o*′-aminophenylphthalamic acids obtained in the first stage undergo cyclodehydration to the polybenzoylenebenzimidazoles:

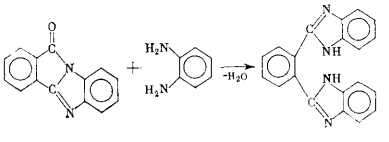
Considerable numbers of patents [61-98] and papers [38,43,44,50-55,99-122] have dealt with the synthesis by this scheme of completely aromatic polybenzoylenebenzimidazoles containing also various aromatic carbocyclic and/or heterocyclic rings. Polybenzoylenebenzimidazoles have been obtained also by the use of dianhydrides or cycloaliphatic tetracarboxylic acids [123-128]. Furthermore, polyesterbenzoylenebenzimidazoles [129] and polyamidobenzoylenebenzimidazoles [130-134] have been synthesised from bis-*o*-diamines and bisphthalic dianhydrides containing ester and amide groups respectively.

The first stage in the preparation—the synthesis of poly-*o*-amino-*o*′-carboxyamides—is usually conducted under conditions of low-temperature polycondensation in a dipolar aprotic solvent, such as dimethylformamide, dimethylacetamide, *N*-methylpyrrolid-2-one, hexamethylphosphoramide, dimethyl sulphoxide, etc. Thermochemical investigations indicate that the interaction of the most widely used bis-*o*-diamines and bisphthalic dianhydrides [135-137] is characterised by considerable exothermic effects, which are responsible in all cases for the high equilibrium constants (owing to the insignificant contribution by the entropy component to the Gibbs free energy) and hence potentially high degrees of polymerisation [138].



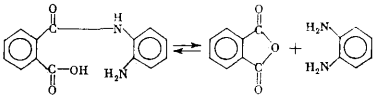
The only problem complicating synthesis of the poly-*o*-amino-*o*′-carboxyamides is the possibility of gel formation, since bis-*o*-diamines in particular are nucleophiles with neighbouring amino-groups of closely similar nucleophilic reactivities, while bisphthalic dianhydrides are the most active of the acylating agents shown in the Table. Therefore, although quantum-chemical calculations [23,24] and thermochemical investigations [137] indicate that, after the first amino-group has undergone acylation, the amino-group *ortho* to the acylated amino-group is the most strongly deactivated, the latter remains sufficiently reactive to react with dianhydrides, forming initially branches and then intermolecular "cross-links". The possibility of gel formation increases in the concluding stage, when the number of *o*-amino-groups exceeds considerably the number of amino-groups at the ends of the macromolecules.

In conformity with the above principles [23,24] success in selective polyamidation depends significantly on the temperature of the reaction and the nature of the solvent. Selectivity is actually increased by cooling from room temperature to −20°C and on passing from dimethyl sulphoxide to dimethylacetamide and thence to dimethylformamide, but gel formation cannot be completely suppressed even by conducting the reaction in dimethylformamide at −20°C. Success therefore requires a continual deficiency of the acylating agent, at least in the last stage: i.e. the last 5–10% of the dianhydride should be added as a solution to the reaction mix.

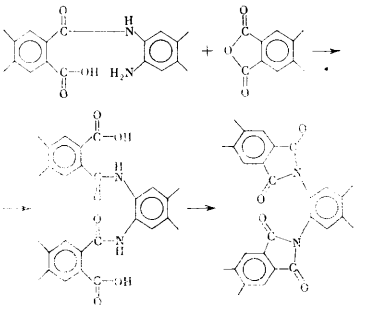


Nevertheless, such addition lowers the viscosity characteristics [139] of poly-*o*-carboxyamides, and this probably applies also to poly-*o*-amino-*o*′-carboxyamides. An alternative procedure for selective polyamidation would be somehow to increase the difference in nucleophilic reactivity between neighbouring reaction centres in the bis-*o*-diamines. With this aim use was made as initial compounds of 5,5′-dichlorobiphenyl-3,3′,4,4′-tetramine [106] and also bis-*o*-diamines in which two amino-groups had been protected by preliminary acetylation or ethoxycarbonylation [140-142], and also by "blocking" with hydrogen chloride [70,109]. However, such deactivation of two amino-groups has an adverse effect on the nucleophilic reactivity of the two remaining amino-groups, since bis-*o*-diamines are monomers with interdependent functional groups. This makes it impossible to obtain *ortho*-substituted polyamides of high molecular weight, and also complicates appreciably the process of cyclisation. Hence the preferred method for preparing initial polymers of polybenzoylenebenzimidazoles is the above interaction of unprotected bis-*o*-diamines and bisphthalic dianhydrides in dimethylformamide; the reaction goes especially smoothly in the presence of triethylamine or other base [62,142] that stabilises solutions of poly-*o*-amino-*o*′-carboxyamides against gelation. Workable polymers of high molecular weight, possessing great resistance to deformation, have been obtained by this method from most of the bis-*o*-diamines and bisphthalic dianhydrides used.

The most common method of cyclising poly-*o*-amino-*o*′-carboxyamides to polybenzoylenebenzimidazoles is thermal solid-phase cyclodehydration of the polymers in a vacuum while the temperature is gradually raised to 350°C. Investigation of the thermodynamics [49,143,144], kinetics [111,112], and mechanism [99,101,111,112] of this process has shown that, although formation of both intermediate polymeric structures—poly-*o*-aminoimides and poly-*o*-carboxyphenylbenzimidazoles—is allowed thermodynamically under the temperature conditions of the first stage of cyclisation (up to 200°C), poly-*o*-aminoimides are formed predominantly. Since both *N*-*o*-aminophenylphthalimide (III) and *o*-benzimidazol-2′-ylbenzoic acid (IV) [49,120,145] were found among the products of the model cyclisation of *N*-*o*′-aminophenylphthalamic acid occurring in the melt under the same temperature conditions, it was suggested [146] that (IV) was formed as a result of the isomerisation of (III), which involved a mutual rotation of the moieties of the molecule. Such rotation is difficult in the case of a solid-phase polymer reaction, so that the cyclisation of poly-*o*-amino-*o*′-carboxyamides to polybenzoylenebenzimidazoles occurs predominantly via poly-*o*-aminoimides. Furthermore, investigation of the cyclisation of poly-*o*-amino-*o*′-carboxyamides has shown [111,112] that imidisation and formation of the benzoylenebenzimidazole ring are superimposed on one another: i.e. the second stage of cyclisation begins before completion of its first stage.

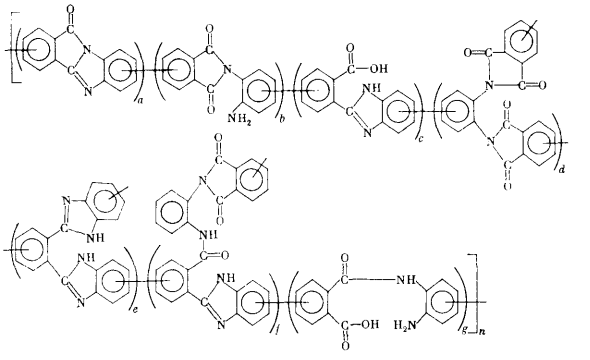


In contrast to earlier results[50] it has now been established that, with few exceptions[56,57], the polymers lose their solubility during cyclisation, and the final polybenzoylenebenzimidazoles in most cases do not dissolve in any of the solvents tested. This is explained not only and not so much by the rigidity of the macromolecular chains as by the three-dimensional structure of the final polymers resulting from a series of secondary processes. Indeed, among the products of the model cyclisation of *N*-*o*'-aminophenylphthalamic acid were detected, together with compounds (III), (II), and (I), respectively intermediate and final products of cyclisation, also *o*-phenylene-*NN*'-diphthalimide (V), *o*-phenylene-2,2'-bisbenzimidazole (VI),[49,120,145], and *o*-benzimidazol-2"-yl-*o*-phthalimidobenzanilide (VII):[145]



The structure of the last three products gives an idea of the nature of the intermolecular "cross-links" in the final polybenzoylenebenzimidazole structures, while the reactions involved in their formation indicate the processes occurring on the heat-treatment of poly-*o*-amino-*o*'-carboxyamides. The most important of the reactions governing the formation of "side" model compounds are most closely connected with the nature of the initial dianhydrides and occur more easily the greater the electrophilic reactivity of these compounds. Thus the product (VII) is formed from (III) and (IV) more readily the larger the positive charge on the carboxyl carbon atom. Formation of *o*-phenylene-2,2'-dibenzimidazole from *o*-phenylenediamine and 1,2-benzoylenebenzimidazole[147-149]

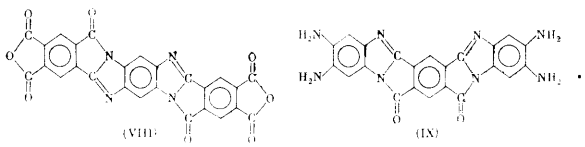
proceeds more easily the higher the positive charge on the carbonyl carbon of the second reactant. Finally, in the formation of (V) the strongly exothermic character of the reaction of bis-*o*-diamines with dianhydrides (becoming stronger with increase in the reactivity of the latter) is responsible for shifting the equilibrium towards the monomers with rise in temperature (also more marked the more reactive the dianhydride):



The regenerated anhydride groups react preferentially with regenerated *o*-phenylenediamine groups but, because of the relatively high temperature and hence diminished selectivity of reaction, some of them interact with amino-groups of the *N*-*o*'-aminophenylphthalamic acid:

This reaction also, of course, occurs more readily the more reactive is the initial dianhydride. Subsequent dehydration of the resulting *o*-phenylene-*NN*'-bisphthalamic acid yields (V).

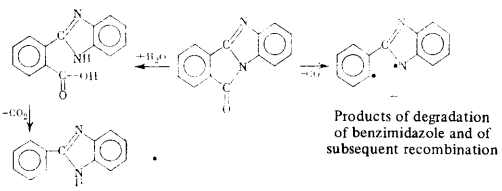
According to these results polybenzoylenebenzimidazoles obtained from the most common bisphthalic dianhydrides would be more correctly represented as "heterounit" polymers having a random distribution along the chain of such units as



This by no means complete set of structural units present in polybenzoylenebenzimidazoles obtained by the solid-phase polycyclodehydration of poly-*o*-amino-*o*'-carboxyamides indicates the high proportion of defects in these systems. Such polymers obtained by polycyclocondensation in polyphosphoric acid would have been less defective, but this method is suitable only for obtaining polymers from dianhydrides of low reactivity[56-59], whereas syntheses using the most common anhydrides terminate in gel formation[49,107,122], caused primarily by interaction of terminal *o*-phenylenediamine groups of some macromolecules with benzoylenebenzimidazole rings of other macromolecules, a process which is especially intense in polyphosphoric acid[147-149].

Owing to their "three-dimensional" structure polybenzoylenebenzimidazoles—products of the solid-phase cyclodehydration of poly-*o*-amino-*o*'-carboxyamides—are infusible and insoluble, and can therefore be worked into articles, mainly at the poly-*o*-amino-*o*'-carboxyamide stage, the subsequent cyclodehydration being conducted on the ready made articles. This procedure has been used to obtain polybenzoylenebenzimidazole films[44,100,150-153] possessing high radiation resistance and photoconductivity, able to compete successfully with cellulose acetate films in the preparation of membranes for the deionisation of

water by reverse osmosis. Such films possess comparatively high tensile strength (up to 1500 kg $cm^{-1}$) but fairly low elongation (up to 10%) at break. The same method has been used to obtain polybenzoylenebenzimidazole fibres [61], extruded and cast articles, adhesives for glass plastics [140,141,154-161], and also foams [162-164] possessing high radiation stability. These and other possible fields of application of the polymers have been surveyed [164].

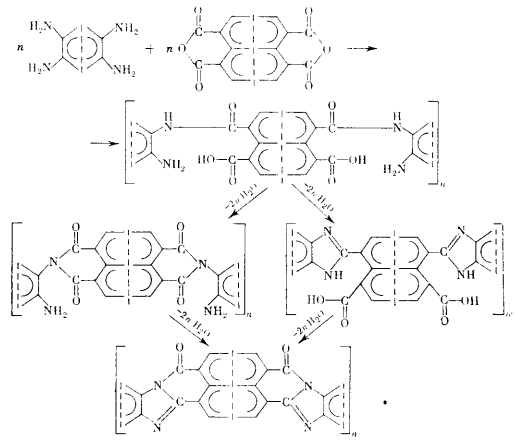


Polybenzoylenebenzimidazoles can thus be used to obtain the most diverse goods, but they differ little in thermal stability from the usual "single-chain" polyheteroarylenes: under the standard conditions of dynamic thermogravimetric analysis in air most of the former polymers already lose weight at 450°C, and under the corresponding isothermal conditions appreciable losses in weight are observed at 350°C even after a short period (up to 10 h). Most investigators link the relatively poor thermal stability [43,44,111,113,165-175] with the comparatively low degree of cyclisation of these polymers, roughly 70% according to thermochemical [143,176] and mass-spectrometric [169] results (this must be regarded as an approximate value, since in both cases only contributions by the main structural units of the polymers were taken into account).

Attempts have therefore been made to raise the degree of cyclisation by "chemical plasticisation" of the macromolecules by saturating them with ether bonds [90,95,112-114], as well as by using as initial compounds oligomers already containing 1,2-benzoylenebenzimidazole rings and possessing degrees of polymerisation of 1.5–5.5, [66] e.g.

However, neither method produced any considerable increase in thermal stability of the polymers.

The question that arises naturally from these results, whether it is fundamentally possible to produce highly thermostable polymers containing 1,2-benzoylenebenzimidazole rings, can be solved only by examining the degradation of model compounds free from the influence of "defective" units, end groups, etc. Investigation of the hydrolytic [177] and thermal [178] stability of the simplest model compound (I) has shown that hydrolysis to (IV) with decarboxylation of the latter begins at 400°C, and homolytic decomposition of the heterocycle with evolution of carbon monoxide at 435°C:



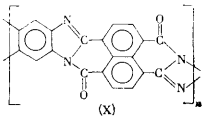
Such mechanisms of hydrolytic and homolytic degradation of (I), which are consistent with several other results [101,165,166,169], indicate that the C–CO and N–CO bonds are the least stable in this compound, a conclusion consistent also with calculation of the molecular diagram of (I) by the Hückel $\pi$-electron approximation in the LCAO–MO method [178]. The comparatively low temperatures of the start of hydrolytic and homolytic decomposition of (I) are evidence that the limited thermal stability of polybenzoylenebenzimidazole is due both to the marked "heterounit" character of the polymers and to the chemical nature of the heterocylic system itself.

## 2. Polynaphthoylenebenzimidazoles

1,2-Naphthoylenebenzimidazole (II) is considerably more thermostable than I. [178] Quantum-chemical calculations by the LCAO-MO method to the Hückel $\pi$-electron approximation indicate that the C–CO and N–CO bonds are the weakest in (II) as in (I), but their bond orders are considerably higher in (II) than in (I), while the positive charge on the carbonyl carbon atom is lower in (II) than in (I). [178] Hydrolytic degradation of (II) therefore begins at 475°C, and homolytic degradation at 525°C. [178]

A considerable amount of research, the main results of which have appeared in several patents [70-75,179-186], and papers [52,53,108,109,187-214], has been done on the synthesis of polymers modelled by (II)—polynaphthoylenebenzimidazoles, also termed polybisbenzimidazobenzophenanthrolines and polybenzobisbenzimidazophenanthrolinediones.

Two main methods—multistage polycyclocondensation [181,203-205,208-214] and single-stage high-temperature polycyclocondensation in an acid solvent [52-58,70-75,108,109,179,180,182,204-209,212,214]—are used to obtain these polymers. The multistage polycyclocondensation of bis-*o*-diamines with bisnaphthalic dianhydrides is conducted in dimethyl sulphoxide containing an inorganic salt (e.g. lithium chloride) to increase the polarity of the solvent, and is followed by solid-phase heat-treatment of the initial polymers:

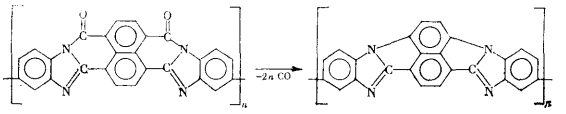


Because of the low reactivity of bisnaphthalic dianhydrides the first stage—the production of film-forming poly-*o*-amino-*peri*-carboxyamides—is accomplished at 80°C or above. In the second stage the thermodynamically advantageous six-membered imide ring is formed preferentially, according to infrared spectroscopy [214]; cyclisation is completed when the temperature is raised to 300°C. Polynaphthoylenebenzimidazoles obtained by multistage polycyclocondensation, owing to the rigidity of their macromolecular chains, which prevents effective solid-phase polycyclisation, probably contain a considerable proportion of incompletely cyclised groups. However, processes leading to three-dimensional structures, similar to those considered above for polybenzoylenebenzimidazoles, do not take place in the present case, so that the

present polymers dissolve in sulphuric acid, methyl hydrogen sulphate, and polyphosphoric acid. The most thermostable polynaphthoylenebenzimidazoles obtained by multistage polycyclocondensation retained 90% and 50% of their initial weight after isothermal heat-treatment in air at 316°C for 140 and 210 h respectively.

High-temperature polycyclocondensation in acid solvents, according to the above scheme but without isolation of initial or intermediate polymer structures, has found considerably wider use. Both bis-*o*-diamines and their salts can be used as monomers, and the acid components can be bisnaphthalic acids and their dianhydrides. The most convenient acid solvents have proved to be polyphosphoric acid alone [52,58,70-75,108,109,179,180,182,183,187-195,198-200,202,204-209,212,214] or mixed with sulphuric acid [201] or a Lewis acid [184], as well as various Lewis acids [30,75,185,186,196,197]. The absence of gel formation is attributed to the lower reactivity of bisnaphthalic than of bisphthalic dianhydrides, the ease of formation of a six-membered heterocycle, and the greater stability of the 1,2-naphthoylbenzimidazole than of the 1,2-benzoylenebenzimidazole ring towards nucleophilic reagents [178].

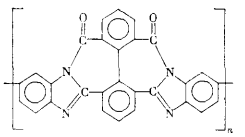
Naphthalene-1,4,5,8-tetracarboxylic acid and its dianhydride are the most generally used acid components; and 3,3′-diaminobenzidine, bis-3,4-diaminophenyl ether, and benzene-1,2,4,5-tetramine are the bis-*o*-diamines. Reaction between the last compound and the dianhydride gave the completely "ladder" polymer



(X)

of high molecular weight, soluble in sulphuric acid, methyl hydrogen sulphate, and polyphosphoric acid, and beginning to lose weight appreciably at ~550°C according to the results of dynamic thermogravimetric analysis [190]. However, the polymer of partly ladder structure based on the more readily available 3,3′-diaminobenzidine has become more common. This polymer is also completely soluble in the three acid solvents, can be obtained with an intrinsic viscosity exceeding 6 dl $g^{-1}$, and is closely similar to the completely ladder polymer in thermal characteristics [190]. Because of the complexity of the nomenclature of these polymers, the polynaphthoylenebenzimidazole obtained from benzene-1,2,4,5-tetramine is usually denoted as BBL, and that based on 3,3′-diaminobenzidine as BBB.

Detailed investigations of the thermal characteristics of polynaphthoylenebenzimidazoles have shown that they surpass the corresponding polybenzoylenebenzimidazoles not only under conditions of dynamic thermogravimetric analysis but also under isothermal conditions both in a vacuum and in an inert environment [109,169-172,202-205,214-218]. Thus after isothermal ageing in air at 316°C for 500 h the polymers BBB and BBL retained 58% and 87% respectively of their initial weight. The higher thermal stability of polynaphthoylenebenzimidazoles is explained both by the greater thermal and chemical stability of the 1,2-naphthoylenebenzimidazole than of the 1,2-benzoylenebenzimidazole ring [178] and by the higher degree of cyclisation of the naphthoylene polymers obtained by high-temperature polycyclocondensation in acid solvents, primarily in polyphosphoric acid. Thus several workers have found that the degree of cyclisation of the polymers obtained in this acid is close to 100% [169,183,190]. Such a high value is not surprising, for the polymers are synthesised in solution, so that increase in the rigidity of the macromolecular chains is not so significant as in solid-phase polycyclisation [219-221], and furthermore polyphosphoric acid is not only a solvent but also a dehydrating agent, catalysing cyclisation.

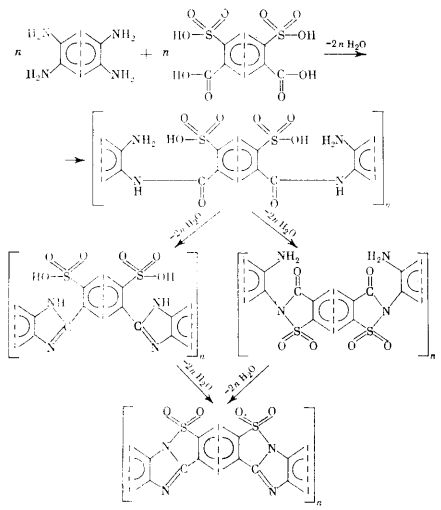


Several methods are now planned for further improving the thermal stability of polymers of this type. In particular, great interest attaches to the use of 1,2,5,6-tetraaminoanthraquinone [195] and 2,3,5,6-tetra-aminopyridine trihydrochloride [109] as initial bis-*o*-diamines. In the latter case the polymers contain only one weak carbon–hydrogen bond, which excludes a quinoid mechanism [222] of thermo-oxidative degradation. As a consequence, polymers obtained from this trihydrochloride and naphthalene-1,4,5,8-tetracarboxylic dianhydride retain 97% of their initial weight when aged at 316°C for 500 h. Another extremely interesting method for improving the thermal stability of polynaphthoylenebenzimidazoles by 40–100 deg consists in removing their weak bonds (C–CO and N–CO) by brief (<50 ms) insertion into the flame of a propane burner at 1000–1300°C. [223,224] Decarbonylation entails the formation of new polymeric structures, which are assumed to have a ladder structure:

After such pyrolytic treatment the polymers have lost their solubility, but the treatment can be applied directly to ready made articles [223,224].

The excellent thermal properties of polynaphthoylenebenzimidazoles and the comparative simplicity of their synthesis have also attracted great practical interest. In particular, the production of thermostable films [191] and ablation-resistant materials [225-227] has been reported, but the use of these polymers for the production of fibres has attracted the greatest interest [228-232]. Spinning BBB polymer from sulphuric-acid solutions into a precipitating bath of 70% sulphuric acid gave fibres which, after being drawn 1.8–2.2-fold at 525–600°C, possessed a tensile strength of 5 g $denier^{-1}$ at room temperature with an extension of 5% at break. The fibres retained 55–60% of their strength after remaining in air at 600°C for 1 min, or at 360°C for 30 h; they were resistant to moisture and ultraviolet radiation [232]. At the present time these are the most thermostable organic fibres and open up a most promising field for the practical application of ladder polyheteroarylenes.

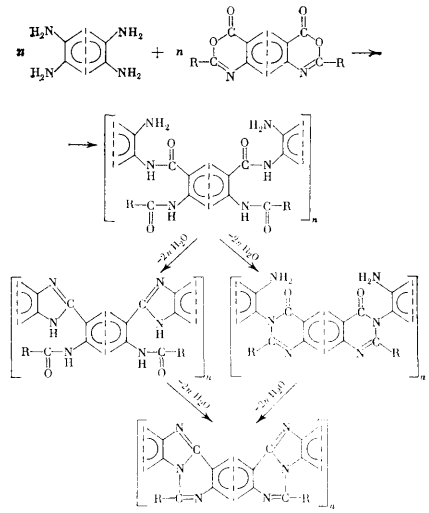
The attention of research workers has been attracted not only to polymers containing heterocycles representing a combination of two five-membered rings or of a five-membered and a six-membered ring but also to those containing combinations of five- and seven-membered heterocyclic systems. In particular, an attempt was made to synthesis a partly ladder polymer, corresponding to the structural formula



from biphenyl-2,2′,6,6′-tetracarboxylic dianhydride and 3,3′-diaminobenzidine [233]. The reaction was accomplished in polyphosphoric acid, when the dianhydride underwent

decarboxylation to the monoanhydride of fluorenedicarboxylic acid. Only polymers of low molecular weight with a low degree of cyclisation were obtained, which began to degrade at low temperatures.

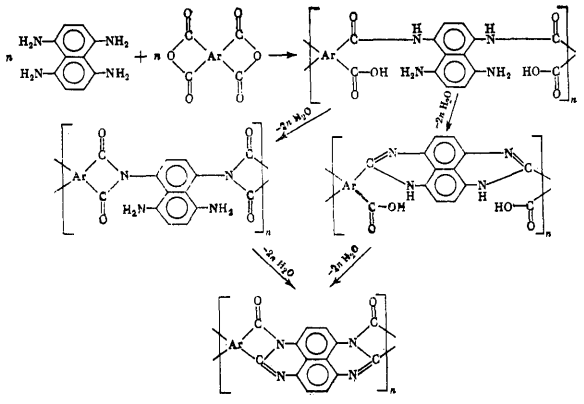
## III. SYSTEMS RELATED TO POLYAROYLENEBENZIMIDAZOLES



No significant advances have been made by research workers in synthesising sulphimide analogues of polyaroylenebenzimidazoles, containing bisbenzimidazobenzodi-isothiazole tetroxide rings and termed "polythiazones"[234-236]. These polymers were obtained by the polycyclocondensation of bis-*o*-diamines with disulphodicarboxylic acids or their derivatives in the melt, in solution in polyphosphoric acid, or as a multistage process:

The first stage was conducted in dimethylacetamide, and gave polymers—*oo'*-disubstituted polyamides—possessing reduced viscosities up to 1.45 dl $g^{-1}$ when dissolved in sulphuric acid. On heat-treatment these polymers underwent desulphurisation, and the final polymers exhibited comparatively low thermal stability (they began to lose weight below 400°C).

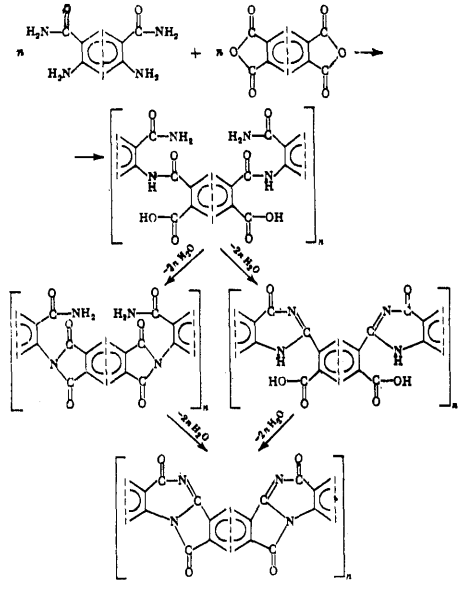
Cyclisation at 420°C of the initial polymers in the presence of triethylamine, i.e. of the triethylammonium salts of the polymers, yielded "polythiazones" that began to degrade above 450°C. Analogous polymers were obtained by conducting the reaction in the presence of triethylamine in the melt[237]. Insoluble "polythiazones" synthesised in polyphosphoric acid began to decompose in air above 450°C.[234-236]. Considerably better thermal characteristics are exhibited by "polythiazones" in an inert atmosphere. Thus the polymer obtained from 3,3'-diaminobenzidine and 4,6-disulphoisophthalic acid does not lose weight when heated in nitrogen to 520°C, and the losses on being heated to 600 and 1000°C are respectively 2.7% and 38.0% of the initial weight.



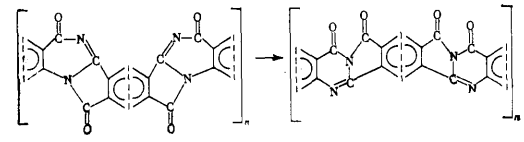
During recent years the attention of research workers has been attracted to polyheteroarylenes and in particular to "ladder" polymers based on "latent" dianhydrides, bisbenzoxazines. Reaction of the latter with bis-*o*-diamines, yielding polymers of completely or partly ladder structure—so called polybenzimidazoloquinazolines—and represented by the scheme

were accomplished by several investigators as a multistage process and as single-stage polycyclocondensation in polyphosphoric acid[238-242]. Multistage polycyclocondensation was achieved by the interaction of bisbenzoxazinones and bis-*o*-diamines in ambipolar aprotic solvents, the most suitable of which was *N*-methylpyrrolid-2-one, followed by solid-phase cyclodehydration of the resulting initial polymers. The low electrophilic reactivity of bisbenzoxazinones—even in comparison with bisnaphthalic dianhydrides—is responsible for the occurrence of this process even at higher temperatures (up to 150°C) without any signs of gel formation, but the same factor makes it difficult to obtain high molecular weights. Attempts to catalyse the process were unsuccessful, and at the present time only initial polymers of polybenzimidazoloquinazolines of comparatively low molecular weight have been obtained. According to spectral data the solid-phase cyclodehydration of these initial polymers involves intermediate formation of poly-*o*-aminoquinazolones, which cyclise to polybenzimidazoloquinazolines with difficulty (owing to the low positive charge on the carbonyl carbon atom of the quinazolone). As a consequence, the polymers formed are shown by spectral data to have a "heterounit" structure determined by the incompleteness of cyclisation, which prevents realisation of the potentially high thermal stability inherent in the benzimidazoloquinazoline ring.

It might have been expected that the problems consequent on the low reactivities of the benzoxazinone and quinazolone rings could be solved by conducting the polycyclocondensation in polyphosphoric acid, but polybenzimidazoloquinazolines of low molecular weight were then obtained, containing according to spectral data other structural residues. Since quantum-chemical calculations and the degradation of model compounds indicate that these rings surpass in thermal stability both 1,2-benzoylene- and 1,2-naphthoylene-benzimidazole rings[243], the search must be continued for methods of synthesising polybenzimidazoloquinazolines of high molecular weight, approaching the idealised structure as closely as possible.



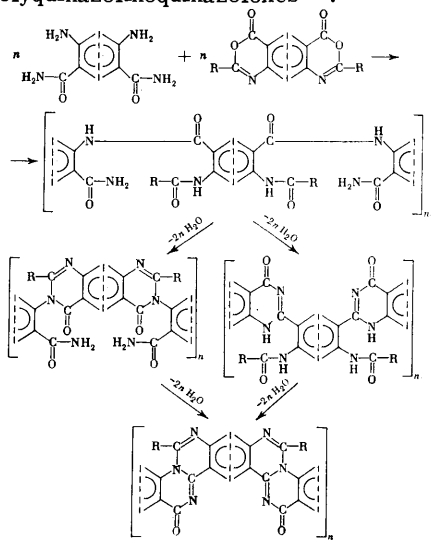
Ladder polyheteroarylenes based on bis-*peri*-diamines are considerably less common than those based on bis-*o*-diamines owing to the relative inaccessibility and very ready oxidisability of the initial compounds, in particular of naphthalene-1,4,5,8-tetramine. Investigations on the interaction of this tetramine with bisphthalic and bisnaphthalic dianhydrides



have shown[50,179,244] the theoretical possibility of synthesising such polymers, but workable polymers of high molecular weight could not be obtained.

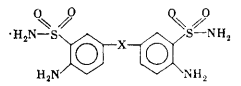
## IV. POLYISOINDOLOQUINAZOLINEDIONES AND RELATED SYSTEMS

Syntheses of polymers of ladder structure from various bis-*o*-amino-amides as tetrafunctional nucleophiles have become quite common. These compounds react with derivatives of bisphthalic acids to form polyisoindoloquinazolinediones[245-256]. The acid derivatives may be either the dianhydrides[245-255] or the dichlorides of diesters[256]. The dianhydrides have been the most widely used:



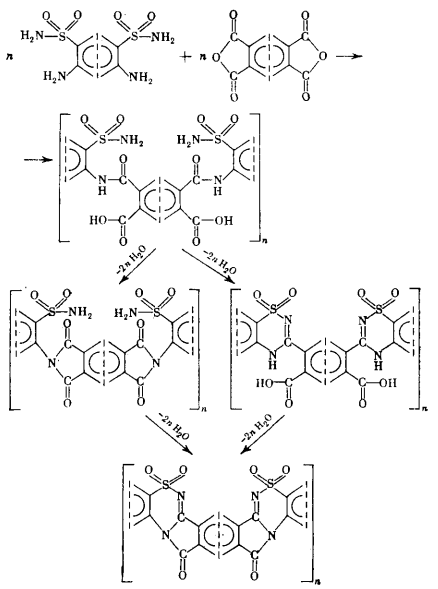
According to Kurihara[246] the final system isomerises into a thermodynamically more advantageous isomer:

Polyisoindoloquinazolinediones have been synthesised by a multistage process[245-250,256,257] and by single-stage high-temperature polycyclocondensation in polyphosphoric acid[251-255]. Multistage polycyclocondensation is effected by low-temperature interaction of the initial compounds in polar solvents followed by solid-phase polycyclodehydration of the resulting poly-*o*-carbamoyl-*o'*-carboxyamides. This process possesses several advantages and disadvantages in comparison with the multistage synthesis of polybenzoylenebenzimidazoles. Its chief merit is that bis-*o*-aminoamides are tetrafunctional nucleophiles whose reactive centres possess markedly different nucleophilic reactivities. As a consequence, the less reactive carbamoyl groups do not undergo acylation, and the first stage is not complicated by the possibility of gel formation[23,24]. On the other hand, the amino-groups are less basic and less strongly nucleophilic than those in bis-*o*-diamines, which in several cases creates difficulties in obtaining initial polymers of high molecular weight. Furthermore, since most investigators find that cyclisation of the polymers involves intermediate formation of poly-*o*-carbamoylimides, the low nucleophilicity of the carbamoyl groups may hinder the formation of isoindoloquinazolinedione rings in the concluding stage. Nevertheless, it has proved possible in several cases to obtain high polymers giving films of strength characteristics approaching those of polybenzoylenebenzimidazole films.



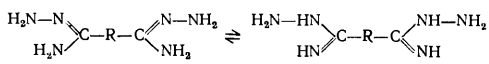
Synthesis in polyphosphoric acid is in considerable measure free from the disadvantage of the multistage process, and can be successfully used to obtain polyisoindoloquinazolinediones of high molecular weight. These polymer structures contain two pairs of weak bonds, N–CO and C–CO, and therefore with few exceptions exhibit limited thermal stability: they begin to lose weight in air at 380–400°C, and in argon above 400°C. In this connection it is somewhat surprising that due attention has not yet been paid to ladder polyheteroarylenes from bis-*o*-aminoamides and bisnaphthalic acids or their derivatives, from which greater themal stability might have been expected than from the polyisoindoloquinazolinediones examined. However, Japanese workers have accomplished the reaction of bis-*o*-aminoamides with

bisbenzoxazinones in polyphosphoric acid, and hence obtained polyquinazolinoquinazolones [258]:



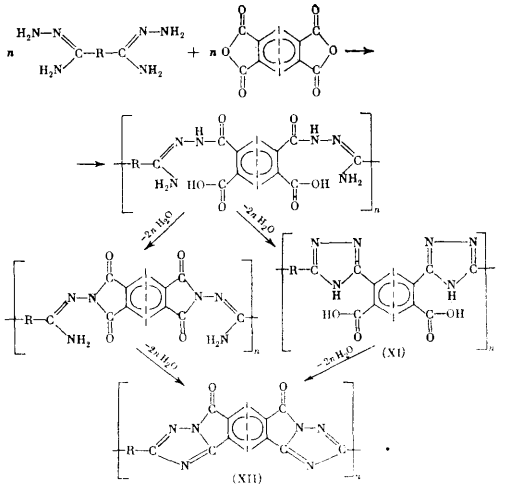
According to the results of dynamic thermogravimetric analysis (in nitrogen with $\Delta T$ = 6 deg min$^{-1}$) the loss of the initial weight at 600°C is 8–13% depending on the structure of the polymers, but it is quite clear that this line of research requires further development.

The possibilities of using bis-*o*-aminothioamides [259] and bis-*o*-aminosulphonamides [260,261] for the synthesis of ladder polyheteroarylenes have been studied still less. The patent literature contains in particular information [261] on a synthesis of such polymers from dianhydrides of aromatic tetracarboxylic acids and bisaminosulphonamides of general formula



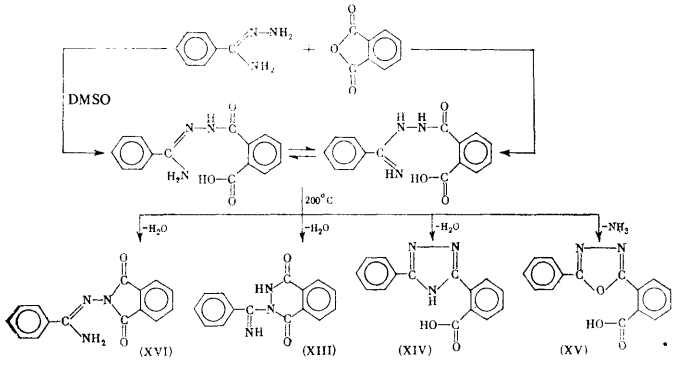
(X = O, CO, $CH_2$, $SO_2$, or S), indicating mild interaction of the starting materials in ambipolar aprotic solvents—*N*-methylpyrrolid-2-one, dimethylacetamide, dimethylformamide, dimethyl sulphoxide, hexamethylphosphoramide, etc.—followed by heat-treatment of the resulting poly-*o*-carboxy-*o*′-sulphamoylamides at 200–400°C:

The first stage of this process, like the synthesis of poly-*o*-carbamoyl-*o*′-carboxyamides, is not complicated by gel formation, since the initial nucleophilic monomers contain neighbouring centres differing markedly in reactivity. Furthermore, the amino-groups in the initial bisamino-sulphonamides are relatively strongly nucleophilic, so that in almost all cases poly-*o*-carboxy-*o*′-sulphamoylamides of high molecular weight were obtained, from whose solutions ($\eta_{red}$ = 0.4–1.2 dl g$^{-1}$) films having tensile strengths up to 1500 kg cm$^{-2}$ and extensions at break up to 10% were formed. The cyclisation of poly-*o*-carboxy-*o*′-sulphamoylamides, like that of poly-*o*-carbamoyl-*o*′-carboxyamides, occurs predominantly via *ortho*-substituted polyimides. As a consequence, the second stage—the formation of benzoylenebenzothiadiazine dioxide residues by interaction of imide carbonyls with sulphonamide units—is hindered by the diminished nucleophilicity of the *o*-sulphamoyl substituents. The final products of cyclisation are probably "heterounit" polymers containing in the macromolecules all four kinds of residues shown in the fundamental scheme of the reaction, with *o*-sulphamoylimide and benzoylenebenzothiadiazine dioxide groups predominating. Indeed, in several cases these polymers already lose weight at 400–450°C, according to dynamic thermogravimetric analysis in air, with $\Delta T$ = 5 deg min$^{-1}$. The most completely cyclised polymers do not lose weight under similar conditions up to 500°C. Poly(benzoylenebenzothiadiazine dioxide) films possess tensile strengths up to 2500 kg cm$^{-2}$ and elongations at break up to 30%.



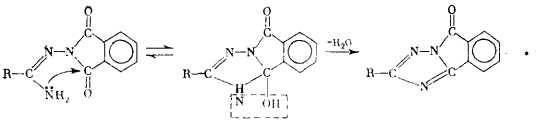
## V. POLYAROYLENE-1,2,4-TRIAZOLES

Among tetrafunctional monomers that during recent years have found considerable application for the synthesis of ladder polyheteroarylenes are bisamidrazones of dicarboxylic acids corresponding to the general formula



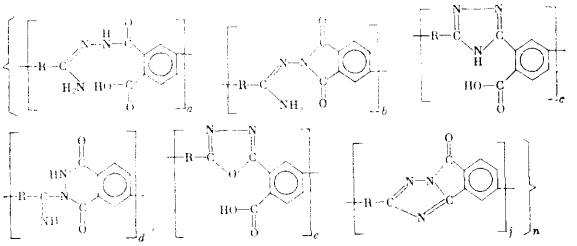
which are relatively easily available, stable compounds [262]. Polymers obtained from bisamidrazones and bisphthalic dianhydrides have been studied in the greatest detail. By 1970 extremely contradictory information had been published on the nature of these products. Thus results obtained by different investigators indicated that the first stage gave poly-*o*-carboxybenzoylamidrazones [263–266], but various structures were ascribed to the final product of

cyclisation, in particular poly-*o*-carboxyphenyl-1,2,4-triazole (XI) [263] and polybenzoylene-1,2,4-triazole (XII): [265, 266]:



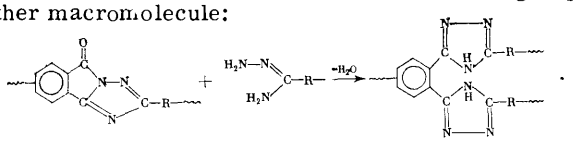
More recent results based on model reactions have shown [19,267-271] that the final products of these reactions are polybenzoylene-1,2,4-triazoles (XII), but these polymers are typical "heterounit" macromolecular compounds, which often hinders unambiguous establishment of their structure.

Several factors are responsible for the "heterounit" character of the polybenzoylenetriazoles. Firstly, although cyclisation of the products of the action of phthalic anhydride on amidrazones, *o*-carboxybenzoylamidrazones, occurs predominantly through the formation of amidino-imides, at least three other modes of cyclisation are possible, with formation of a six-membered cyclic hydrazide (XIII) [272] or of products of cyclisation of the acyl-amidrazone residue—the 3,5-disubstituted 1,2,4-triazole (XIV) and the 2,5-disubstituted 1,3,4-oxadiazole (XV): [273-275]



Only two of the four possible intermediate products of cyclisation—(XVI) and the *N*-amidinophthalimide (XIV)—are able to undergo a further stage of cyclisation, whereas the other two products—(XIII) and (XV)—cannot be converted into the final benzoylene-1,2,4-triazole, which is responsible for appearance of the "heterounit" character during synthesis of the polymers. The formation of structures other than (XVI) can be suppressed by treating the reaction mixture with the complex of pyridine and acetic anhydride [267], which acts as an imidisation catalyst [20], but this procedure complicates the synthesis and processing of the polymers.

Another factor contributing to the "heterounit" character of the polybenzoylenetriazoles (even when the *N*-amidinophthalimide is the sole intermediate product in the cyclisation) is the low nucleophilic reactivity of the amino-group in this intermediate, since the limiting stage is nucleophilic attack by the amino-group on a carbonyl carbon of the imide:

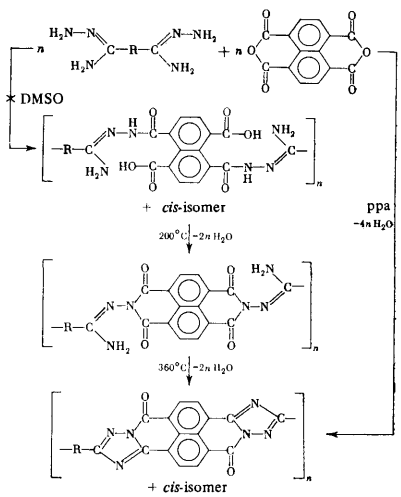


Because of the low nucleophilic strength of the amino-group this reaction is a slow process, but at higher temperatures it may be accompanied both by degradation of the *N*-benzamidinophthalimide at the weak nitrogen–nitrogen bond and by thermal and hydrolytic degradation of the benzoylenetriazole rings.

Taking into account all the above considerations, we must represent the structure of polybenzoylene-1,2,4-triazoles by the "heterounit" system

with the benzoylenetriazole units predominating. The thermochemical method of estimating degree of cyclisation developed and applied to a series of polyheteroarylenes by Korshak, Rabinovich, et al. [143,176], which involves determining heats of combustion, indicates that the final polymers contain ~80% of benzoylene-1,2,4-triazole rings. However, it must be borne in mind that estimation of the degree of cyclisation is based on the postulate that only amidino-imide and the benzoylenetriazole units are present in the polymers.

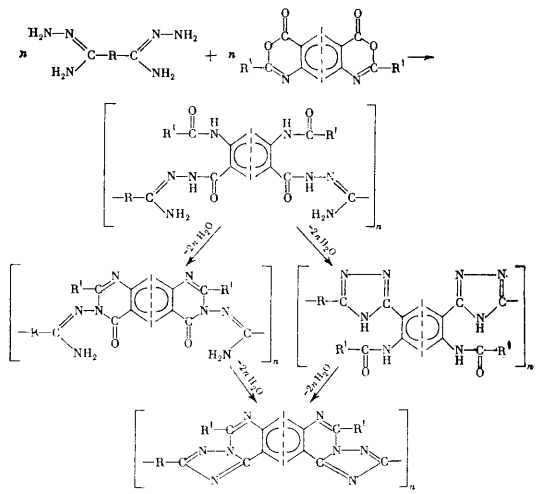
The above formula suggests that the polybenzoylenetriazoles are linear polymers, so that their heterounit character should be apparent in enhanced solubility. Nevertheless, none of the polymers obtained dissolved in any of the solvents tried. There is no doubt that, as with polybenzoylenebenzimidazoles [49], these products are "cross-linked" structures, in which the intermolecular branch points are most probably *o*-phenylenebistriazolyl residues formed by interaction between a benzoylenetriazole ring of one macromolecule and a terminal amidrazone group of another macromolecule:



The heterounit character of the polybenzoylenetriazoles has a significant effect on their properties. X-Ray diffraction indicates that they are all amorphous, which is not surprising if they are regarded as copolymers containing various structural units. The effect on the thermal characteristics is very significant: even dynamic thermogravimetric analysis indicates the comparatively low thermal stability of these polymers, which at 350–410

and 400–440°C (rate of heating in air 4.5 deg $min^{-1}$) lose 5% and 10% respectively of their initial weight. It is interesting that polymers based on pyromellitic dianhydride are in most cases thermally less stable than corresponding polymers obtained from dianhydrides of other tetracarboxylic acids. This is probably caused by the lower degree of cyclisation due to the enhanced rigidity of macromolecules based on pyromellitic dianhydride.

Thus polybenzoylene-1,2,4-triazoles, like polybenzoylenebenzimidazoles, are cross-linked heterounit polymers, undergoing degradation at comparatively low temperatures. Yet the synthesis of their initial polymers, poly-*o*-carboxybenzoylamidrazones, owing to the differences in nucleophilic reactivity between hydrazine and amide amino-groups of amidrazones, is not complicated by branching and gel formation, so that this reaction can be conducted under the most favourable conditions to give poly-*o*-carboxybenzoylamidrazones that can easily be worked into the most diverse articles.



Polynaphthoylene-1,2,4-triazoles—products of the reaction of bisamidrazones with naphthalene-1,4,5,8-tetracarboxylic acid or its dianhydride—differ significantly from the corresponding benzoylene polymers both in methods of preparation and in their main characteristics. Study of model reactions indicates [19,271] that the polynaphthoylenetriazoles can be obtained either by a multistage or by single-stage polycyclocondensation in polyphosphoric acid:

However, attempts to effect polycyclocondensation with any bisamidrazone and the naphthalenetetracarboxylic dianhydride as monomers in a multistage process did not yield macromolecular products, since oligomers having a naphthalimide structure (according to their infrared spectra) separated from the solutions in the early stages. Hence the single-stage polycyclocondensation of bisamidrazones with naphthalene-1,4,5,8-tetracarboxylic dianhydride in polyphosphoric acid was chosen as general method for the synthesis of polynaphthoylene-1,2,4-triazoles [19,271,276–279]. The structure of the products was considerably more nearly perfect than that of the corresponding benzoylene polymers.

The polynaphthoylenetriazoles resemble polynaphthoylenebenzimidazoles in being completely soluble in sulphuric, methanesulphonic, ethanesulphonic, and polyphosphoric acids. Their high viscosities ($\eta_{log} \leq 3.0$ dl $g^{-1}$) are evidence of their high molecular masses. The most thermostable of these polymers lose 10% of their weight at 520–530°C under the conditions of dynamic thermogravimetric analysis, are stable in air at 400°C under conditions of isothermal thermogravimetric analysis, and do not soften up to 500°C. Polymers of this group possess high ablation resistance, and are of considerable interest as potential fibre-forming polymers.

Summarising these results, we note that on the whole polyaroylene-1,2,4-triazoles are closely similar to polyaroylenebenzimidazoles of corresponding structure and somewhat inferior to the latter in thermal stability. Considerable similarity is evident also on comparing products of the interaction of bisbenzoxazinones with bis-*o*-phenylenediamines and with bisamidrazones. The latter products, polytriazoloquinazolines, obtained in conformity with the general reaction scheme [280]

are closely similar to polybenzimidazoloquinazones. With neither structure has it yet been possible to realise the high thermal characteristics potentially inherent in them, owing to incompleteness of cyclisation and the low molecular weights of the polymers.

Critical analysis of all the above results indicates that the best classes of "ladder" polyheteroarylenes, obtained by three-stage polycyclocondensation, e.g. polynaphthoylene benzimidazoles, are significantly superior to the usual polyheteroarylenes in thermal stability and in operating temperatures. The achievement of the same or still higher thermal stability in other structures, e.g. polybenzimidazoloquinazolines, requires further research aimed at finding methods of synthesising polymers having high molecular weights and high degrees of cyclisation. Overall these polymers may make a significant contribution to the further enhancement of the thermal stability and the operating temperatures of polymeric materials on the solution of several problems facing the chemistry and the technology of ladder polyheteroarylenes—problems of the raw materials base, of processing, and of the production of almost perfect structures.

# Photoinitiation of the Reactions of Quinones

A.V.El'tsov, O.P.Studzinskii, and V.M.Grebenkina

The primary photochemical reactions of quinones as well as secondary dark or light-induced processes involving either the initial quinones or the products of their primary photochemical reactions are considered and the reaction mechanisms are discussed. The bibliography includes 262 references.

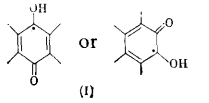
## I. INTRODUCTION

Under the influence of light, quinones are capable of undergoing numerous reactions. Some of the photochemical reactions (for example photochemical reduction) are components of important processes such as photosynthesis in green plants and photochemical degradation of materials coloured by vat dyes. Other photoinitiated reactions of quinones can also be of considerable theoretical and practical interest, since many of them have no analogues among dark chemical reactions.

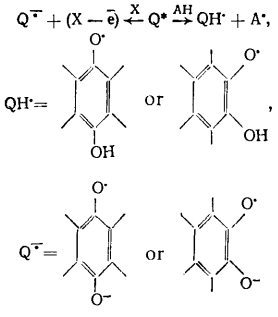


Attempts to survey the light-induced reactions of quinones were made outside the Soviet Union in 1947,[1] 1967,[2] and 1969,[3] the last review dealing with *o*-quinones only. However, since the publication of these reports, a series of new photochemical reactions of quinones have been discovered and those already known have been investigated in greater detail, which has led to the revision of old views and to the appearance of new ones in this field. Bearing in mind these factors and the fact that similar reviews have not been published in the Soviet Union, we attempted to survey the published data (up to 1974 inclusive) and to demonstrate as fully as possible the entire wide variety of the photochemical reactions of quinones. Equal attention has been devoted both to the primary photochemical steps and to the secondary processes leading to the final photolysis products.

## II. PHOTOCHEMICAL REDUCTION

### 1. Primary Photochemical Processes

Photochemical reduction is the simplest photochemical reaction of quinones (Q). It involves the addition of an electron or a hydrogen atom to the oxygen atom of the carbonyl group under conditions where the analogous dark



reactions are impossible. The formation of ketyl radicals (I) (or the corresponding anions), the redistribution of electron density in which leads to semiquinones or their dissociated forms, is assumed under these conditions[4]. Ketyl structures, mesomeric with respect to semiquinones, can also make a definite contribution to their resonance hybrid[5]:

(I)

The products of one-electron reduction of quinones can be obtained in two ways. In one of these, which is less frequently encountered and has therefore been less thoroughly studied, the quinone molecule in the ground state behaves as the electron (or hydrogen) acceptor in relation to the photoexcited molecules of certain pigments (chlorophylls, porphyrins, etc.), usually in the triplet state[6]. The process proceeds as a result of the significant decrease, following electronic excitation, of the ionisation potentials of the pigments or the increase of their capacity to donate a hydrogen atom. Mainly 1,4-benzoquinones[7-14] and in a few instances naphtho- and anthra-quinones[6,15-20] have been studied in such photochemical reactions, unrelated to the excitation of the quinone molecule.

Another, more frequently encountered process used in the photochemical reduction of quinones has been studied in much greater detail. It involves the abstraction of an electron by the excited quinone molecule Q* from a molecule (anion) X with conversion of the latter into a radical-cation (radical) $(X - \bar{e})$ or the abstraction of a hydrogen atom from a molecule AH with formation of a radical A· from the latter[1-3,15]:

When the side chain of quinones contains substituents which are potential electron (hydrogen) donors, the photochemical reduction of quinones also proceeds via an intramolecular mechanism. On the other hand, when both photochemical reduction pathways are possible, it is frequently difficult to decide whether the process proceeds intramolecularly or intermolecularly or via both mechanisms simultaneously.

One should note that the possibility of subdividing reagents (or substituents in quinone molecules) into electron and hydrogen donors of the kind discussed above, which seemed an obvious approach, has now given rise to doubts. One cannot rule out the possibility that the semiquinones QH· are not formed in a single-stage step involving the abstraction of a hydrogen atom from a neutral reactant molecule but are produced as a result of the abstraction of an electron from such a molecule with subsequent rapid proton transfer from the resulting radical-cation $AH^{+}$ to the radical-anion $Q^{\bar{\cdot}}$:[21,22]:

$$Q^{*} + AH \rightarrow Q^{\bar{\cdot}} + AH^{+} \rightarrow QH^{\cdot} + A^{\cdot}.$$

In particular, this mechanism has been suggested for the photochemical oxidation of hydrocarbons[2,23] and alcohols[24,25] by quinones in matrices. In view of the lack in the vast majority of instances of rigorous evidence for one- or two-step abstraction of a hydrogen atom by excited quinone molecules, it appears more correct to regard the process as the transfer of $(\bar{e} + H^{+})$ with the possibility of a two-stage mechanism (see, for example, Refs. 2 and 23–25).

The driving force of the photochemical reduction of quinones is the increase in the electron affinity of the quinonoid system on excitation. It is therefore natural that the efficiency of the process should depend primarily on the oxidation–reduction potential of the quinone in the reactive electronically excited state. However, these quantities have so far been determined only in a few instances[15]; attempts to relate the efficiency of photochemical reduction to the polarographic characteristics of quinones in the ground state have been made much more frequently[15]. Because of this, it is at present impossible to resolve adequately the problem of the comparative reactivities of various quinones and of its relation with their structure in photochemical reduction processes; one can only assess their behaviour in photolysis in reducing media, with reference to the nature of the lowest excited states.

It was believed that the reactive excited states of quinones in their photochemical reduction may be both triplet and singlet states; for some quinones (for example duroquinone), the involvement of only the singlet state is postulated[2]. Incidentally, numerous experiments have made it possible to exclude in almost all the known instances the involvement of the $S$ state of quinones (without denying such a possibility in individual cases)[15,26-28] and to give preference in this role to the long-lived biradical[4,29] triplet[15,30,31] state.

Of the two states $T_{n,\pi^*}$ and $T_{\pi,\pi^*}$, the former should be more active despite its shorter lifetime[4,29], because the delocalisation of $\pi$ electrons in the $T_{\pi,\pi^*}$ state leads to a low unpaired electron density at the reaction centre, while the localisation of excitation in the carbonyl group and the radical-like nature of the oxygen atom are characteristic of the $T_{n,\pi^*}$ state[4,15,29]. Indeed, this hypothesis has been found to hold and photoexcited quinones with the lowest $T_{n,\pi^*}$ level are effective oxidants. The transitions to this reactive state from higher energy levels usually proceed with the same probabilities (frequently close to unity), which are manifested by the constancy of the quantum yield of the photochemical reduction of the substrate over the entire wavelength range of its absorption[2,15,25,32]. If the photochemical reduction of quinones of this type is inefficient, which happens rarely, the phenomenon is usually attributed[15] to a low interconversion quantum yield $\Phi_{ST}$—for example, $\Phi_{ST}$ for ubiquinone-30, which is difficult to reduce, amounts to approximately 0.04.[30]

A small change in the ratio of the number of $n$ and $\pi$ orbitals on passing from quinones with a $T_{n,\pi^*}$ lowest excited state to polyquinones does not lead to significant changes in the ordering of the energy levels and in the photochemical properties[33,34]. However, when the solvent is altered, a specific substituent is introduced, etc., there is a possibility of the inversion of the quinone levels and the relatively unreactive $T_{\pi,\pi^*}$ or $T_{c.t.}$ levels can become the lowest†[2,15,22,35]. Anthraquinone (as well as

† The $S_{c.t.}$ or $T_{c.t.}$ levels correspond to the state with charge transfer.

other quinones [33]), with powerful electron-donating groups (OH, $NH_2$, $NR^1R^2$) as ring substituents, can serve as a characteristic example of the considerable decrease of photodehydrogenating capacity under the influence of the substituent [2,15,36,37]. The fact that such quinones do not lose completely their capacity for photochemical reduction is explained either by the involvement in the process of their $T^2_{n,\pi^*}$ state, whose level lies above the $T^1_{\pi,\pi^*}$ (or $T_{c.t.}$) [38] level, or by their reduction in the relatively inactive $T_{\pi,\pi^*}$ (or $T_{c.t.}$) state [35,37]. Nevertheless even compounds of this kind can be reduced photochemically with a fairly high efficiency. For this purpose, one uses as the light absorbing substrate a hydrogen (electron) donor, i.e. a pigment [6] which interacts with the quinone in the ground state (see above) or the photochemical reaction is carried out with the usual reducing agents but in acid media with excitation of the protonated molecules of the quinones, which have the lowest $T_{n,\pi^*}$ state [26,39,40].

Quinones can form fairly stable charge-transfer complexes (CTC) with the other reactant (solvent). If $T_{n,\pi^*}$ remains the lowest state under these conditions, then excitation by light corresponding to their absorption band is accompanied by the reduction of the quinone. The formation of such CTC is assumed for the reaction of 1,4-benzoquinone and its derivatives with ethanol [41], of sulphoanthraquinones with halide anions in aqueous solutions [42], and of quinones with aliphatic amines [2,25] and has been observed for the reactions of 1,4-benzoquinone with certain aliphatic-aromatic hydrocarbons in low-temperature matrices [23] but not solutions [43]. If the CTC energy level is lower than the $T_{n,\pi^*}$ level of the quinone (which is characteristic of powerful electron donors), then, as in the photolysis of quinones with the lowest $T_{\pi,\pi^*}$ (or $T_{c.t.}$) levels (see above), the photochemical reduction of the quinonoid structure is inhibited [23].

Water [15,16,18,19,44] and virtually all organic compounds (hydrocarbons [6,45], alcohols [2,5,15,45-51], aldehydes [1], ketones [52,53], ethers [52], amines [46,54], and amides [55]), which are usually regarded as hydrogen donors, can serve as reductants in the intermolecular photochemical reduction of quinones. Organic anions (for example alkoxide anions [15,32,39,42,56], $CH_3COO^-$, and $CCl_3COO^-$ [15]), inorganic anions ($OH^-$, $SO_4^{2-}$, $SO_3^{2-}$, $SeO_3^{2-}$, $SCN^-$, $CO_3^{2-}$, $PO_4^{3-}$, $NC_3^-$, [15,57,58] and $Hal^-$ [15,59]), and sometimes alcohols [24-26,60], and amines [2,46] are believed to be electron donors. Quinones with side-chain substituents, resembling the above reductants in their capacity to donate an electron (hydrogen), undergo intramolecular photochemical reduction.

The properties of the reductants as well as those of the quinones determine the efficiency of the photochemical reduction. This applies in the first place to the capacity of the reductant to give up an electron or hydrogen. The latter is clearly illustrated by the reactivity series of alcohols in their photochemical dehydrogenation by quinones: t-BuOH $\ll$ MeOH $<$ EtOH $<$ i-PrOH; [47] this series has been explained [2,15] by the increased mobility of hydrogen atoms at the carbinol carbon atoms as a result of the increased positive inductive effect of the alkyl group in the alcohol molecule. The conclusion that a hydrogen atom is abstracted from this position was reached on the basis of the analysis of the products of the photochemical oxidation of alcohols [2,15,47,48]. One must also take into account the steric characteristics of the reacting molecules: in particular, it has been suggested that the bulk and mass of the substituents in the quinone molecule can influence significantly its photodehydrogenating capacity in intermolecular photochemical reduction [2]. The steric factors in the reductant molecules are important in their turn; for example, in ethers the hydrogen atom is abstracted from the carbon atom involved in the ether linkage and an increase in the length and branching of the alkyl groups reduces the reactivity of the ether by shielding [2,15,47]. Steric factors play an even greater role in the intramolecular photochemical reduction of quinones, where the feasibility of the process is determined, apart from other requirements, by the possibility of achieving a cyclic transition state [2].

The photochemical reduction of quinones has been investigated in greatest detail in alcohol matrices [24,25]. It has been shown recently by electronic spectroscopy and ESR that the hydroxy-group of the alcohol $R^1R^2CHOH$ serves in this case as the donor of hydrogen (an electron and then a proton); the $R^1R^2\dot{C}OH$ radicals are formed from the radicals $R^1R^2CHO^\cdot$ in secondary reactions (cf. the interaction of photoionised quinone molecules with alcohols in the gas phase [61]):

$$(R^1R^2CHOH)^{\cdot+} + Q^{\cdot-} \leftarrow Q^* + R^1R^2CHOH \xrightarrow{R^1R^2CHOH} R^1R^2\overset{+}{C}HOH_2 + R^1R^2\dot{C}OH \qquad Q^{\cdot-} + R^1R^2\overset{+}{C}HOH_2 + R^1R^2CHO^\cdot,$$

$$R^1R^2CHO^\cdot \rightarrow R^1R^2\dot{C}OH \quad \text{or}$$

$$R^1R^2CHO^\cdot + R^1R^2CHOH \rightarrow R^1R^2CHOH + R^1R^2\dot{C}OH,$$

$$Q^{\cdot-} + R^1R^2\overset{+}{C}HOH_2 \rightarrow QH^\cdot + R^1R^2CHOH,$$

$$QH^\cdot + R^1R^2CHOH \rightarrow QH_2 + R^1R^2CHO^\cdot, \quad \text{or}$$

$$QH^\cdot + R^1R^2CHOH \rightarrow QH_2 + R^1R^2\dot{C}OH.$$

The above mechanism agrees with the hypothesis that the hydrogen bond between the alcoholic hydroxyl and the carbonyl group of the quinone in the ground state should facilitate the abstraction of a hydrogen atom ($e + H^+$) from the OH group [62-64]. Possibly the above mechanism is also applicable to the photochemical dehydrogenation of alcohols by quinones in solution (see, for example, the studies on the photochemical reduction of tetrachloro-1,4-benzoquinone in alcohols [26,60]); this process is still being discussed [24,25,47]. On the other hand, in the photochemical reduction of certain quinones in solution by acetone and aromatic [65] and acetylenic ($RC \equiv CH$) [25] hydrocarbons, the primary electron transfer in the abstraction of a hydrogen atom from their molecules is believed to have been experimentally demonstrated.

The photochemical reduction of anthraquinone and its derivatives on cellulose [66] and the hydrated surface of silica gel [67] is evidently closely related to the photochemical dehydrogenation of alcohols in matrices as regards mechanism (in the sense that a hydrogen atom is abstracted from the hydroxy-group). On the other hand, in solutions the abstraction of a hydrogen atom by excited quinone molecules from the hydroxy-group of the reductant (other than water) has been observed for certain oximes ($R^1R^2C=NOH$) with formation of iminoxy-radicals ($R^1R^2C=NO^\cdot$) from the latter [68] and for t-butylphenols with formation of the corresponding phenoxy-radicals [69]. In the latter case, the radicals produced from the substrate and the reductant have the same spin polarisations (which has been demonstrated by chemically induced dynamic electron polarisation), in agreement with the theoretical model propoced by the authors [69]. The spin states of the radicals formed in the photochemical reduction of quinones were also considered in other studies [23,70].

Finally, we shall consider the possibility of a type of intermolecular photochemical reduction of quinones where the reductant is the quinone molecule in the ground state. It is suggested, for example, that at fairly high concentrations of 2-sulphoanthraquinone, its excited molecules

react with the unexcited molecules and form the corresponding radical-anion ($Q^{\cdot-}$) and radical-cation ($Q^{\cdot+}$). Their interaction with $H^+$ and $OH^-$ ions (from water) leads to anthrasemiquinonesulphonate ($QH^{\cdot}$) and the $^{\cdot}OH$ radical [71-74]:

$$Q^* + Q \longrightarrow [Q^{\cdot-}\ Q^{\cdot+}] \longrightarrow Q^{\cdot+} + Q^{\cdot-}$$
$$\downarrow H_2O/{}^-OH \qquad\qquad \downarrow H_2O/{}^-OH$$
$$\longrightarrow Q + {}^{\cdot}OH,$$
$$Q^{\cdot-} + H^+ \rightarrow QH^{\cdot}.$$

It is suggested that this mechanism be regarded as a pathway competing with other pathways to the photochemical reduction of 2-sulphoanthraquinone (as well as quinones of other types) under any conditions [72], although its feasibility has frequently aroused doubts [73-76] or has been rejected on energetic grounds [15], the photochemical reduction of 2-sulphoanthraquinone being attributed solely to the interaction of the excited substrate ($Q^*$) and the reductant ($^-OH/H_2O$).

It is assumed that the excited quinone molecule may also be reduced by a quinone molecule in the ground state as a result of the oxidation of a substituent and not the quinonoid ring—for example, such a pathway is possible (but has not been demonstrated rigorously), in the photochemical reduction of alkoxymethyl-1,4-benzoquinones [2].

## 2. Secondary Intermolecular Photochemical Reduction Reactions

Intermolecular photochemical reduction involves numerous secondary reactions in which quinones and their reduced forms, the reductants, and their oxidation products participate in various combinations.

Apart from its formation in the photochemical process, the product of the one-electron reduction of the quinone can be obtained also in a secondary dark reaction of the quinone with the radical (radical-anion) produced from the reductant, as happens, for example, in alcoholic media [2,77]:

$$Q + R\dot{C}HOH \rightarrow QH^{\cdot} + RCHO.$$

The interaction of the product of the one-electron reduction of the quinone and the oxidised substance can lead to the regeneration of the initial compounds. Thus, this type of reaction is fairly rapid in the photochemical reduction of sulphoanthraquinones by the $CO_3^{2-}$ ion [6,15,78]:

$$Q^* + CO_3^{2-} \rightarrow Q^{\cdot-} + CO_3^{\cdot-}, \qquad Q^{\cdot-} + CO_3^{\cdot-} \rightarrow Q + CO_3^{2-}.$$

photochemical (forward) reaction — dark (reverse) reaction

The reverse reaction is frequently comparatively slow and there is then sufficient time for the product of the one-electron reduction of the quinone to undergo other reactions. In particular, regardless of which of the species ($QH^{\cdot}$ or $Q^{\cdot-}$) arises in the primary photochemical step, an equilibrium is established among the photolysis products:

$$QH^{\cdot} \underset{+H^+}{\overset{-H^+}{\rightleftarrows}} Q^{\cdot-}.$$

Its position is determined by the acid–base properties of these species and the medium [2,15,21,79-81].

In the ground or a high vibrationally excited state, the semiquinone can abstract a hydrogen atom from the reductant, forming the hydroquinone ($QH_2$): [2,82]

$$QH^{\cdot} + AH \rightarrow QH_2 + A^{\cdot}.$$

The study of the photochemical reduction of anthraquinone in alcohols with added alkali led the author to the conclusion that there is also a possibility of the photochemical reaction of the products of the one-electron and two-electron reduction of the quinone [83,84]:

$$(QH^{\cdot})^* \xrightarrow{AH} QH_2 + A^{\cdot}$$
or
$$(Q^{\cdot-})^* \xrightarrow{X} Q^{2-} + (X - \bar{e}).$$

However, hydroquinones are not formed solely in the processes enumerated above. It is believed that the main pathways to their formation is the disproportionation of the semiquinones $QH^{\cdot}$ and the radical-anions $Q^{\cdot-}$ in the reversible process [2,15,72,77,79,82,85-87]; the semiquinones then disproportionate approximately 10 and more times as efficiently as the radical-anions [2,15,79]. All these substances are at the same time involved in an acid–base equilibrium:

$$2\,Q^{\cdot-} \rightleftarrows Q^{2-} + Q \qquad 2\,QH^{\cdot} \rightleftarrows QH_2 + Q$$
$$\uparrow\downarrow \quad \overset{+H^+}{\rightarrow} \quad QH^- \quad \overset{+H^+}{\leftarrow} \quad \uparrow$$
$$-H^+ \qquad\qquad -H^+$$

where $QH^-$ and $Q^{2-}$ are the hydroquinone mono- and di-anions.

In certain cases (see Refs. 88–90), the hydroquinones thus produced can retard the photochemical reduction of the quinone, deactivating its excited state (chemical quenching) via the reaction

$$Q^* + QH_2 \rightarrow 2QH^{\cdot} \rightarrow Q + QH_2$$

or can undergo further photochemical reduction. Thus it has been established that prolonged irradiation of anthrahydroquinone and its derivatives produced photochemically in hydrocarbons [91] and alcohols as well as aqueous alcoholic media [31,40,92-94] leads to the corresponding anthrols, anthrones, and anthracene.

Taking into account the above formation reactions and subsequent transformations of the reduced forms of quinones, a mathematical model has been devised for the intermolecular photochemical reduction of quinones, which describes satisfactorily the process as a whole [95,96].

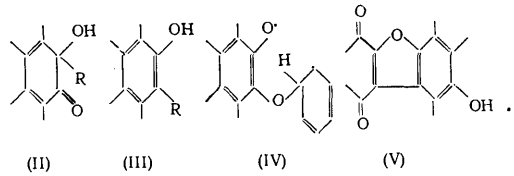
Semiquinones as well as radical-anions, hydroquinones, and their dissociated forms are produced in deaerated media, since they are all readily oxidised by oxygen (and are capable of being oxidised by other reagents [2,15,97]) with regeneration of the initial quinone [15,47,72]:

$$QH^{\cdot} + O_2 \rightarrow Q + HO_2^{\cdot}; \quad Q^{\cdot-} + O_2 \rightarrow Q + O_2^{\cdot-};$$
$$QH_2 + O_2 \rightarrow Q + H_2O_2.$$

Under aerobic conditions, the overall process appears to involve the photochemical oxidation of the reductant and there is good reason for the term "photochemical oxidation sensitised by quinones" frequently given to it [15]. When the reductant is an alcohol, the overall mechanism is as follows [72]:

$$Q^* + RCH_2OH \rightarrow QH^{\cdot} + R\dot{C}HOH,$$
$$Q + R\dot{C}HOH \rightarrow QH^{\cdot} + RCHO,$$
$$QH^{\cdot} + O_2 \rightarrow Q + HO_2^{\cdot},$$
$$R\dot{C}HOH + O_2 \rightarrow RCH(O_2^{\cdot})OH,$$
$$RCH(O_2^{\cdot})OH + HO_2^{\cdot} \rightarrow RCHO + H_2O_2 + O_2,$$
$$2\,RCH(O_2^{\cdot})OH \rightarrow 2\,RCO_2H + H_2O_2,$$
$$RCH(O_2^{\cdot})OH \rightarrow RCHO + HO_2^{\cdot},$$
$$2\,HO_2^{\cdot} \rightarrow H_2O_2 + O_2.$$

The mechanism does not include hydroquinones $QH_2$, since there is insufficient time for their formation from



the semiquinones QH$^{\cdot}$ owing to the rapid oxidation of the latter [15]‡. Naturally, such photochemical oxidation of the reductant can be achieved only in those cases where oxygen does not quench or only slightly quenches the reactive state of the quinone. In particular, this happens for anthraquinone and its derivatives owing to the short lifetime of their $T$ states [6,15,75,76,100].

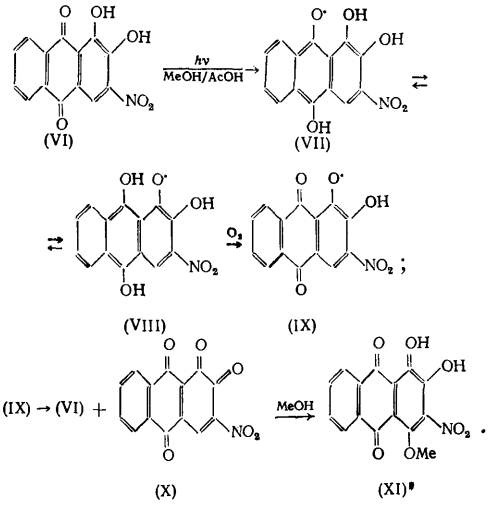
In the light of the foregoing considerations, the photochemical reduction of anthraquinone dyes in matrices in the presence of air as a result of the transfer of a hydrogen atom (or electron) appears fairly probable and is believed to be the main primary process in the theory of the photochemical degradation of materials coloured by such dyes which is most widely held at the present time [15, 38,39,100–105].

The secondary intermolecular photochemical reduction processes, described above in the most general form, are the most typical examples; the specific products of similar and other secondary reactions as well as the pathways leading to their formation are discussed below.

Hydrocarbons. The hydrocarbon radicals arising in the photochemical oxidation of hydrocarbons by *p*-quinones under anaerobic conditions alkylate the quinone (semiquinone) ring and add to the oxygen atom, forming ultimately a hydroquinone ether, or are dehydrogenated by the quinone (semiquinone) to alkenes [1,2]. In the photochemical reduction of *o*-quinones by hydrocarbons, 1,2-addition [compounds (II)] and 1,4-addition [compounds (III)] products are obtained [1–3]. Thus the cyclohexyl radicals generated in the photolysis of 1,4-benzoquinone in cyclohexane give rise to cyclohexyl-1,4-benzoquinone and cyclohexene in the corresponding reactions [2]. By irradiating quinizarin in aliphatic hydrocarbons, alkyl derivatives of its leuco-form were obtained, but the positions of the alkyl groups were not established [106].

Mainly cycloaddition products are formed in the photochemical reactions of *o*-quinones with olefins, but the photolysis of phenanthrenequinone in the presence of isobutene, *cis*- and *trans*-but-2-enes, and tri- and tetramethylethylenes also results in the formation of the compounds (II, R=$CH_2CR^1=CR^2R^3$, $CR^2R^3CR^1=CH_2$) as a result of the capture of the allyl radical by the semiquinone [3]:

(II) (III) (IV) (V)

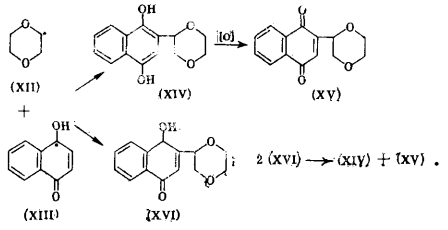


The nature of the secondary products of the photochemical reduction of quinones by alkylbenzenes as a function of the nature of the quinone and the radical formed from the reductant has been more thoroughly investigated than for aliphatic hydrocarbons. The photochemical reduction of *p*-quinones with a relatively high oxidation-reduction potential yields products of the addition of radicals of the type $Ar\dot{C}H_2$ to the oxygen atom and of the dehydrogenation of radicals of the type $Ar\dot{C}H-CH<$. Thus irradiation of tetrachloro-1,4-benzoquinone (but not of 1,4-benzo- and naphthoquinones) in the presence of *p*-xylene, cumene, or tetralin leads respectively to the mono-*p*-methylbenzyl ether of 1,4-dihydroxybenzene, methylstyrene, and 1,2-dihydronaphthalene [2].

The radicals obtained by the abstraction of a benzyl hydrogen atom in the photolysis of the corresponding compounds in the presence of *o*-quinones are sometimes dehydrogenated [107], but 1,2- and 1,4-addition products are normally formed [1,2,5]. The ratio of the products of the 1,2- and 1,4-addition of the *p*-$RC_6H_4\dot{C}H_2$ radicals has been shown [2] to be determined by the nature of the substituent R—the fraction of the 1,2-addition product increase with increase of its electron-donating capacity owing to the electron deficiency at the carbon atom and the electron excess at the oxygen atom of the semiquinone.

By irradiating phenanthrenequinone [3,108] and tetrachloro-1,2-benzoquinone [3] in benzene, the monophenyl ethers of the hydroquinones (III, R = Ph) were obtained together with the corresponding hydroquinones and biphenyl. In the case of phenanthrenequinone, the formation of a 1,4-adduct is assumed to result from the intramolecular abstraction of a hydrogen atom from the biradical (IV) produced photochemically; incidentally, the usual pathway involving the recombination of the semiquinone and phenyl radicals, but without their emergence from the solvent cage, is not excluded either.

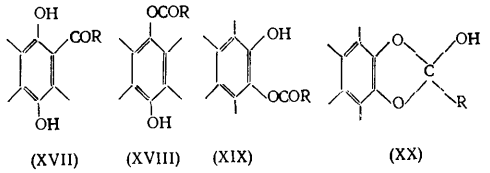
One should bear in mind that, apart from the above pathways leading to the stabilisation of hydrocarbon radicals, another pathway, which is not discussed here, frequently occurs, namely their recombination [2,109].



Alcohols. In contrast to hydrocarbon radicals, the $R^1R^2\dot{C}OH$ radicals obtained in the photochemical oxidation of alcohols by quinones do not form adducts with the latter or with their reduced forms. They are stabilised by disproportionation or are dehydrogenated by the quinone or the semiquinone. Semiquinones are stabilised in alcoholic solutions by an intramolecular mechanism or interact (sometimes after conversion into other intermediates) with the solvent. An example of the first pathway is the formation of the cyclic products (V) when 2,2′-biphenyl- and 2,2′-binaphthyl-1,4,1′,4′-diquinones are irradiated in alcohols [2]. The second pathway is illustrated by the conversion of 1,2-dihydroxy-3-nitroanthraquinone (VI) into 1,2-dihydroxy-4-methoxy-3-nitroanthraquinone (XI): [2]

(VI) (VII) (VIII) (IX) (X) (XI)

‡ All the secondary reactions of semiquinones or the corresponding radical-anions discussed above can be suppressed by combining the reactive species into complexes and micelles [98,99].

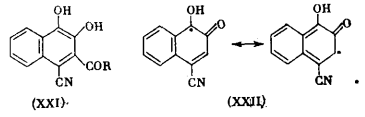


Ethers and related compounds. The radicals generated in the photochemical oxidation of ethers (thioethers) by quinones alkylate *p*-semiquinones in the ring form 1,2- and 1,4-addition products with *o*-semiquinones. For example, the dioxanyl radical (XII) was found to react with the radical (XIII) (obtained from 1,4-naphthoquinone), compound (XV) being the final product [110]. The dioxanyl derivative of 1,4-benzoquinone may be present among the unidentified products of the photolysis of 1,4-benzoquinone in dioxan [2]. Phenoxymethyl-1,4-benzoquinone is obtained similarly by the irradiation of 1,4-benzoquinone in aqueous anisole [2]:

1,4-Addition products are formed by the recombination of radicals generated from *o*-quinones and ethers (thioethers), i.e. by the reactions of tetrachloro-1,2-benzoquinone with dioxan [2] and of phenanthrenequinone with di-isopropyl, dibutyl [110], benzyl phenyl, and dibenzyl ethers as well as the dibenzyl ethers of ethyleneglycol and 1,4-dihydroxybenzene [111], ethyl acetate and propionate, dithian [2], and ethyl vinyl sulphide [3]. In most cases the products are unstable and readily decompose in air, for example as a result of hydrolysis, while on irradiation they can rearrange to 1,2-addition products, as shown for the adducts of phenanthrenequinone with anisole and dioxan [2].

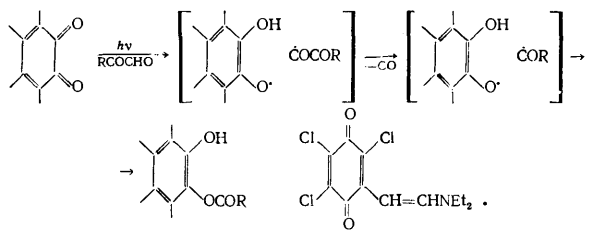
The formation of the 1,2-addition product in the photolysis of acenaphthenequinone in tetrahydrofuran [112] and of 1,4-dihydro-2-hydroxy-1-oxo-4-xanthylnaphthalene on irradiation of 1,2-naphthoquinone or its 3-chloro, 3-bromo-, and 6-bromo-derivatives in the presence of xanthene are rarer examples [113,114].

Aldehydes. The products of the secondary reactions in the photochemical reduction of *p*-quinones by aldehydes are compounds of type (XVII) and (or) (XVIII):



Ring acetylation by the $CH_3\dot{C}O$ radical occurs in the photolysis of 1,4-benzoquinone and its mono-, di-, and tri-methyl, acetyl, and 2,3-dichloro-derivatives, 1,4-naphthoquinone, 2-methylnaphthoquinone [2], 1,4,9,10-anthradiquinone, 1,4,5,8-naphthodiquinone, the anhydride of 1,4-benzoquinone-2,3-dicarboxylic acid, and 2,3-dicyano-1,4-benzoquinone [115,116] in acetaldehyde; the products of the photolysis of anthraquinone in acetaldehyde were not identified [2]. Acyl derivatives of type (XVII) have also been obtained in the photolysis of 1,4-benzoquinone in the presence of trimethylacetaldehyde and acrylaldehyde [2,115]. Diacylhydroquinones are sometimes formed in these processes [2].

The final products of the reactions of tetrasubstituted 1,4-benzoquinones (dichlorodicyano- and tetrachloro-derivatives) are hydroquinone monoethers, which are formed also in the photolysis of quinizarin in the presence of the aldehydes *p*-$XC_6H_4CHO$ (X = H, $NO_2$, or MeO). [2] Irradiation of 1,4-benzoquinone in the presence of cinnamaldehyde yielded only the hydroquinone monoether [3], irradiation of cortonaldehyde gave both possible substances of types (XVII) and (XVIII), [115] and irradiation of the benzaldehydes *p*-$XC_6H_4CHO$ resulted in the formation of benzoylhydroquinones (X = Me, t-Bu, or MeO) and monobenzoates (X = $NO_2$, CHO, CN, or $CF_3$). [115]

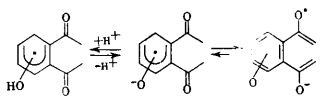


Together with the view that the $R\dot{C}O$ radicals and the semiquinone are involved in the formation of compounds (XVII) and (XVIII), there exists another hypothesis, namely that the $R\dot{C}O$ radical reacts with the quinone [2,115]. It is believed that the nature of the reaction product [(XVII) or (XVIII)] depends on the nucleophilic properties of the $R\dot{C}O$ radical: the more nucleophilic the radical, the greater the probability of attack on the ring (if not all its positions are occupied) and, conversely, a decrease of nucleophilicity leads to an increased yield of the ether. The oxidation-reduction potential of the quinone plays a significant role. Thus, it is assumed that a competitive mechanism involving electron transfer from the $R\dot{C}O$ radical to the quinone Q and the formation of the radical-ion pair $[Q^-RCO^+]$, in which the acylium ion should be localised near one of the oxygen atoms, operates in the case of quinones with high oxidation-reduction potentials (1,4,9,10-anthradiquinone, 1,4,5,8-naphthodiquinone, the anhydride of 1,4-benzoquinone-2,3-dicarboxylic acid, and 2,3-dicyano-1,4-benzoquinone). This also explains the interaction of acyl radicals with the above quinones at the oxygen atom.

The photolysis of *o*-quinones in the presence of aldehydes yields mainly 1,4-addition products—the monoethers of 1,2-enediols (XIX) and (or) the cyclic acetals (XX): [2,3,117]

By irradiating 1,2-naphthoquinone and many of its derivatives in aliphatic (but not aromatic [2]) aldehydes, it was possible to obtain ring-acylation products (XXI) [evidently by the recombination of the radicals (XXII) and $R\dot{C}O$ [2,3,109]], in addition to enediol ethers of type (XIX), and to substitute the halogen atom (if present) in the 3-position in the acyl group.

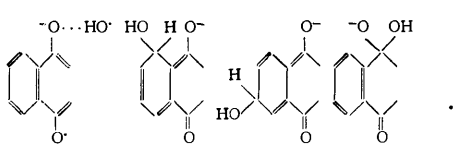
Compounds of type (XIX) are formed on recombination of the radicals $RCO\dot{C}O$ obtained from glyoxals and semiquinones as a consequence of decarbonylation in the solvent cage [118]:



Amines. The excitation of [amine$^+$ quinone$^-$] CTC or the [(amine – H)$^\cdot$ (quinone + H)$^\cdot$] radical pair in quinone

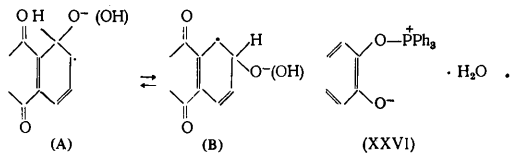
(2,5-dichloro-3,6-dimethoxy- and tetrachloro-1,4-benzoquinones)–tertiary amine (triethylamine and 2-methylpiperidine) systems leads to the hydroquinone monoanion ($QH^-$) and an ion of the type $Et_2\overset{+}{N}=CHCH_3$. When they interact, the chlorine atom is substituted with formation of aminovinylquinones, for example (XXIII).[2]

Water, $H^+$ and $OH^-$ ions, and ammonia. The photolysis of tetramethyl-1,4-benzoquinone in water yields only the corresponding hydroquinone[2,119], while 1,2,4-trihydroxybenzene and (or) 2-hydroxy-1,4-benzoquinone have been obtained from 1,4-benzoquinone in addition to 1,4-dihydroxybenzene[2,119–122]. The formation of these substances has been explained[121] by the interaction of the photochemically generated ·OH radical with the quinone (or semiquinone). The 1,2,4-trihydroxybenzene thus produced reacts with the initial quinone to form 2-hydroxy-1,4-benzoquinone and 1,4-dihydroxybenzene. This oxidation is faster in acid and alkaline solutions and is slow in solutions close to neutrality; consequently the pH of the medium determines the composition of the final products. The alternative mechanism involving the abstraction of the ·OH radical from water by the excited quinone followed by attack by a hydrogen atom on the quinone molecule in the ground state[2] appears much less probable.



The efficiency of the single-photon process involving the disappearance of 1,4-benzoquinone is independent of its concentration in solution and of the wavelength of the exciting light, remaining constant in the pH range between 0.4 and 8; according to some data, the quantum yield is smaller than unity[2,119–121], while according to others[122] it is greater than unity. The variation of the quantum yield in the photolysis of 1,4-benzoquinone in micellar systems (increased and decreased respectively in the presence of anionic and cationic surfactants) can indicate, according to some workers[119], the involvement of cationic intermediates in the process.

The weakly electrophilic ·OH radicals generated in the photolysis of 2-sulphoanthraquinone in neutral, aqueous alkaline[15,75,123–127], and aqueous alcoholic[2,48,124,128] media hydroxylate sulphoanthraquinone in the range without the sulpho-group[15]. The adduct (XXIV) formed is oxidised by the initial quinone or oxygen to hydroxysulphoanthraquinone[15,123,129,130]:



(XXIVa) (XXIVb) (XXIVc)

A hydrogen-bonded complex (XXVa) or an adduct of type (XXVb)–(XXVd) may precede the intermediate (XXIV) and only their interaction with an unexcited sulphoanthraquinone molecule leads to the adduct (XXIV) and the radical-anion $Q^{\cdot-}$:[75]

(XXVa) (XXVb) (XXVc) (XXVd)

The composition of the products of the hydroxylation of 2-sulphoanthraquinone as well as 1,4-benzoquinone depends on the pH of the medium: in highly alkaline solutions (pH ≥ 12), the main products are 6- or 7-hydroxyanthraquinone-2-sulphonates, while in neutral and weakly alkaline solutions (pH ≤ 12), the main products are 6-, 7-, 5-, and 8-hydroxy-derivatives[15,130], this is attributed either to the different natures of the hydroxylating agents (·OH or $O^{\cdot-}$ formed as a result of the $\cdot OH \rightleftharpoons O^{\cdot-} + H^+$ equilibrium)[15,126] or to the reversible interconversion of forms A and B, which depends on the pH of the medium[75]:

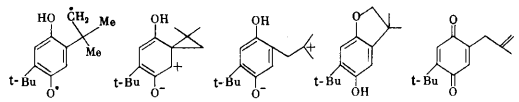
(A) (B) (XXVI)

1-Sulphoanthraquinone, which is photochemically reduced with greater difficulty and has therefore been less thoroughly investigated in photochemical hydroxylation reactions, evidently yields hydroxy-1-sulphoanthraquinones by a similar mechanism.

Photochemical hydroxylation yields dihydroxy-derivatives of sulphoanthraquinones in addition to the monohydroxy-derivatives; their formation is promoted by the decrease in the concentration of the substrate and when the photolysis is carried out under aerobic conditions[130]. The selectivity of the hydroxylation reaction and the possibility of introducing the OH group into other aromatic compounds present in the reaction mixture, particularly in a cyclic process using oxidants, can make it useful for the synthesis of aromatic hydroxy-derivatives[15].

Amination of 2-sulphoanthraquinone in its photolysis in aqueous ammonia, hydrazine, and methylamine solutions, resulting in the preferential formation of 6(7)-amino-(methylamino)-2-sulphoanthraquinones[15], is tentatively assumed to involve a mechanism similar to that of photochemical hydroxylation.

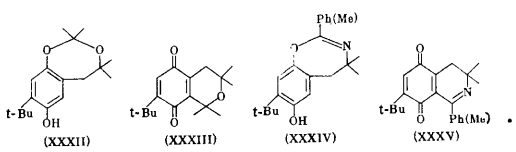
In the instances described above, the oxidised form of the reductant interacts with the quinone, but processes are also known where the reduced forms of the quinones interact with the reductants (solvents). For example, the displacement of methoxy-group by the $OH^-$ ion (dark process) on irradiation of 1- and 2-methoxyanthraquinones in alkaline aqueous alcoholic solutions occurs precisely in the way described—in the photochemically generated dissociated methoxyanthrasemiquinones[131]. The semiquinone obtained by the photochemical reduction of phenanthrenequinone in water reacts similarly with triphenylphosphine and then either with water or with the ·CH radical, forming the dipolar hydrate (XXVI), which is unstable in air[132].



The functional groups in quinones reduced by the two-electron mechanism are also capable of reacting under the influence of the reductant. In particular, it has been established that anthrahydroquinonesulphonic acids dissociated at the alcoholic hydroxyl—the products of the reaction of photochemically generated anthrasemiquinonesulphonates—eliminate the sulpho-group on photoexcitation[15,94,133,134]. The quantum yield of this single-photon process has been shown in the case of 1-sulphoanthrahydroquinone to be higher for the dianion than for the monoanion and to be independent of the concentration of $OH^-$ ions in the region corresponding to the existence of both forms. It is assumed that the highest electronically excited state of the substrate is reactive, since desulphonation proceeds effectively only on excitation with light corresponding to the absorption band at the shortest wavelength. The sulpho-group in the $\beta$-position is eliminated with greater difficulty than that in the $\alpha$-position; halogenoanthrahydroquinonesulphonic acids undergo photochemical dehalogenation together with photochemical

desulphonation[15,94]. The photochemical desulphonation of undissociated anthrahydroquinonesulphonic acids, obtained by the photolysis of sulphoanthraquinones in aqueous alcoholic solutions of inorganic acids proceeds via a different (hydrolytic) mechanism; in this case, light is photochemically active over the entire region corresponding to absorption by sulphoanthrahydroquinones[135,136].

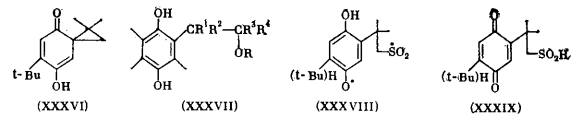
### 3. Secondary Intramolecular Photochemical Reduction Reactions



Intramolecular photochemical reduction of quinones almost always involves the abstraction of a hydrogen atom from the 2'-position of the side chain via a readily achieved six-membered cyclic transition state. This determines both the structure of the biradicals generated and the nature of the products formed on their stabilisation (intramolecular or intermolecular) with participation of the solvent.

Quinones with a hydrocarbon side chain. The radicals (XXVII), obtained from t-butyl-1,4-benzoquinones on photolysis of the latter in benzene, dioxan[137], acetone, acetonitrile, and benzonitrile[138], are converted into a zwitter-ionic spirocyclopropane structure (XXVIII), which exhibits a strong tendency towards aromatisation. Because of this, the three-numbered ring is cleaved and converted into the structure (XXIX):

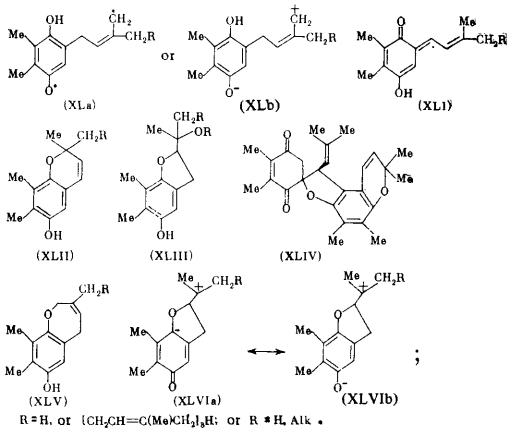
(XXVII) (XXVIII) (XXIX) (XXX) (XXXI)



When the latter is subjected to nucleophilic attack, it can give rise to dihydrobenzofuran (XXX), the products of the rearrangement of the side chain (XXXI), and the products (XXXII)–(XXXV) resulting from the 1,4- and 1,5-cycloaddition of solvents (acetone, nitriles)[138,139]:

(XXXII) (XXXIII) (XXXIV) (XXXV)

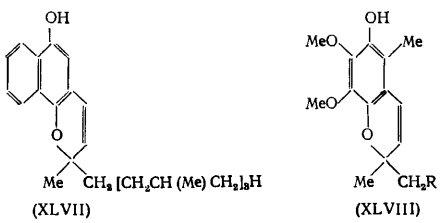
Incidentally, one cannot rule out the possibility that the spiroketone (XXXVI) is an intermediate, the anomalous Claisen rearrangements of which yields compound (XXXI), while the remaining substances, (XXX) and (XXXII)–(XXXV), are formed as a result of the opening of the cyclopropane ring[138,139]. It is noteworthy that other compounds, in addition to those described, are formed, but their yields are insignificant[140].



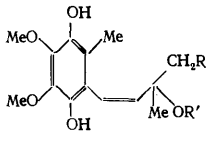
The exclusive formation of dihydrobenzofuran derivatives of type (XXX) was noted in the photolysis of 2-(2-phenylethyl)- and 2-(2,2-diphenylethyl)-1,4-benzoquinones in benzene[141]. Apart from similar substances, products resulting from the introduction of an alkoxy-group in the 2'-position [compounds (XXXVII)] are formed preferentially from 2-ethyl-, 2-isobutyl-, 2,5-dipropyl-,[139] 2-t-butyl-,[2,137] 2,5-di-t-butyl-, and 2,6-di-t-butyl-1,4-benzoquinones[2,137,142], probably via the interaction of the ROH alcohol molecule with a structure of type (XXVII) or (XXIX). *O*-Alkylation of the hydroquinones thus produced is possible[2], but data concerning the insertion of an alkoxy-group in the hydroquinone rings[143] are erroneous[2]:

(XXXVI) (XXXVII) (XXXVIII) (XXXIX)

The interaction of biradicals of type (XXVII), generated in the photolysis of t-butyl- and 2,5-di-t-butyl-1,4-benzoquinones with $SO_2$, leads to structures (XXXVIII), and the migration of hydrogen in the latter results in the formation of unstable sulphinic acids (XXXIX).[144]

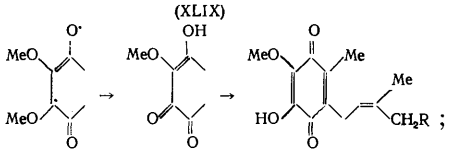


Structures (XL), formed by the intramolecular photochemical reduction of plastoquinones 1 [145,146] and plastoquinones 9 [146,147] on photolysis in benzenes, alcohols R'OH, and aqueous organic mixtures, are believed[145–147] to be stabilised by conversion into intermediate hydroxy-derivatives of *o*-methylenequinones (XLI) or into the corresponding anions. Their intramolecular cyclisation leads to compounds (XLII) and the reactions of the latter with addition of alcohol or water result in the formation of dihydrobenzofuran derivatives (XLIII); attack by a plastoquinone molecule yields the spiro-compound (XLIV). Compound (XLV) can be obtained from the intermediate structure (XL). The previously assumed[145] formation of dihydrobenzofurans (XLIII) in the interaction of alcohols (water) with the zwitter-ions (XLVI) and the involvement in this process of the radicals obtained by the intermolecular abstraction of a hydrogen atom are less likely:



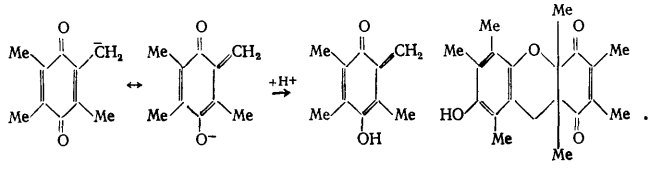
(XLa) (XLb) (XLI) (XLII) (XLIII) (XLIV) (XLV) (XLVIa) (XLVIb)

R = H, or $[CH_2CH=C(Me)CH_2]_3H$; or R = H, Alk.



Irradiation of vitamin $K_1$ in benzene, ethanol, and water[148–151] and of certain coenzyme quinonoid structures in alcohols (R'OH)[2,152] leads in a similar manner—via the intermediate hydroxy-*o*-methylenequinones—to naphthopyranol (XLVII) and chromenols (XLVIII). The formation of the latter is accompanied by hydroquinones (XLIX), which are converted on oxidation into the corresponding quinones and the series of transformations (L) → (LI) → (LII) leads to demethylation products (LII):

(XLVII) (XLVIII)

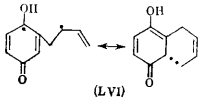


(XLIX)

(L) (LI) (LII)

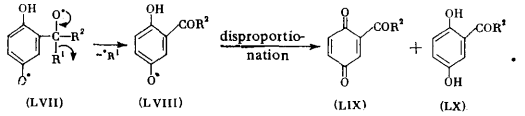
R=[$CH_2CH$=C (Me) $CH_2$]$_n$H, $n$=3,6,9.

The formation of the adduct (LV) is also explained by the photochemical generation of hydroxy-*o*-methylenequinone (LIV) from tetramethyl-1,4-benzoquinone and its interaction with the unexcited substrate. The deprotonation of tetramethyl-1,4-benzoquinone in the $T$ state and the subsequent protonation of structure (LIII) at the oxygen atom is considered to be a possible reaction pathway [27,64,153]:



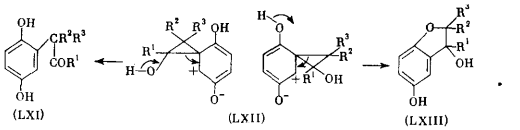
(LIII) (LIV) (LV)

The possibility that hydroxy-*o*-methylenequinones can indeed serve as intermediates in the processes discussed has been demonstrated by the detection of long-lived compounds of type (XLI) and their anions in the flash photolysis of 1-tocoquinone and vitamin $K_1$ in alcohols and hydrocarbons [154,155].



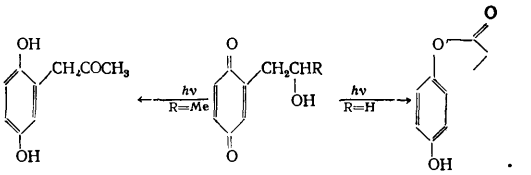
If there is a multiple bond in the 1-position in the side chain, as in 2-(1-methylvinyl)- and 2-(2,2-diphenylvinyl)-1,4-benzoquinones, then photolysis yields benzofuran structures exclusively [2].

The formation of 1,4-dihydro-5,8-dihydroxynaphthalene on irradiation of 2-(3-but-1-enyl)-1,4-benzoquinone under the same conditions is explained by the stabilisation of the biradical (LVI) [2]:



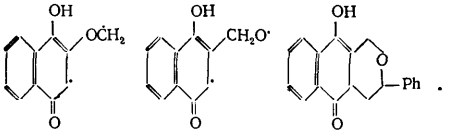
(LVI)

Quinones with oxygen-containing groups. A hydrogen atom may be abstracted during the intramolecular photochemical reduction of hydroxyalkylquinones both from the hydroxy-group and from a carbon atom in the side chain. The former mechanism operates with (1-hydroxyalkyl)quinones in the absence of a hydrogen atom in the 2′-position (hydroxymethyl-1,4-benzoquinone [2] etc.). The biradicals (LVII) formed from these quinones are stabilised either by the addition of a solvent molecule to the radical oxygen atom in the side chain or by the elimination of the alkyl substituent (hydrogen atom) with conversion into radicals (LVIII); disproportionation of the latter leads to the quinones (LIX) and hydroquinones (LX) with an oxidised side chain [2,156]:



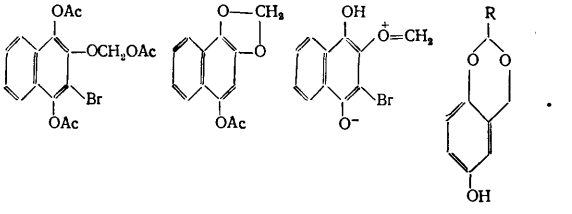
(LVII) (LVIII) (LIX) (LX)

The presence of a hydrogen atom in the 2′-position of (1-hydroxyalkyl)quinones, permits photochemical reduction via two pathways, the second of which gives rise to structures (LXII) analogous to those obtained from alkylquinones (see above). Subsequent reactions of these spirocyclopropane dipolar ions can lead to dihydrobenzofurans (LVIII); owing to the presence of the hydroxy-group, rearrangement to compounds (LXI) becomes possible at the same time [156]:



(LXI) (LXII) (LXIII)

The reactions of the biradicals formed as a result of the abstraction of a hydrogen atom exclusively from the 2′-position on photolysis of (2-hydroxyalkyl)-1,4-benzoquinones (LXV) leads to similar products [(LXIV) and (LXVI)]: [2]

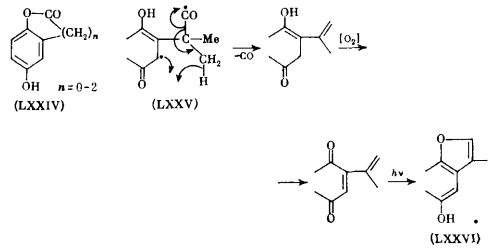


(LXIV) (LXV) (LXVI)

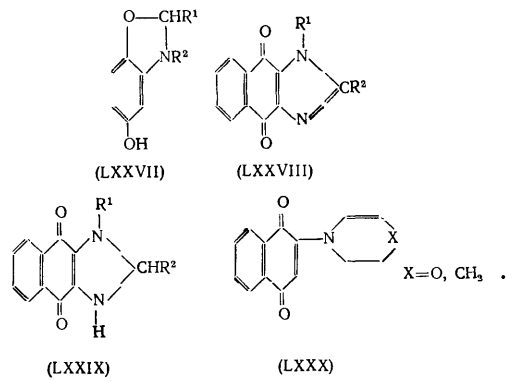
The biradical (LXVII), generated in the photolysis of 2-methoxy-1,4-naphthoquinone in benzene solution, apparently rearranges to the more stable biradical (LXVIII), to which styrene adds, forming compound (LXIX); [157] at the same time, there is sufficient time for the biradical (LXVII) obtained in acetic anhydride to react with the solvent, forming 1,4-diacetoxy-2-methoxynaphthalene [158]:

(LXVII) (LXVIII) (LXIX)

The photolysis in acetic anhydride of the same quinone but with a bromine substituent in the 3-position leads to compounds (LXX) and (LXXI), tentatively via the intermediate dipolar structure (LXXII): [158]



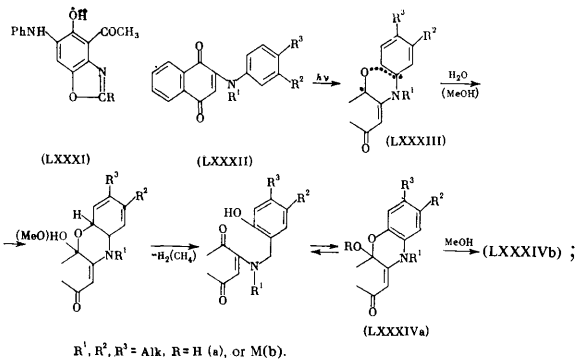
(LXX) (LXXI) (LXXII) (LXXIII)



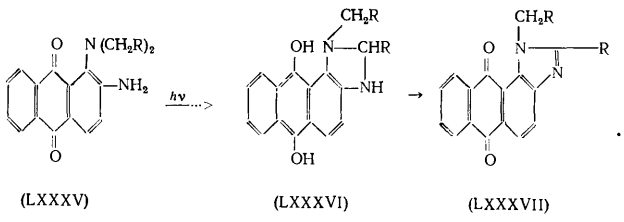
On photolysis, alkoxymethyl-1,4-benzoquinones yield polymeric phenolic acetals as a result of the intermolecular interaction of the substrate which has undergone intramolecular reduction. Benzo-1,3-dioxans (LXXIII) are sometimes formed, which may indicate the possible involvement of radicals generated by intermolecular photochemical reduction [2].

The presence of an ester group in the 2′-position of 1,4-benzoquinone does not lead to unexpected results following its photolysis: the corresponding benzofuran

derivative was obtained from 2-(2-ethoxycarbonylethyl)-1,4-benzoquinone in benzene[2]. If the side chain contains a terminal formyl group, the photochemical reaction products are lactones (LXXIV) or the corresponding hydroquinonecarboxylic acids[159]. The stabilisation of the biradicals (LXXV), obtained photochemically from 2-(1-formyl-1-methylethyl)-1,4-benzoquinone and the corresponding naphthoquinone, proceeds in a different way (with decarbonylation) and leads to benzo- and naphtho-furans of type (LXXVI) as a result of subsequent reactions[159]:

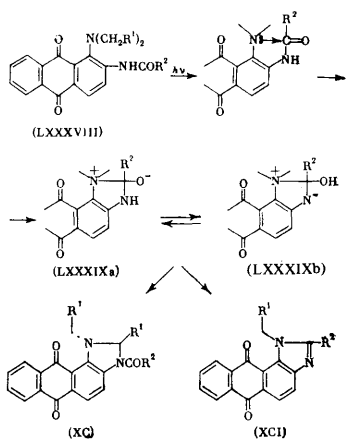


Aminoquinones. Amino-1,4-benzoquinones, containing the fragment $\rangle N-CH\langle$, give rise on photolysis to cyclisation products—derivatives of dihydro-oxazole (LXXVII).[2,160,161] Similar products were obtained from *NN*-dialkyl- or *N*-alkyl-2-amino-*N*-aryl-1,4-naphthoquinones when there was no amino-group in the 3-position[2,162,163]. Compounds (LXXVII) are unstable and undergo oxidative hydrolysis particularly readily, forming products resulting from the dealkylation of the initial quinones[2,161-163]:



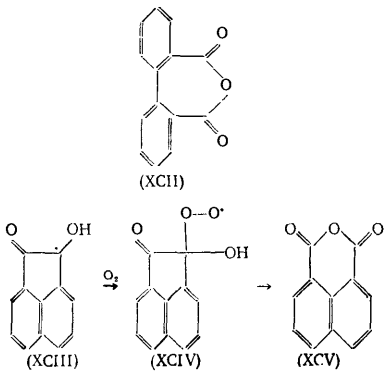
Naphthimidazoles (LXXVIII) and their dihydro-derivatives (LXXIX) have been obtained by the photolysis of 3-amino-2-dimethylamino(piperidino, morpholino)-1,4-naphthoquinones[164]. 2-Piperidino- and 2-morpholino-1,4-naphthoquinones do not cyclise but are dehydrogenated, forming compounds (LXXX).[165,166]. Although the mechanism of the formation of compounds (LXXVII)–(LXXX) has not been discussed, one cannot rule out intramolecular photochemical reduction as the first stage in such cases also.

The biradicals formed by the photochemical reduction of 2-acetyl-3-alkylamino-6-phenylamino-1,4-benzoquinones are converted, as a result of hydrogen transfer followed by ring closure and aromatisation (there is also a possibility of the formation of intermediate spiro-aziridines or imines) into the benzoxazole (LXXXI):[167,168]

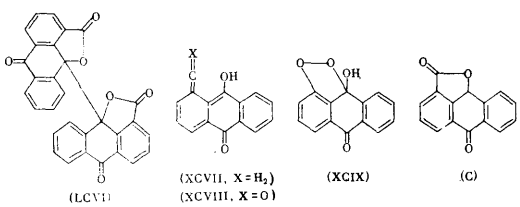


In the photolysis of *N*-substituted 2-phenylamino-1,4-naphthoquinones (LXXXII) in aqueous methanol solution, there is insufficient time for the intramolecular and intermolecular abstraction of a hydrogen atom by the biradical (LXXXIII) formed and the latter is stabilised by combining with a solvent molecule; the cyclisation products (LXXXIV) are formed ultimately[169].

The intramolecular photochemical reduction of the aminoanthraquinones (LXXXV) stabilises the intermediate biradicals by their conversion into anthrahydroquinones (LXXXVI), which are in turn converted into imidazoles (LXXXVII):[164]

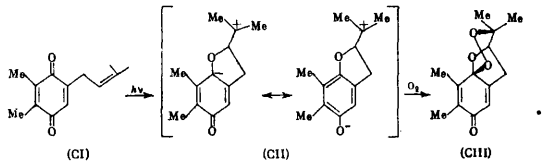


On the other hand, when an acylamino-group is present in the 2-position instead of the amino-group, it is reduced photochemically instead of the quinonoid moiety; the resulting dipolar structures (LXXXIX) are converted into imidazolines (XC) and imidazoles (XCI);[170,171] thus data[165,166] concerning the photochemical conversion of the acylamino-group of compounds (LXXXVIII) into the oxaziridine group were not confirmed:

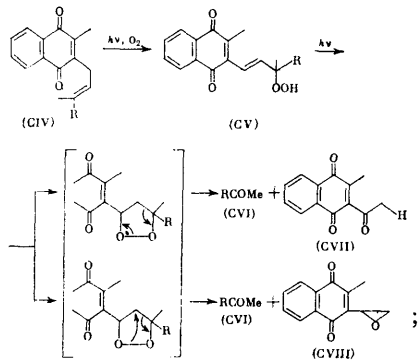


## III. PHOTOCHEMICAL OXIDATION

The photochemical oxidation of quinones reduces either to the oxidation of the side chain, which is characteristic of *p*-quinones or to the oxidative cleavage of the quinonoid fragment, which is characteristic of *o*-quinones. The primary step in the process is usually believed to be the photochemical reduction of the carbonyl group in one form or another. Thus the formation of the anhydrides (XCII) and (XCV) when aerobic solutions of phenanthrenequinone [3] and acenaphthenequinone [3,112] in acetonitrile, benzene, tetrahydrofuran, etc. are irradiated is attributed to the photochemical generation of a radical of type (XCII). The latter interacts with oxygen and gives rise to the peroxy-radical (XCIV), which is then converted into the anhydride (XCV):



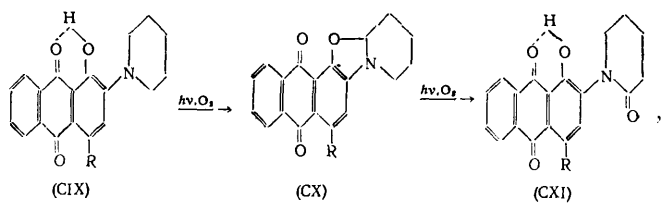
The photolysis of 1-methylanthraquinone in benzene saturated with oxygen yields compound (XCVI), while in the presence of air anthraquinone and anthraquinone-1-carboxylic acid are also formed [172,173]. In this case, the formation in the primary step of a photochemically enolised form of the quinone (XCVII) is postulated, the latter being converted by reaction with oxygen into the peroxide (XCIX) and then into 1-formylanthraquinone. The photochemical enolisation of the latter to the keten (XCVIII) and intramolecular attack by the hydroxyl on the keten group lead to the lactone (C) or its ketone tautomer. These compounds can be readily oxidised to the dilactone (XCVI). Anthraquinone is probably formed on photochemical decarbonylation of 1-formylanthraquinone:



Products with a related structure have also been obtained from methyl-1,4-naphthoquinone [173].

1-Acetylanthraquinone was obtained by the photochemical oxidation of 1-ethylanthraquinone. The photochemical oxidation of the less reactive isomer (2-methyl- and 2-ethyl-anthraquinones) leads to anthraquinone-2-carboxylic acid and 2-acetylanthraquinone respectively [172,173], but the mechanism involving photochemical enolisation is apparently not applicable to these reactions.

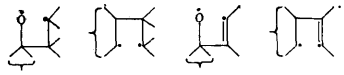
The presence of a multiple bond (a $\pi$-electron donor) in the side chain of the quinone can lead to intramolecular cyclisation on excitation of the molecule. It has been suggested [145,174,175] that plastoquinone 1 (CI) is in fact converted in this way into the zwitter-ion (CII), which reacts with oxygen to form the peroxide (CIII). Oxygen is apparently involved in the process in its ground state, since the peroxide (CIII) is not formed when singlet oxygen generated with the aid of sensitisers acts upon compound (CI):



Other isoprenoid *p*-quinones (CIV) which have been investigated participate in the photochemical oxidation reaction in a different way: on reaction with singlet oxygen (generated in control experiments by means of dyes), they form hydroperoxides (CV). On irradiation, these substances are then converted into ketones (CVI) and compounds (CVII) and (CVIII); the latter were not isolated owing to their instability [176]:

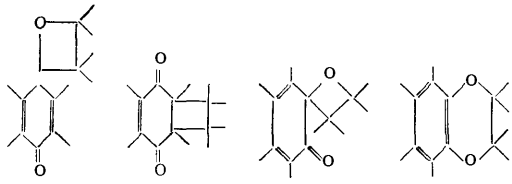
R = Me, $CH_2CH_2CH{=}CHMe$, $(CH_2)_4Me$, $(CH_2CH{=}CMeCH_2)_2H$, or $(CH_2CH_2CHMeCH_2)_3H$.

The specific influence of the quinonoid fragment appears unlikely in the oxidative cyclisation of 2-dialkylamino-1-hydroxyanthraquinones (CIX) (but not the 1-amino-derivatives), leading to anthraoxazolines (CX), and in the photochemical oxidative cleavage of the heterocycle of the latter [177], as in the previous reaction:



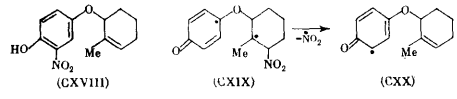
R=H,OH, or $NHCOCH_3$.

## IV. PHOTOCHEMICAL ADDITION



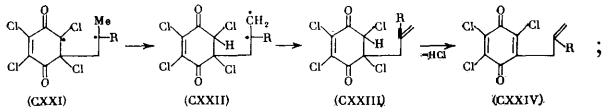
In almost all the processes examined, the reductant, a neutral molecule or an anion, behaves as a hydrogen atom or electron donor in relation to the excited quinone. We believe that one should not combine in a special group of reductants substances with multiple carbon–carbon bonds, differing from those described above by the nature of their interaction with quinones, since they are potential donors of $\pi$ electrons. Presumably the transfer of $\pi$ electrons from these substances to the oxygen or carbon

atom of the quinone leads to the formation of C–O and C–C bonds respectively in the photochemical step. The biradical structures (CXIIa) and (CXIIb) generated (by the addition of alkenes) or (CXIIIa) and (CXIIIb) (by the addition of alkynes) are subsequently stabilised by ring closure:



(CXIIa) (CXIIb) (CXIIIa) (CXIIIb)

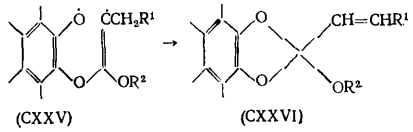
As a result of photochemical addition to the C=C bond of such substances, *p*-quinones are converted into oxetans (CXIV) and cyclobutane derivatives (CXV), while *o*-quinones give rise to oxetans (CXVI) and 1,4-dioxens (CXVII); the photochemical addition of quinones to the C≡C bond of the reductant leads to the corresponding oxeten, cyclobutene, and 1,4-dioxin derivatives:



(CXIV) (CXV) (CXVI) (CXVII)

Substances with a different structure are formed much more rarely. Their generation is usually associated with the fact that there is insufficient time for the biradicals produced on addition of unsaturated hydrocarbons to undergo ring closure and they are stabilised in a different way. For example, the photochemical reaction of 1,4-benzoquinone with 1-methyl-6-nitro-1-cyclohexene gave compound (CXVIII), probably as a result of the elimination of the $NO_2$ group from the biradical (CXIX) with its subsequent addition to the radical (CXX):[178]

(CXVIII) (CXIX) (CXX)

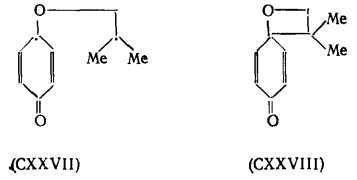


In another instance, the photolysis of tetrachloro-1,4-benzoquinone in the presence of 2-methylpropene or 2,3-dimethylbuta-1,3-diene produces biradicals (CXXI) which are converted as a result of hydrogen migration into (CXXII), after which pairing of electrons leads to (CXXIII); the latter compound is unstable, splits off HCl, and thus gives rise to compound (CXXIV):[179]

(CXXI) (CXXII) (CXXIII) (CXXIV)

R = Me or CMe = $CH_2$ .

The formation of dioxoles (CXXVI) on photolysis of phenanthrenequinone in the presence of alkyl- or alkoxyacetylenes has been explained[3,180,181] by a 1,2-hydrogen shift in the biradicals (CXXV) formed, which leads to allyl biradicals, stabilised by closure to a dioxole ring:



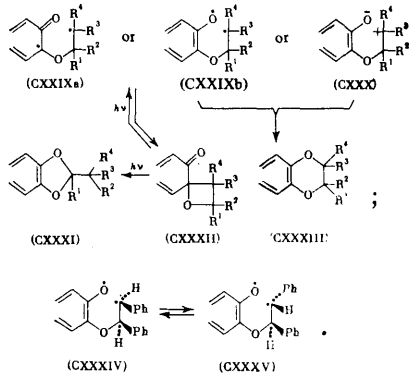
(CXXV) (CXXVI)

The quinone always participates in photochemical addition reactions in the excited state. In most but not all instances the triplet state of the substrate is then reactive and it is therefore desirable to explain the nature of the reactive excited state in each specific instance. The photochemical reaction of tetramethyl-1,4-benzoquinone with cyclo-octene is interesting from this point of view: in the presence of an excess of the quinone, the product is an oxetan and in the presence of an excess of cyclo-octene, it is a 1:2 adduct formed via the C=C bonds of the quinone[2]. It has been established that the oxetan is formed with participation of the *T* state of the quinone, while an increase in the concentration of the olefin should favour (in the absence of other complicating factors) the reactions of the quinone in the singlet state. If this interpretation is correct, significant differences between the photochemical reactions of quinones in the *S* and *T* states should naturally be expected.

Photochemical addition occurs successfully only when $E_T$ for the hydrocarbon (olefin, acetylene) is comparable or greater than $E_T$ for the quinone, so that there is no transfer of the energy of the triplet state. In particular, this factor is associated with the observation that simple ketones (for which usually $E_T > 60$ kcal mole$^{-1}$) rarely react with dienes and conjugated polyenes ($E_T < 60$ kcal mole$^{-1}$), whereas quinones ($E_T \leq 60$ kcal mole$^{-1}$) frequently enter into this reaction.

The following view appears to predominate at the present time concerning the $n,\pi^*$ or $\pi,\pi^*$ nature of the reactive state of quinones: quinones react via their C=C bonds in the $\pi,\pi^*$ state and via their C=O bonds in the $n,\pi^*$ state[2,179]. The distribution of the corresponding energy levels should be, from this standpoint, one of the principal characteristics determining the type of addition. The capacity of quinones for the simultaneous formation of different products can be accounted for either by the competition of processes involving energetically similar $n,\pi^*$ or $\pi,\pi^*$ states or by the fact that the excitation energy ($n,\pi^*$) is not fully localised in the carbonyl group, but is partly transmitted also to the C=C bonds of the quinone.

The photochemical addition of olefins to the carbonyl group of quinones is a specific instance of such a photochemical reaction in the series of ketones. It has been shown for the simplest ketones that the cryptoradical mechanism of such a process permits the correct prediction of the structure of the principal isomer among the oxetans formed: the oxetan corresponding to the most stable biradical with the largest number of alkyl or aryl groups at radical centres always predominates. This rule proved to be valid also in the photochemical reactions of certain *p*-quinones with olefins[2,179]: for example, the isomer (CXXVIII), formed from the biradical (CXXVII), predominates among the oxetans in the photolysis of 1,4-benzoquinone in the presence of 2-methylpropene:

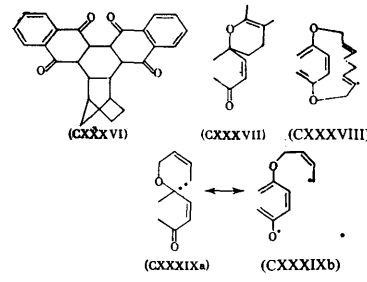


(CXXVII) (CXXVIII)

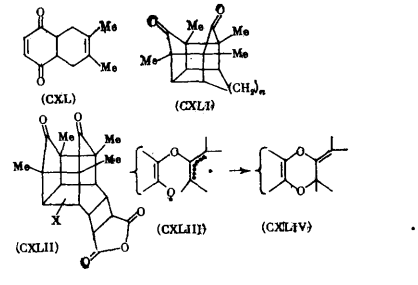
Predictions of this kind can probably be made for the photochemical reactions of both *p*- and *o*-quinones when the addition is to the carbonyl group; one cannot rule out the applicability of this rule also to photochemical addition to the C=C bonds of the quinone.

In the photochemical reactions of olefins with *o*-quinones, the biradical (CXXIX), obtained by the addition of the olefin to the quinone, gives rise to a dioxen (CXXXIII) and

(or) an oxo-oxetan (CXXXII), which, being unstable, is converted photochemically into the starting materials and (to a slight extent) into the dioxole (CXXXI):



If the olefin contains the appropriate substituents, the above products [for example (CXXXIII)] can be obtained in the form of a mixture of stereoisomers. Thus the photochemical addition of phenanthrenequinone to simple *cis*- or *trans*-alkenes (but-2-ene, oct-4-ene, etc.) leads to a mixture of *cis*- or *trans*-dioxens [2,3]. Evidently the intermediate triplet biradical (CXXIX) is sufficiently long-lived for the establishment of conformational equilibrium, which in fact determines the proportions of the *cis*- and *trans*-adducts formed on pairing of the electrons. The observed stereospecificity in the photochemical reactions of tetramethyl-1,2-benzoquinone with *trans*-stilbenes and a certain selectivity in the photochemical addition of phenanthrenequinone to stilbenes [3] have been explained by the considerable contribution in such cases of the ionic structure (CXXX) to the resonance hybrid of the intermediate biradical; the interaction between the charges to a large extent limits the free rotation about the C–C bond, which should ensure steric control.

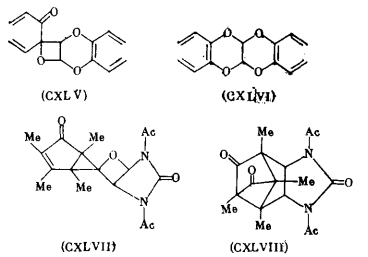


The above assumptions are in good agreement with the finding that the ratio of the *cis*- and *trans*-adducts formed from simple olefins does not depend on temperature, while the addition of phenanthrenequinone to stilbenes exhibits a decrease of selectivity with increase of temperature [3]. In the latter case, the interconversion of the radicals (CXXXIV) and (CXXXV) probable begins to compete with ring closure, since there is only a small energy barrier to rotation.

The simplest of the *p*-quinones (1,4-benzoquinone) forms only oxetans in photochemical reactions with non-conjugated acyclic and cyclic alkenes [2,179]. 2,3-Dimethyl- and tetramethyl-1,4-benzoquinones combine with alkenes only via the C=C bond [2,179,182]; tetrachloro-1,4-benzoquinone gives rise to both cyclobutanes and oxetans [2,179]; in the presence of an excess of the olefin, biscyclobutane structures may be obtained.

1,4-Naphthoquinone combines with alkenes to form oxetans and cyclobutanes [2,183,184]; its characteristic feature is the ability to form 2:1 quinone–olefin adducts [for example, the reaction with norbornene results in the formation of the adduct (CXXXVI) [185]]. The photolysis of anthraquinone in the presence of cyclo-octene and cyclo-octa-1,5-diene leads exclusively to oxetans [186]. All *o*-quinones give rise to oxetans or dioxens in reactions with alkenes; the addition to the C=C bond of the quinone has not been observed [1-3,187-193]:

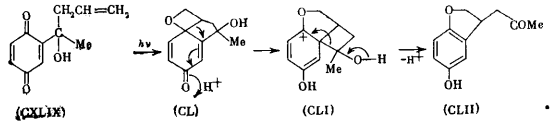
Spirodihydropyrans (CXXXVII) are the products of the photochemical reactions of *p*-quinones (1,4-benzo- [2,282] and naphtho-quinones [179]) and certain conjugated olefins, while the macrocyclic adduct (CXXXVIII) is also formed in the reaction of buta-1,3-diene and 1,4-benzoquinone. The macrocyclic adduct is believed to be produced as a result of the addition of a second buta-1,3-diene molecule to the biradical (CXXXIXb), while compound (CXXXVII) is formed as a result of the intramolecular stabilisation of the mesomeric form (CXXXIXa) of the biradical. Depending on the photolysis conditions, compounds (CXXXVII) or (CXL) can be obtained for 2,3-dimethylbuta-1,3-diene. The reactions of tetramethyl-1,4-benzoquinone with certain conjugated dienes (cyclopentadiene, cyclohexa-1,3-diene) result in the formation of cage structures (CXLI), [194] while 1:1:1 adducts have been obtained in the photolysis of the benzoquinone in benzene derivatives ($C_6H_5X$, X = H, $CH_3$, or a halogen) in the presence of maleic anhydride [2]:



It is believed [195-197] that, in the photochemical reactions of allenes with *o*-quinones (phenanthrenequinone, tetrachloro-1,2-benzoquinone), the central carbon atom of the allene system is attacked with formation of the biradicals (CXLIII), whose stabilisation leads to dioxens (CXLIV).

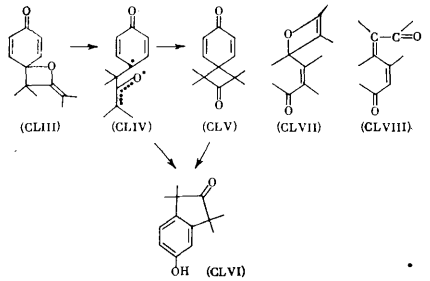
Cyclobutene structures have been obtained in the photochemical addition of mono- and di-substituted acetylenes to 1,4-naphthoquinone and its methyl and acetoxy-derivatives [198,199]. The exclusive addition of acetylenes to the C=C bond of methoxy-1,4-naphthoquinones [2,200-203] has been explained [202] by the fact that the $OCH_3$ group localises the excitation at this bond and stabilises the intermediate biradical, promoting the formation of cyclobutene derivatives.

Phenanthrenequinone and tetrachloro-1,2-benzoquinone add to alkenynes with conjugated multiple bonds only at the C=C bond with formation of the corresponding oxetans and dioxens [204].



The primary products of the photochemical addition of unsaturated hydrocarbons to the C=C and C=O bonds of

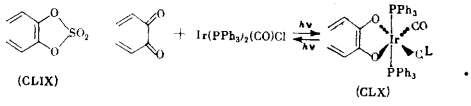
quinones are frequently unstable and cannot be isolated, since they undergo further dark or photochemical reactions. For example, the photo-adducts of phenanthrenequinone with chloro-olefins split off HCl and the compound thus produced adds to the excited phenanthrenequinone, forming adducts with 2 : 1 quinone : olefin ratios [compounds (CXLV) and (CXLVI)]: [2,205]



The oxetan obtained by irradiating tetramethyl-1,4-benzoquinone in the presence of 1,3-diacetyl-$\Delta^4$-imidazolin-2-one is converted photochemically into compound (CXLVII), from which compound (CXLVIII) is formed via a dark process [2].

The spiro-oxetan (CL) produced by the photolysis of compound (CXLIX) in benzene ultimately gives rise to dihydrobenzofuran (CLII); it is noteworthy that the conversion of (CXLIX) into (CL) is the only known example of the intramolecular formation of an oxetan from quinones with an unsaturated side chain [156]:

As in the examples quoted above, it is assumed that the photochemical reactions of *p*-quinones (1,4-benzo- and naphtho-quinones) with allenes result in the formation of an oxetan (CLIII), which rearranges to the phenolic derivative (CLVI) either directly or via an intermediate spirocyclobutanone (CLV): [206]



Mono- and di-substituted acetylenes undergo photochemical addition to the carbonyl groups of 1,4-benzoquinone, tetramethyl-1,4-benzoquinone, anthraquinone [2,179,186], 1,4-naphthoquinone, and its methyl and acetoxy-derivatives [198] with formation of quinonemethines (CLVIII) via the intermediate oxetens (CLVII). Phenanthrenequinone and tetrachloro-1,2-benzoquinone form 1 : 2 adducts of type (CXLVI) with individual acetylenes, since the initial dioxyns subsequently undergo a further photochemical addition reaction [3,180,181].

Apart from the instances described above, in photochemical addition processes the excited *p*-quinone molecule frequently reacts with another molecule of the same quinone but in its ground state; such examples are unknown for *o*-quinones. This type of photochemical dimerisation of the simplest *p*-quinones (1,4-benzo- and naphthoquinones and their derivatives) [2,207-211] and more complex natural products [2,212] takes place in solutions and in the solid state, resulting in the formation of spiro-oxetan, cyclobutane, and cage structures similar to those discussed above.

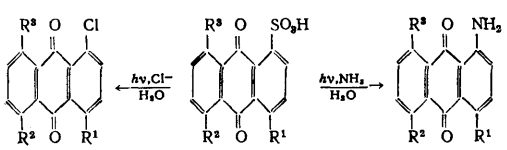
The ability to undergo photochemical dimerisation is determined to a large extent by the stabilisation energy of the exciplexes of quinones: those which are converted into stable adducts (for example, the species formed from 2,3-, 2,5-, and 2,6-dimethyl-1,4-benzoquinones) have a significantly greater stabilisation energy than those which do not form dimers (for example, the species formed from tetramethyl-1,4-benzoquinone) [213].

In contrast to solutions [2,214-216], the crystal structure, which determines the feasibility and direction of the reaction (the type of the product and its stereochemical characteristics), plays an important role in solid-phase photochemical dimerisation. Thus the process occurs when the reaction centres are separated by not more than 4 Å; on the other hand, the structure of the dimer is determined by the relative orientations of the monomers (the geometrical disposition of the parallel C=C and C=O bonds) in the crystal. The formation of polymeric materials in the photolysis of certain *p*-benzoquinones (1,4-benzoquinone, tetramethyl-1,4-benzoquinone) in the solid phase is attributed to the fact that the crystal structures of these compounds are characterised by an infinite chain of close C...C contacts between non-parallel C=C chains; their interaction leads to dimeric biradicals, which initiate polymerisation [2].

Whereas a characteristic feature of *p*-quinones is their capacity for photochemical dimerisation, a specific feature of *o*-quinones is their ability to combine on photochemical excitation with inorganic substances and organic derivatives of the elements with formation of C—element (element ≠ carbon) bonds. A reaction of this type, which has been known for a long time, is the so called "cyclosulphate synthesis" [2,3]—the addition of sulphur dioxide to the oxygen atoms of *o*-quinones (tetramethyl-1,2-benzoquinone, 1,2-naphthoquinone, its 3-nitro-derivative, phenanthrenequinone, its 2-, 3-, and 4-nitro-derivatives, chrysenequinone) with formation of compounds (CLIX):

The oxidative photochemical addition of $Ir(PPh_3)_2(CO)Cl$ to *o*-quinones (tetramethyl-1,2-benzoquinone, phenanthrenequinone, 1,2-naphthoquinone) [217] may be a convenient method for the synthesis of complexes of type (CLX). The process is reversible and takes place until the attainment of a specific equilibrium. Although both components are excited, the authors believe that the triplet state of quinones is reactive, by analogy with the cyclosulphate synthesis.

## V. PHOTOCHEMICAL SUBSTITUTION

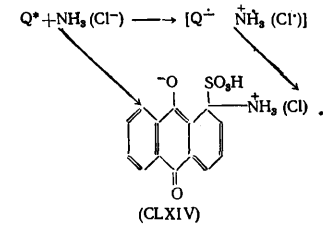


It is clear from the foregoing data, that the structure of the final photolysis products cannot in all cases constitute a sufficient criterion for the assignment of the photochemical reactions of quinones to a particular type. This is due to the formal nature of this feature, since the final products which can be isolated from the photolysed mixture do not always arise as a result of the photochemical

reaction of the excited quinone molecule with a given reactant. They are frequently formed in secondary dark or photochemical reactions, while the primary photochemical processes generate only the reactive species necessary for their occurrence. It is not even an obligatory condition that the quinone should participate in the secondary processes; the species produced by its primary reaction may be involved. All the foregoing considerations apply fully also to the photochemical reactions in which products resulting from substitution in the quinone ring or in its side chain are formed. For example, the photochemical process in the light-induced hydroxylation of sulphoanthraquinones, the elimination of their sulpho-group in reducing media, and the substitution of the $OCH_3$ group in methoxyanthraquinones by a hydroxy-group is the reduction of the quinone (see above), while the substitution of chlorine in tetrachloro-1,4-benzoquinone by an unsaturated hydrocarbon takes place as a result of the photochemical addition of hydrocarbons to the quinone (see section IV). One must therefore investigate in detail the mechanisms of such photochemical reactions before concluding that they are photochemical substitution reactions.

This section is concerned with the photochemical reactions of quinones which have been assigned on the basis of available data to photochemical substitution processes, and with reactions whose mechanism still has to be refined.

In concentrated aqueous solutions of inorganic acids, the sulpho-group is eliminated photochemically from 1-sulphoanthraquinone (but not the 2-derivative) via a hydrolytic mechanism with simultaneous formation of 1-hydroxyanthraquinone. The quantum yield of the photochemical hydrolysis is independent of the wavelength of the exciting light and its limiting value (approximately $10^{-3}$) is low, probably owing to the quenching of the excited substrate molecules by $H^+$ ions [15,135,136].

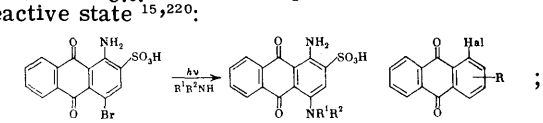


The irradiation of $\alpha$-sulphoanthraquinones (CLXII) in aqueous solutions containing chloride ions or ammonia results in the substitution of the sulpho-group by a chlorine atom or an amino-group respectively [15] (see also Eckert [218]). The yields of chlorination products are higher than those of the amination products, since the side products formed in the latter case (water-soluble hydroxy- and amino-sulphoanthraquinones) filter out photochemically active light. In contrast to electron-accepting substituents ($SO_3H$, $NO_2$, halogens), electron-donating substituents (OH, $NH_2$) inhibit the photochemical process; contrary to one report [54], the substitution of $\beta$-sulpho-groups always takes place with a very low efficiency. The photochemical substitution of $\alpha$- and $\beta$-sulpho-groups by alkyl- or aryl-amino-groups does not take place; traces of 1-methylaminoanthraquinone have been detected only when 1-sulphoanthraquinone was irradiated in aqueous methylamine solution with long-wavelength light ($\lambda_{exc} > 300$ nm): [15]

(CLXI) (CLXII) (CLXIII)

$R^1, R^2, R^3$ = H, Cl, $SO_3H$, or $NO_2$.

The available data suggest that the mechanisms of the photochemical chlorination and amination are the same and that the same excited state of the substrate (probably $n,\pi^*$) is reactive [15,136,219]. Two hypotheses have been put forward concerning the reaction pathways in the above processes. The first involves the nucleophilic substitution (in the classical sense, via an intermediate $\sigma$-complex) of the sulpho-group. The structure (CLXIV) can then be formed also as a result of the interaction of the radical (radical-ion) pairs generated by electron transfer in the solvent cage [15,54]:



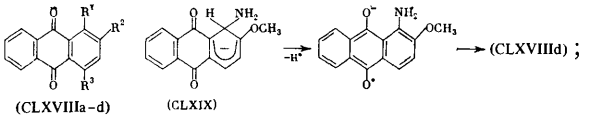
(CLXIV)

The second, alternative pathway involves the radical substitution of the sulpho-group. For example, the photochemical stage in the chlorination process may involve the generation of a Cl· atom by electron transfer from the $Cl^-$ ion to the excited substrate molecule; in the subsequent dark process, the sulpho-group is substituted by chlorine:

$$Q^* + Cl^- \rightarrow Q^{\cdot-} + Cl^\cdot; \; Q + Cl^\cdot \rightarrow QCl.$$

Apart from the sulpho-group, it is also possible to substitute photochemically the halogen atom in the anthraquinone ring by an amino-group. Thus the bromine atom is readily substituted by amino-, alkylamino-, and dialkylamino-groups in the photolysis of 1-amino-4-bromo-2-sulphoanthraquinone (CLXV) in aqueous aerated solutions of the corresponding amines. The increased rate of the process following the introduction of additives (MeCN > PrOH > dioxan > $H_2O$) is treated as evidence of the formation of a polar intermediate. The cleavage of the carbon–halogen bond under the influence of light is believed to be unlikely; the $S^1_{c.t.}$ state of compound (CLXV) is treated as the reactive state [15,220]:

(CLXV) (CLXVI) (CLXVII)



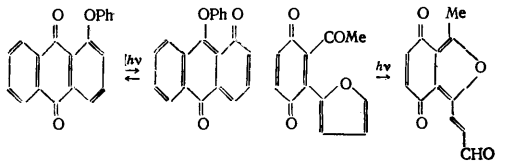
R = 4-OH, 2-$NH_2$, or 4-$NH_2$; Hal = Cl, or Br; $R^1, R^2$ = H, or Alk.

The capacity for the photochemical substitution of the halogen by an amino-group in aerobic alcoholic solutions of ammonia is characteristic of 1-halogenoanthraquinones when there are powerful electron-donating substituents in the 2- or (and) 4-positions, i.e. is characteristic of compounds of type (CLXVII). The process does not occur in the absence of substitutions, in the presence of only electron-accepting or weak electron-donating (methyl) groups, and also when strong electron-donating substituents are located in positions other than those indicated [221–224]. It has been possible to show that the $T^1_{c.t.}$ (or $\pi,\pi^*$) state is reactive in the case of 1-amino-4-chloroanthraquinone and 1-amino-4-bromoanthraquinone [223].

The role of oxygen is not merely oxidative, since the corresponding anthrasemiquinones and anthrahydroquinones are not involved in photoamination, while in deaerated media in the presence of other oxidising agents the halogen is not substituted (in polar solvents) [15,220,224]. The interaction of the substrate with singlet oxygen (obtained as a result of energy transfer from a triplet halogenoanthraquinone molecule) or attack by the amine (ammonia) on the exciplex of the excited substrate and oxygen is believed to be possible [220]. It has been shown for 1-amino-2,4-dibromoanthraquinone that the substrate

interacts in the $S^1_{c.t.}$ state in a polar solvent (MeCN), while in a non-polar solvent ($C_6H_6$) the compound in the $T^1_{c.t.}$ state is attacked by the amine and there is no necessity for oxygen. This change in the nature of the reactive excited state is attributed to a change in the disposition of the energy levels of the substrate when the nature of the solvent is altered [225].

The amino-group can substitute photochemically both the hydrogen atom and the $OCH_3$ group in the anthraquinone ring [226,227]. Thus compounds (CLXVIII, a–d) were obtained from 1- and 2-methoxyanthraquinones on irradiation in an acetonitrile–water mixture containing ammonia. Since the addition of radical acceptors does not decrease the rate of reaction, it is concluded that it is heterolytic. Whereas the formation of aminoanthraquinones is believed to proceed in the usual way, it is assumed that the $\sigma$-complex (CLXIX) is stabilised on formation of compound (CLXVIIId) by the abstraction of atomic hydrogen and not a hydride ion; accordingly, the rate of formation of compound (CLXVIIId) is reduced in the absence of oxygen. The $S^1_{n,\pi^*(\pi,\pi^*)}$ state of the substrate is assumed to be reactive:

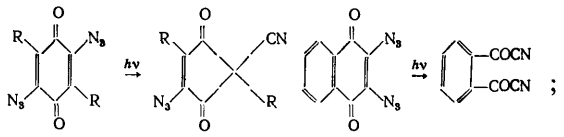


(CLXVIIIa–d) (CLXIX)

(a) $R^1 = NH_2$, $R^2 = R^3 = H$; (b) $R^1 = OCH_3$, $R^2 = H$, $R^3 = NH_2$;
(c) $R^1 = R^3 = H$, $R^2 = NH_2$; (d) $R^1 = NH_2$, $R^2 = OCH_3$, $R^3 = H$

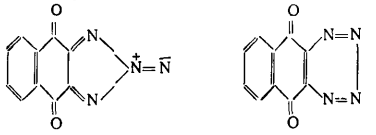
When 1-phenoxyanthraquinone is irradiated with ultraviolet light in benzene solution, it is converted into a coloured form. If irradiation is not interrupted, the product is 1-hydroxyanthraquinone, which is also formed on contact between the light-induced coloured form of 1-phenoxyanthraquinone and $Al_2O_3$. The mechanism of the process has not been discussed [228,229].

## VI. UNIMOLECULAR PHOTOCHEMICAL REACTIONS OF QUINONES UNRELATED TO THEIR PHOTOCHEMICAL REDUCTION



Reactions of the above type are few and are characterised by the fact that electronic excitation is localised in side chains; the primary photochemical reactions of the latter can be accompanied by secondary processes involving the quinonoid fragment. An exception is probably the formation, already mentioned, of the light-induced coloured forms of 1-phenoxy-, 1,5-diphenoxy-, and 1,8-diphenoxyanthraquinones and 10-phenoxynaphthacenequinone on their irradiation in non-polar solvents [228–230]. The spectra of the starting materials are restored when the irradiated solutions are kept in the dark or are irradiated with light corresponding to the new absorption band ($\lambda_{max} > 440$ nm). There are no exact data available for the mechanism of the photochromic transformations, but the authors assume that the colour of the light-induced form is associated with the polarisation of the carbonyl groups [229] or with the photoisomerisation of the *p*-quinone to an isomer with a higher oxidation-reduction potential—anaquinone [for example, (CLXX) → (CLXXI)]: [230]

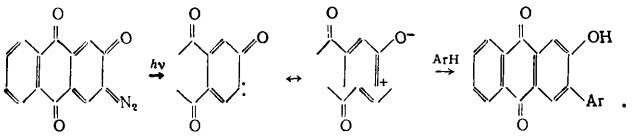
(CLXX) (CLXXI) (CLXXII) (CLXXIII)



The photochemical rearrangement of the quinone (CLXXII) to compound (CLXXIII) is explained by the local excitation of the acetyl group [2].

Photolysis of 2,5-diazido-1,4-benzoquinones (CLXXIV) [231] and 2,3-diazido-1,4-naphthoquinone (CLXXVI) [232] leads to the elimination of one and two nitrogen molecules respectively; the resulting nitrenes are stabilised by conversion into compounds (CLXXV) and (CLXXVII). In the latter case, structures (CLXXVIII) and (CLXXIX) are postulated as intermediates which split off nitrogen:

(CLXXIV) (CLXXV) (CLXXVI) (CLXXVII)



R=Me, $Me_3C$

(CLXXVIII) (CLXXIX)

The esters of 1,2-naphthoquinonediazosulphonic acids and di(tri)hydroxyanthraquinones, containing 1–2 free hydroxy-groups, also eliminate a nitrogen molecule on irradiation and the ketocarbenes formed rearrange to ketens [233]; a similar process is characteristic of *o*-quinone diazides, used as the main component in various light-sensitive layers [234]. The sensitisation of the photochemical decomposition by the anthraquinone residue is postulated in this case [233].

The electrophilic ketocarbenes (CLXXXI), formed by the photolysis of compound (CLXXX), interact with a solvent of type ArH and give rise to 2-hydroxy-3-arylanthraquinones (CLXXXII): [235]

(CLXXX) (CLXXXI) (CLXXXII)

## VII. THE INITATION AND INHIBITION OF PHOTOCHEMICAL REACTIONS BY QUINONES

One of the possible mechanisms of the initiation of photochemical reactions by quinones involves the transfer of the triplet state energy by the latter to various reactants. This sensitisation pathway§ is facilitated by the wide range of values of $E_T$ for different quinones (see Table) and the fairly high values of $\Phi_{ST}$ (as shown by the quantum yields of the photochemical reduction of many quinones, which are close to unity); for example, $\Phi_{ST} \simeq 0.9$ for anthraquinone [236].

The decomposition of 1-iodonaphthalene [242], the *cis-trans*-isomerisation of stilbenes, 2-, 3-, and 4-styrylpyridines, and 1- and 2-styrylnaphthalenes [243,244], and the

§ The term "sensitisation" is used here in a wide sense and implies the initiation of the photochemical process in the presence of an additive, regardless of the method by which initiation is achieved.

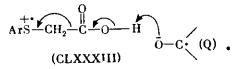
The energetic characteristics of the excited states of certain quinones.

| Compound | $E$, kcal mole$^{-1}$ | Compound | $E$, kcal mole$^{-1}$ |
|---|---|---|---|
| 1,4-Benzoquinone | 59 ($S^1$)[237]; 53.5 ($T^1$)[239]; 53 ($T^1$)[237]; 50 ($T^1$)[238] | 2,7-Disulphoanthraquinone (disodium salt) | 60 ($T^1$) |
| 1,4-Benzoquinone-$d_4$ | 53.5 ($T^1$)[239] | 1-Chloroanthraquinone | 60.5 ($T^1$) |
| 1-Methyl-1,4-benzoquinone | 54.7 ($T^1$)[239] | 1,5-Dichloroanthraquinone | 59.4 ($T^1$) |
| 2,5-Dichloro-1,4-benzoquinone | 55 ($T^1$)[239] | 1,8-Dichloroanthraquinone | 59.7 ($T^1$) |
| Tetramethyl-1,4-benzoquinone | 52 ($T^1$)[238] | 2-Chloroanthraquinone | 60 ($T^1$) |
| 1,4-Naphthoquinone | 62.8 ($S^1$)[239]; 58 ($T^1$)[237]; 53,7 ($T^1$)[239] | 1-Aminoanthraquinone | 52.2 ($S^1$) |
| 2-Methyl-1,4,-naphthoquinone | 63.3 ($S^1$)[239]; 53.8 ($T^1$)[239] | 2-Aminoanthraquinone | 54.1 ($S^1$) |
| 9,10-Phenanthrenequinone | 49 ($T^1$)[240] | 1-Amino-2-methylanthraquinone | 53 ($S^1$) |
| Anthraquinone | 67.8 ($S^1$)[239]; 62 ($T^1$)[238]; 60,5 ($T^1$)[241] | 1-Amino-5-chloroanthraquinone | 51.3 ($S^1$) |
| 2-Methyl-anthraquinone | 68 ($T^1$)[239]; 60,2 ($T^1$)[241] | 1-Amino-4-hydroxyanthraquinone | 48.9 ($S^1$) |
| 2-Sulphoanthraquinone (sodium salt) | 60 ($T^1$) * | 1,4-Dihydroxyanthraquinone | 53.8 ($S^1$) |
| 2,6-Disulphoanthraquinone (disodium salt) | 60 ($T^1$) * | 1,4-Di(methylamino)anthraquinone | 39.8 ($S^1$) |
| | | 1-Methylamino-4-*p*-toluidinoanthraquinone | 38 ($S^1$) |

*Data taken from Dearman and Chan [241].

reaction of anthracene with $CCl_4$ [245] may be quoted as examples of this type of sensitisation. In all cases, the systems were irradiated with light corresponding to the absorption band of the triplet energy donor (anthraquinone) and the occurrence of sensitisation confirmed the triplet nature of the excited states of the reactants.

Together with the solution of theoretical problems, energy transfer from quinone molecules has been used also for practical purposes. Thus the graft-copolymerisation of natural rubber with various monomers (styrene, methyl methacrylate) can be achieved in an emulsion under the influence of ultraviolet and visible light if 1-chloroanthraquinone is added to the mixture [246]. Various polycyclic quinones are used to initiate the photopolymerisation of acrylic or $\alpha$-alkylacrylic esters [247]. In order to "sensitise" layers based on organic azides towards light with wavelengths $> 300$ nm, anthraquinone is added to cyclorubber based on 4,4′-bisazidodiphenylmethane [248], while 1,4-benzoquinone and 1,2-benzanthraquinone are added to the polymer $[-CH_2CH.(O_2CC_6H_4N_3\text{-}p)-]_n$ [249].



The photochemical oxidation of isopropylbenzene, tetralin, and benzaldehyde is sensitised by anthraquinone, 2-chloroanthraquinone, and 2-aminoanthraquinone [250–252]. It is believed that the biradical $^{\cdot}QO_2^{\cdot}$, formed on interaction between the excited quinone molecule and oxygen, is the initiator in this radical process; it is noteworthy that the yield of triplet quinone (Q) molecules increase under the influence of oxygen [253]. The intermediate form $^{\cdot}QO_2^{\cdot}$ either has a sufficiently large energy store to convert the substance being oxidised into a biradical (triplet) state or, if this condition is not fulfilled, it initiates the chain, dehydrogenating the substance AH undergoing oxidation:

$$Q\,(S^1) + O_2 \rightarrow {}^{\cdot}Q^{\cdot}\,(T^1),$$
$$Q\,(T^1) + O_2 \rightarrow {}^{\cdot}QO_2^{\cdot},$$
$${}^{\cdot}QO_2^{\cdot} + AH \rightarrow QO_2 + {}^{\cdot}AH^{\cdot}\,(T^1) \longrightarrow \text{chain},$$
$$\text{or } {}^{\cdot}QO_2^{\cdot} + AH \rightarrow {}^{\cdot}QO_2H + A^{\cdot} \longrightarrow \text{chain}.$$

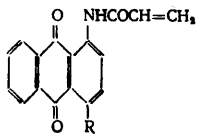
Apart from the photochemical oxidation of alcohols sensitised by quinones, which was examined previously (see Section II), other photochemical reactions are known, whose initiation by quinones involves the photochemical reduction of the latter. This applies particularly to the decarboxylation of acids of the type $RXCH_2CO_2H$ (R = alkyl or aryl; X = O, S, or NH) in the presence of quinones (1,4-benzoquinone, tetrachloro-1,4-benzoquinone, anthraquinone). The process mechanism can be represented as follows [254]:

$$Q^{\cdot} + RXCH_2CO_2H \longrightarrow QH^{\cdot} + RX\dot{C}H_2 + CO_2,$$

$$QH^{\cdot} + RX\dot{C}H_2 \longrightarrow Q + RXCH_3,$$

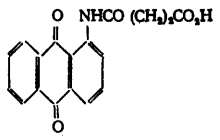
(CLXXXIII)

One cannot rule out the possibility of decarboxylation in a cage formed by the charge-transfer complex (CLXXXIII) of the acid and the quinone, where the most mobile hydrogen atom of the carboxy-group approaches the oxygen atom of the carbonyl group of the quinone.



Anthraquinone-$\beta$-sulphonates which have been reduced photochemically in aqueous or aqueous alcoholic solutions (to sulphoanthrahydroquinone in neutral media or a radical anion at pH $> 11$) can serve as electron donors in relation to many compounds The process may involve only electron transfer (to stable radicals, quinones, and $Fe^{3+}$ ions) or the simultaneous initiation of a chain of chemical reactions (the reduction of nitro-compounds, certain decomposition reactions, etc.). $\beta$-Sulphoanthraquinones thus behave as sensitisers of the reduction of electron acceptors, which are themselves relatively inactive photochemically [255].

The introduction of anthraquinone during the irradiation of toluene increases the yield of 1,2-diphenylethane [256]. Since there is no energy transfer under these conditions [$E_T$(toluene) $> E_T$(anthraquinone)], the increase in process efficiency is probably caused by the greater number of benzyl radicals due to the photochemical dehydrogenation of toluene by anthraquinone.



The photochemical degradation of *cis*-1,4-polyisoprenes in solutions is believed [257] to be caused by radicals formed from additives—quinones (1,4-naphthoquinone, anthraquinone, 1,2-benzanthraquinone, phenanthrenequinone).

Anthraquinone is used as the sensitising additive to photochemically polymerisable materials for photographic films [258] and to phototropic thermoplastic resins [259], while 1,5-diphenoxy-, 1,6-diphenoxy-, and 1,5-di-(*p*-methoxyphenoxy)-anthraquinones are also added to thermoplastic resins. The purpose of the addition of quinones to certain polymers is exactly the opposite; for example, 1,2- and 1,4-naphthoquinones, anthraquinones, and 1,2-benzanthraquinones are added to polystyrene in order to decompose it by photochemical oxidation [260].

It has been suggested that quinones can be used for this purpose also in compositions with other polymers in order to solve the problem of the degradation of packing materials. In this and many other examples enumerated above, it has not been established exactly how the photochemical reactions are initiated—by energy transfer from quinone molecules or by the reactive semiquinones formed on their photochemical reduction. Both initiation mechanisms may operate simultaneously:

(CLXXXIV)
R=H,OH

(CLXXXV)

Cases are known where quinones do not sensitise but actually inhibit photochemical processes: thus 1,4-naphthoquinone and anthraquinone diminish the extent of the photochemical degradation of vinyl polymers[261], while dyes of the anthraquinone series (CLXXXIV) and (CLXXXV) stabilise poly(methyl methacrylate)[262]. Such phenomena have so far been attributed only to the light filtration effect, but this explanation is probably not the only one possible.

---o0o---

It has been found that excited quinones almost always behave as electron (hydrogen) acceptors in the primary photochemical step; on the other hand, the secondary processes reduce to intermolecular interaction with the reductant (solvent) or to the intramolecular stabilisation of the radical or biradical intermediates formed. We have endeavoured to demonstrate this in a logical manner in the description of the entire relevant data. This approach may not be entirely rigorous, since in many instances the formation of intermediates and the reaction mechanism as a whole have not been fully demonstrated and are tentative or have been assumed by analogy. Nevertheless, we believe that it can serve as a basis for a systematic treatment of the photochemical reactions of quinones.

# The Reactions of Isatin and Its Derivatives with Aromatic and Heterocyclic *o*-Diamines

A.V.Ivashchenko and V.M.Dziomko

Studies on the reaction of isatin and its derivatives with aromatic and heterocyclic *o*-diamines are reviewed, and the mechanism of these reactions as well as the methods for the identification of their products are examined.
The bibliography includes 57 references.

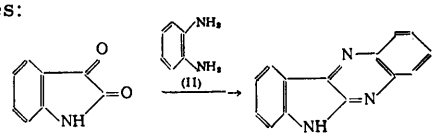
## I. INTRODUCTION

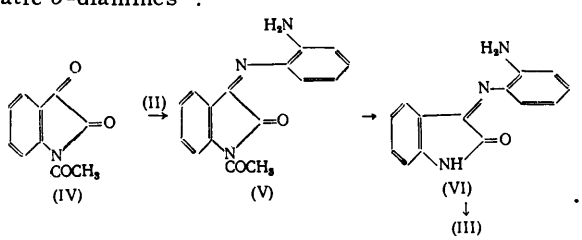


The reactions of isatin and its derivatives with aromatic and heterocyclic *o*-diamines, discovered in 1886 by Hinsberg[1], constitute an important method for the synthesis of condensed heteroaromatic systems, particularly purine analogues, as well as heteropolymers. The products of the reactions of isatins with aromatic heterocyclic *o*-diamines are of considerable interest as biologically active substances[2-15] (antimetabolites[2] and bactericidal[3-6], antifungal[7], antispasmodic, etc. agents), catalysts in colour photography[16], dyes for wool[17], and polydentate ligands capable of forming metal chelates stabilised by intramolecular hydrogen bonds[18-21], and are of interest as selective extractants[22].

It was believed for many years that the condensation of isatins with *o*-diamines always leads to derivatives of indolo[2,3-*b*]quinoxaline, but the latest data[15,20,21,23] have shown that the reaction does not proceed unambiguously and not only indolo[2,3-*b*]quinoxaline derivatives but also spiro-compounds are formed depending on the reaction conditions and the structures of the initial compounds.

Since the condensation of isatins with *o*-diamines has been attracting increasing attention in recent years, it is useful to survey the results of research on this reaction taking into account the latest data, with due attention to spectroscopic methods for the identification of the compounds formed.

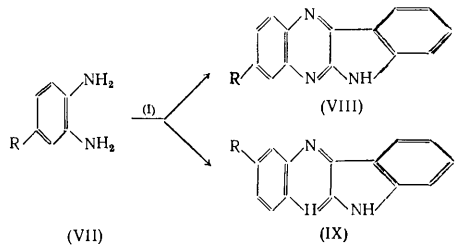
## II. THE REACTIONS OF ISATINS AND ITS DERIVATIVES WITH AROMATIC *o*-DIAMINES



Schunk and Marchlewski[24-28] were two of the first investigators who studied the reactions of isatin (I) and its derivatives with aromatic *o*-diamines (II) in connection with the investigation of the properties of isatin. They obtained indolo[2,3-*b* quinoxaline] (III) and some of its derivatives:

(I) (III)

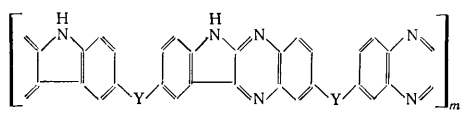
Subsequently the reactants employed in this reaction were isatin[1,15,17,21,23,24,27-35], *N*-substituted[6,23,28,30], alkyl- and alkoxy-[12,25,31,36-38], halogeno-[17,24,25,34,36,37], nitro-[17,34,36,37], naphtho-[37], and hydro-isatins[39,40] and isatin-carboxylic acids[8], on the one hand, and *o*-phenylenediamine[6,8,12,24-26,28,30,31,36,38-42], *o*-aminoalkylanilines and their salts[27,28,34,37,43-47], mono- and di-alkyl (alkoxy)-[1,17,21,26,28,33], mono- and di-halogeno[17], halogenoalkyl-[29], halogenonitro-[37], and nitro-*o*-phenylenediamines[31,37], *o*-diaminobenzoic acids[28], and *o*-naphthylenediamines[23], on the other. The reaction is usually carried out in aqueous or anhydrous acetic acid[23-25,33] and ethanol[15,23,48], more rarely in aqueous ethanol[38,48], benzene[32,33], and polyphosphoric acid[49,50], or without solvent[1].



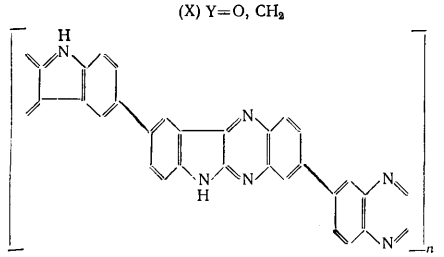
When 1-acetylisatin (IV) was condensed with *o*-phenylenediamine, Schunk and Marchlewski[38] obtained the acetylhydrazone (V), which was converted by hydrolysis into the hydrazone (VI), the latter being cyclised to 6*H*-indolo[2,3-*b*]quinoxaline (III). Similar hydrazones were obtained also by the reaction of 1-acetylisatin with other aromatic *o*-diamines[36]:

(IV) (V) (VI) (III)

When asymmetric *o*-diamines (VII) interact with isatin and its derivatives, there is a possibility of the formation of the structural isomers (VIII) and (IX), but, as a rule, one of the isomers is the dominant product[17], both isomers being obtained in approximately equal amounts only in the



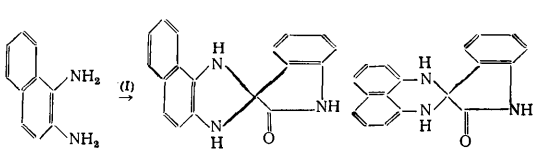
reactions of isatin with 4-ethoxy-*o*-phenylenediamine[28] and of 5-bromo-7-nitroisatin with 4-methoxy-*o*-phenylenediamine[17].



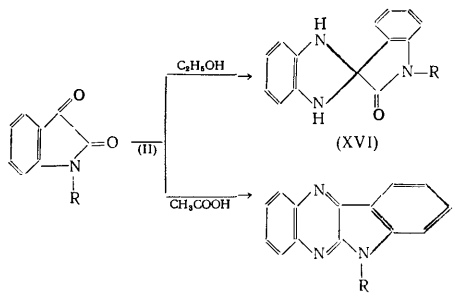
(VII) (VIII) (IX)

It is noteworthy that none of the structures of the indolo[2,3-*b*]quinoxalines obtained by the reactions of isatins with asymmetric *o*-diamines have been demonstrated.

The use as reactants in this process of 5,5′-oxybisisatinyl[49,50] and 5,5′-bisisatinyl[51], on the one hand, and oxybis-(3,4-diaminobenzene)[50], 4,4′-methylenebis-(*o*-phenylenediamine)[49], and 3,3-diaminobenzidine, on the other, made it possible to obtain the heteropolymers (X) and (XI). The condensation was carried out in polyphosphoric acid:

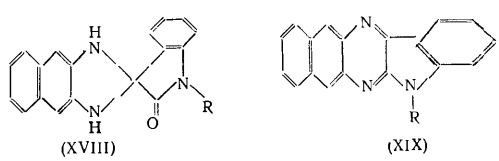


(X) Y=O, $CH_2$



(XI)

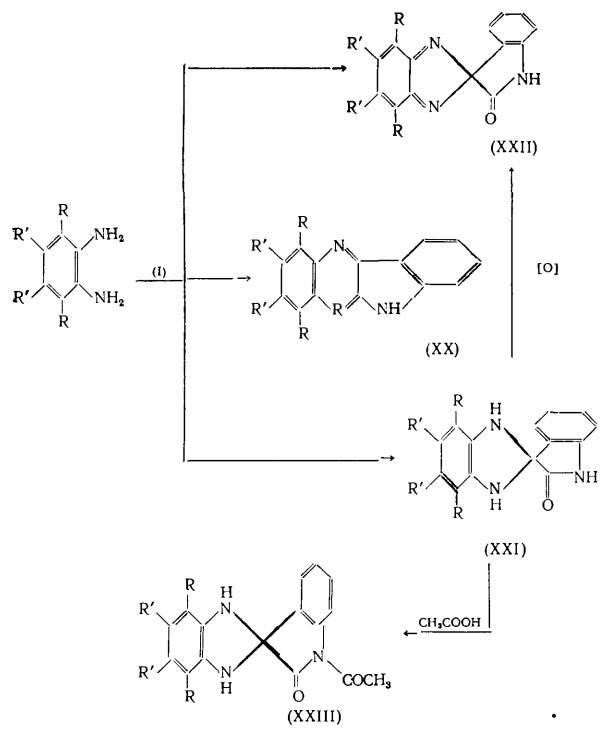
Until 1958, it was believed that the only products of the reactions of isatins with *o*-diamines are derivatives of indolo[2,3-*b*]quinoxaline. However, Henseke and Lemke[48] established that the condensation of 1,2-naphthylenediamine (XII) with isatin proceeds with liberation of one water molecule. They suggested the spiro-structure (XIII) for the product of this reaction[48] by analogy with compound (XIV) obtained previously by Sachs[52] from 1,8-naphthylenediamine and isatin:



(XII) (XIII) (XIV)

Popp showed later[15,23] that, depending on the reactants and the reaction conditions (solvent), either linear products, or spiro-compounds, or both simultaneously may be formed. For example, the reaction of 1-methylisatin (XV) with *o*-phenylenediamine (II) in ethanol leads to the formation of 1′-methylspiro[benzimidazoline-2,3′-indolin]-2′-one (XVI), while in dilute acetic acid the product is 6-methylindolo[2,3-*b*]quinoxaline (XVII):

(XV) (XVI) (XVII)

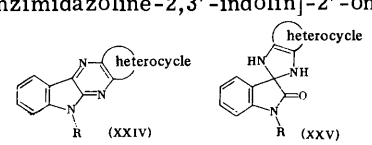


The reaction of 1-methylisatin with 2,3-diaminonaphthalene proceeds similarly. In contrast to its reaction with 1-methylisatin, 2,3-diaminonaphthalene reacts with 1-acetylisatin in ethanol to form a mixture of the spiro-compound (XVIII) and 8,9-benzo-6-acetylindolo[2,3-*b*]-quinoxaline (XIX), while the interaction in acetic acid of 9,10-diaminophenanthrene with 1-acetylisatin yields, in contrast to the reaction of the latter with *o*-phenylenediamine, only the spiro-compound:

(XVIII) (XIX)

The study of the reactions of 3,6- and 4,5-di-n-butoxy-*o*-phenylenediamines with isatin showed[21,33] that derivatives of spiro[2*H*-benzimidazole-2,3′-indolin]-2′-one (XXII) are formed together with derivatives of indolo-[2,3-*b*]quinoxaline (XX) and spiro[benzimidazoline-2,3′-indolin]-2′-one (XXI). When 3,6-di-n-butoxy-*o*-phenylenediamine interacts with isatin in 50% acetic acid, the product is a mixture consisting of indolo[2,3-*b*]quinoxaline (XX, R = n-BuO) and the spiro-compounds (XXI) and (XXII) with R = n-BuO and R′ = H, while in benzene in the presence of acetic acid only the spiro-compound (XXI, R = n-BuO, R′ = H) is formed. The mixture of products formed as a result of this reaction can be readily resolved owing to the different solubilities of these compounds in aqueous alcoholic solutions of alkalis and in benzene. The spiro-compound (XXI, R = n-BuO) is oxidised to the spiro-compound (XXII, R = n-BuO, R′ = H) by silver (I) oxide and is

acetylated by 80% acetic acid to the acetyl derivative (XXIII, R = n-Bu, R = H):

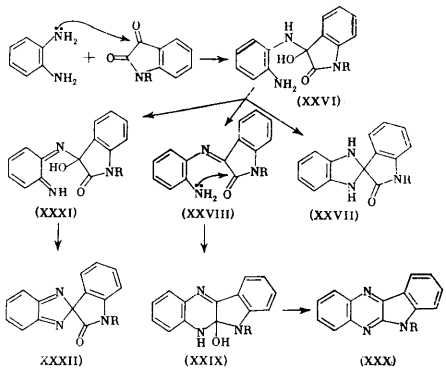


In contrast to 3,6-di-n-butoxy-*o*-phenylenediamine, the interaction of 4,5-di-n-butoxy-*o*-phenylenediamine with isatin in 50% acetic acid results in the formation of only the indolo[2,3-*b*]quinoxaline (XX, R = H, R′ = n-BuO) and the spiro-compound (XXII, R = H, R′ = n-BuO), while the reaction of these compounds in benzene in the presence of acetic acid results in the formation of only the indolo-[2,3-*b*]quinoxaline (XX, R = H, R′ = n-BuO).

## III. THE REACTIONS OF ISATINS WITH HETEROCYCLIC *o*-DIAMINES

The heterocyclic *o*-diamines employed in this reaction were 1,2-diamino-5-n-propyl-4-phenylimidazole[32], 2,3- and 3,4-diaminopyridines[23], 4,5-diaminopyrimidine[15,23] and its derivatives[23,33], and 4,5-diaminobenzothiazole[53], the products consisting of a series of heterocyclic systems.

In contrast to the reactions with aromatic *o*-diamines, the reactions of isatins with heterocyclic *o*-diamines yielded only analogues of indolo[2,3-*b*]quinoxaline (XXIV) and spiro[benzimidazoline-2,3′-indolin]-2′-one (XXV):



The structures of the initial compounds and the reaction conditions have a marked influence on the mode of reaction. Thus the interaction of 1,2-diamino-5-n-propyl-4-phenyl-imidazole[32], 4,5-diaminobenzothiazole[53], and certain derivatives of 4,5-diaminopyrimidine[33] with isatin yielded only linear products (XXIV). When 4,5-diamino-1,3-dimethyluracil was allowed to interact with isatin in acetic acid[23], the spiro-product (XXV) was obtained, while the interaction with 1-acetylisatin gave the linear product (XXIV).

The reaction of 3,4-diaminopyridine with isatin in ethanol leads to the formation of the linear product (XXIV), while 2,3-diaminopyridine and 4,5-diaminopyrimidine yielded the spiro-compound (XXV) under the same conditions[15]; the reactions of 2,3-and 3,4-diaminopyridines and 4,5-diaminopyrimidine with 1-acetylisatin also give rise to the spiro-compound (XXV).[15]

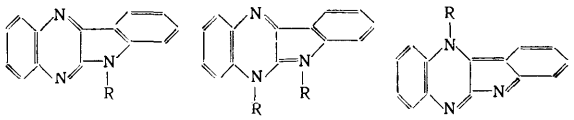
## IV. THE MECHANISM OF THE REACTIONS OF ISATINS WITH *o*-DIAMINES

The studies examined above suggest the following mechanism for the interaction of *o*-diamines with isatins. The first stage involves the formation of the hydroxy-compound (XXVI), which loses a water molecule and is converted either into spiro[benzimidazoline-2,3′-indolin]-2′-one (XXVII) or into a Schiff base (XXVIII):

It is noteworthy that the formation of the Schiff base (XXVIII) was observed by Schunk and Marchlewski[36,38] in the reaction of 1-acetylisatin with aromatic *o*-diamines.

The Schiff base (XXVIII) cyclises to the hydroxy-compound (XXIX), which liberates a water molecule and is converted into the indolo[2,3-*b*]quinoxaline (XXX).

The formation of spiro[-2*H*-benzimidazole-2,3′-indolin]-2′-one (XXXII) can be regarded as oxidation, during the reaction, of the hydroxy-compound (XXVI) to compound (XXXI), which cyclises to the spiro-compound (XXXII) with liberation of a water molecule. This mechanism of the formation of the spiro-compound (XXXII) may be put forward in view of the fact that the latter is not formed during the reaction from the spiro-compound (XXII).[33]

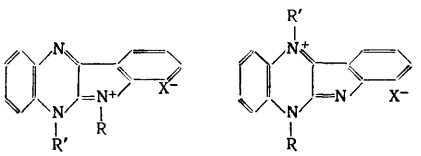


## V. METHODS FOR THE IDENTIFICATION OF THE REACTION PRODUCTS

Since the reactions of isatins with *o*-diamines do not proceed unambiguously, with the possibility of the formation of not only the isomeric indolo-[2,3-*b*]quinoxalines (VIII) and (IX) but also of the spiro-compounds (XXI) and (XXII), depending on the reaction conditions and the initial compounds, the problem arises of the identification of the reaction products.

Ultraviolet Spectra

The ultraviolet spectra of indolo[2,3-*b*]quinoxaline derivatives have been investigated by a number of workers[33,35,42,54-56], but systematic studies have been made only by Badger and Nelson[56], who investigated the ultraviolet spectra of 6*H*-indolo[2,3-*b*]quinoxaline and its *N*-methyl derivatives in neutral, acid, and alkaline media.



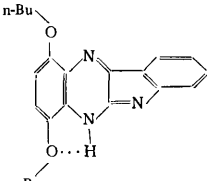
In theory, indolo[2,3-*b*]quinoxaline can exist in the form of three tautomeric forms (XXXIII)–(XXXV). By comparing its ultraviolet spectra with those of the *N*-methyl derivatives, it was shown[56] that indolo[2,3-*b*]quinoxaline exists preferentially in the 6*H*-form (XXXIII, R = H), since its ultraviolet spectrum is very similar to that of 6-methylindolo[2,3-*b*]quinoxaline and differs markedly from the spectrum of 5-methylindolo[2,3-*b*]quinoxaline in the range 400–520 nm.

(XXXIII) (XXXIV) (XXXV)

The spectrum of indolo[2,3-*b*]quinoxaline in sodium hydroxide solution is therefore similar to that of 5-methylindolo[2,3-*b*]quinoxaline, so that an appreciable proportion of the negative charge in the anion of indolo[2,3-*b*]quinoxaline is localised at the nitrogen atom in the 5-position.

The study of the spectra of the quaternary salts obtained by the protonation and methylation of indolo[2,3-*b*]quinoxaline showed that 6-methylindolo[2,3-*b*]quinoxaline is methylated and protonated in the 5-position with formation of the salt (XXXVI, R = R′ = $CH_3$; R = $CH_3$, R′ = H). 6*H*-Indolo[2,3-*b*]quinoxaline is also protonated in the 5-position, but this salt is capable of tautomerism and the solution probably contains both forms—(XXXVI) and (XXXVII) with R = R′ = H:

(XXXVI) (XXXVII)

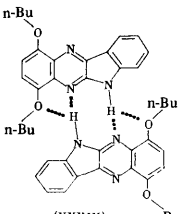


Methylation of 6*H*-indolo[2,3-*b*]quinoxaline by methyl toluene-*p*-sulphonate and methyl iodide as well as its protonation by toluene-*p*-sulphonic acid and HI lead to 5-methyl-11*H*-indolo[2,3-*b*]quinoxalinium iodide or toluene-*p*-sulphonate (XXV, R = $CH_3$, R′ = H, X = $CH_3C_6H_4SO_3^-$ or $I^-$). It is noteworthy that methylation of 6*H*-indolo[2,3-*b*]quinoxaline by methyl iodide or dimethyl sulphate in the presence of alkali as well as by diazomethane always yields a mixture of 5- and 6-methylindolo[2,3-*b*]quinoxalines. The formation of 11-methylindolo[2,3-*b*]quinoxaline was never observed under these conditions[56].

5-Methylindolo[2,3-*b*]quinoxaline is methylated in the 11-position with formation of 5,11-dimethylindolo[2,3-*b*]quinoxalinium toluene-*p*-sulphonate (XXXVII, R = R′ = $CH_3$, X = $CH_3C_6H_4SO_3^-$). Its ultraviolet spectrum resembles that of the protonated 5-methylindolo[2,3-*b*]quinoxaline, so that the latter is probably also protonated in the 11-position (XXXVI, R = $CH_3$, R′ = H, X = $CH_3C_6H_4SO_3^-$). Thus ultraviolet spectra can be used successfully for the identification of *N*-alkylindolo[2,3-*b*]quinoxalines.

Infrared Spectra

Owing to their low solubility in the corresponding solvents, the infrared spectra of the majority of the known indolo[2,3-*b*]quinoxalines and spiro[-2*H*-benzimidazole-2,3′-indolin]-2′-ones have not been investigated. The infrared spectroscopic data obtained by Ivashchenko and coworkers[21,33] are of interest, since they make it possible to interpret the structures of certain indolo[2,3-*b*]quinoxalines and demonstrate the possibility of using infrared spectroscopy for the identification of the products of the reactions of isatins with *o*-diamines.



The infrared spectra of dilute solutions of indolo[2,3-*b*]-quinoxalines (XX) in chloroform have absorption bands characteristic of the stretching vibrations of the unassociated N–H bond (3425 and 3432 $cm^{-1}$). This shows that compound (XX) exists in the 6*H*-form, since otherwise the infrared spectrum of indolo[2,3-*b*]quinoxalines (XX, R = n-BuO, R′ = H) would be expected to exhibit a marked bathochromic shift of $\nu$(NH) relative to the spectrum of indolo[2,3-*b*]quinoxaline (XX, R = H, R′ = n-BuO) owing to the formation of an intramolecular hydrogen bond, as in formula (XXXVIII):

(XXXVIII)

The existence of the 6*H*-forms of compounds (XX) is also confirmed by their ultraviolet spectra[33] which do not have absorption bands in the long-wavelength region.

The infrared spectra of solid specimens of indolo-[2,3-*b*]quinoxalines (XX) differ markedly from one another in the presence of different substituents in the region of the stretching vibrations of the N–H bon[21]. On the other hand, the spectrum of compound (XX) with R = H and R′ = n-BuO has a broad absorption band in the range 3000–3300 $cm^{-1}$ with the fine structure characteristic of polyassociated compounds; the spectrum of compound (XX, R = n-BuO, R′ = H) has a single broadened band in this region at 3230 $cm^{-1}$), which apparently corresponds to the dimer. It is noteworthy that there is a possibility of two three-centre hydrogen bonds in the dimer of compound (XX, R = n-BuO, R′ = H), as in formula (XXXIX):

(XXXIX)

Since the formation of a "purely" three-centre hydrogen bond is extremely rare, it would be of undoubted interest to carry out X-ray diffraction studies on this compound.

The infrared spectrum of the spiro-compound (XXI, R = n-BuO, R′ = H) has an absorption band at 1668 $cm^{-1}$ (amide-I) and two bands in the region of the stretching vibrations of the N–H bond. The band intensities led to the following assignments[33]: the 3454 $cm^{-1}$ band ($\epsilon$ = 147)

to the stretching vibrations of the N–H bonds of the indoline ring and the 3370 $cm^{-1}$ band ($\epsilon$ = 428) to the stretching vibrations of the N–H bonds of the benzimidazoline ring. When this compound is acylated, the 3454 $cm^{-1}$ band disappears, while that at 3370 $cm^{-1}$ remains unchanged, which indicates the acylation of the spiro-compound (XXI, R = n-BuO, R′ = H) at the NH group of the indoline ring with formation of compound (XXIII, R = n-BuO, R′ = H).

The infrared spectra of the spiro-compounds (XXII) [33] contain bands due to the stretching vibrations of the N–H bond of the indoline ring at 3390 $cm^{-1}$ and the amide-I bands at 1732 and 1721 $cm^{-1}$.

## Mass Spectrometry

The mass spectra of indolo[2,3-*b*]quinoxaline and spiro-[-2*H*-benzimidazole-2,3′indolin]-2′-one have been studied in greatest detail in three investigations[21,33,57], where they were used successfully to identify the products of the reactions of isatins with aromatic heterocyclic *o*-diamines.

The mass spectra of the isatin–*o*-diamine reaction products contained intense peaks due to the molecular ions. The main decomposition pathways of indolo[2,3-*b*]quinoxaline, spiro[2*H*-benzimidazole-2,3′-indolin]-2′-one and spiro[benzimidazoline-2,3′-indolin]-2′-one in dissociative ionisation have been examined in detail[21,33,57].

In conclusion, we must emphasise that the reactions of isatins with aromatic and heterocylic *o*-diamines do not proceed unambiguously, so that they can lead to derivatives of indolo[2,3-*b*]quinoxaline, spiro-compounds, or both simultaneously. The study of the ultraviolet, infrared, and mass-spectra of derivatives of indolo[2,3-*b*]-quinoxaline, its analogues, and spiro[2*H*-benzimidazole-2,3′-indolin]-2′-one showed that these methods can be used successfully in many instances for the identification of the compounds formed in the condensation reactions of isatins with *o*-diamines.

Many studies carried out without taking into account the latest data and the evidence for the structures of the compounds obtained must be treated critically, since the structures of indolo[2,3-*b*]quinoxaline derivatives have been traditionally attributed without proof (and without demonstrating their individuality) to the products of the reactions of isatins with *o*-diamines.

The reactions have not been studied systematically and analysis of the data discussed in this review does not reveal systematic features in the formation of derivatives of indolo[2,3-*b*]quinoxaline and spiro-compounds as a function of the reaction conditions and the structures of the initial reactants. The study of these reactions is therefore of undoubted interest from both practical and theoretical points of view.

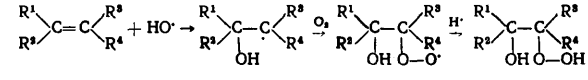
## I. INTRODUCTION



There is much interest at the present time in the role of organic peroxides in biochemical processes. After the discovery by Latarjet et al.[1] concerning organic peroxides in radiobiology, a study was published[2] on the biochemical importance of lipid peroxides, which subsequently served as a basis for a large review on this subject[3]. In recent years particular attention has been devoted to the oxidation of azo-compounds under the influence of molecular oxygen (in the triplet or singlet states). The studies published in recent years are concerned with the sensitised photochemical oxidation of aliphatic amines and oxides, various pyrrole, imidazole, oxazole, and isoindole derivatives, and also the oxidation of nucleic acid derivatives in the aqueous phase initiated by ionising radiation. Apart from the numerous original studies, the action of molecular oxygen on azo-compounds has been examined in a review[4] (containing 143 references to studies published up to 1967), while nucleic acids are dealt with in a major article[5] (70 references to studies published up to 1964). All these considerations led the present author to write a survey on the subject[132], combining all the latest and older studies on the autoxidation of aliphatic amines (in the gas phase), indoles, tetrahydrocarbazoles, dihydro-oxazines, tetrahydropyrazines, and hydrazones (in the liquid phase). Furthermore, in the studies published after 1967 (44 publications) the properties of the peroxides formed have been described in detail and an attempt has been made to relate, as far as possible, their formation to biological processes such as the decomposition of enzymes, the formation of pigments (kynurenine and melanin), the structural changes in alkaloids, and changes at the cellular level.

The results of 30 similar studies carried out in recent years, seven of which were published in 1975, are analysed in the present review. In particular, the review is concerned with the problem of the intermediate formation of peroxides in bioluminescence.

In the section dealing with oxidation mechanisms (oxidation by molecular oxygen), it was thought unnecessary to include the description of the classical chain mechanism of autoxidation.

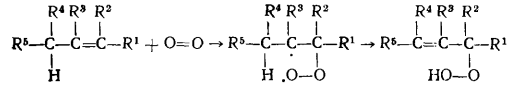
## II. THE MECHANISMS OF OXIDATION UNDER THE INFLUENCE OF MOLECULAR OXYGEN

The classical mechanism of the oxidation of hydrocarbons under the influence of $O_2$ is applicable to aldehydes, ethers, and esters[6-10]. Initiation may be due to the radical generated from a source other than the substrate; for example, in the presence of ionising radiation, the autoxidation of unsaturated compounds in the aqueous phase is initiated by HO· radicals formed from $H_2O$. It is terminated by formation of hydroxyhydroperoxides via the mechanism

The H· atom is also formed from $H_2O$. The reaction involving nucleic acids proceeds in this way.

The oxidation of nitriles, hydroxylamines, (ketones and branched esters), and pyrazolones is very strongly accelerated in the presence of bases. It is suggested[12,13,183] that this type of oxidation proceeds via a mechanism similar to that described above but with participation of the anion $R^-$ (rather than the radical R·):

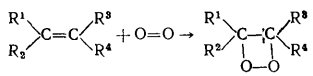
$$RH + HO^- \rightarrow R^- + H_2O;\ R^- + O^3 \rightarrow RO{-}O^-;$$
$$RO{-}O^- + HR \rightarrow RO{-}OH + R^- .$$



Sensitised photochemical oxidation proceeds in the presence of light and certain dyes (Methylene Blue, Rose Bengal, haematoporphyrin, and chlorophyll). In certain cases, for example in the presence of anthracene hydrocarbons, the substrate itself plays the role of the sensitiser. The sensitisation can be achieved via two different mechanisms.

1. In the first mechanism, the dye in the excited (biradical) state plays the role of a dehydrating agent, leading to the formation of a radical R·, which is then oxidised via the classical mechanism (involving $O_2$ as the triplet $^{\cdot}O{-}O^{\cdot}$).

†This review was written specially for the journal "Uspekhi Khimii". It was translated from French into Russian by T.V. Chernysheva.



2. In the second mechanism, $O_2$ is involved in the singlet form O=O (formed in a certain amount under the conditions described above), which is capable of adding to ethylenic double bonds.

(a) In the oxidation of a mono-olefin having hydrogen atoms in the $\alpha$-position relative to the double bond, a hydroperoxide is usually formed in accordance with the equation

Many unsaturated hydroperoxides, for example those of $\alpha$- and $\beta$-pinenes [14] and of carvomenthene [15] have been obtained by this method. One should note that, in the presence of even one $\alpha$-methylene hydrogen atom at the double bond, two peroxide isomers are usually formed.

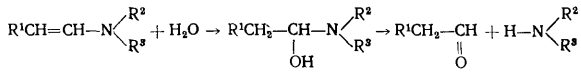
(b) In the absence of an $\alpha$-methylene hydrogen atom, O=O may add to the double bond with formation of a 1,2-peroxide:

This reaction proceeds more readily in the presence of nucleophilic substituents.

(c) In a system with conjugated double bonds, the addition in the 1,4-positions is stereospecific and proceeds only in the *cis,cis*-configuration. Numerous endoperoxides have been obtained in this way as a result of the sensitised photochemical oxidation of the corresponding 1,3-dienes (for example of ascaridole—from $\alpha$-terpinene in the presence of chloropyll [16]).

The mechanism of sensitised photochemical oxidation has been discussed in a number of publications [17-21,181,184]. The stereospecificity of the reaction has also been considered [21]. Schaap and Faler [22] and Hasty and Kearns [23] examined the photochemical oxidation of alkenes and dienes.

The biological importance of the photochemical oxidation sensitised by various dyes, inducing the decomposition of aminoacids (aromatic and heterocyclic), nucleic acids, and various proteins, as well as the inactivation of viruses and cells of multicellular organisms has been discussed by Spikes [176].

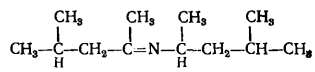


## III. THE AUTOXIDATION OF AMINES

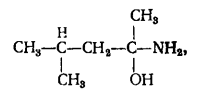
### 1. The Reactions of Aliphatic Amines with Hydroperoxides

These reactions proceed via a mechanism different from that operating in the oxidation of amines by peracids (involving electrophilic attack by the oxygen of the peracid on the nitrogen atom of the amine). In the reactions with hydroperoxides, the dominant feature is the dehydrogenation of the amines simultaneously at the C and N atoms (when this is possible), which leads to the formation of an alcohol, water, or an imine. The hydrolysis of the latter leads to a carbonyl compound and the dealkylated amine:

$$RO{-}OH + R^1CH_2NHR^2 \rightarrow ROH + H_2O + R^1CH{=}NR^2,$$
$$R^1CH{=}NR^2 + H_2O \rightarrow R^1CHO + H_2NR^2.$$



The molecules of the carbonyl compound may condense with one another (this reaction is favoured in an alkaline medium), with the initial amine, or with the dealkylated amine, forming respectively unsaturated carbonyl compounds and aldimines (or ketimines). The formation of a secondary amine and a carbonyl compound from a tertiary amine apparently proceeds as a result of the hydrolysis of the intermediate imine:

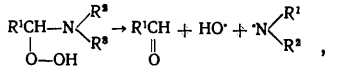


which is probably obtained as a result of the disproportionation of the radical $R^1CH_2CHNR^2R^3$:

The action of $O_2$ at 60–100°C on 4-methyl-2-pentylamine (I), 2,4,4-trimethyl-2-pentylamine (II), di-isopropylamine (III), and tri-n-propylamine (IV) has been considered [3] and it has been shown that $(CH_3)_3COH$, $H_2O$, and $NH_3$ (or $RNH_2$) are formed in satisfactory yields. In the reaction with the amine (I), the yields were 100, 82, and 60%; in addition, the compound

was isolated in 24–40% yield. The first compound, identified by infrared spectroscopy, is an aminoalcohol:

the subsequent decomposition of which to a carbonyl compound and $NH_3$ is facilitated by the formation of a hydrogen bond.



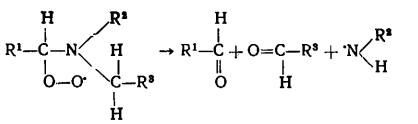
In the reaction with the amine (III), the yields of $(CH_3)_3COH$, $H_2O$, $(CH_3)_2CHNH_2$, and acetone were 85, 45, 88, and 95% respectively. The yields of t-butyl alcohol and dipropylamine from the amine (IV) were 80 and 32%.

We may note that the corresponding nitro-derivative is formed in 2% yield from compound (II), which has no hydrogen atoms in the $\alpha$-position relative to the nitrogen atom, and that the reaction is very slow. The mechanism of the action of hydroperoxides on amines has been examined in detail [24,25] and the mobility of the hydrogen atom linked to the nitrogen atom and the carbon atom in the $\alpha$-position relative to the former has been discussed [26,27].

### 2. The Autoxidation of Aliphatic Amines in the Gas Phase

The autoxidation of aliphatic amines in the gas phase has been considered [28-34]. Studies have shown that the temperature of their oxidation (300°C) is lower by 200°C than the pyrolysis temperature. In contrast to hydrocarbons, ethers, and aldehydes, their oxidation is self-inhibited, but there is no appreciable induction period. The rate of oxidation depends on the structure of the amine and increases greatly as a result of branching both at the nitrogen and carbon atoms [30]. Table 1 presents the relative rates of oxidation $K$ of various amines at 310°C, the relative rate of oxidation of $CH_3NH_2$ having been adopted as unity.

The products of the reaction consist of carbonyl compounds and dealkylated amines, apparently formed from the intermediate hydroperoxides,



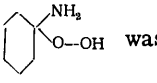
whose presence has been demonstrated in the oxidation of $CH_3NH_2$ at 350°C; their content reaches a maximum of $2 \times 10^{-6}$ mole/mole of amines after 2 min, decreasing subsequently and reaching zero after 4 min. In the light of the above, one may assume that the carbonyl compound and the dealkylated amine may be formed as a result of the decomposition of the intermediate aminoalcohol $R^1CH(OH).NR^2R^3$ produced by the action of the hydroperoxide $R^1CH(OOH)NR^2R^3$ on the initial amine. The absence of alcohols ROH shows that the hydroperoxide cannot be cleaved in the $\beta$-position.

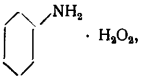
Table 1. [30]

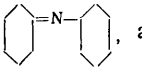
| Primary amine | $K$ | Secondary amine | $K$ |
|---|---|---|---|
| Methylamine | 1 | Dimethylamine | 19 |
| Ethylamine | 5.6 | Ethylmethylamine | 150 |
| Propylamine | 48 | Diethylamine | 255 |
| Butylamine | 230 | Methylpropylamine | 580 |
| Isopropylamine | 107 | Dipropylamine | 760 |
| Isobutylamine | 170 | | |

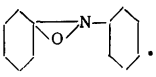
There is a possibility of the direct formation of a primary amine from the tertiary amine via the reaction [33]

The reactions of $C_1-C_9$ primary amines have also been discussed [28,29], while other workers considered secondary amines [31] and tertiary amines [32-34].

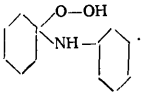








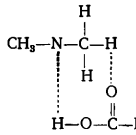
## 3. The Sensitised Photochemical Oxidation of Aliphatic and Aromatic Alkylamines in the Liquid Phase



It has been shown [14] that primary amines (methyl-, ethyl-, propyl-, isopropyl-, and isobutyl-amines), secondary amines (diethylamine, pyrrolidine, and piperidine), and tertiary amines (triethylamine) are capable of absorbing oxygen and forming peroxides as a result of photochemical oxidation in the presence of chlorophyll, eosin, and haematoporphyrin. The amounts of absorbed $O_2$ (in moles per mole of the amine) are respectively 1, 2, and 2.6. On the other hand, $(CH_3)_3.CHNH_2$ does not absorb oxygen under these conditions owing to the absence of hydrogen atoms at the carbon atom in the $\alpha$-position relative to the nitrogen atom. These findings indicate attack on the carbon atom in the $\alpha$-position with the formation of a hydroperoxy-group in this position (as in the oxidation of amines in the gas phase).

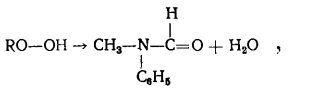
The photochemical oxidation of the primary amines $C_3H_7NH_2$, $C_6H_5NH_2$, and $C_6H_5CH_2NH_2$, the secondary amine $(C_3H_7)_2NH$, and the tertiary amines $(C_2H_5)_3N$, $(C_3H_7)_3N$, $(C_6H_5CH_2)_3N$, $C_6H_5N(CH_3)_2$, and $C_6H_5N(C_2H_5)_2$, sensitised by benzophenone and dyes (Methylene Blue, eosin, and Rose Bengal) at room temperature in benzene or methanol solution, has been investigated in detail [35]. Primary and secondary amines proved to be relatively inactive and their decomposition products were not detected. In the reactions of tertiary amines, aldehydes and aldimines, formed as a result of the condensation of the aldehydes with initial amines or amines produced by dealkylation, were identified.

The formation of aldimines, corresponding to the formation of primary amines in the photochemical oxidation of tertiary amines, suggests the direct formation of the former from the latter (via a mechanism similar to that operating in the gas phase). Analogous results were obtained [36] in a study of the tertiary amines $(C_3H_7)_3N$, $(C_2H_5)_3N$, and $C_6H_5N(CH_3)_2$ using polycyclic aromatic hydrocarbons (naphthalene, perylene, anthracene, and phenanthrene) as sensitising agents. These investigations showed that the initial stage of the reaction involves the dehydration of the amines by the sensitiser and the formation of the radical $R^1CH_2\dot{C}HNR^2R^3$, the subsequent behaviour of which should be similar to but not identical with its behaviour in the gas phase.

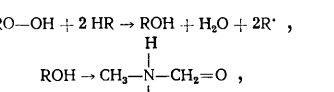


Indeed, apart from the cleavage in the $\alpha$-position, there is also a possibility of the cleavage in the $\beta$-position as a result of the addition of singlet $O_2$ to the double bond of the enamine produced by the disproportionation of the radical. In a study of the autoxidation [37] of mono-, di-, and tri-butylamines, it was shown that, apart from the postulated products (butylidenebutylamine, butylaldehyde, and propylamine), produced as a result of cleavage in the $\alpha$-position, considerable amounts of mono- or di-formamides are formed, indicating cleavage in the $\beta$-position. The reaction mechanism is discussed and the formation of reaction products as a function of the type of amine and solvent (ethanol, acetone, acetonitrile, and methyl methacrylate) is explained [37].

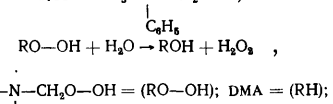
In certain cases it has been possible to isolate the corresponding hydroperoxide. In a study [28] of the benzophenone-sensitised photochemical oxidation of cyclohexylamine at temperatures between −20° and 20°C using ether and its mixtures with alcohol as solvents, the hydroperoxide  was isolated together with some of the decomposition products: the adduct  , the cyclohexylideneamine  , and the oxaziran  . Under conditions identical to those described above, the hydroperoxide

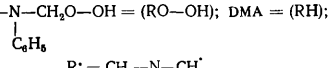


was also isolated from dicyclohexylamine [38].



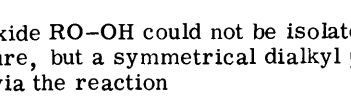
Aromatic alkylamines can also be oxidised in the absence of sensitisers. The autoxidation of *NN*-dimethylaniline (DMA), which has been investigated in particular detail by Horner and Knapp[40], has been described[29]. The autoxidation of DMA is catalysed by radical initiators—benzoyl peroxide[39], azobisisobutyronitrile[40], and particularly cobalt salts (manganese salts are less active and nickel and copper salts are completely inactive). Carboxylic acids also exhibit a catalytic activity, which is probably a consequence of the neutralisation of the amine and partly the formation of a cyclic complex in which a C–H bond in $CH_2$ is weakened, which favours attack by $O_2$ at this site:

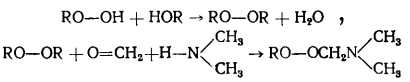




At 20°C, 80 mole % $O_2$ is absorbed in 90 min in the reaction catalysed by 0.2 mole % (relative to DMA) of cobalt stearate using a mixture of acetic acid, acetic anhydride, and benzene as solvent. The product consists of 50 mole % of peroxides (40% of $H_2O_2$ and 60% of organic peroxide), 90 mole % HCHO (45% in a free state), and 88 mole % $C_6H_5NHCH_3$. Apart from the compounds enumerated above, $(CH_3)_2NC_6H_4CH_2C_6H_4N(CH_3)_2$ can also be formed (as a result of the condensation of HCHO with DMA).

The nature of the products obtained and their relative amounts suggest the following mechanism of their formation from the hydroperoxide:

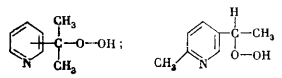




where

The hydroperoxide RO–OH could not be isolated from the reaction mixture, but a symmetrical dialkyl peroxide RO–OR, formed via the reaction

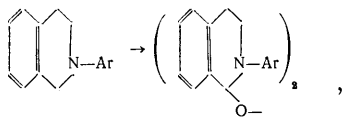
was isolated. The melting point of the peroxide RO–OR is identical with that of the peroxide obtained as a result of synthesis via the reaction described by Horner and Knapp[41]:



Symmetrical ($R^1R^2NCH_2O–OCH_2NR^1R^2$) and asymmetric ($R^1R^2NCH_2O–OR$) peroxides, synthesised by the action of secondary amines on formaldehyde in the presence of $H_2O_2$ or RO–OH respectively, are also known[42].

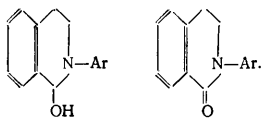
Similar results were obtained with certain DMA derivatives substituted in the benzene ring. We may note that nucleophilic groups increase and electrophilic groups decrease the rate of absorption of $O_2$.[39,40] On the other hand, aliphatic amines do not absorb $O_2$ in the presence of cobalt salts even at 40°C. All the methods and the complete composition of the products of the reactions are quoted by Horner and Knapp[40].

Primary aromatic amines absorb oxygen at room temperature only in a highly alkaline medium (in the presence of alkali metal alkoxides). The dominant process is dehydrogenation, leading to the formation of the corresponding diazo-compounds. This reaction may be inhibited by benzene derivatives disubstituted in the *ortho*- and *para*-positions; $\alpha$- and $\beta$-naphthylamines yield the corresponding phenazines. This reaction has been discussed in detail by Horner and Dehnert[43].



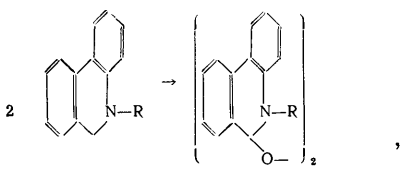
Non-hydrogenated or partly hydrogenated heterocyclic amines can also yield hydroperoxides or dialkyl peroxides as a result of autoxidation.

The stable crystalline hydroperoxides

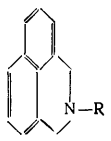


have been obtained by the autoxidation at 100–120°C of isopropylpyridines (the 2-, 3-, and 4-isomers) and 5-ethyl-2-methylpyridine.[46] Here the decomposition products are the alcohols $CH_3\diagdown$ / $CH_3—COH$ / Py and the ketone $CH_3–C(=O)–Py$. Preferential migration of the $CH_3$ group (in relation to pyridine) from carbon to oxygen always takes place in the cation $CH_3\diagdown$ / $CH_3—CO^+$ / Py. The synthesis and decomposition of hydroperoxides of this type have been described[44–46].

In other instances, dialkylperoxides were obtained. Thus *N*-aryltetrahydroisoquinolines yield, as a result of autoxidation, the peroxides

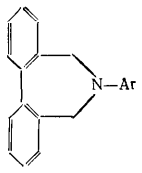


where Ar = $C_6H_5$, $C_6H_4$, or naphthyl. On boiling in $CHCl_3$, they undergo homolytic cleavage as a result of the rupture of the oxygen bridge. The radicals formed in this way disproportionate to a hydroxy-derivative and a ketone:



$\alpha$-Substituted derivatives of these compounds do not react with oxygen. The properties of peroxides and the methods used to synthesise them have been described[47].

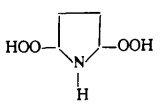
As a result of autoxidation, dihydrophenanthridines also give rise to dialkyl peroxides:



where R = $CH_3$ or $C_6H_5$ (they decompose on heating as in the previous case).

*N*-Substituted dihydroisoquinolines do not react[48]:

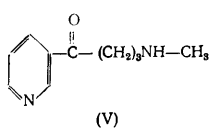
*N*-Aryldihydrobenzoazepines



(Ar=$C_6H_5$, *p*-$CH_3C_6H_4$, *p*-$ClC_6H_4$, *p*-$CH_3OC_6H_4$)

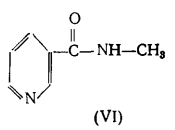
form peroxides whose properties have been described[49].

We may note that these three types of dialkylperoxides can also be synthesised by treating the corresponding $\alpha$-bromo-derivatives with $H_2O_2$ and that $\alpha$-aminated hydroperoxides $R^1R^2C(COH)NHR$ have been obtained by treating the corresponding ketimines $R^1R^2C = NR$ with $H_2O_2$.[60] The simultaneous action of $H_2O_2$ and $NH_3$ on cyclic ketones gives rise to aminoperoxides of different structures[51].

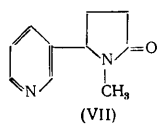


The different ways of obtaining peroxides from amines and related compounds have been described recently[52].

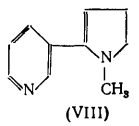
Pyrrolidinone absorbs two moles of $O_2$ at room temperature as a result of sensitised photochemical oxidation, forming a dihydroperoxide [14]:



The sensitised photochemical oxidation of nicotine in an aqueous medium at 37° and 40°C has been investigated[53,54]. The structural changes apparently involve only the pyrrolidine ring, but the reaction goes beyond the hydroperoxide stage. Indeed the ring is cleaved, which entails the decomposition of the t-amino-group, resulting in a decrease of pH. The pyrrolidine ring is probably initially dehydrated with subsequent attack by $O_2$, causing the rupture of the ring owing to the formation of the very unstable intermediate 1,2-peroxide. This can probably account for the absorption of one mole of $O_2$ instead of two moles, as in another investigation[14]. The only peroxide detected was $H_2O_2$.

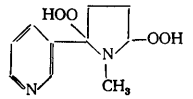


Methylaminopropyl pyridyl ketone (V), methylnicotinamide (VI), cotinine [1-methyl-5-(3-pyridyl)-2-pyrrolidinone] (VII), and methylmyosmine (VIII) have been isolated from tobacco leaves subjected to aerobic fermentation:



(V)

(VI)

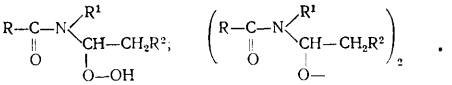


(VII)

(VIII)

The nature of these compounds suggests attack on the 2- and 5-positions of the pyrrolidine ring with formation of the corresponding mono- or di-hydroperoxides:

Compound (V) is probably obtained as a result of the decomposition of the monohydroperoxide with rupture of the ring between N and $C_{(2)}$, compound (VI) is produced by the decomposition of the dihydroperoxide with rupture of the ring between N and $C_{(2)}$ and between N and $C_{(5)}$, compound (VII) is formed by the dehydration of the hydroperoxide without the rupture of the ring, and compound (VIII) results from the dehydration of the alcohol without the rupture of the ring. The last compound is formed by the reactions

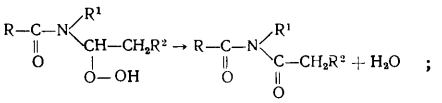


$$RO{-}OH \rightarrow RO^{\cdot} + {\cdot}OH\ ,$$
$$RO^{\cdot} + HR \rightarrow ROH + R^{\cdot}$$

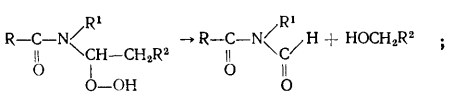
(RH = nicotine).

## IV. THE REACTIONS OF AMIDES WITH MOLECULAR OXYGEN

### 1. The Autoxidation and Sensitised Photochemical Oxidation of Aliphatic Amides



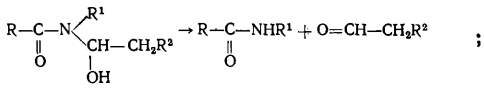
These reactions, involving aliphatic amides having the general formula $R{-}\underset{\underset{O}{\|}}{C}(R_1){-}N{-}CH_2{-}CH_2{-}R^2$, have been the subject of an extensive investigation[57]. It has been shown that in all cases the carbon atoms in the $\alpha$-position with respect to N are attacked with formation of a hydroperoxide or a dialkyl peroxide depending on the reaction conditions:



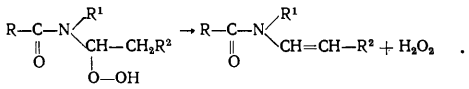
Using $^{14}C$, it had been shown earlier[58] for *N*-pentylhexanamide that valeraldehyde is formed from the carbon chain linked to the nitrogen atom and caproamide is formed from the chain linked to C=O.

The peroxides formed and decomposed into

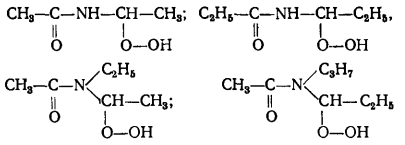
(a) a diacylamide and water:



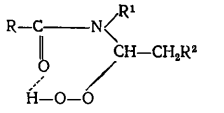
(b) an acylformamide and an alcohol:



(c) an acylamino alcohol $R{-}\underset{\underset{O}{\|}}{C}{-}N(R_1){-}\underset{\underset{OH}{|}}{CH}{-}CH_2R^2$, the

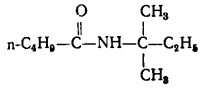


subsequent decomposition of which yields an amide and an aldehyde:

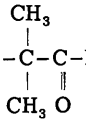


(d) an unsaturated amide and hydrogen peroxide:

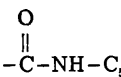
The hydroperoxides



may be isolated in a pure state in a yield of the order of 2%. The autoxidation is carried out at 130° for 30 to 60 min. The excess amide is removed in a high vacuum at room temperature, the crude hydroperoxide being recrystallised from an appropriate solvent. These compounds are stable for several weeks at 0°C. Infrared spectroscopic and NMR data showed that they have a cyclic structure:

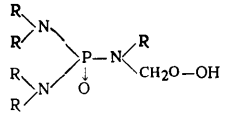


The photochemical oxidation at 0°C leads to the formation of dialkyl peroxides, which were isolated in a pure state in two instances:



It is noteworthy that the rate of oxidation depends mainly on the structure of the carbon chain at the nitrogen atom and not at C=O; the oxidation does not occur in the presence of a tertiary carbon atom attached to the nitrogen atom; thus the amide

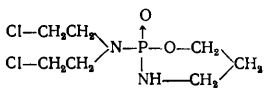
does not absorb oxygen in photochemical oxidation at 50°C,



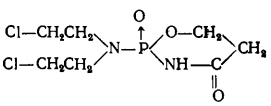
while the amide  absorbs it at the

same rate as the amide n-$C_5H_{11}$-C(=O)-NH-$C_5H_{11}$-n.[58]

The quite likely presence of the peroxide and the hydroperoxide

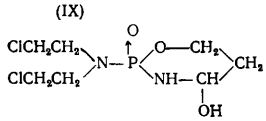


(R=$CH_3$)

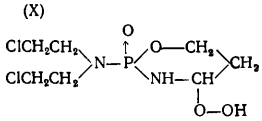


was proved[177] by iodometric and polarographic methods in the photochemical oxidation of hexamethylphosphoramide (HMP); owing to its instability, the hydroperoxide was not isolated in a pure state. The formation of formaldehyde following its thermal decomposition was demonstrated.

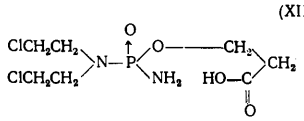
The phosphoramide (IX) is used in the treatment of various types of cancer. The reactions of this compound *in vivo* involve the carbon atom in the α-position relative to the nitrogen atom. Indeed the mixed amide (X) and the open-chain acid (XIII) have been found in the urine of animals receiving intravenous injections of the amide (IX) [178, 179]; however, when compounds (X) and (XIII) were injected, they proved to be less active than the amide (IX), while the hydroxy-compound (XI) and the hydroperoxide (XII) exhibit a strong cyclotoxic activity both *in vivo* and *in vitro*.



The hydroxy-compounds and mixed amides are probably formed via the intermediate hydroperoxide (XII), which can be obtained by treating the hydroxy-compound (XI) with Fenton's reagent[180]:

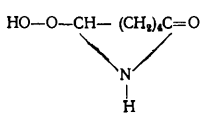


(IX)



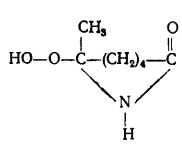
(X)

(XI)



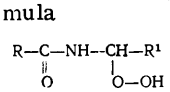
(XII)

(XIII)



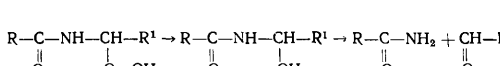
## 2. The Photochemical Oxidation of Lactams and Polyamides

The photochemical oxidation of ε-caprolactam (95°C, 48 h) led to the formation of the hydroperoxide

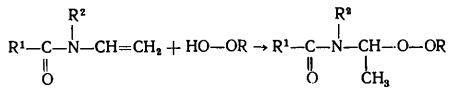


in 5% yield[59], the compound decomposing on heating in benzene solution into water and adipamide.

Under conditions identical with those described above, the lactam ring in methylcaprolactam is opened with formation of acetylvaleramide; the intermediate hydroperoxide

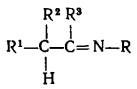


could not be isolated.

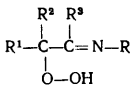


It is interesting to note that, when various polyamides are heated in the presence of oxygen, hydroperoxides having the general formula

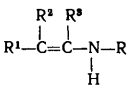
are also formed. Depending on the experimental conditions, they give rise to the cross-linking of the chains accompanied by the formation of bridges with and without oxygen atoms, or to degradation of the type



The autoxidation of polyamides has been discussed[60-62]. We may note that certain amide peroxides can be obtained by treating vinyl derivatives of amides with hydroperoxides[185]:

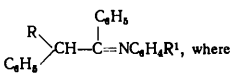


## V. THE OXIDATION OF IMINES AND ENAMINES



Imines having the general formula

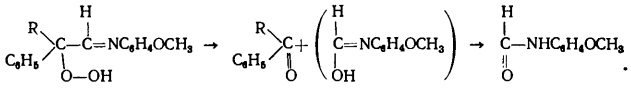
with a hydrogen atom in the $\alpha$-position relative to the nitrogen atom and in the $\beta$-position relative to the double bond, undergo autoxidation with conversion into the corresponding hydroperoxides:



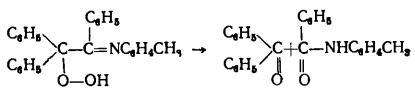
The same may be said of the enamines

containing a hydrogen atom linked to the nitrogen atom, which give rise to the same hydroperoxides after their isomerisation to the corresponding imines.

There are also several examples where the double bond and the nitrogen atom are outside a ring; these are the anils[63] derived from *p*-methoxyaniline, methylphenylacetaldehyde (XIV), and diphenylpropionaldehyde (XV) and the anils of *p*-methylaniline and diphenylacetophenone (XVI):[64]

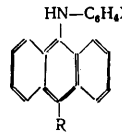


R=CH$_3$, R$^1$=OCH$_3$ ; (XIV)



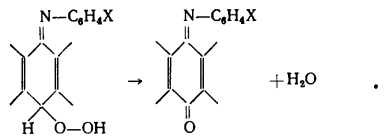
R=C$_6$H$_5$, R$^1$=OCH$_3$ ; (XV)

R=C$_6$H$_5$, R$^1$=CH$_3$ . (XVI)

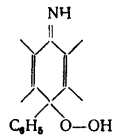


At room temperature in ether or ethyl acetate, compounds (XIV) and (XV) rapidly absorb one mole of $O_2$, forming hydroperoxides (iodine is liberated from iodides), which decompose fully into the corresponding ketone and formylamisidine (R = $CH_3$ or $C_6H_5$); in the case of compound (XV), the peroxide vanishes completely after 2 h at room temperature:

The same may also be said of the anil (XVI) from which only benzophenone and *p*-methylphenylbenzamide could be isolated:

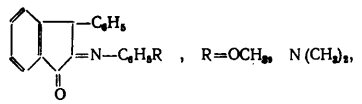


Derivatives of 9-aminoanthracene



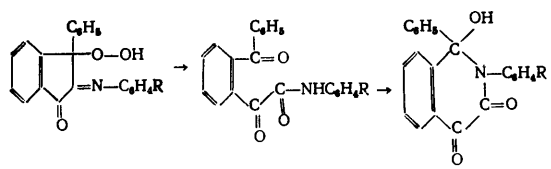
are of considerable interest. The rate of autoxidation depends on the nature of the substituent X in the *para*-position in the benzene ring linked to the nitrogen atom. For example, at room temperature (in ethereal solution) when R = $C_6H_5$ and X = $NO_2$ the absorption of $O_2$ is not observed for 7 days, while with X = $OCH_3$ or $N(CH_3)_2$ one mole of $O_2$ is absorbed after 4 days or after several hours respectively[65].

The stability of the hydroperoxide obtained depends not only on the nature of X but also on that of R. Thus, with R = H and X = $OCH_3$ or $N(CH_3)_2$, it was possible to obtain only quinone imines, formed as a result of the decomposition of the corresponding hydroperoxides:

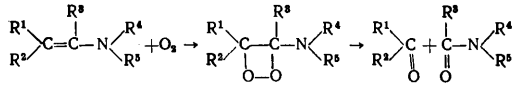


With R = $C_6H_5$, the corresponding hydroperoxides were isolated, but the hydroperoxide with X = $N(CH_3)_2$ was obtained only in a crude form and were not purified owing to its instability and low solubility in organic solvents. The hydroperoxide with X = $OCH_3$ was obtained in a pure form in a yield of 65%.

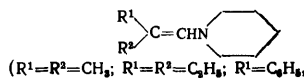
The hydroperoxide[66]



without substituents at the nitrogen atom, was isolated in 35% yield; the autoxidation was carried out in an ethereal solution at 0°C. The hydroperoxide decomposes fully into the corresponding quinone imine and phenol in several hours at 0°C. The methods of synthesis are described and the reaction is discussed in detail by Cauquis[65].

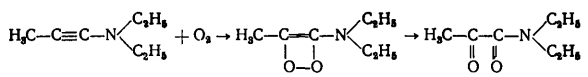


The autoxidation of the indandione anil

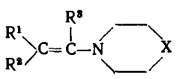


leads to the formation of the corresponding hydroxyisoquinolinedione.[67] Although the presence of the peroxide has not been established chemically, nevertheless one can postulate the intermediate formation of a very unstable hydroperoxide, the decomposition of which is probably due to the corresponding isoquinoline derivative:

Enamines without a hydrogen atom linked to the nitrogen atom can combine with singlet $O_2$ in certain cases and give rise to a carbonyl compound and a substituted amide via the intermediate formation of a very unstable 1,2-peroxide:

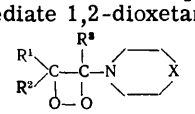


It has been shown[68] that the sensitised photochemical oxidation of the compound

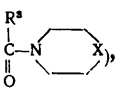


$(R^1=R^2=CH_3;\ R^1=R^2=C_2H_5;\ R^1=C_6H_5,\ R^2=CH_3)$

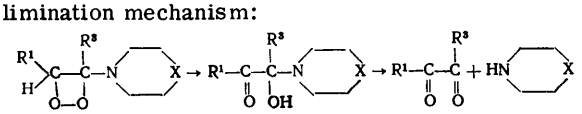
(solvent—benzene, sensitiser—haematoporphyrin) at room temperature leads to the rapid absorption of one mole of $O_2$ with formation of the ketone $R^1R^2C{=}O$ (in a high yield) and formylpiperidine.



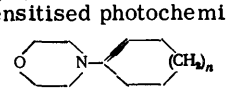
Under the same conditions, *NN*-dimethylpropynylamine yields the *NN*-dimethylamide of pyruvic acid:

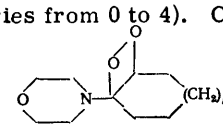


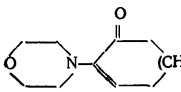
The photosensitised oxidation at room temperature of enamines of the type

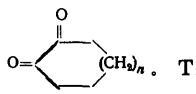


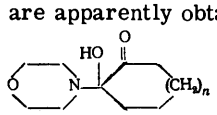
where X = $CH_2$ or O, has been examined[186]. It involves the rapid absorption of 1.2 moles of $O_2$ with formation of a very unstable intermediate 1,2-dioxetan





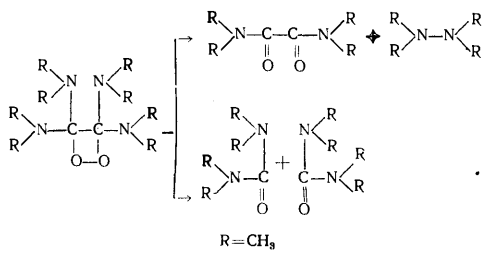






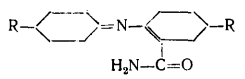
which may decompose as a result of the dissociation of the C–C bond, with formation of the monoketone $R^1R^2C{=}O$ and the amide,  , or the C–N bond with formation of the $\alpha$-diketone $R^1{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{O}{\|}}{C}{-}R^3$. The latter reaction depends to a large extent on the nature of $R^3$. For $R^1 = R^2 = CH_3$ and X = O, the degree of dissociation of the C–N bond is 32% when $R^3 = C_6H_5$, falling to zero when $R^3 = H$.

The presence of the hydrogen atom in the $\beta$-position relative to the nitrogen atom ($R^1$ or $R^2$ = H) also promotes the dissociation of the C–N bond in accordance with the $\beta$-elimination mechanism:



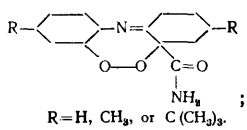
Thus, when $R^1 = CH_3$, $R^3 = C_6H_5$, and X = O, the degree of dissociation of the C–N bond increases from 32 to 71% following the replacement of $R^2 = CH_3$ by $R^2 = H$.

An interesting instance[187] of the sensitised photochemical oxidation of morpholine enamines  has been discovered (*n* varies from 0 to 4). Crystals of the intermediate dioxetans  , were isolated at −78°C in dimethyl ether (for *n* = 1, 2, or 3), but at room temperature the main compounds are the monoketone enamines  and the diketone  . They are apparently obtained from the aminohydroxyketone  by dehydrogenation in the former case and by the dissociation of C–N bond in the latter. The aminohydroxyketone may be formed from the dioxetan on dissociation of the peroxy-bridge and subsequent hydrogen transfer (the $\beta$-elimination mechanism).



The photochemical oxidation of 3-morpholinocholest-3-ene in ether at −78°C leads to the formation of cholestane-2,3-dione and 3-morpholinocholest-3-en-2-one.[187]

The autoxidation of tetrakisdimethylaminoethylene in polar and non-polar solvents has been investigated[69]. The mechanism of this reaction is very complex, depends on the nature of the solvent, and has been investigated inadequately. The principal autoxidation products (the composition of the products varies depending on the nature of the solvent) are dimethylurea, tetramethyloximide, and tetramethylhydrazine. They are probably obtained from a very unstable intermediate peroxide:

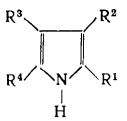


R=$CH_3$

Conjugated unsaturated imines, in which one nitrogen atom and one of the double bonds are outside the ring and which are described by the formula

constitute an interesting case[70]. At room temperature in chloroform they rapidly absorb one mole of $O_2$ (the reaction is appreciably accelerated by the addition of 0.1% of cobalt naphthenate) with formation of endoperoxides:

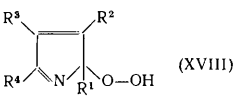
R=H, $CH_3$, or $C(CH_3)_3$.



## VI. THE AUTOXIDATION OF COMPOUNDS WITH A DOUBLE BOND AND A NITROGEN ATOM IN THE RING

### 1. Pyrroles

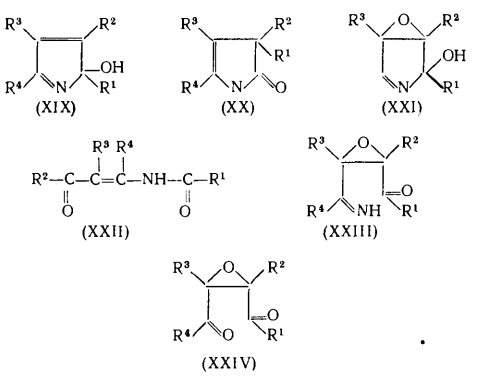
The pyrrole rings are important components of compounds which are of great biological significance: chlorophyll, haemoglobin, and certain alkaloids (chydrine and



stachydrine). The various methods for their oxidation by oxygen are therefore of special interest. Numerous, very important studies have been devoted to them in recent years [72-84]. Non-sensitised autoxidation at room temperature yields only a mixture of compounds which are difficult to determine [71], the rate of absorption of $O_2$ increasing sharply in the presence of alkali metal alkoxides. Two moles of $O_2$ are absorbed and trimers with two pyrrole rings are formed [72]. Sensitised photochemical oxidation leads to the formation of readily identifiable compounds, which are probably obtained as a result of the isomerisation of the 1,4-endoperoxide, formed initially with or without the rupture of the pyrrole ring. The nature and proportions of the products depend on the structure of the pyrrole derivative and the conditions of preparation. In certain cases a hydroperoxide may be formed.

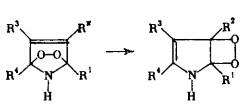
The tetrasubstituted pyrrole (XVII)

(XVII)



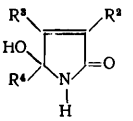
can lead to the formation of the hydroperoxides (XVIII)

(XVIII)



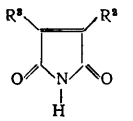
(a) $R^1=R^2=R^3=$ t-Bu, $R^4=H$;
(b) $R^1=R^2=$ t-Bu, $R^3=R^4=H$;
(c) $R^1=R^2=R^3=R^4=C_6H_5$;
(d) $R^1=R^4=C_6H_5$, $R^2=R^3=H$,

as well as an alcohol (XIX), a lactam (XX), an epoxyalcohol (XXI), a chalcone (XXII), an epoxyketoimine (XXIII), and its hydrolysis product (XXIV):



(XIX) (XX) (XXI) (XXII) (XXIII) (XXIV)

In order to account for the formation of some of the above products, obtained in consequence of the dissociation of the $C_{(1)}-C_{(2)}$ bond, the formation of the intermediate 1,2-peroxide (XXVI) as a result of the isomerisation of the 1,4-endoperoxide (XXV) was examined:



(XXV) (XXVI)

Pyrroles unsubstituted in the 1- and 4-positions can give rise to the formation of the hydroxylactam (XXVII)

(XXVII)

as a result of the base-catalysed rearrangement of the endoperoxide (XXV) and its more far-reaching oxidation products, for example derivatives of maleimide (XXVIII):

(XXVIII)

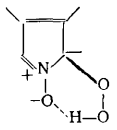
(in the case of pyrroles unsubstituted in both 1- and 4-positions).

Unsubstituted pyrrole (as well as its *N*-methyl derivative), subjected to photochemical oxidation at room temperature (with eosin as the sensitiser), yields a hydroxylactam (XXVII). [73] On photochemical oxidation in benzene solution, 2,4-dimethylpyrrole gives rise to the hydroxylactam (XXVII), $R^1 = R^3 - H$, $R^2 = R^4 = CH_3$) but with the OH group in the 2-position (the 4-position is blocked). It is apparently obtained on rearrangement of the 1,2-peroxide (XXVI). [74] The photochemical oxidation of 2,3-diethylpyrrole in solution in methanol (with Rose Bengal as sensitiser) gives a methoxy-derivative of the hydroxylactam (XXVII) and the corresponding maleimide (XXVIII) in a yield of the order of 35%. [75]

We may note that in certain cases the hydroxylactam and maleimide are formed as a result of the dealkylation of the $C_{(4)}$ atom. Thus the photochemical oxidation of 3-ethyl-2,3,4-trimethylpyrrole and 3-ethyl-2,4-dimethylpyrrole (in methanol solution with Rose Bengal as the sensitiser) gives rise to the hydroxylactam (XXVII) and the corresponding maleimides in yields of 40 and 3% respectively [75].

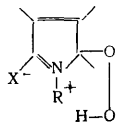
The sensitised photochemical oxidation of 1,4-di-t-and 1,2,4-tri-t-butylpyrroles (in methylene chloride with Methylene Blue as sensitiser) gives rise to hydroperoxides with a strong hydrogen bond [76].

The behaviour of 1,2,3,4-tetraphenylpyrrole, the photochemical oxidation of which has been investigated [77-79], is most characteristic of pyrroles. This compound is similar to lophine (1,3,4-triphenylimidazole), the sensitised photochemical oxidation of which gives rise to a hydroperoxide and not an endoperoxide, as was believed previously. The irradiation of a 2% solution of compound (XVII, $R^1 = R^2 = R^3 = R^4 = C_6H_5$) at room temperature or −50°C in $CS_2$, $CH_3OH$, $CHCl_3$, or ether for 10–15 min in the presence of 1% of the sensitiser (heterocoerdianthrone, dibenzoperylenequinone) leads to the formation of a hydroperoxide in 35% yield. It is noteworthy that this hydroperoxide, like that of lophine, can decompose into the initial pyrrole and $O_2$.



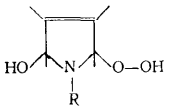
When compound (XVII) is subjected to autoxidation without a solvent at 120–130°C or refluxed in propanone, dioxan, or benzene, 2,4-substituted pyrroles are formed preferentially in yields of 66, 75, and 82% respectively. When the compound is refluxed in methanol, the main products are compounds (XXI) and (XXII) in yields of 30 and 15% respectively.

The reduction of the hydroperoxide (XVIII) at room temperature (KI solution in acetic acid) gives rise to



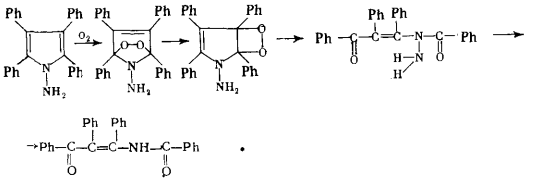
compound (XIX) (90% yield). Decomposition in a sealed tube in benzene solution with added anhydrous KOH results in the formation of compounds (XX) and (XXII) in yields of 28 and 10% respectively. The formation of a hydrogen bond between the H atom of the HO–O group and the nitrogen atom of the pyrrole ring facilitates the dissociation of the CO–OH and HO–O–C linkages with evolution of $O_2$, which proceeds more readily the lower the degree of association of the solvent. We may note that compounds (XXI) and (XXII) are formed in the sensitised photochemical oxidation of compound (XVII) without the preliminary isolation of the hydroperoxide (XVIIIc).

The sensitised photochemical oxidation of 1,4-diphenylpyrrole also leads to the corresponding hydroperoxide (XXVIId), but the latter is very unstable, which makes it impossible to reduce it by iodides. Its thermal decomposition *in vacuo* at 80°C leads to the formation of a tarry residue with slight evolution of $O_2$.[79]



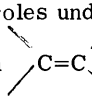
The sensitised photochemical oxidation of 1,2,3,4-tetraphenylpyrroles substituted at the nitrogen atom by OH,[80] $C_6H_5$,[81] benzoyl,[82] and $NH_2$ [83] groups has been investigated. When R = OH, the product is a nitrone peroxide

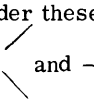
which is converted into the corresponding hydroxynitrone on reduction with KI solution in acetic acid. Similar results were obtained for R = $C_6H_5$ [81] and benzoyl.[82] In both cases the initial product (a 1,4-endoperoxide) isomerises to the 1,2-peroxide, which was detected iodometrically in the course of photochemical oxidation in ethereal solution at −65°C. In the first instance, the peroxide may be isolated as the hydroperoxide salt, which readily hydrolyses to compound (XIX) and $H_2O_2$ (X = halogen or $CH_3C_6H_4SO_3$):



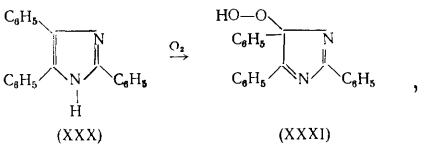
If R = benzoyl, treatment with the above acids leads to the hydrolysis of the initial hydroperoxide and the formation of a hydroxyhydroperoxide

The decomposition products of these two peroxides are similar to the products obtained from tetraphenylpyrrolyl hydroperoxide (XVIIc) unsubstituted at the nitrogen atom. In both cases the chalcone (XXII) is formed in chloroform solution with $C_6H_5$ and $C_6H_5COO$ groups respectively at the nitrogen atom; when R = $C_6H_5COO$, the second reaction product is the epoxyoxoimine (XXIII); when R = $C_6H_5$, the epoxyoxoimine hydrolyses with formation of the epoxyketone (XXIV).





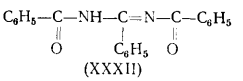
If R = $NH_2$, [83] the formation of a peroxide could not be observed even at −60°C regardless of the solvent. The main products of this sensitised photochemical oxidation were benzoyltriphenylpyrazole and tetraphenylpyridazine. The former compound is apparently formed from a very unstable intermediate peroxide:



The sensitised photochemical oxidation of *N*-phenylpyrrole unsubstituted at the carbon atoms, which is used to synthesise the hydroxylactam (XXVII, $R^1 = R^2 = R^3 = R^4 = H$), necessary for the synthesis of various mitomycins, has been investigated[87].

The sensitised oxidation of pyrroles substituted and unsubstituted at the nitrogen atom has also been examined[85,86].

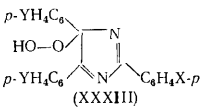
## 2. Imidazoles



The behaviour of imidazoles under autoxidation and sensitised photochemical oxidation conditions is similar to that of pyrroles under these conditions except that compounds with  and  bonds are formed respectively in the two cases.

Triphenylimidazole (lophine) (XXIX) gives rise to a hydroperoxide,

(XXX) (XXXI)



as a result of non-sensitised (in $CS_2$) [87] or sensitised (in chloroform) photochemical oxidation[88] in yields of 20 and 68% respectively. The hydroperoxide is relatively stable at room temperature in the solid state but is very unstable in solution (particularly in acid or alkaline solutions). On heating, it decomposes into lophine (with a yield of 50%) and $O_2$. This reaction is accompanied by luminescence and the formation of *MN*-dibenzoylamidine (XXXII):

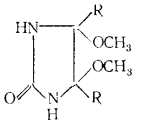
(XXXII)

The latter compound is also formed as a result of the oxidation of compound (XXX) in organic solvents.

Certain hydroperoxides derived from lophine, described by the formula

(XXXIII)

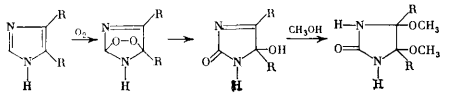
have been obtained by the photochemical oxidation of compound (XXXIII) in solution in a mixture of methylene chloride (95%) and ethanol (5%).[89]



The pure hydroperoxides have been obtained for X = $H_3CO$, Y = H and X = $H_3CO$, Y = $H_3CO$; for X = $(CH_3)_2N$, Y = H and X = $(CH_3)_2N$, Y = $H_3CO$, the hydroperoxides proved to be very unstable[89]. The luminescence of hydroperoxides

of this type has been discussed[89]. It is probably associated with the formation of *NN*-dibenzoylamidine in an excited state.

The luminescence in the case where the substituents in the three benzene rings of compound (**XXXIII**) are chlorine atoms (one chlorine atom in the *ortho-*, *meta-*, or *para*-position and two chlorine atoms in the 2,4- and 3,4-positions) has been discussed in another investigation[90].

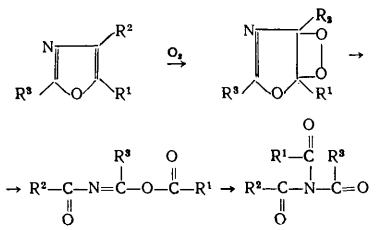


We may note that the sensitised photochemical oxidation of *N*-phenyl-lophine in solution gives rise to a very unstable peroxide, which was detected iodometrically at −60°C. The product in this instance is probably a 1,4-endoperoxide, the hydrolysis of which results in the formation of hydroperoxide salts, similar to those of *N*-substituted pyrroles[91].

The sensitised photochemical oxidation (in solution in methanol) of unsubstituted imidazole and 1,2-diphenylimidazole has been examined[92]. The final reaction products are methoxyimidazolidinones (**XXXIV**) (in 45% yield):

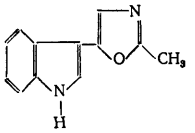
(XXXIV)

Their formation with participation of the solvent can be represented as follows on the basis of the formation of a 1,4-endoperoxide:



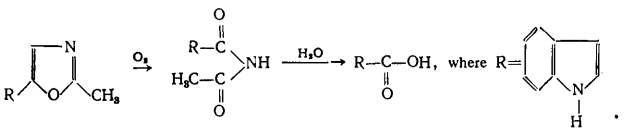
The decomposition of the imidazoline ring of histidine on sensitised photochemical oxidation of enzymes in the aqueous phase is associated with a decrease of their activity. A relation between the degree of decomposition of the imidazole ring of histidine in bovine insulin and the biological activity of this hormone can be established[93]. We may note that the absorption of 2.25 moles of $O_2$ lowers the histidine content from 5.4 to 0.1%, while the content of other aminoacids remains almost constant [93].

Similar phenomena have been observed for phosphoglucomutase [94] and chymotrypsin.[95] The change in the properties of lactoglobulin [96] is also associated with the decomposition of the imidazole ring in histidine.



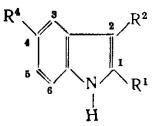
## 3. Oxazoles

The sensitised photochemical oxidation of oxazoles leads to the formation of triamides. A study[97] of the photochemical oxidation of 3-methyl-1,2-diphenyl- and 2-methyl-1,4-diphenyl-oxazoles (at room temperature in methanol) showed that the final product of the reaction is *N*-acetylbenzamide in both cases. It is probably formed as a result of a rearrangement of the 1,2-peroxide (which is apparently in its turn a product of the isomerisation of the 1,4-endoperoxide):

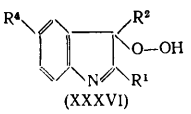


The mechanism of this reaction has been considered in detail[97,98].

The conversion of pimprinine



in sensitised photochemical oxidation into indolecarboxylic acid is a reaction of this type[97,99]:

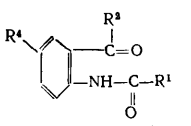


## 4. The Autoxidation of Indoles

Alkylindoles (**XXXV**) having the general formula

(XXXV)

give rise to the corresponding hydroperoxides (**XXXVI**)

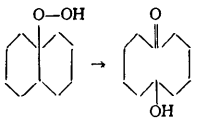


(XXXVI)

on autoxidation. Their formation requires the presence of a hydrogen atom linked to the nitrogen atom. The nature of the group $R^2$ in the pyrrole ring (in the β-position relative to N) is very important; for example, the reaction does not occur when $R^2 = C_6H_5$. The nature of the group $R^4$ in the 4-position of the benzene ring (in the β-position relative to the common double bond) also influences the reaction; the latter proceeds more readily in the presence of a nucleophilic group, for example $OCH_3$. The results are presented in Table 2.

Table 2. Data on the autoxidation of indoles.[100]

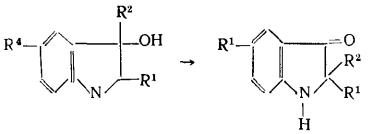
| Группа | | | Yield of hydroperoxide |
|---|---|---|---|
| $R^4$ | $R^1$ | $R^2$ | |
| H | $CH_3$ | $CH_3$ | 25 |
| $CH_3O$ | $CH_3$ | $CH_3$ | 50 |
| $CH_3O$ | $C_6H_5$ | $CH_3$ | 100 |



On being refluxed with dilute acids or alkalis, indolyl hydroperoxides are converted into amidoketones (**XXXVII**)

(XXXVII)

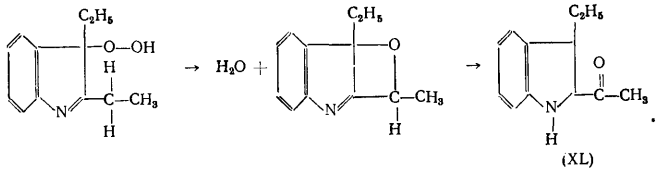
via two possible mechanisms:



(1) The mechanism described by Criegee, which consists in the conversion of decalinyl hydroperoxide into hydroxycyclodecanone:

The reaction proceeds with heterolytic dissociation of the O–O bond followed by rupture of the $C_{(1)}$–$C_{(2)}$ bond and the migration of the OH group from O to $C_{(6)}$.

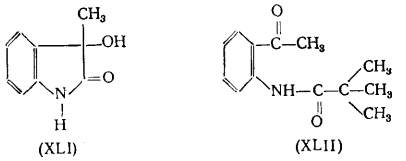
(2) The mechanism (operating in the case of tetraphenylpyrrolyl hydroperoxide) involving the heterolytic dissociation of the O–H bond (in RO–O–H), resulting in the formation of $RO-O^-$ and $H^+$, and the addition of the anion $RO-O^-$ and the proton $H^+$ to the $-N=C\langle$ double bond.



On being reduced with hydrosulphites, hydroperoxides are converted into the corresponding alcohols (XXXVIII), which are further converted into lactams (XXXIX) in an alkaline medium. This reaction is analogous to that which occurs with pyrrole derivatives:

(XXXVIII) (XXXIX)

The methods for the synthesis and decomposition of hydroperoxides of this type have been described [100].

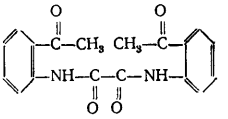


The behaviour of 1,2-diethylindole is interesting [102]. The hydroperoxide (XXXVI, $R^3 = H$, $R^1 = R^2 = C_2H_5$), with the OOH group in the 2-position, is converted into 1-acetyl-2-ethylindole (XL):

(XL)

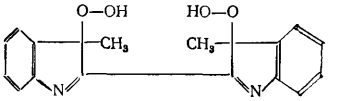
(The presence of the N=C double bond renders the hydrogen atoms in $CH_2$ mobile). One should note that (XL) is formed from diethylindole at room temperature in the presence of atmospheric oxygen in the light.

The behaviour of 1-isopropyl-2-methylindole is more complex [103]. The resulting hydroperoxide with the OOH group in the 2-position, gives rise on decomposition to compounds (XLI) and (XLII):



(XLI) (XLII)

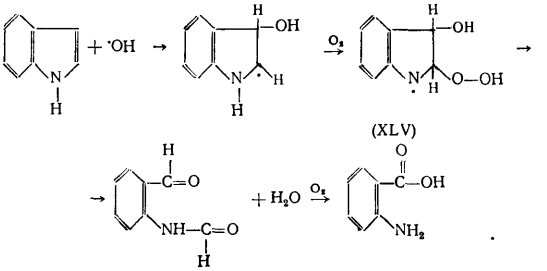
The mechanism of these anomalous reactions has already been discussed [103–105].



The formation of 1-acylindoles during the *in vivo* oxidation of derivatives of 1,2-dialkylindoles in alkaloids such as dregamine [106], voacafrine [107], and vobasine [108] apparently proceeds via a mechanism similar to that operating with 1,2-diethylindole.

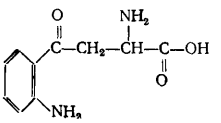
A more complex instance involving indoles (XXXV, $R^4 = H$, $R^2 = CH_3$, $R^1$ = methylindolyl) has been examined [109].

The monohydroperoxide (XXXVI) is formed initially and its subsequent oxidation (on passing $O_2$ into a boiling xylene solution) yields the oxamide (XLIII):



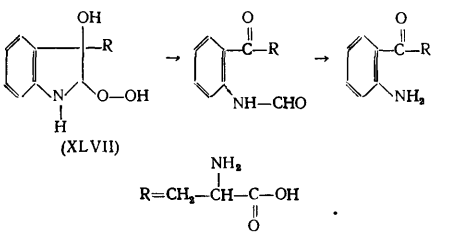
which is apparently formed from the intermediate dihydroperoxide (XLIV):

(XLIV)



The formation of indolyl hydroperoxides is probably associated with the bioluminescence of certain marine organisms. This hypothesis has been confirmed by studies on the hydroperoxides (XXXVI, $R^4 = H$, $R^2 = CH_3$, $R^1 = CH_3$ of $p$-$CH_3OC_6H_4$). [110]

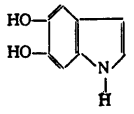
The action of $\gamma$-radiation in the presence and absence of $O_2$ on indole, $N$-methylindole, 2,$N$-dimethylindole, and 1,2-dimethylindole in aqueous solution has also been investigated [111]. It was shown that attack by the $^{\cdot}OH$ radicals formed from $H_2O$ is initially directed to the 2-position (the $\beta$-position relative to the nitrogen atom) of the pyrrole ring (which does not in any way exclude attack on the benzene ring) and that, depending on the presence or absence of oxygen, different reaction products are obtained. In particular, anthranilic acid is formed from indole only in the former case—probably as a result of the formation of the intermediate hydroxyhydroperoxide (XLV) in accordance with the equation



(XLV)

The formation of kynurenine (XLVI)

(XLVI)

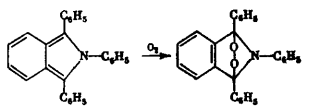


from tryptophan apparently proceeds via a mechanism similar to that involving the formation of the intermediate hydroxyhydroperoxide (XLVII):

(XLVII)

This reaction was achieved *in vitro* when an aqueous solution of tryptophan (at a concentration of 0.001 M) was exposed to X-rays at room temperature in the presence of oxygen[112]. Kynurenine is a product of the decomposition of tryptophan in living cells and in micro-organisms and is one of the controlling factors in transmitting hereditary information[113]. It has been shown[114] that the conversion of tryptophan into kynurenine in rat liver proceeds via the intermediate formation of formylkynurenine. Various metabolic aerobic transformations of tryptophan have been examined[192].

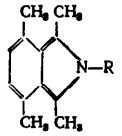
The role of indolyl hydroperoxides in the formation of melanin pigments has not been completely elucidated as yet. These pigments are formed as a result of the biological oxidation of tyrosine with intermediate formation of 4,5-dihydroxyindole:[115]



The attempts to oxidise 4,5-dihydroxyindole and its 1- and 2-methyl derivatives in an aqueous alkaline medium have shown[115] that $O_2$ is absorbed in all cases, but a black deposit is formed only from the 2-methyl derivative; the 1-methyl derivative gives rise to an amorphous blue precipitate, while the unsubstituted derivative is converted into a purple solution. Presumably these three indole derivatives are oxidised via different mechanisms.

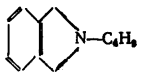
## 5. The Autoxidation of Isoindoles

The non-sensitised photochemical oxidation of isoindoles has been the subject of several studies[116-119]. In the autoxidation of *N*-substituted isoindoles the intermediate is apparently an endoperoxide, the stability of which and hence the nature of the final product depend to a large extent on the nature of the 1,2-substituents in the pyrrole ring.



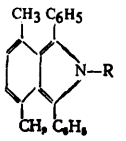
The corresponding endoperoxide (XLIX)

(XLVIII) (XLIX)



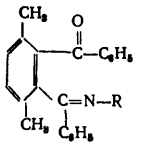
was isolated in the autoxidation of 2,3-*N*-triphenylisoindole (XLVIII). This endoperoxide decomposes on heating in oxygen up to 118°C; acid hydrolysis leads to the rupture of the pyrrole ring with formation of dibenzoylbenzene and aniline[116].

The autoxidation of *N*-alkyl-1,2,4,7-tetramethylisoindoles (L)



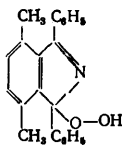
(L)
R=$CH_3$, $C_6H_5$, $C_6H_5$

has been examined[117]. The final oxidation products in boiling tetrahydrofuran (THF) are the corresponding phthalimides, which are believed to be formed on decomposition of the intermediate endoperoxides as a result of the elimination of $CH_3$ groups. The $CH_3$ groups are abstracted from the pyrrole ring (which is retained, in contrast to the previous case).



The autoxidation of *N*-butylisoindoline 

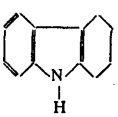
has been investigated[118] and it has been shown that the first reaction stage involves the dehydrogenation of the corresponding isoindole and depends to a large extent on the nature of the solvent. The products of this reaction are phthalimidines and a phthalimide. The reaction has a non-classical mechanism, which is believed to involve peroxy-radicals[118]. The autoxidation of the isoindoles



(R=H, $CH_3$, $C_6H_5$, or $C_6H_5CH_3$)

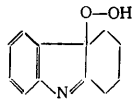
(in boiling THF) has been studied[188] and it has been shown that, owing to the greater difficulty of the elimination of $C_6H_5$ groups compared with $CH_3$ groups, the ketimines

are formed instead of phthalimides (R can be any group other than a hydrogen atom) as a result of the rupture of the pyrrole ring. When R = H, the product is the hydroperoxide



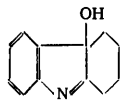
which is rapidly converted into the corresponding alcohol.

## 6. The Autoxidation of Tetrahydrocarbazoles



The autoxidation of tetrahydrocarbazole derivatives has been studied in detail[120-127]. It is to some extent similar to the autoxidation of dialkylindoles, in particular in view of the necessity for the presence of a hydrogen atom linked directly to the nitrogen atom and as regards the influence of the substituent in the benzene ring. The formation of hydroperoxides at the beginning of the reaction (which have been isolated in many instances) is accompanied by the formation of interesting products on their decomposition.

The unsubstituted tetrahydrocarbazole (LI)

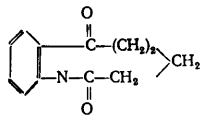


(LI)

gives rise, under conditions analogous to those in the reactions of dialkylindoles, to the hydroperoxide (LII)

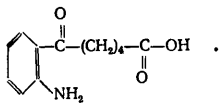
(LII)

which may be reduced to the alcohol (LIII)



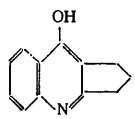
(LIII)

by an aqueous solution of $Na_2S_2O_4$ in the presence of NaOH.



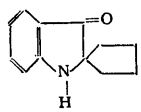
Here one should note that the catalytic hydrogenation of compound (LII) in the presence of palladium yields the tetrahydracarbazole (LI), while in the presence of $PtO_2$ the hydrogenation proceeds with formation of hexahydrocarbazole.

The formation of the lactam (LIV)



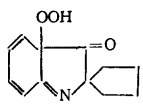
(LIV)

from compound (LII) proceeds at room temperature in polar solvents and is strongly catalysed by acids [121]. Under the influence of acids, the lactam is converted into *o*-aminobenzoylvaleric acid (LV):



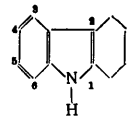
(LV)

Compounds of two types are formed in an alkaline medium (2 *N* NaOH) at room temperature: hydroxycyclopentanoquinoline (LVI)



(LVI)

as a result of the internal condensation of the lactam (LIV) and the oxospiran (LVII)

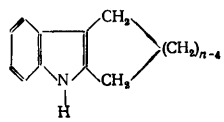


(LVII)

which is a product of the isomerisation of the hydroxy-derivative. As a result of catalytic hydrogenation, the oxospiran is converted into the corresponding dihydro-derivative, which yields the hydroperoxide (LVIII) on autoxidation [120,121]:

(LVIII)

The autoxidation of tetrahydrocarbazoles substituted in the benzene ring has been investigated [122-124]:

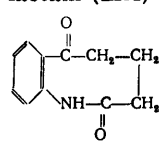


(LIX)

| substituent | position |
|---|---|
| $OCH_3$ | 4,5 |
| Br | 4 |
| $NO_2$ | 6 |
| $H_2N-C(=O)-CH_3$ | 4 |
| $COOCH_3$ | 3 |
| $COOCH_3$ | 4 |

In the presence of the same substituent, the rate of autoxidation is a maximum for the isomer substituted in the 3-position and a minimum for the isomer substituted in the 6-position. Thus the reaction proceeds in a different manner when the 6-position is occupied by the $NO_2$ and $COOCH_2$ groups. Particular attention has been devoted to the study of derivatives with the $COOCH_3$ and COOH substituents in the 3-, 4-, 5-, and 6-positions.

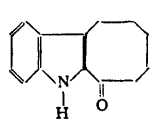
In the first case, the autoxidation proceeds only in an organic solvent. The corresponding hydroperoxides have been isolated (except for the isomer substituted in the 6-position). In the second case the autoxidation occurs only in an aqueous alkaline medium and intermediate peroxides could not be isolated. The corresponding hydroxyquinolines have been obtained for 6- and 8-bromo-derivatives and the 3-methoxycarbonyl-derivatives.



A study has been made of the influence of the size of the hydrogenated ring in compound (LX)

(LX)

(where *n* is the number of carbon atoms in the ring) on the rate of autoxidation and on the nature of the products [125]. It was found that the rate decreases with increase of *n* and the corresponding hydroperoxides could not be isolated in any of the instances considered (except for $n = 6$).

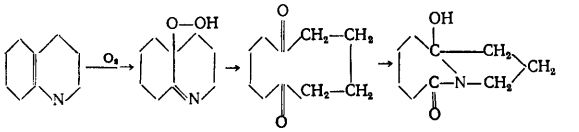


The corresponding lactam (LXI)

(LXI)

formed from the compound with a five-membered ring is readily hydrolysed to *o*-aminobenzoylbutyric acid, but the corresponding hydroxyquinoline (LVI) could not be isolated. The hydroxyquinoline is formed from the compound with a seven-membered ring, but the OH group is in the $\alpha$- and not the $\gamma$-position as in compound (LVI).

It is interesting to note that attack by $O_2$ on the compound with the eight-membered ring is directed to the $\alpha$-position of the hydrogenated ring relative to the nitrogen atom with formation of the corresponding cyclic ketone (LXII)



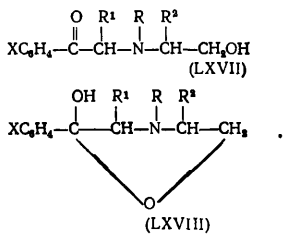
(LXII)

probably via a mechanism similar to that of the formation of 1-acetyl-2-ethylindole from 1,2-diethyl-2-hydroperoxyindole.

The rearrangements occurring in the series of indoles and tetrahydrocarbazoles in connection with structural changes in alkaloids such as quinamine and cinchonamine has been examined in a major article [126].

### 7. The Autoxidation of Octahydroquinoline

The autoxidation of octahydroquinoline (LXIII) [127] at room temperature in ethyl acetate leads to the absorption of 0.9 mole of $O_2$ per mole of compound with formation (in 87% yield) of the crystalline hydroperoxide (LXIV), which is relatively unstable at room temperature but is fairly stable at −5°C. In polar solvents, it is transformed into 7-hydroxy-1-azabicyclo[5,3,0]decan-2-one (LXVI)

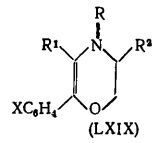


(LXIII) (LXIV) (LXV) (LXVI)

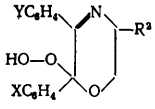
as a result of the rearrangement of the intermediate lactam (LXV).

### 8. The Autoxidation of Dihydro-oxazines

β-Hydroxyethylaminoacetophenones can exist in linear and cyclic forms. This tautomerism and its dependence on steric and polar factors have been discussed [128,129]:



(LXVII)

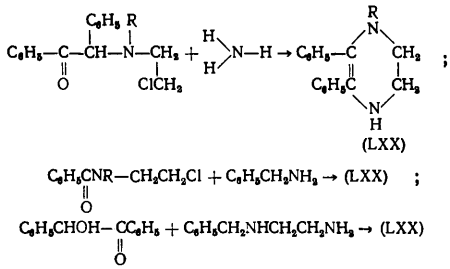


(LXVIII)

Some of these compounds have antimalarial and carcinolytic properties [128]. They readily split off $H_2O$, being converted into dihydro-oxazines [129]:

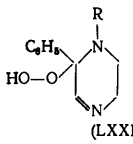
(LXIX)

When R = H and $R^1$ is a *para*-substituted phenyl group *p*-$YC_6H_4$, compounds (LXIX) readily give rise to hydroperoxides under the influence of atmospheric $O_2$:



The hydroperoxides are unstable and decompose rapidly close to their melting points. On heating in an acid medium, they are converted into esters:

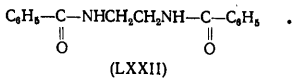
The hydroperoxides were isolated for the following substituents: $R^1 = CH_3$, X = Y = H or Cl; $R^2 = C_2H_5$, X = Y = H or Cl; $R^2 = C_6H_5$, X = Y = H, Cl, or $CH_3O$; $R^2 = C_6H_5CH_2$, $X = CH_3O$, Y = H. On the other hand, they could not be obtained in the presence of the following substituents: $R^2 = C_2H_5$, $X = CH_3O$, Y = H; $R^2 = C_6H_5CH_2$, $X = CH_3O$, Y = H, X = Y = Cl or X = Y = $CH_3O$.



### 9. The Synthesis of 1,2-Dehydropiperazinyl Hydroperoxides

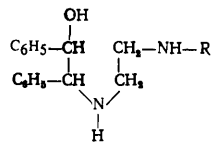
The attempts to synthesise *N*-alkyl(or aryl)-1,2-diphenyl-1,2-dehydropiperazines (in ethereal solution at 70–80°C) in the presence of atmospheric oxygen according to the mechanisms

(LXX)



led to the formation of the hydroperoxides (LXXI) [130]:

(LXXI)

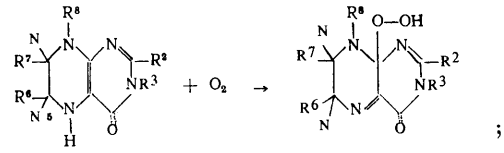


which are crystalline compounds, rapidly decomposing close to their melting points when R = $C_2H_5$, $C_6H_5CH_2$, or $C_6H_5$.

Their decomposition in an acid medium (3 *N* HCl) leads to dibenzoylalkylethylenediamines, e.g.

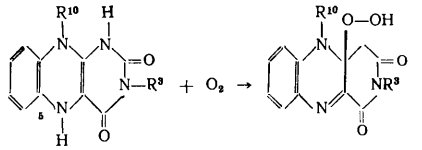
(LXXII)

Catalytic hydrogenation results in ring opening with formation of compound (LXXIII):



(LXXIII)

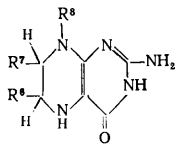
while reduction with $LiAlH_4$ yields the corresponding piperazine. The experiment has been described and discussed [130].



The attempts to synthesise compound (LXXI) with R = H by treating 1,2-diphenyl-4,5-dihydropyrazine with $H_2O_2$ led to the synthesis of its decomposition products only, which included, apart from the expected dibenzoylethylenediamine, a multiplicity of compounds, the nature and content of which varied as a function of the experimental conditions (for example, depending on the presence of water). It is interesting to note that in certain cases the ring may contract with formation of imidazolines [131].

Partly hydrogenated pyrazines and isoalloxazines, such as tetrahydropteridines (LXXVI) or dihydroisoalloxazines (LXXV), also give rise to the intermediate hydroperoxides

(XXVI) and (XXVII) as a result of autoxidation[132] (their presence has been established chemically and polarographically in some instances). An exception is the case where the nitrogen atom in the 5-position has a substituent:



(LXXIV) (LXXVII)

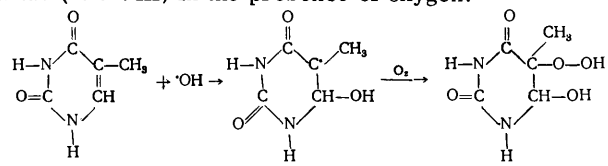
(LXXV) (LXXVI)

In the pteridine series, 2-amino-4-hydroxy-derivatives have been investigated:

(1) $R^6=R^7=CH_3$ and $R^8=H$;
(2) $R^6=R^7=CH_3$ and $R^8=C_2H_5$ or $CH_2—CH_2OH$;
(3) $R^6=R^7=C_6H_5$ and $R^8=C_2H_5$ .

The first case has been investigated in particularly great detail. The initial solid compound is stable at room temperature, but in solution absorbs $O_2$ rapidly. The intermediate hydroperoxide interacts with the initial compound, forming a dihydro-derivative via the mechanism

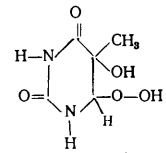
$$H_3PterO—OH + H_4Pter \rightarrow 2H_2Pter + 2H_2O .$$



Tetrahydropteridines (cases 2 and 3) and the corresponding isoalloxazine with R = H behave similarly. In the presence of an appropriate reducing agent, $H_2Pter$ can be reconverted into $H_4Pter$. It has been noted that $H_4Pter$ has an accelerating effect on the oxidation of various compounds, for example thiols ($\beta$-mercaptoethanol, cysteine) as well as more complex compounds, for example dihydronicotinamide-adenine nucleotide. This effect has been examined in detail[132]. The possible involvement of tetrahydropteridine and dihydroisoalloxazines in biochemical hydroxylation is discussed in the same report[132].

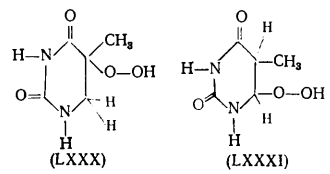
5,6,7,8-Tetrahydrofolic acid and its 5-methyl derivative have been recently reinvestigated[189]. Traces of an organic peroxide could not be detected, but $H_2O_2$ was found in the distillation products. Hence one can apparently conclude that the oxidising radicals (chain-transfer agents) are HO–O· and not RO–O·, which leads to the formation of $H_2O_2$ and not ROOH.

## 10. Nucleic Acid Derivatives



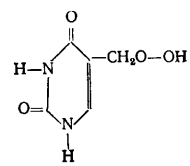
The influence of ionising radiation on the organism causes cell damage such as aberrations in chromosomes, mutation, and carcinogenesis, which are a result of changes at the molecular level. Radiation has a particular influence on the cell nucleus, since it has been established that the latter is twenty times more sensitive to radiation than cytoplasm. It is now believed that exposure to ionising radiation leads mainly to the formation of ·OH radicals, produced by the radiolysis of the aqueous medium. It was found previously that, in the radiolytic process, attack by the ·OH radicals is directed to the extent of 80% towards the pyrimidine base and only to the extent of 20% towards the sugar component of DNA. Purine bases are apparently more resistant to this attack. The foregoing findings suggest that the action of ionising radiation on pyrimidine bases *in vitro* in an aqueous medium is of considerable interest: since 1966, it has been the subject of numerous studies[133-150]. In particular, much attention has been devoted to thymine.[139-147]

The studies have shown that attack is directed mainly to the $C_{(5)}=C_{(6)}$ double bond; the preferred site of the initial attack by ·OH radicals is the 6-position, with formation of a hydroxy-radical, which gives rise to the hydroxyhydroperoxide (LXXVIII) in the presence of oxygen:



(LXXVIII)

Apart from the hydroxyhydroperoxide (LXXVIII) (consisting of a mixture of the *cis*- and *trans*-isomers), compound (LXXIX) was also obtained (as a result of attack by ·OH radicals in the 5-position):

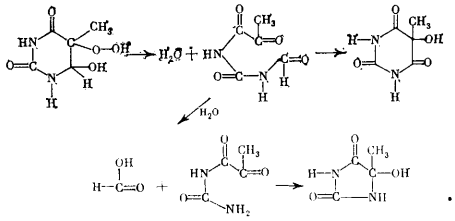


(LXXIX)

and the hydroperoxides (LXXX) and (LXXXI) as a result of attack by H· atoms in the 5- or 6-position:

(LXXX) (LXXXI)

Apart from the $C_{(5)}=C_{(6)}$ double bond, the $CH_3$ group in the side chain can also be attacked by ·OH radicals, which leads to the formation of the primary hydroperoxide (LXXXII):

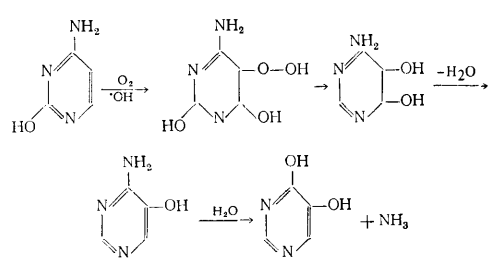


(LXXXII)

In a neutral medium, the rate of this reaction is very insignificant, but increases with increase in alkalinity owing to the aromatisation of the pyrimidine ring[143,147].

Hydrogen peroxide is also formed as a result of the dimerisation of ·OH radicals and the hydrolysis of the hydroxyhydroperoxides (LXV). The existence of these different peroxy-compounds has been established chromatographically[146] and spectroscopically (mass spectrometry, infrared and ultraviolet spectroscopy, NMR, ESR)[144]. NMR and particularly ESR made it possible to demonstrate the existence of intermediate radicals.

At 12°C, pH 5, and an irradiation dose of $9 \times 10^3$ rad $min^{-1}$, a reaction time of 1 h, and a concentration of 0.001 M, the contents of the hydroperoxides (LXXVIII), (LXXIX), (LXXX), and (LXXXI) were respectively 4.0, 4.4, 2.4, and 2.1%. The hydroperoxides (LXXVIII) and (LXXIX) were synthesised (by treating the corresponding glycol with $H_2O_2$). The hydroperoxide (LXXVIII) is fairly stable, decomposing slowly at 30°C. When thymine is radiolysed in an aqueous medium in the presence of $O_2$, the decomposition products of the hydroperoxide (LXXVIII) are formed, namely 5,6-dihydroxy-5,6-dihydrothymine, pyruvylurea, 5-hydroxy-5-methyl-barbituric acid, 5-hydroxy-5-methyl-hydantoin, urea, and formic and pyruvic acids:



The results of a study of the radiolysis ($^{60}Co$ $\gamma$-radiation) of an aqueous solution of thymine (12°C, pH 5, dose $9 \times 10^3$ rad $min^{-1}$) have been published[145] and the kinetics of the formation of various compounds as a function of the irradiation dose (between $2 \times 10^2$ and $10^6$ rad) under the above conditions have been investigated[143,144].

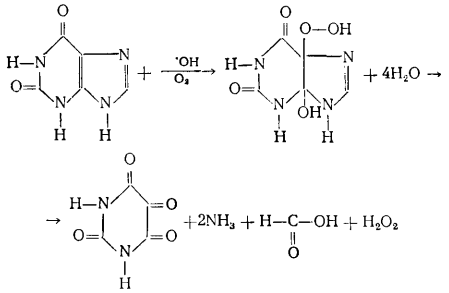
Under analogous conditions, uracil also yields a hydroxyhydroperoxide, since the O–OH group is likewise located in the 5- or 6-position, but it is much more unstable than in the case of thymine; its presence has been detected by NMR.[148] Its decomposition products are similar to those of the hydroperoxide derived from thymine (with the $CH_3$ group replaced by an H atom); they include hydroxybarbituric acid, hydroxyhydantoin, formylglyoxylurea, and products of more extensive oxidation—alloxane, parabanic acid, and dialuric acid.

The complete list of compounds and the methods for their isolation in the radiolysis of uracil in an aqueous medium (at room temperature, pH 6, a concentration of 0.001 M, and a $\gamma$-radiation dose of 90 rad) has been published[148].

The hydroxyhydroperoxide derived from cytosine is still less stable than that derived from uracil. Thus irradiation of this base (under conditions similar to those described above) leads to the formation of isobarbituric acid via the mechanism[136,149]

Products of more far-reaching oxidation are formed from isobarbituric acid: alloxan, dialuric acid, and parabanic acid.[150]

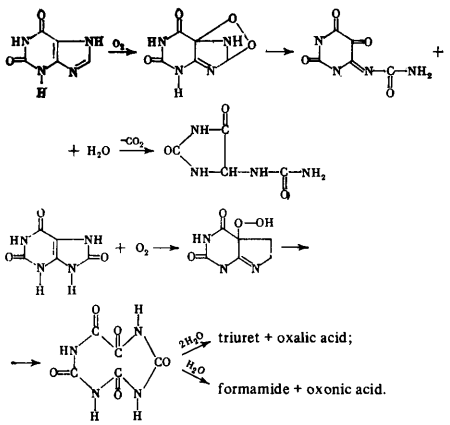
Pyrimidine nucleosides and nucleotides also form peroxides under conditions similar to those in the formation of the corresponding bases[133]. Attack by ·OH radicals is mainly directed to the 6-position, in the double bond of the 5,6-pyrimidine ring, and not to the bond between the nitrogen-containing base and the monosaccharide or between the monosaccharide and phosphoric acid.[154]



The radiolysis of thymidine has been investigated at 16°C, pH 6, and an irradiation dose of $8 \times 10^3$ rad.[152,190] Molecular asymmetry at the level of the sugar component indicates the occurrence of diastereoisomerism leading to the formation of two forms of the *cis*-peroxide derived from 5-hydroperoxy-6-hydroxy-5,6-dihydrothymidine and two forms of the corresponding *trans*-hydroperoxide. These hydroxyhydroperoxides have properties similar to those of the hydroxyhydroperoxide derived from thymine. In particular, they are readily hydrolysed to the corresponding glycols (with retention of the configuration), which are the main reaction products.

The presence of the sugar component makes the pyrimidine ring appreciably resistant to the dissociation of the $C_{(5)}=C_{(6)}$ bond. Indeed hydroxymethylribofuranylbarbituric acid, which can be obtained as a result of the rearrangement of formylpyruvylribofuranylurea, could not be detected[152].

The formation of organic peroxides and $H_2O_2$ was also established following the irradiation of an aqueous DNA solution (at 22°C, a concentration of 0.001 M, and a dose of $7 \times 10^3$ rad).[163] The kinetic curves for the decomposition of these peroxides at 52°C, 62°C, 72°C, and 79°C indicate the existence of two different peroxy-compounds[153], which are in all probability hydroxyhydroperoxides derived from thymine and cytosine nucleotides. These hydroperoxides probably play an important role in the development of the consequences of the irradiation of organisms as a result of their further decomposition into the products discussed above[153].

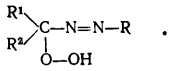


It is noteworthy that only pyrimidine compounds are formed. Indeed not even traces of a peroxide could be detected after the irradiation of an aqueous solution of quanine and adenine as well as their nucleosides and nucleotides[133].

However, purine bases can be subjected to oxidative degradation under the influence of $\gamma$-radiation in an aqueous solution with rupture of the imidazole ring. Thus xanthine is converted into alloxan, formic acid, $NH_3$, and $H_2O_2$. The preferred site attacked by the ·OH radical is apparently the $C_{(4)}=C_{(5)}$ double bond. In order to account for the formation of the above compounds[155], the formation of very unstable hydroxyhydroperoxides was postulated:

In addition, purine bases (in contrast to pyrimidine bases) decompose at room temperature as a result of sensitised photochemical oxidation. For example, in an aqueous alkaline medium containing added dyes, they absorb approximately one mole of $O_2$ following exposure to light with formation of various decomposition products consisting of allantoin in the case of xanthine and triuret in the case of uric acid.

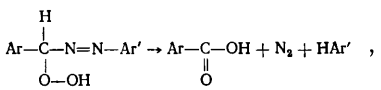
In order to account for the formation of these compounds, it was suggested that a very unstable endoperoxide (in the case of xanthine) and a very unstable hydroperoxide (in the case of uric acid) are formed as intermediates:



The compounds formed in accordance with the experimental conditions have been described and their formation discussed [156,157].

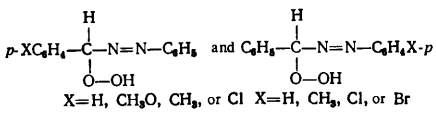
## VII. THE OXIDATION OF HYDRAZONES

Hydrazones having the general formula

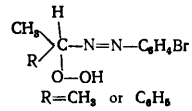


yield hydroperoxides on autoxidation at room temperature in an organic solvent:

Hydrazones disubstituted at the nitrogen atom are not oxidised under these conditions.

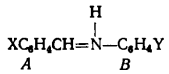


The hydroperoxides derived from hydrazones are yellow crystalline substances, which explode in the dry state, are more or less stable in solution, are soluble in alcohol and ether, and are sparingly soluble in petroleum ether. They decompose to a carboxylic acid, a hydrocarbon, and nitrogen,



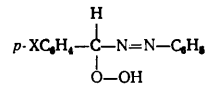
and on reduction (with KI in acetic acid) give rise to the corresponding hydroxy-derivatives, which rearrange to acylhydrazines.

Hydroperoxides of the type



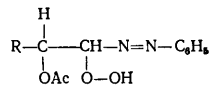
have also been investigated.

Apart from the above hydroperoxides, there exist a further two hydroperoxides:



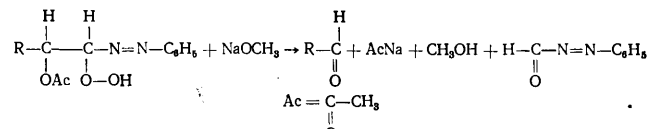
Hydrazone hydroperoxides were obtained for the first time by Bush and Dietz [158] and their structures have been established by Pausacker [159] and Criegee and Lohaus [160].

Any substituent in ring *A* of the hydrazone having the general formula



decreases the rate of autoxidation; the autoxidation is accelerated in the presence of nucleophilic substituents and is retarded in the presence of electrophilic substituents in ring *B*. [159]

The stability of the hydroperoxides



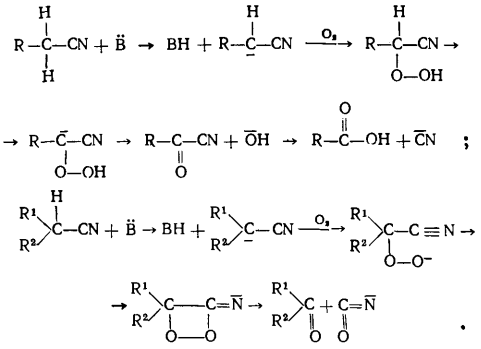
increases in the presence of nucleophilic substituents and diminishes in the presence of electrophilic substituents. For example, when **X** = $CH_3O$, the hydroperoxide decomposes very slowly at room temperature and can be stored for several weeks at 0°C, while in the case where **X** = Cl it decomposes already during crystallisation [161].

Interesting results have been obtained for hydrazones derived from monosaccharides. [162] Thus when a stream of $O_2$ is passed into a benzene solution of penta-acetylgalactose phenylhydrazone, the product is the hydroperoxide

which decomposes under the influence of sodium methoxide in methanol solution to lyxose and *N*-phenyldi-imine formate:

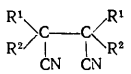
Deoxyarabinose is formed similarly from rhamnose.

Thus the above method can be convenient for the synthesis of $C_{n-1}$ monosaccharides from a $C_n$ monosaccharide.



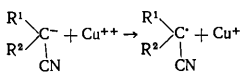
## VIII. THE BASE-CATALYSED AUTOXIDATION OF AZO-COMPOUNDS VIA AN IONIC MECHANISM

### Nitriles

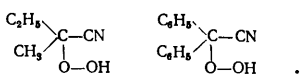


The autoxidation of a number of mono- and di-substituted nitriles (phenyl-, diphenyl-, and cyclohexylphenyl-acetonitriles) has been examined [163,164] and it has been established that there is no absorption of $O_2$ at room temperature even in solvents such as pyridine, but it begins rapidly after the addition of a strong base (sodium methoxide, benzyltrimethylammonium hydroxide), reaching a maximum

of 0.7–0.8 mole of $O_2$ in the course of several hours. Disubstituted nitriles lead to the formation of ketones and cyanates, while monosubstituted nitriles yield benzoic and hydrocyanic acids (in the form of alkali metal salts). The yield of benzophenone from diphenylacetonitrile is 65%.



The following reaction mechanism has been proposed [164]:



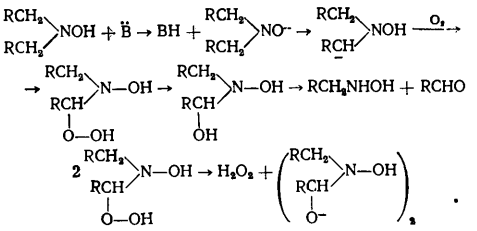
In the presence of copper ions (1–2 mole %), the acceleration of the absorption of $O_2$ is accompanied by the formation of the dinitriles

which are apparently a result of the dimerisation of the radicals formed via the mechanism

When the oxidation was carried out at −40° and −75°C with added $(CH_3)_3COK$ in solution in $CH_3OCH_2CH_2OCH_3$, pure hydroperoxides were obtained from the corresponding nitriles in 67% yield:

## Hydroxylamines

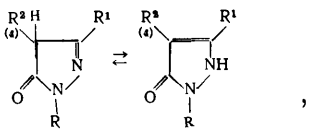
The study of the autoxidation of symmetrical disubstituted aliphatic hydroxylamines (in the form of oxalates) [165,166]



shows that alkalis have a marked accelerating effect on the absorption of $O_2$. $Mn^{2+}$ and particularly $Cu^{2+}$ ions greatly accelerate the absorption of $O_2$.

A monosubstituted hydroxylamine ($RCH_2NHOH$) aldehydes (RCHO), and peroxy-compounds are formed in the autoxidation reaction. The content of peroxides passes through a maximum, then falls, but does not reach zero. The formation of $H_2O_2$ and of an organic peroxide from the compound

has been demonstrated by the polarographic method [166]. However, the latter could not be isolated in a pure state.

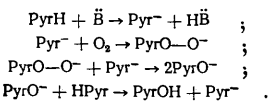


The following mechanism of the reaction involving the formation of a hydroperoxide, a dialkyl peroxide, and $H_2O_2$ is possible:

The accelerating effect of metal ions can probably be accounted for by the conversion of anions into radicals, as for nitriles.

## Pyrazolones

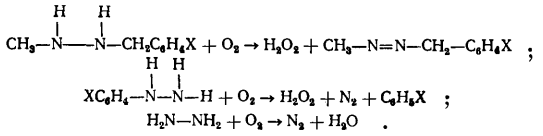
Pyrazolones, which exist in two tautomeric forms,



are converted in the presence of atmospheric oxygen into the corresponding dimers linked via the carbon atoms in the 4-positions. The study of the autoxidation of pyrazolones with R = $C_6H_5$, $R^1 = CH_3$, and a variable $R^2$ shows that one mole of $O_2$ is absorbed in an alkaline medium [167].

The primary autoxidation products are apparently pyrazolones hydroxylated in the 4-position, which yield dimers as a result of the reaction with the initial pyrazolone [167]:

The autoxidation proceeds with formation of intermediate pyrazolone anions in the following manner:

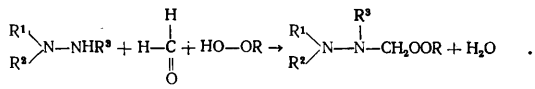


This mechanism has been discussed in detail with changes caused by any change in the nature of the base [167].

The autoxidation of 3,4-dialkyl-1-(methylpiperidinyl)-5-pyrazolones, which have interesting pharmacological properties, has been examined. A study has also been made of pyrazolidine-3,5-diones [169].

# IX. THE INTERACTION OF HYDRAZINES WITH OXYGEN

Hydrazines containing at least one hydrogen atom linked to each nitrogen atom undergo autoxidation at room temperature (in the form of salts in aqueous solution) with dissociation of N–H bonds and the formation of $H_2O_2$ and a diazo-compound. The latter may decompose into $N_2$ and a hydrocarbon. The rates of the reactions of *N*-benzyl-*N'*-methylhydrazines [170], *N*-arylhydrazines [171], and



unsubstituted hydrazine [172] at room temperature are consistent with the following equations:

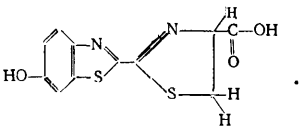
The reactions are vigorously catalysed by $Cu^{2+}$ ions.

In the presence of $O_2$, hydrazines exhibit a cytotoxic activity owing to the possible formation of $^{\cdot}OH$ radicals (via the reaction between $H_2O_2$ and the initial hydrazine), which disrupt the structure of nucleic acids by adding to the $C_{(5)}=C_{(6)}$ double bonds of the pyrimidine bases. We may note that benzyl-*N*-isopropyl-*N*-methylcarbamoylhydrazine is present in the blood and in urine and is probably capable of being oxidised *in vivo*, exhibiting a cytotoxic activity [170,173-175].

Despite the absence of hydroperoxides from the autoxidation products of hydrazines, it has been possible to obtain several peroxides (derived from these compounds) by treating hydrazines with RO–OH in the presence of formaldehyde [191]:

We may note that in certain instances hydroperoxides can be obtained when RO–OH is replaced by $H_2O_2$.

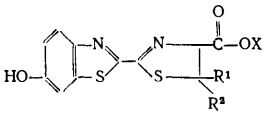
## X. THE INTERMEDIATE FORMATION OF PEROXIDES IN THE BIOLUMINESCENCE PROCESS



Since many substrates exhibiting bioluminescence contain nitrogen, it was thought useful to examine briefly the intermediate formation of peroxides at the instant of the manifestation of bioluminescence.

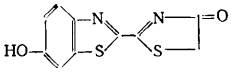
Luminescing organisms are frequently encountered among animals, particularly among the marine fauna. The only luminescing organisms among vertebrates and plants are fish and fungi respectively. Luminescence is also characteristic of certain bacteria. However, only a few of the many thousands of the existing species of organisms have so far been investigated owing to the difficulty of collecting them and the very low content of the active compound (several milligrams per tens of thousands of individuals).

All the reactions associated with the manifestation of bioluminescence require oxygen or a peroxide formed beforehand. In the presence of the enzyme luciferase, the substrate called luciferin is oxidised. During the last decade, bioluminescence has been the subject of serious research and development [195-200].



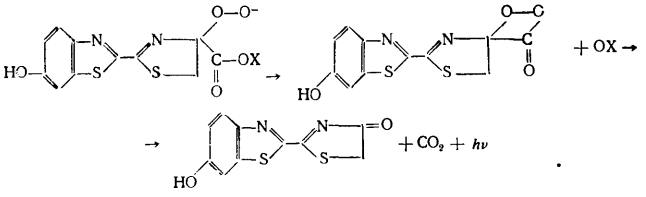
### Luciferins

Particular attention has been devoted to the study of the luciferin of the North American *Photinus pyralis*, which emits a bright yellow light. The luciferin from *Photinus pyralis* was isolated in a pure form and characterised by elemental analysis infrared spectroscopy [201], and by the identification of the decomposition products [202]. It is a benzothiazole derivative having the formula



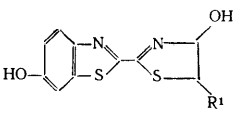
It was synthesised by treating cysteine with 2-cyano-4-hydroxybenzothiazole. [202] The corresponding luciferase was also isolated. Its molecular weight is 100 000 and it has an isoelectric point of 6.2–6.3. [203]

Numerous luciferin derivatives having the general formula [215]

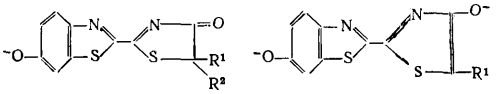


where X = $C_6H_5$ or adenyl, $R^1 = R^2 = CH_3$, or $R^1 = H$, and $R^2 = CH_3$, have also been synthesised. The disubstituted derivative ($R^1 = R^2 = CH_3$) is particularly interesting because it cannot decompose via dehydroluciferin (which is readily formed when $R^1 = R^2 = H$). The bioluminescence arises as a result of the enzymatic oxidation of luciferyl adenylate formed when adenosine triphosphoric acid is acted upon by luciferin in the presence of luciferase and $Mg^{2+}$ ions.

The light emitting compound is the lactam

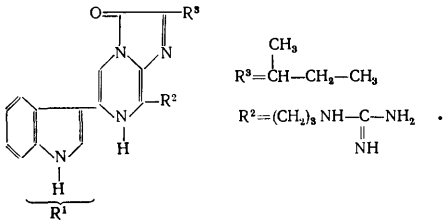


(in the excited state), which is probably formed via the very unstable dioxetan:

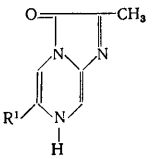


Indeed one mole of $O_2$ per mole of compound is absorbed and one mole of $CO_2$ per mole of compound is evolved in the bioluminescence process.

The above lactam was identified and isolated (in the form of the diacetate) from glow worm extracts [204]. Furthermore, the chemiluminescence spectrum of luciferin is identical with the fluorescence spectrum of the lactam, synthesised [204] by the condensation of the above nitrile with ethyl thioglycolate. Similar lactams have also been obtained from various substituted luciferin derivatives [205]. The chemiluminescence of these lactams varies with pH owing to the possibility of their existence in the enolic form

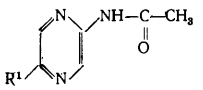


which can lead to the formation of a mono- or di-anion in an alkaline medium:

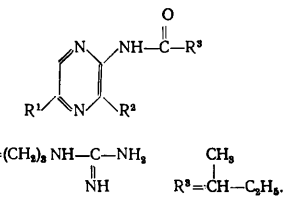


When $R^1 = R^2 = CH_3$ in the disubstituted derivative, only the monoanion can exist.

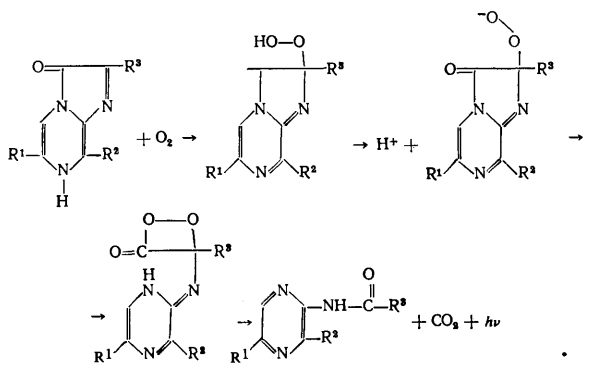
## The Bioluminescence of Cypridina hilgendorfi



This crustacean lives in the Sea of Japan and near the shores of Jamaica. When the contents of two glands containing luciferin and luciferase respectively are introduced into air-saturated water, a blue glow is observed. The luciferin of this crustacean was identified[208] as an indolopyrazine derivative having the formula

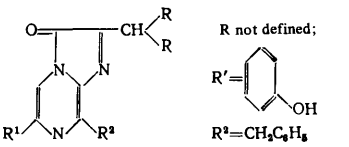


Simpler model compounds

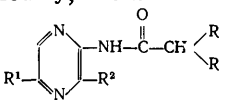


where $R^1 = C_6H_5$ [209] or β-indolyl [210], have also been synthesised. They inhibit luminescence and decompose after the absorption of $O_2$ into the corresponding amides:

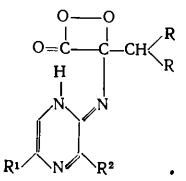
Luciferin itself (obtained from natural extracts) absorbs $O_2$ in the presence of luciferase and evolves $CO_2$ in equimolar amounts[211,212]. The reaction yields the amide



All the foregoing facts suggest the following sequence of reactions proceeding via an intermediate dioxetan, yielding an amide in an excited state:

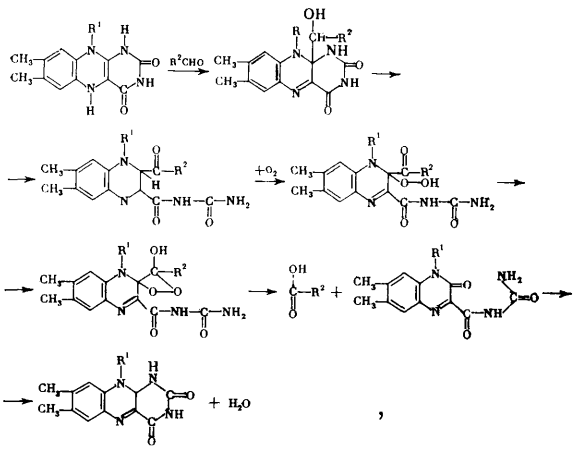


## The Bioluminescence of the Jellyfish *Renilla* and *Aequorea*



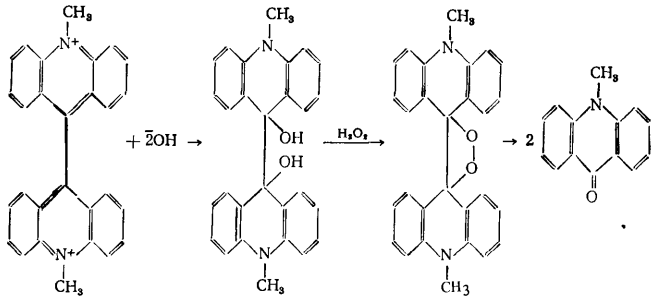
The mechanism of the bioluminescence of the jellyfish *Renilla* is similar to that of Cypridina, but is more complex. Since a photoprotein, containing a peroxide formed beforehand, is present in this organism apart from luciferin identical with that from Cypridina [213], light emission begins only after the addition of ions (in the presence of $O_2$). The luciferase from *Aequorea* [214] has the following structure:

In conformity with a sequence of reactions analogous to that described previously, the amide



is obtained in an excited state via the intermediate dioxetan

## The Bioluminescence of Bacteria



The luminescence of fish, dead animal tissues, and plants is caused by bacteria, various species of which have been described[215]. In this case, there is no luciferin or luciferase, but two other compounds are active: flavinmononucleotide (in a reduced form) ($FMNH_2$) and a linear long-chain aliphatic aldehyde. The aldehyde is apparently oxidised to the corresponding acid[217,218] in an excited state via the peroxide in accordance with the mechanism

where $R^1$ = ribosyl and $R^2$ = aldehyde group.

Synthetic Luminescent Compounds

Studies have shown that the conversion of lucigenin (*NN*-dimethyl-2,9-biacridinium dinitrate) under the influence of $H_2O_2$ in an alkaline medium into *N*-methylacridone (in an excited state), accompanied by the emission of a green light, proceeds via the formation of an intermediate peroxide[218]:

# Photochromic Polymers

V.D.Ermakova, V.D.Arsenov, M.I.Cherkashin, and P.P.Kisilitsa

The chief methods of preparation and the photochromic properties of polymers containing covalently bound photochromic groups in the main or a side chain of the macromolecule are surveyed. The properties of such polymers differ from those inherent in analogues of low molecular weight or in mechanical mixtures of the latter compounds with polymers. The difference in behaviour is explained by the steric and polar influence of the macromolecule on the initial and the photo-induced forms of the photochromic compound. A list of 55 references is included.

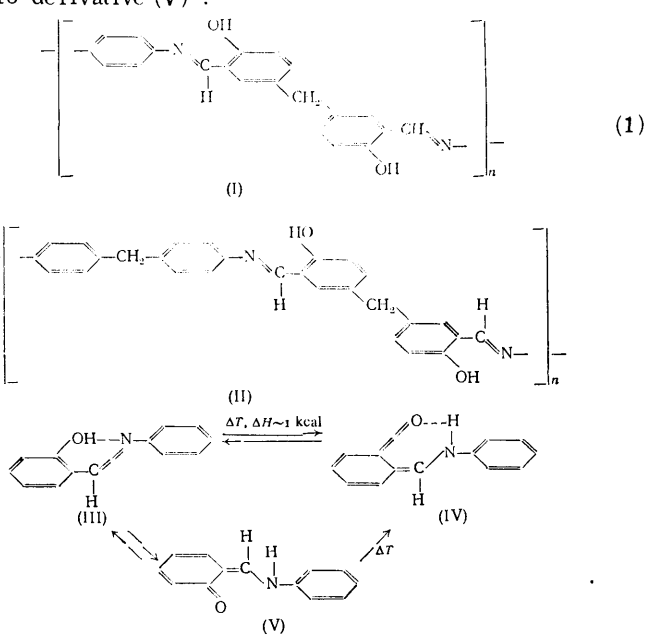
## I. INTRODUCTION

The phenomenon of photochromism—a reversible change in colour under the influence of light of definite wavelength—is observed in many classes of organic compounds, and during recent years has been intensively studied in connection with the wide prospects for its application. Photochromic materials may be used to obtain images and as memory units in electronic computers and light filters of variable density, automatically varying the transmission according to the conditions of illumination[1,2].

Comparatively recently several papers have appeared on the preparation and study of a new class of photochromic compounds—polymers containing covalently attached photochromic groups in the main or a side chain. Methods for preparation and the photochromic behaviour of polymers containing mainly spiropyran groups have been surveyed by Smets[3].

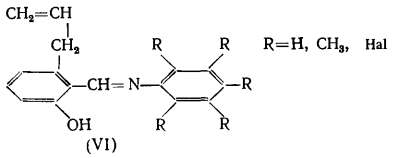


The photochromism of the simpler organic compounds may be due to isomerisation, heterolytic and homolytic bond cleavage, tautomerism, redox reactions, dimerisation, and triplet transitions. Various aspects of the photochromism of organic substances have been covered in a number of reviews and monographs[4-6]. The development of photochromic polymers is based on the assumption that the same mechanisms underly their action.

Distinctive features of the photochromism of polymers are the restricted mobility of the photochromic groups contained in the macromolecule, the dependence of their properties on the conformation, and the influence of the polarity of the comonomer. The present Review considers the main methods of preparing polymers containing covalently linked photochromic groups, the kinetic and spectral behaviour of the polymers in solutions and in films as functions of their chemical nature and structure, and also the photochemical reactions of the polymers. In order to study the steric and polar influence of the macromolecule on the behaviour of the photochromic groups, the properties of copolymers are compared with those of relatively simple photochromic compounds (model compounds), and also with solid solutions of photochromic compounds in a polymer matrix (photochromic matrix polymers).

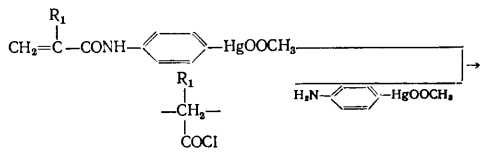
The Review does not cover many papers on matrix polymers in which attention was paid mainly to investigating the mechanism of photochromic transitions in relatively simple compounds, with the polymers used merely as media for such investigations.

## II. PHOTOTAUTOMERISATION WITH MIGRATION OF HYDROGEN

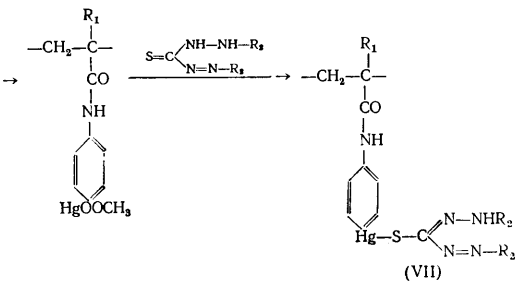


The photochromism and thermochromism of polyazomethines containing a salicylidenanil group in the main polymer chain (I) and (II) was studied by Laverty and Gardlund[7]. The phototautomerisation of anils involves intramolecular migration of hydrogen from an *o*-hydroxy-substituent (III) to the azomethine group to form a *trans*-keto-derivative (V)[7]:

(1)



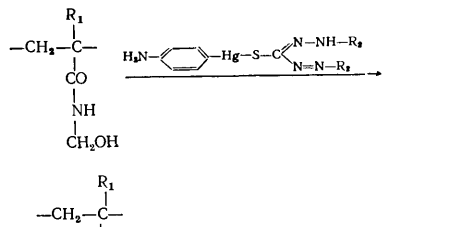
The *trans*-keto-form of the anil isomerises thermally into the *cis*-keto-form (IV), which is converted into the *cis*-enol (III) before equilibrium is established. The polymers (I) and (II), which are insoluble in the usual organic solvents, are not photochromic: they exhibit only the thermochromic transition (III) → (IV), but the bathochromic shift when heated from 25 to 100°C is merely 20 nm.

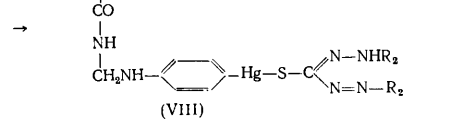


Photochromic polyazomethines can be obtained[8] by the copolymerisation of styrene and methyl methacrylate with the unsaturated salicylidenanil derivative

(VI)

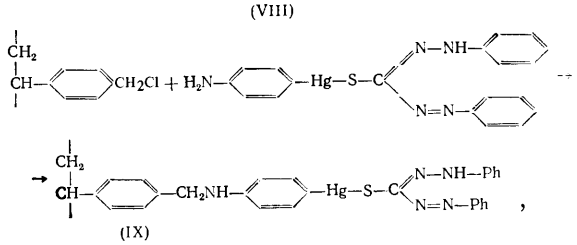
Photochromic transitions in copolymers of the two monomers with unsaturated derivatives of mercury dithiozonates were subjected to detailed investigation by Kamogawa et al.[9,10] Such polymers were obtained by various polymer-like conversions[9-12]:





(VII)

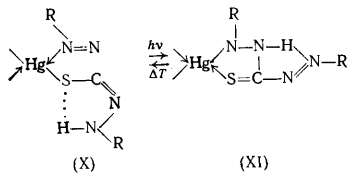
(2)



(3)

(VIII)

(4)



(IX)

(5)

where $R_1$ = H, $CH_3$ and $R_2$ = $C_6H_5$, 2-$C_{10}H_7$, *p*-$C_6H_4Br$, *p*-$C_6H_4Cl$, *p*-$C_6H_4CH_3$, *o*-$C_6H_4CH_3$, *o*-$C_6H_4OCH_3$, *o*-$C_6H_4CF_3$.

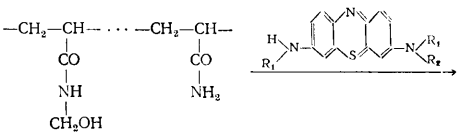
The photochromism of metal dithiozonates is due to geometrical isomerisation of the ligand about the C=N bond with migration of hydrogen (X) → (XI):

(X) (XI)

(6)

In the copolymers (VII)–(IX) the initial form (X) absorbs at 500 nm, but the photoinduced (XI) in the region of 600 nm. Photocoloration and thermal decoloration are described by first-order equations. The rates of forward and reverse reactions depend on the composition of the copolymer, the chemical structure of substituents in the dithiozonate group, and the viscosity of the system.

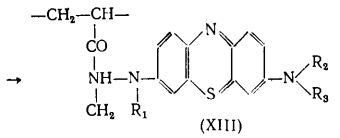
The steric influence of the macromolecule depends on the mobility of the comonomer. The rate of thermal fading of copolymers of (VII) with styrene is lower than that of copolymers containing more mobile residues (the copolymer with methyl acrylate)[9]. Both forward and reverse reactions are slowed down by the introduction into the dithiozonate group of electron-accepting substituents ($R_2$ = *o*-trifluoromethylphenyl) or substituents that cause steric hindrance ($R_2$ = 2-naphthyl, *o*-tolyl)[10]. Electron-donating and electron-accepting substituents produce bathochromic and hypsochromic shifts respectively in the spectra of initial and photoinduced forms.



Photoconversion and decolorisation are greatly retarded in films of copolymers of (VII)–(IX) owing to the considerable steric hindrance to *cis–trans*-isomerisation. This is confirmed by the shortening by a factor of 50 in the half-period of the dark reaction of copolymers of (VII) with styrene when the temperature is raised from 15 to 65°C, and also by the lowering of the glass point $T_{gl}$ of the polymer and the increase in the rate of photochromic conversions of the copolymers with increase in the content of butyl acrylate groups[9].

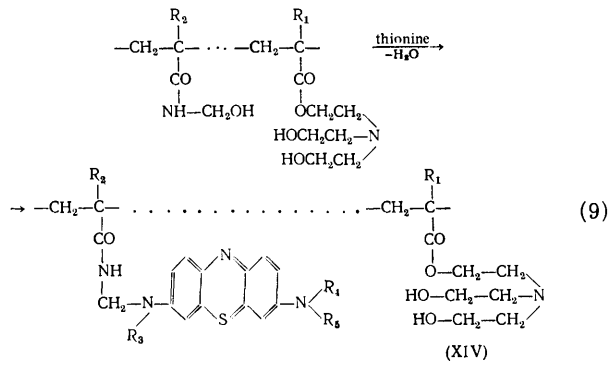
## III. REDOX POLYMERS

The reversible photodecolorisation of thionine introduced into a polymer chain in the presence of a reductant ($Fe^{2+}$), which was accompanied by photochemical redox reactions, was first observed by Kamogawa[13]. Photochromic polymers have been obtained also by the copolymerisation of a thionine monomer (XII) with acrylamide[14] and by chemical reactions on polymers[14-16]:

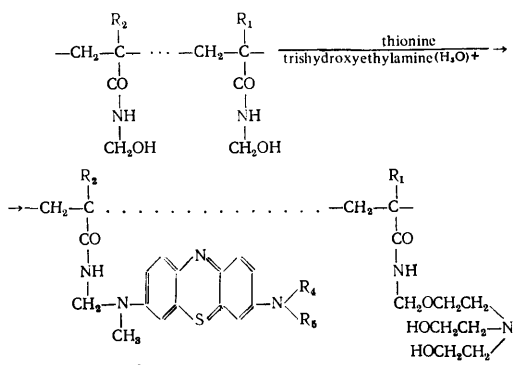


(XII)

(8)†

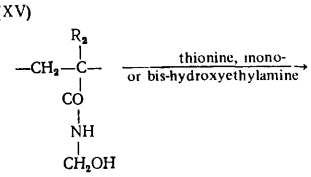


† Equation (7) is absent from the Russian text (Ed. of Translation).

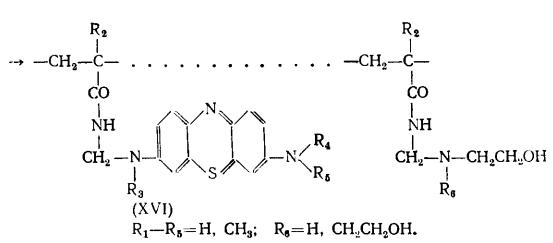


(XIII)

$R_1=R_2=R_3=H$; $R_1=H$, $R_2=R_3=CH_3$;
$R_1=R_2=R_3=CH_3$; $R_1=R_2=H$, $R_3=CH_3$; $R_1=CH_3$, $R_2=R_3=H$

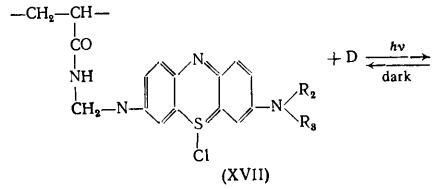


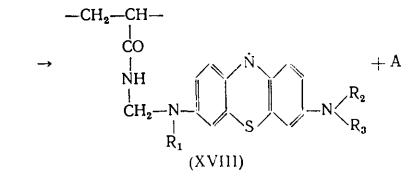
Polymers containing thionine dye and hydroxyethylamine residues have been synthesised[16]:



(XIV) (9)

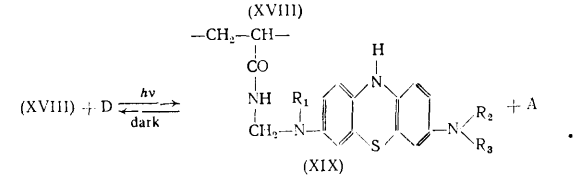
(XV) (10)





(XVI) (11)

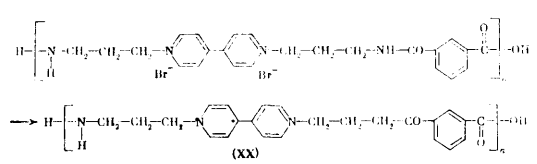
$R_1$—$R_5$=H, $CH_3$; $R_5$=H, $CH_2CH_2OH$.



In the solid state thionine polymers fade reversibly (absorption diminishes in the region of 600 nm) on exposure to visible light. Kamogawa[15] attributed this reaction to photoactivated reduction of the coloured form of thionine (**XVII**), in the presence of an electron donor D, to the colourless semiquinone form (**XVIII**), which disproportionates rapidly into the colourless leuco-thionine (**XIX**) and the coloured thionine (**XVII**) forms:

(XVII)

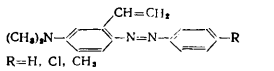
(XVIII) (12)

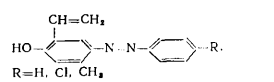


(XIX)

The reverse reaction takes place in the dark, and involves slow oxidation of leuco-thionine successively to the semiquinone and to the coloured thionine form in the presence of an electron acceptor A.

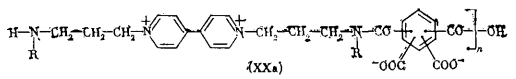
Introduction of electron-donating components such as $Fe^{2+}$ ions, poly(vinyl alcohol), hydroxyethylamines, certain enzymes (e.g. papain) confers considerable photosensitivity on the polymers. However, the mechanism of reaction (12) is probably more complicated, since the photochromic behaviour of thionine systems depends in considerable measure on the moisture content of the polymer film. It is suggested[15] that water molecules adsorbed on active groups in the polymer, just like atmospheric oxygen, are involved in redox reactions. Increasing the concentration of the donor D in the polymer chain somewhat enhances the sensitivity to photochromic reactions, but hydroxyethylamine residues inserted into the polymer chain are comparable with the monomeric analogues in effectiveness[16].





The rate of fading is somewhat affected by the method of preparation of the thionine polymers. Increasing the acidity of the polymer films (**XV**) diminishes the electron-donating power of the hydroxyethylamine residues, with a consequent slower rate of fading of the polymer[16]. The rate of restoration of the colour diminishes on introduction of the iron(II)–(III) system as carboxylate salts[15].

Photochromic redox polymers containing an *NN'*-dialkyl-4,4'-bipyridinium group (a viologen) have recently been prepared and studied[17]. New polyviologens (**XX**) and (**XXa**) possessing film-forming properties have been obtained by the interfacial polycondensation of *NN'*-bis-aminoalkyl-4,4'-bipyridinium salts with di-, tri-, or tetra-functional acid derivatives. On chemical and electrical reduction or exposure to light the polymer films become coloured owing to formation of a viologen radical:



(XX) (13)

**Table 1.** Photochromic polymers containing azo-groups, obtained by radical copolymerisation.

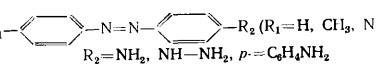
* R = $N(CH_3)_2$ and $^+N(CH_3)_3$ for copolymer (XXIIg); R = H for the remaining copolymers (XXII).
** Intrinsic viscosity of the polymer.
*** Photochrome content, mole %.

With pyromellitoyl chloride a betaine type of polymer is formed:



(XXa)

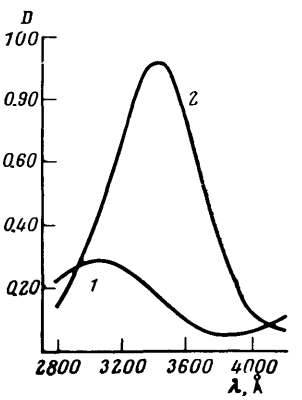
(R = H, $CH_2CH_2CH_3$)

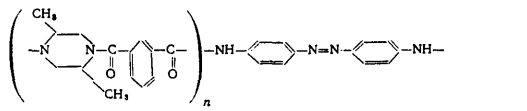
Decolorisation of the films takes place in air in the dark after 8 h, or under the influence of water after 1 min.

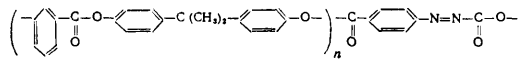
## IV. *cis–trans*-ISOMERISATION OF AZO-GROUPS

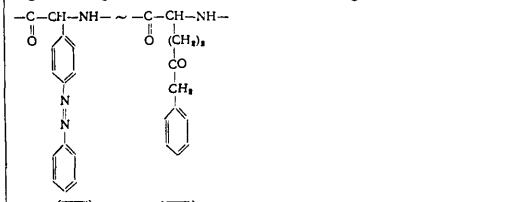
The principle of *cis–trans*-isomerisation about the N=N bond has been utilised for the preparation of photochromic polymers containing an azo-group. Copolymers containing an azo-group in the side-chain have been obtained by the radical copolymerisation of vinyl derivatives of azo-compounds with unsaturated monomers. Similar photochromic copolymers can be prepared also by chemical modification of poly-*o*-hydroxystyrene with diazonium salts of aniline derivatives or of a ternary copolymer of *N*-hydroxymethylacrylamide with derivatives of *p*-aminoazobenzene[14,18]

$R_2 = NH_2$, $NH-NH_2$, $p$-$C_6H_4NH_2$









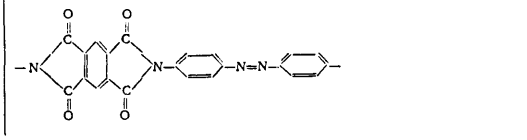


Figure 1. Absorption spectra of *p*-acetamidoazobenzene (0.01 M at pH 8): 1) initial form; 2) photoinduced form.

Polycondensation has been used to introduce an azo-group into the main chain of the polymer. Data on the structure and the composition of copolymers obtained by radical copolymerisation and copolycondensation are summarised in Tables 1 and 2 respectively.

Initial and photoinduced forms of the azo-group usually have absorption bands close together in the near ultraviolet or the visible spectrum (Fig. 1).

Goodman and Falxa showed[19] that the photoisomerisation of azo-groups on introduction into a polypeptide chain (XXXIII) (Table 2) is accompanied by a change in the optical activity of the isomers. The photochromic properties of polymeric azo-compounds are strongly influenced by the conformation of the macromolecule. This effect is especially clearly developed in polyelectrolytes containing an azo-group in the side-chain. Polymers of this type were first obtained by Lovrien[20] (XXIa, b) and later by Fink[21] (XXIIa, c, d) (Table 1).

Both photoinduced and dark reactions are influenced by conformational transitions of polyelectrolyte macromolecules depending on their degree of ionisation, so that the isobiestic wavelength in the absorption spectra of copolymers of acrylic acid and 4-acrylamido-2,2′-dimethoxyazobenzene (XXIa, b) depends on the pH and becomes considerably shorter with increase in the reduced viscosity (pH 5–7) owing to uncoiling of the polyelectrolyte chains[20]. This is responsible also for the diminution in the rate of the dark reaction of (XXIb) at pH 6–10, although the rate of transition of the model monomeric azo-compound increases in the same pH range because of the catalytic effect of hydroxide ions[20].

The pH dependence of the rate of the dark *cis–trans*-isomerisation of azo-groups is influenced by the type of polyelectrolyte[21]. At pH < 8–9 the macromolecule of the polyanion of (XXIIa, b) is coiled up, which slows down the isomerisation; conversely, this transition is facilitated when the macromolecule has straightened out (pH > 8–9). The rate constant of the dark reaction of (XXIIa, b) has its minimum value at pH = 8–9. The opposite dependence is observed for the polycation (XXIIc), for which the minimum rate constant occurs at pH 5–6. The polyampholyte (XXIId) is similar in behaviour to the model photochromic compound, for which a minimum rate constant is observed at pH ≃ 7. The uncoiling of the polypeptide (XXXIII) macromolecule in trifluoroacetic-acid solution increases the yield of the *cis*-isomer on photoexcitation relative to that observed in dioxan solution, in which the polypeptide has a coiled conformation[19].

On the other hand, photoisomerisation of constituent azo-groups in the polyelectrolyte changes the conformation of the macromolecule and hence the viscosity of the polymer solutions (the "photoviscous effect")[22], which opens up the possibility of photocontrolling the conformation of a polyelectrolyte by means of photochromic compounds. An example of one of the two main mechanisms distinguished by Lovrien[22] is provided by a copolymer of methacrylic acid such as (XXIIa). In the absence of irradiation the balance between two types of interaction—van der Waals cohesion of hydrophobic lateral *trans*-azo-groups and electrostatic repulsion of like charges—determines the degree of coiling of the polyelectrolyte. On *trans–cis*-photoisomerisation the hydrophobic interaction of the azo-groups diminishes owing to the increased polarity of the *cis*-isomer, leading to uncoiling of the macromolecule and increase in the viscosity of the polyelectrolyte solutions.

An example of the second type of system is a macromolecule of polymethacrylic acid with adsorbed ligands of a charged azo dye (e.g. anions of Chrysophenine). The addition of photochromic ligands uncoils the polyelectrolyte macromolecule as a consequence of interaction of like charges. On *trans–cis*-conversion the increased dipole moment of the *cis*-isomer makes the ligand more hydrophilic, which leads either to its desorption from the macromolecule or to an increase in the dielectric constant along the chain. In either case the macromolecule coils up: i.e., in contrast to the first mechanism, solutions of the polyelectrolyte will become less viscous after exposure‡. With degrees of ionisation of polymethacrylic acid < 0.075 (pH < 4.9) the addition of ligands—Chrysophenine anions—coils up the polymer chain and lowers the dissociation constant (p$K$) of the carboxy-groups on *trans–cis*-photoisomerisation[23].

Photocontrol of the conformation of polymethacrylic acid in solution at degrees of ionisation of 0.2 (pH 4.5–5.5), at which the polyelectrolyte macromolecule uncoils, is

‡ It is undoubtedly of interest to study such processes, since this would open up the possibility of using membranes and photochromic polyelectrolytes for the photoregulation of biological processes.

possible with the use of cationic ligands based on *p*-phenylazophenyltrimethylammonium iodide or the copolymers (XXIIa)[24]. Solutions of polymethacrylic acid with cationic ligands exhibit a decrease of 0.2 in the p$K$ on *trans–cis*-photoisomerisation, caused by a change in the degree of coiling of the polyelectrolyte molecules. The photochromic copolymers (XXIIa) also display an induced photochemical jump in p$K$ when the azo-groups pass into the *cis*-form. Since

$$pK = pH + \lg[(1+\alpha)/\alpha],$$

the degree of ionisation of polymethacrylic acid modified by photochromic groups, and hence the conformation of the polyelectrolyte, should be controlled photochemically in buffered solutions.

A usual consequence of the addition of azobenzene groups to a polymer chain is steric hindrance to *cis–trans*-isomerisation, which is apparent in a diminished rate of photochromic transitions of copolymers in comparison with model compounds[14,21,19,25]. An increased rate of thermal isomerisation relative to the reaction with model compounds has been observed with the copolymers (XXIIIa), (XXV), and (XXXII)[14,26]. Such anomalous behaviour was attributed to diminished aggregation of azobenzene groups when separated by an inert comonomer. This is supported by the decrease in the rate of photochromic transitions with increase in the aggregation of azobenzene molecules due to polar groups capable of forming hydrogen bonds, e.g. in the copolymer (XXIV)[14].

Thus the effects of aggregation of azobenzene groups and steric hindrance by the macrochain tend to balance each other, and the photochromic behaviour of the macromolecule will depend on the relation between them. Another view[26] is that the introduction of azobenzene groups into the main chain of the polyamide (XXXII) does not impede isomerisation, since the time required for conversion of the macromolecular conformation into a form corresponding to the transition state in the *cis–trans*-isomerisation of azo-groups is comparable with the time of isomerisation of these groups in a model compound.

The steric effect of a polymer chain on *cis–trans*-isomerisation is evident also in the dependence of the rate of photochromic transitions on the mobility of the macromolecule. The rate of the thermal *cis–trans*-isomerisation of copolymers on methyl methacrylate with *p*-dimethylamino-*p'*-vinylazobenzene (XXIIIb) in benzene solution exceeds that of copolymers with styrene (XXIIIa) because of the greater mobility of poly(methyl methacrylate). For the polystyrene macromolecule, which has a straight conformation in benzene solution, isomerisation processes in side-chains are difficult[25]. Analogous results were obtained by Kamogawa et al.[14]: the rate of the thermal *cis–trans*-isomerisation of copolymers falls with decrease in the flexibility of the macromolecule—polystyrene and poly(methyl methacrylate) compared with poly(butyl acrylate).

Since the mobility of a macromolecule in solution depends on the interaction of the polymer with the solvent, the rate of a photochromic transition is influenced by the parameter $\chi$ of this interaction. The higher value of $\chi$ for polystyrene than for poly(methyl methacrylate) in benzene is responsible for the lower *cis–trans*-isomerisation rate constant of vinyldimethylaminoazobenzene in copolymers with styrene than in those with methyl methacrylate (XXIIIa) and (XXIIIb)[25]. The decrease in the rate constant with increase in the content of vinyldimethylaminoazobenzene in the copolymer (XXIIIb) is also explained by an increase in $\chi$. The departure from this relation observed for simultaneous increase in the content of this monomer and increase in the concentration of the copolymer in the solution is probably due to inter- and intra-molecular transfer of excitation energy[25].

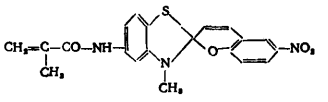
The loss of mobility of a macromolecule in a film results, as would be expected, in a considerable decrease in the rates of photochemical transitions relative to those observed in solution, especially if the polymer has a rigid chain[14,27]. Sometimes the longer-wavelength absorption band of the polymer undergoes a bathochromic shift in a film in comparison with the maximum in solutions[14].

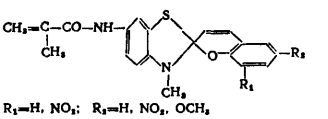
However, it was found[27] that, after a photostationary state had been reached in a film, the dark *cis–trans*-isomerisation of photochromic copolymers containing azobenzene groups—whether in side-chains (XXIIe), (XXIIf), and (XXVIII) or in the main chain (XXIX)–(XXXI)—takes place at a constant rate differing little from that in dilute solutions of analogous polymers. This unexpected phenomenon was explained in terms of the fundamental postulate of the theory of rate processes that the transition state in a reaction is in equilibrium with the initial state, and the reaction velocity is unaffected by the reduced mobility of the reactants imposed by increase in the viscosity of the medium.

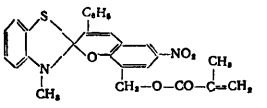
In solutions of polymers photochemical *trans* $\rightleftharpoons$ *cis*[25,19] and thermal *cis–trans*-isomerisation[21,25,26,19] are usually first-order reactions. The latter type of isomerisation in dilute formic-acid solutions of the polyamide (XXIIa) containing azobenzene groups in the main chain diverged from this rule[27]. Its kinetics are described by the equation

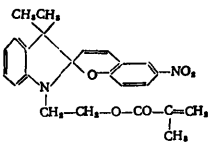
$$c/c_0 = \alpha \exp(-k_1 t) + (1-\alpha)\exp(-k_2 t)$$

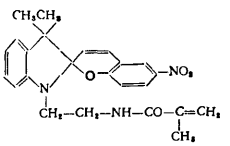
where $c_0$ is the concentration of the *cis*-isomer at zero time, $c$ is its concentration at time $t$, and $k_1$ and $k_2$ are rate constants of the *cis–trans*-isomerisation of the azobenzene groups. Here $k_1 \simeq 3k_2$, with the latter approaching the isomerisation constant of a model compound. The presence of rapidly isomerising azo-groups in the polyamide is probably connected with their oxidation to azoxy-derivatives. This view is supported by the decrease in the ratio $k_1/k_2$ in a more acid medium.

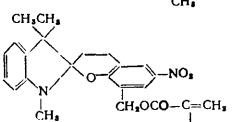


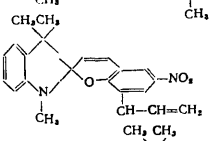


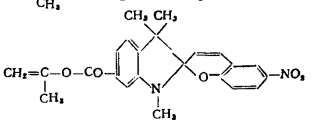


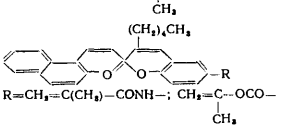


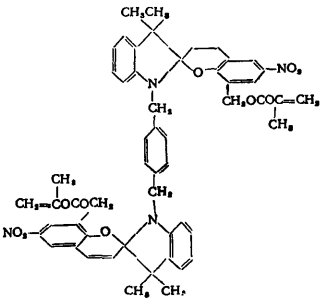












Kinetic investigation of the thermal *cis–trans*-isomerisation in a film of polymers containing azobenzene and azonaphthalene groups in side-chains—(XXIIe), (XXIIf), and (XXVIII)—revealed a relation between the glass point and the departure from first-order kinetics[27]. A first-order equation was obeyed by polymers in a state of rubber-like elasticity. A proportion of rapidly isomerising azoarene groups and the associated departure from first-order kinetics appear at temperatures below the glass point. Such anomalous behaviour of polymer films was attributed[27] to the non-equilibrium character of the vitreous state, which causes a non-uniform distribution of free volume in the polymer. Similar results were obtained for solid solutions of 2,2'-azonaphthalene or *p*-ethoxyazobenzene in polystyrene[28]. The content of *cis*-isomers in the photostationary state decreases with increase in the viscosity of the medium, but the kinetics of the dark reaction deviates from a first-order equation at temperatures below the glass point.

It has recently been reported[28] that the photoisomerisation of polymers containing azo-groups in the main chain may be accompanied by mechanical changes. When poly-*pp'*-azobenzene–pyromellitimide (XXXVI) was subjected to temperature cycles involving heating to 200°C under constant pressure, shrinkage and expansion of the film were

observed. With the length of the film maintained constant, on the other hand, the stress applied to the film during exposure increased with time.

Since the activation energy of compression of a film is insignificant, whereas the activation enthalpy of isomerisation of azo-compounds in solution is ~ 20 kcal mole$^{-1}$,

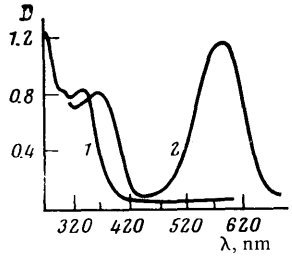
Agolini and Gay [29] suppose that the rate of expansion or contraction is determined by the elastic properties of the polymer rather than by the rate of *cis–trans*-isomerisation. This seems a very probable interpretation in view of data obtained [27] for polyamides and polyesters containing azoarene groups and the absence of a direct relation between the rates of isomerisation of the polymer and of expansion or contraction of the film. Water-swollen membranes of a copolymer of 2-hydroxyethyl methacrylate and ethylene dimethacrylate with adsorbed molecules of Chrysophenine shrink by 1.2% on illumination, and return to their original dimensions in the dark [30,31]. This phenomenon was explained [30,31] by a change in the conformation of the polymer chain resulting from the difference between the solubilities of *trans*- and *cis*-isomers in the hydrophobic part of the macromolecule.

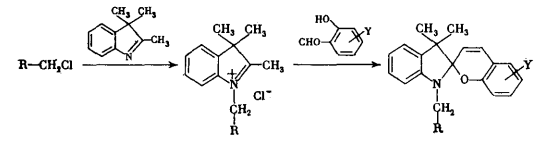
## V. POLYMERS BASED ON SPIROPYRANS

The photochromism of polymers containing spiropyran residues has been subjected to most detailed investigation. Ultraviolet irradiation causes dissociation of the carbon–oxygen bond, with coloration of the colourless photochromic systems [34]. The reverse process of ring closure takes place either in the dark or under the influence of visible light in the region of absorption by the merocyanine form:

(14)

Polymers containing spiropyran units in the side-chain have been obtained by the copolymerisation of unsaturated photochromic monomers with vinyl comonomers (Table 3), as well as by chemical reactions on polymers.





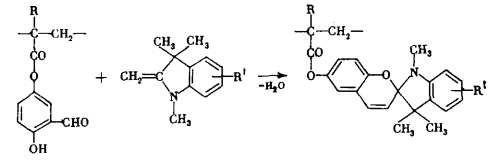


Figure 2. Absorption spectra of forms of copolymer (XLVa): 1) initial; 2) photoinduced.

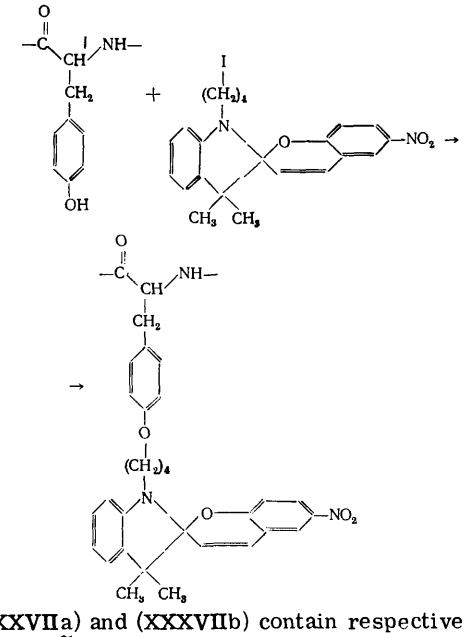
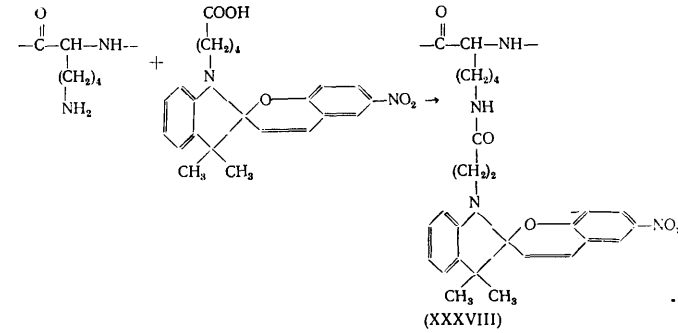
The absorption bands of the coloured form $\lambda_{max}^{vis}$ are located over the range 470–600 nm depending on the structure of the spiropyran and the nature of the comonomer. Fig. 2 shows typical spectra of initial and photoinduced forms of an indolinospiropyran copolymer.

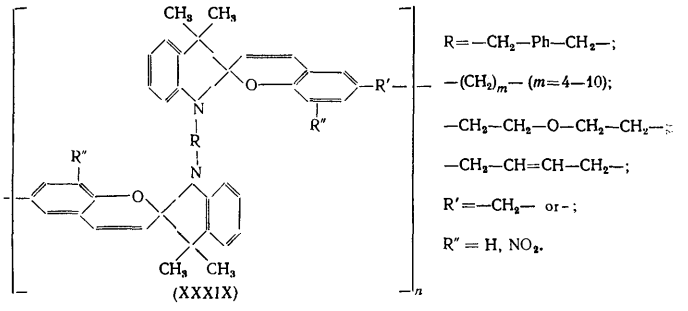


Polymers may be obtained by reaction between chloromethylated polystyrene and Fischer's base [43]:

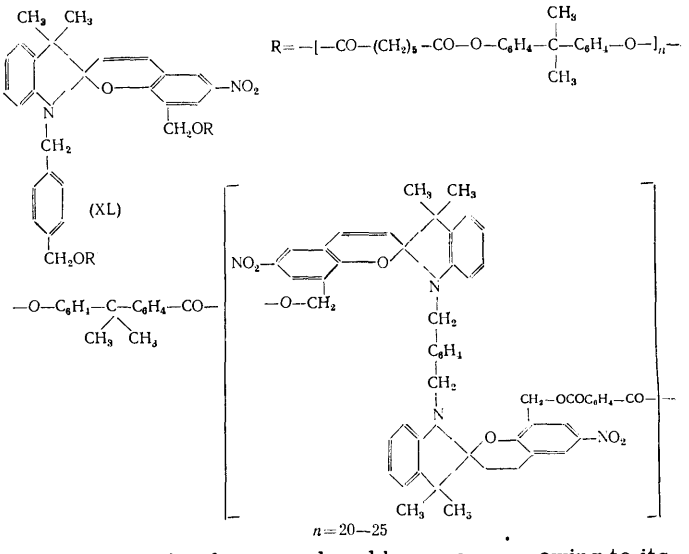


(R represents a macroradical and Y different substituents—$NO_2$; $NO_2$, $NO_2$; $NO_2$, $OCH_3$; $NO_2$, Hal). An alternative reaction is [44]

where R = H, $CH_3$, Hal and R′ = $CH_3$, $NO_2$, Hal, AlkO, AlkS). Some Japanese workers [45] have obtained photochromic polymers by the action of "live" polymers, such as the polystyrene or the poly-α-methylstyryl anion, on a spiropyran having a chloromethyl, bromoaryl, or ester group as reactive centre. Photochromic polypeptides were obtained [46] by the reaction of *N*-ω-halogenoalkylindolinospiropyrans with poly-L-tyrosine:



where (XXXVIIa) and (XXXVIIb) contain respectively 54.7 and 72.3 mass % of the photochrome. Alternative reactants are an *N*-carboxyalkyl derivative of indolinospiropyran and polylysine [3]:



(XXXVIII)

Smets[3,47] used the polycondensation of bisindolenines with bis-salicylaldehydes to introduce photochromic groups into the main chain of the polymer:

(XXXIX)

Because of the sparing solubility of the condensation products (XXXIX), only oligomers having $n = 5$–$10$ were obtained. The copolycondensation of a bishydroxymethyl derivative of indolinospiropyran or a bisindolinospiropyran or of bisphenol A with pimeloyl chloride or a mixture of iso- and tere-phthaloyl chlorides gave polyesters (XL) and (XLI) containing respectively 4.0 and 9.5 mass % of the photochrome[3,30]:

The merocyanine form produced by exposure, owing to its zwitterionic nature, possesses strong negative solvatochromism (especially in benzothiazolinospiropyrans), which affects both $\lambda^{vis}_{max}$ and the rate of decolorisation. As a consequence, the specific effect of the polymer chain on the photochromic transitions of spiropyran units can be determined by comparing the photochromism of simple spiropyrans with that of their copolymers.

The kinetic and spectral behaviour of spiropyran polymers differs depending on whether the polymer is in solution or in the solid state. Furthermore, differences have been found in the behaviour of polymers into which spiropyran groups have been introduced chemically and of solid solutions of the corresponding photochromic monomers in the homopolymers.

## 1. Photochromic Transitions in Solution

The steric and polar effects of the macrochain depend on the polarity of the solvent[34,36]. In strongly polar media (e.g. dimethylformamide, pyridine) the copolymers (XLIIa–e) (Table 3) exhibit strong negative solvatochromism similar to that of model compounds[34]. The thermal decolorisation of such copolymers obeys a first-order kinetic equation. The activation energy in dimethylformamide solution varies from 24.9 to 25.6 kcal mole$^{-1}$ depending on the comonomer, which compares with the value of 22.1 kcal mole$^{-1}$ for the model benzothiazolinospiropyran.

The photochromic polypeptides (XXXVIIa, b) also undergo first-order thermal decolorisation in dimethylformamide[46]. In strongly polar protic solvents (ethylene glycol and formamide) both polytyrosine (XXXVII) and its model compound, the latter obtained by reaction between 1-(4-iodobutyl)-3,3-dimethyl-6′-nitrospiro(indolino-2,2′-[2*H*-1]-benzopyran) and the methyl ester of *N*-acetyltyrosine, exhibit reverse photochromism, a phenomenon due to the high content of the merocyanine form in thermal equilibrium with the spiropyran[46].

In solvents of low polarity (acetone, dichloromethane, oxolan) the copolymers (XLIIa–e) and (XLVIIa, b) differ considerably from the model compound in photochromic behaviour[34,41]. In such solvents the polar influence of the comonomer becomes appreciable. Interaction of the merocyanine form of the spiropyran with the comonomer is confirmed by the hypsochromic shift in $\lambda^{vis}_{max}$ of the copolymers relative to the lower spiropyrans[34,40,41], which increases with the polarity of the comonomer. If the macromolecule is not solvated, the merocyanine form may also interact with spiropyran units to produce a hypsochromic shift in $\lambda^{vis}_{max}$ and a decrease in the rate of decolorisation with increase in the spiropyran content of the copolymer[34,41].

Thermal decolorisation of the copolymers (XLIIa–e), (XXXVIIa, b), (XLVIIa, b), and (XXXIX) in solvents of low polarity, in contrast to that of model compounds, diverges from first-order kinetics, and can be represented by the sum of at least two first-order reactions[3,34,41,46]. The variation in optical density of the $\lambda^{vis}_{max}$ band can be described by the equation

$$D = a\exp(-x_1 t) + b\exp(-x_2 t) \quad . \qquad (15)$$

which presupposes the existence of several *trans*-isomers—with respect to the central bond 3′–4′ in Eqn. (14)—of the merocyanine form, the rate of whose interconversion is far smaller than their rate of decolorisation. In formula (15) $a$ and $b$ are the contributions of each geometrical isomer to the optical density at $t = 0$, while $x_1$ and $x_2$ are their decolorisation rate constants.

The above regularities have been attributed[34,41] to the steric and polar effects of the macromolecule in raising the potential barrier separating the geometrical isomers. The polar influence of the comonomer diminishes with increase in the polarity of the medium, so that, when a polar precipitant (t-butyl alcohol) is added to a solution of the copolymer (XLIIa) in chlorobenzene, the first-order kinetics of decolorisation are restored up to degrees of conversion of 60%[34].

As a consequence of incomplete solvation of polytyrosine macromolecules by solvents of low and high polarity the photochromism of solutions of copolymers (XXXVIIa, b) is almost independent of the polarity of the solvent, in contrast to that observed for the model compound. The specific effect of the polypeptide chain is evident also in the appearance of two absorption maxima in the visible range, due to different geometrical isomers of the merocyanine form[46].

Equilibrium between spiropyran and merocyanine forms is established in solutions of copolymers (XLVc–j) of indolinospiropyran with comonomers differing in polarity and in three-dimensional structure[40]. The equilibrium constant depends on the polarities of the solvent and of the comonomer.

Furthermore, the spectra of the homopolymer (XLVk) and of the copolymers (XLVc–e) contain a band due to a *cis*-cisoid isomer ($\lambda_{max}$ = 470 nm) formed immediately after dissociation of the carbon–oxygen bond in the pyran part of the molecule. The absence of such a band in the spectrum of the model compound, as well as in those of mixtures of the corresponding homopolymers with the model compound, suggests that steric hindrance by the macromolecule to interconversion of colourless and coloured forms is responsible for the appearance of this isomer. A polar solvent, as well as a polar comonomer, promotes rapid transition through the stage of formation of the *cis*-cisoid isomer, and stabilises the merocyanine form (*trans*-isomer)[40].

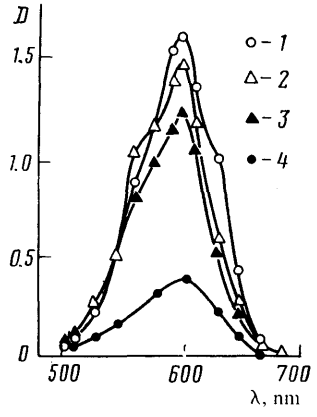


Figure 3. Absorption spectra of coloured form of copolymer (XLVc) (0.3 mM solution in benzene) after: 1) 40 μs; 2) 0.66 ms; 3) 0.1 s; 4) 15 s.

The use of flash photolysis[48] to investigate photochromic processes, including those accompanied by formation of short-lived intermediates on photoexcitation of copolymer (XLVc), confirms the existence of geometrical isomers of the merocyanine form having different lifetimes. The mechanism of photoconversion of the copolymer involves the formation of a short-lived *cis*-cisoid isomer ($\lambda_{max}$ = 490 nm), which passes rapidly (lifetime < 1 s) into more stable interconvertible geometrical isomers having absorption maxima at 560, 600, and 640 nm (Fig. 3). At times exceeding 1 s the spectrum still contains the band due to the thermally stable isomer ($\lambda_{max}^{phot} \simeq$ 600 nm), the decrease in whose optical density monitors the kinetics of the dark decolorisation after long periods of time.

The thermal decolorisation rate constants of copolymers in solution depend on many factors—the structure of the spiropyran, the nature of the comonomer, and the polarity of the solvent[34,41,39] (Tables 4 and 5). The copolymers (XLVIIb) and (XLIX) fade more slowly than do model compounds. The opposite effect is observed with the copolymers (XLVa) and (XLVI). This confirms that the rate of decolorisation is affected by the site at which the photochrome is attached to the polymer chain[39]. In the case of the benzothiazolospiropyran (XLIV) the rate of decolorisation of the copolymer is about half that of the model compound. Steric hindrance to rotation of the polymer chain about the 3′–4′ bond operates here[3].

Table 4. Photochromic behaviour of copolymers of spirobenzopyrans with methyl methacrylate (sp.) and their model compounds (mod.) in acetone solution[3,39].

| Structure | (XLVa) | | (XLVIIb) | | (XLIIa) | | (XLIX) | | (XLVI) | |

The viscosity of the medium has a considerable influence on the kinetics of the photoconversion of copolymers[34,38]. Thermal decolorisation diverges from a first-order reaction as solutions of the copolymers become more viscous[34].

The introduction of the photochrome into the polymer molecules (XLVa) and (XLVIII) does not lower the quantum efficiencies of coloration and decolorisation.

The substantial decrease in mobility of photochromic groups on introduction into the main chain of the oligomers (XXXIX) halves the rate of decolorisation in comparison with the corresponding dimers, and the thermal process diverges from the first order even in polar solvents[3].

Solutions of benzothiazoline polymers (XLII) are less strongly coloured than are the indolinospiropyran copolymers (XLV). When a solution of the polymer (XLIII) is cooled, the fluorescence becomes more intense, while the efficiency of the photodecolorisation of coloured solutions diminishes[35].

## 2. Photochromism of Copolymers in the Solid State

The photochromism of copolymers in the solid state is of especial interest in connection with practical application. The rate of the thermal decolorisation of copolymer films and solid solutions depends significantly on the glass point of the polymer, especially when the spiropyran forms part of the macromolecule. This effect is most clearly developed in copolymers containing the photochrome in the main chain[30]. The rates of the dark decolorisation of copolymers and solid solutions of spiropyran monomers in a polymer matrix drop sharply (by factors of 100–500) at temperatures below the glass point[3,38,39,41,49,50]. The optical density of the absorption band of the copolymer $\lambda_{max}^{vis}$ decreases by 90% after a few minutes in solution, but after several months in a film[41]. A long-lived coloured state of spiropyrans has been obtained in polymer matrices containing reactive groups, which may undergo photochemical cross-linking[36].

The kinetics of the thermal decolorisation of copolymer films is described by a first-order equation at temperatures above the glass point, but diverges from it below this temperature. Such behaviour of films is consistent with the existence of two or more geometrical isomers, the rate of interconversion of which differs considerably depending on the mobility of the macromolecule at temperatures below and above the glass point[50,51]. In the latter case the rate is so high that decolorisation is a first-order reaction, whose velocity is comparable with that for solutions of spiropyrans[50]. Below the glass point isomerisation slows down considerably, and decolorisation can be regarded as the sum of two or more parallel first-order processes, each characterised by its own rate constant and activation energy[3,50].

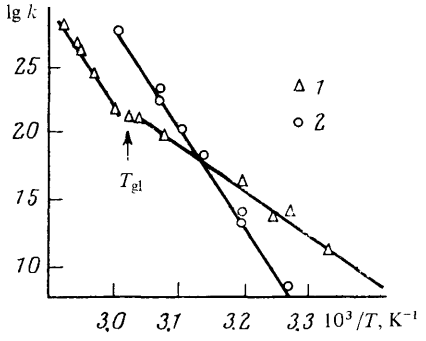

**Figure 4.** Temperature dependence of rate constant of dark decolorisation plotted in Arrhenius coordinates for: 1) copolymer (XLVI); 2) matrix mixture.

However, Lawrie and North[52], studying the rate of decolorisation of 1,3,3-trimethyl-6′-nitrospiro(indolino-2,2′-[2*H*-1]benzopyran) in various polymer matrices, concluded that the deviation from first-order kinetics for copolymers in a film below the glass point must be attributed to the non-uniform distribution of free volume in the vitreous state of the polymer and its relatively uniform distribution in the rubberlike elastic state. Thermal decolorisation of this spiropyran dispersed in a poly(methyl methacrylate) matrix is a first-order reaction below the glass point, owing to the short relaxation times (10–100 s) of the free volume in the polymer. The time of decolorisation of solid solutions of the above spiropyran increases in the sequence poly(methyl methacrylate) < poly(vinyl chloride) < polystyrene < poly-*p*-chlorostyrene owing to the intensifying polar and steric influence of the macromolecule[52].

The mechanism of the thermal decolorisation of three different indolinospirobenzopyrans in amorphous polymer matrices—poly(methyl methacrylate), poly-(n-butyl methacrylate), poly(vinyl acetate), and poly(vinyl n-butyrate)—has also been discussed in terms of a discrete distribution of free volume in a vitreous matrix[53]. The presence of two decolorisation rate constants, together with the change in activation energy below the glass point, is due to the existence of kinetic units of the macromolecule differing in ability to relax (e.g. end and side groups) and also to interaction of the photochromic molecule with the matrix[53].

The decolorisation of films of copolymers differs from that of solid solutions of a spiropyran in a polymer matrix: whereas the Arrhenius plot (Fig. 4) for a solid solution of 1-(2-methacryloyloxyethyl)-3,3-dimethyl-6′-nitrospiro-(indolino-2,2′-[2*H*-1]benzopyran) in poly(isobutyl methacrylate) exhibits a rapid increase in rate of decolorisation with rise in temperature, a film of the copolymer (XLVI) gives a curve with an inflexion near the glass point. The increase in the effective activation energy above this temperature is due to the additional activation energy of viscous flow[3]. The effect of a polymer matrix on the rate of decolorisation of spiropyrans is determined mainly by the polarity of the polymer and is fully consistent with the strong negative solvatochromism of the merocyanine ring system[3,50,52,39,53]. This fact, as well as the sensitivity of the merocyanine form to steric factors, enables benzopyrans to be used as indicators of molecular interaction of polymers[3,49,50,52].

Photochromic conversions in spiropyran copolymers in the solid state, in contrast to solutions, are accompanied by photodecomposition and oxidation. This phenomenon, which has been termed *fatigue*[54], is a result of two photoprocesses involving the colourless and coloured forms respectively. A scheme suggested[38] for photochromic conversions of copolymers (XLVa) and (XLVIII) can be written

$$C \xleftarrow{h\nu} A \underset{h\nu_1}{\overset{h\nu}{\rightleftarrows}} B \xrightarrow{h\nu} E,$$
$$\qquad\qquad\quad \downarrow h\nu_1$$
$$\qquad\qquad\quad F$$

where A and B are initial and coloured forms of the spiropyran, and C, F, and E are products of photodecomposition under the influence of ultraviolet radiation $h\nu$ and visible light $h\nu_1$. Fatigue of the copolyester (XL) at temperatures above the glass point is illustrated[55] by Fig. 5, which shows that the optical density of the coloured form in the photostationary state decreases after each period of exposure. This effect is considerably less well defined in a vacuum, which indicates that the process is influenced by oxygen.

It has recently been found[38] that the quantum efficiencies of the photodecolorisation of copolymers (XLVa) and (XLVIII) are one-third of those observed in solid solutions of spiropyrans in a polymer matrix. This is due to

inhibition of the relative rotation of parts of the spiropyran molecule, as a consequence both of the great structural viscosity of the medium and of the attachment of one part of the photochrome molecule to a polymer chain[38].

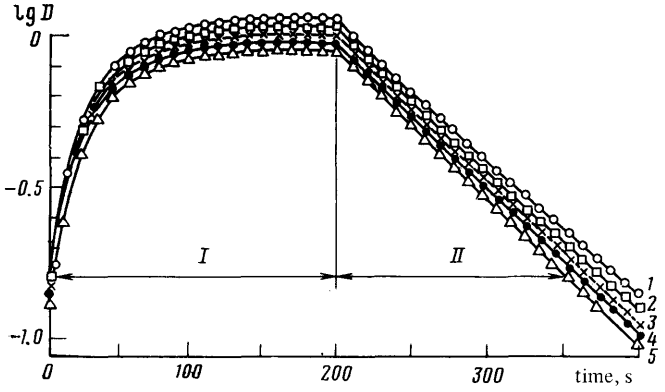

Figure 5. Photochromic behaviour of copolyester of bisindolinospiropyran at 65.3°C: I) period of irradiation; II) dark period; 1)–5) curves after first, second, etc. exposure cycles.

Interesting phenomena associated with the photochromism of spiropyran polymers—enhanced stability of copolymers with spiropyran groups during degradation induced by light and radiation[35] and a photomechanical effect[3,30]—have been discovered recently. The latter is observed on filaments and films prepared from photochromic cross-linked poly(ethyl acrylate) (LI). A shrinkage of 2–3% occurs on ultraviolet irradiation under strictly isothermal conditions; the original dimensions are regained in the dark. These photomechanical phenomena show good reproducibility, and are caused by the increase in entropy of the polymer chain resulting from the enhanced flexibility of open-chain merocyanines in comparison with rigid spiropyrans[30]. The amount of shrinkage depends on the applied stress, the temperature, the degree of cross-linking, and the position of attachment of the photochrome. The considerably lower activation energies than in dark decolorisation and shorter times of returning to the initial dimensions in the dark indicate that the photomechanical behaviour of photochromic polymers not only is controlled by isomerisation but also is connected, as in the case of azo-compounds[29], with the properties of the polymer matrix.

## VI. CONCLUSION

Investigation of the spectral and kinetic properties of photochromic polymers, as well as the quantum efficiencies of their photodecolorisation, has revealed in several cases differences from the lower analogues. Furthermore, marked differences are observed in the behaviour of photochromic polymers in the solid state and in solution. With strong interaction between solvent and polymer the photochromic properties of the latter approach those of the simple analogues. When such interaction is less clearly defined, as e.g. in the case of copolymers of styrene and methyl methacrylate with indolinospiropyran in solvents of low polarity, the mechanism of the dark decolorisation of the polymers differs from that for the model compound, and is determined by the polar and steric influence of the macromolecule. The variation with solution pH in the conformation of polyelectrolytes containing azo-groups correlates with the rate constant of the dark reaction.

In the case of solid polymers the photochromic behaviour of groups forming part of the macromolecule depends on the physical state of the polymer. If an appreciable change in conformation of photosensitive groups, e.g. *cis–trans*-isomerisation, accompanies a photochromic transition, the latter is slowed down significantly in the solid, vitreous state because of strong steric hindrance. In the rubberlike elastic state deviations from the behaviour of the polymer in solution are less marked.

The behaviour of copolymers having covalently bound photochromic groups, especially when the latter form part of the main chain of the macromolecule, differs from that of matrix polymers. Smets[55] has recently shown experimentally that the rate constant of the dark decolorisation of a matrix mixture containing indolinospiropyran is only around 10% of the value for photochromic copolyesters.

Thus by varying the polymer structure and the orientation of the polymer matrix it is possible to obtain materials having various photochromic characteristics ($\lambda_{max}^{vis}$, rate constant of dark decolorisation—i.e. colour and stability of the image). These factors, together with the improved technology for obtaining photochromic materials from photochromic copolymers rather than introducing a low-molecular-weight photochromic compound into a polymer matrix, explain the increasing interest taken by research workers during recent years in the study of photochromic copolymers.

Nevertheless, despite the extensive study of the spectral and kinetic characteristics of photochromic transitions, little attention has been paid to the photochemical characteristics of polymers such as the quantum efficiency of photocoloration and photodecolorisation, as well as photosensitivity. Few papers have appeared on the mechanism of photoreactions in polymers. Because of the lack of such information it is impossible in several cases to assess the possibility of practical application of the synthetic photochromic polymers.

# Structural Peculiarities of Homo- and Co-polyurethanes

Yu.Yu.Kercha and Yu.S.Lipatov

Recent advances in the investigation of polyurethanes are surveyed. Considerable attention is paid to copolyurethanes based on multicomponent initial constituents, which may exhibit thermoplastic or thermoelastoplastic properties depending on the distribution of the components in the chain and the length of the glycol constituent. A list of 142 references is included.

II. Polyurethanes based on lower glycols 158
III. Polyurethanes based on oligomeric glycols 162

## I. INTRODUCTION

Almost all technically valuable polymeric materials—rigid and elastic fibres and rubbers, film materials, coatings, adhesives, rigid and elastic foam plastics, etc.—can be based on polyurethanes. The possibility of obtaining such diverse materials is governed by peculiarities of the chemical structure of the polyurethanes, which in turn are determined by the structure of the initial components and the conditions of synthesis. Because of the variety exhibited by the chemical structure it is especially important to establish the fundamental relations between chain structure and properties, and to elucidate specific aspects of structure formation in polyurethanes. Information on structure and properties has been summarised previously [1], but new advances have been made during recent years, and a tendency has appeared to develop new lines of investigation, primarily in the field of random copolyurethanes and segmented polyurethanes (block copolyurethanes). Moreover, the literature reveals no uniform approach to the separation of polyurethanes into individual groups or types on the basis of their structure or properties. Depending on their chemical structure these polymers may acquire the properties either of thermoplasts or of elastomers and thermoelastoplasts, so that the segregation of polyurethanes as a single class of polymers is extremely arbitrary. In this connection it is very convenient to classify polyurethanes according to the molecular mass of the glycol component [2].

The present Review discusses mainly the principal papers that have appeared during the past five years on the structure and the physicochemical properties of polyurethanes and related compounds [polyurethanureylenes, poly(urethane semicarbazides), polyamidourethanes, etc.]. We shall base our survey on one of the main parameters of the chemical structure of a polyurethane—the molecular mass of the glycol component of the polyurethane chain.

At the present time polyurethanes comprise a very large class of polymers, often differing significantly in chemical nature and chain structure, but invariably containing a number of urethane groups $-NH.COO-$, [1-4] e.g. polyesterurethanes based on oligoesters, etc. The chemical structure of linear polyurethanes can be represented by the general formula

$$[-R_1-OCONH-R_2-NHCOO-]_x \quad (1)$$

where $R_1$ and $R_2$ are chain segments of the initial glycol and di-isocyanate components respectively. Hence, by varying the structure and the chemical nature of $R_1$ and $R_2$, we can obtain polyurethanes of diverse molecular structure, with different concentrations of urethane groups governed by the length of the glycol component. The latter factor largely determines the type of polymer properties acquired by the polyurethane materials. The use of mixtures of glycols differing in molecular mass, as well as trifunctional compounds to provide a three-dimensional structure, provides wide opportunities for controlling the properties of polyurethanes.

In view of the above considerations we have divided polyurethanes into two main classes, obtained respectively from lower glycols and from oligomeric glycols, for the discussion of their structure and properties.

## II. POLYURETHANES BASEDON LOWER GLYCOLS

### 1. Linear Homopolyurethanes†

One of the chief representatives of this type is that obtained from tetramethylene glycol and hexamethylene di-isocyanate (4,6-polyurethane)

$$[-OC(OCH_2CH_2CH_2CH_2)_nOCONH(CH_2)_6NH-]_x \quad (2)$$

($n = 1$), which, because of its good fibre-forming properties, has long been the subject of comprehensive investigation [2]. This polymer crystallises well, with a lattice exhibiting sharply defined anisotropy [5,6], for it comprises "planar networks", between which van der Waals bonds operate; within a network the macromolecules are combined by regular hydrogen bonds. This is a necessary condition for the establishment of a fully crystalline structure within 4,6-polyurethane, and is responsible for the peculiarities of its formation and its breakdown. The crystal lattice contains both di-isocyanate and glycol units. Thermographic and calorimetric investigations have shown [7-9] that structural features of 4,6-polyurethane also effect the variation in its thermodynamic properties.

Calorimetric investigations were made [10] on a series of polyurethanes synthesised from carbon-chain glycols $HO.[CH_2]_n.OH$ ($n = 2-10$) and various di-isocyanates—hexamethylene, methane-*pp'*-diphenylene, and 4-methyl-1,3-phenylene di-isocyanates. The melting points of the polyurethanes investigated, like those of polyamides,

† We apply the term *homopolyurethanes* to polyurethanes formed from single initial components (glycol and di-isocyanate).

depend on whether $n$ is odd or even. The maximum glass point is found with specimens obtained from the diphenylmethane derivative, for which it falls uniformly with increase in $n$. For the tolylene series the glass points vary irregularly with increase in $n$, and the glass points of the hexamethylene polymers are independent of $n$.

Structural changes [11] and structure [12] were investigated in oligourethanes of general formula $CH_3.CO.\{O.[CH_2]_5.NH.CO\}_nO.CH_3$ ($n = 2-5$, $8-10$) as well as in a specimen of high molecular weight. Crystals grown from solution were studied. In oligourethanes having $n = 2-8$ the size (height) of the crystallites was independent of the conditions of heat-treatment, but for the remaining oligourethanes it increased on annealing at high temperatures, which indicates structural rearrangement with transition of chains from a folded to an elongated conformation (for $n = 9$, 10). The heat of fusion and the crystallinity of the oligourethanes diminish with increase in $n$. The crystallites have a two-phase structure, consisting of a very dense crystalline phase and a less dense intercrystalline phase containing mobile free ends of macromolecules.

When the length of the glycol component is increased and an oxygen atom is introduced to give 5-oxanonane-1,9-diol, the resulting polyurethane [formula (2) with $n = 2$] has a lower melting point and exhibits a characteristic change in crystalline structure, becoming polymorphic [13,14]. Infrared spectroscopy reveals three modifications, denoted $\alpha$, $\alpha'$, and $\beta$. [13] The transition $\alpha \rightarrow \beta$ is a polymorphic process accompanied by change in the conformation of the chain with rotation of the urethane group. The transition from the $\alpha$ to the $\alpha'$ structure does not fit into a simple scheme of fusion of the former and appearance of the latter at this temperature, but involves an "intermediate" structure, which subsequently melts [14]. The change from the $\alpha$ to the intermediate structure is a transition from one crystal lattice to another, accompanied by a change in the chain conformation, which in this case, however, does not involve urethane group. The transition from the intermediate to the $\alpha'$ structure is in turn also accompanied by changes in crystal lattice and chain conformation, which become the same for the $\alpha'$ as for the $\alpha$ structure.

It will be of interest to examine the structure and properties of polyurethanes based on ethylene glycols [8,15-26], whose general formula can be written

$$[-OCO(CH_2CH_2O)_nCONH(CH_2)_6NH-]_x \quad , \qquad (3)$$

where $n = 1-6$. The structure [15,21] and the thermodynamic properties [16] of the product having $n = 2$, i.e. polyurethane-2 based on diethylene glycol and hexamethylene di-isocyanate, have been investigated. Conditions were found for the appearance of two different crystallographic modifications, $\alpha$ and $\beta$, melting at 124 and 128°C respectively. The dimorphism of polyurethane-2 must explain the complicated fusion peak on the heating thermogram [8] and the temperature dependence of the heat capacity [16]. Furthermore, polyurethane-2 is able to form two types of supermolecular structure (annular and needle-shaped spherulites) [21]: the former correspond to only one of the two crystallographic modifications, but the latter spherulites contain crystals of both modifications.

A multiplicity of thermal transitions [8,17,25-27] and a variety of supermolecular structures [19] are found also when $n = 3$. Optical microscopic investigation of the spherulitic crystallisation of polyurethane-3 (from triethylene glycol and hexamethylene di-isocyanate) has shown [19] that extremely diverse structures (annular and radial spherulites, lamellar spherulitic aggregates, etc.) may appear depending on the conditions of crystallisation (temperature, from solution or melt, thickness of crystallising film). X-Ray examination has in turn revealed [18] the presence of two crystalline modifications ($\alpha$ and $\beta$). However, calorimetry indicates [25,27,28] a more complicated pattern of structural changes when this polyurethane is heated. Indeed, more detailed investigations of the structure and structural transitions of polyurethane-3 shows [26] that it can crystallise in at least four crystallographic modifications $\alpha-\delta$, and many transitions appearing in particular on the heating thermograms and the temperature dependence of the heat capacity are a consequence of polymorphic transitions and the melting of individual modifications, in one case of melting followed by recrystallisation. These polymorphic transitions are realised only with relatively slow heating.

At least two crystalline modifications $\alpha$ and $\beta$ may appear in polyurethane-4 [based on tetraethylene glycol and hexamethylene di-isocyanate—formula (3) with $n = 4$]. [23] This polymer is also characterised by a variety of supermolecular structures (positive and negative annular spherulites of different degrees of perfection, sheathlike spherulites). A significant feature is the coexistence of two crystalline modifications—positive rings comprising $\alpha$-crystallites, and negative rings of $\beta$-crystallites—in an annular spherulite of polyurethane-4. This provides further confirmation of the formation of annular spherulites by "rhythmic" crystallisation [29-31]. However, the opposite phenomenon has been observed with polyurethane-2 [21] and polyurethane-3: [26] i.e. annular spherulites grew in the temperature range of one crystalline modification, and their optical patterns were consistent rather with a structural hypothesis suggested by other workers for annular spherulites [32,33].

Calorimetric investigations [34] on polyurethane-4 and polyurethane-6 (the latter from hexaethylene glycol and hexamethylene di-isocyanate) have yielded information on their thermodynamic properties. In particular, true values were obtained for the enthalpy and entropy of fusion of polyurethane-4: $\Delta H_f = 28.5$ cal $g^{-1}$ and $\Delta S_f = 29.0$ cal $mole^{-1}$ $deg^{-1}$; the corresponding values for polyurethane-6 were 30 cal $g^{-1}$ and 40.0 cal $mole^{-1}$ $deg^{-1}$. The contributions of urethane groups to the entropies of fusion of these polyurethanes were estimated. It is interesting that the contributions of methylene groups and of urethane groups differ not only in absolute magnitude but also in sign, respectively 2.4 and $-4$ cal $mole^{-1}$ $deg^{-1}$. The negative entropy indicates that the presence of urethane groups diminishes the number of conformations of the chain in the melt: i.e. it lowers the configurational entropy of the melt. Hence increasing the concentration of urethane groups in the chain should raise the melting point of the polyurethanes (with closely similar true heats of fusion). Such regular rise in the melting point is indeed observed on passing from polyurethane-6 to polyurethane-2. [8,9,16,17,34].

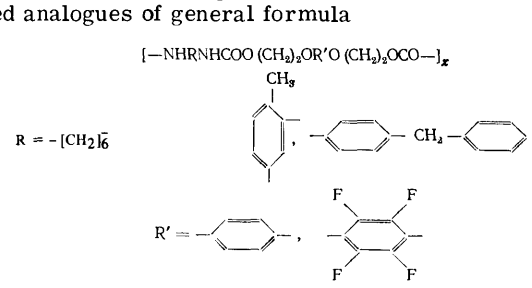
It is significant also that the glass points of this series of polyurethanes increase linearly [27] with the concentration of urethane groups. Extrapolation to zero concentration then gives $T_{gl} = -83$°C, which will yield the glass point of poly(ethylene oxide), the macromolecular polymer-homologue of the glycol chain segments of these polyurethanes. For polyurethane-4 and polyurethane-6 the excess entropy at the glass point has also been obtained, as well as the contributions thereto made by urethane groups. The energy of hydrogen bonds involving urethane groups in these polyurethanes was estimated as ~4 kcal $mole^{-1}$.

A new structural feature of this series of polyurethanes (formula 3) has been revealed by the X-ray examination of oriented fibres and films[24]: the observed identity periods were shorter than the theoretical values $C_{exp} < C_{theor}$. The difference was due to the divergence between the $c$ axis of the inverse lattice and the texture axis of the polyurethanes, and was increased by any spatial position of the crystallite axes relative to the orientation drawing axis. The parameters of the unit cell of polyurethane-3 were found to be

$$\begin{aligned} a &= 9.24\ \text{Å}; & \alpha &= 77°; \\ b &= 8.01\ \text{Å}; & \beta &= 90°; \\ c &= 23.90\ \text{Å}; & \gamma &= 68°; \\ \rho_{exp} &= 1.23; & \rho_{X\text{-ray}} &= 1.31; \\ & N = 4. \end{aligned}$$

with the presence of sloping crystallites taken into account. Another peculiarity of the orientational behaviour of crystallites of polyurethane-3 in the $\beta$ form was that on elastic deformation they underwent three-dimensional rotation until the axes of the molecules coincided with the texture axis. Furthermore, elastic deformation of a polyurethane-3 specimen containing the $\gamma$ modification leads to breakdown of the $\gamma$ form with transition to the $\beta$ modification.

Replacement of the aliphatic di-isocyanate unit in polyurethane-3 by an aromatic unit, i.e. passing to a polyurethane based on triethylene glycol and methane-*pp'*-diphenylene di-isocyanate (polyurethane-F3), [35] results not only in loss of the ability to crystallise but also in a rise in the glass point and an anomalous process of vitrification. This is indicated by the occurrence of two successive jumps in heat capacity in the region of the glass point. Analysis of the process suggested that the first abrupt change in heat capacity corresponded to the development of mobility in microregions of the polyurethane in which were concentrated glycol chain segments, whereas the higher-temperature jump was due to disintegration of microregions with associated methanediphenylene di-isocyanate chain segments.



The diminished degree of hydrogen bonding on passing to *N*-substituted polyurethanes is responsible for several structural and thermal peculiarities. This was demonstrated in an investigation by infrared spectroscopy and thermography of *N*-methylated and *N*-benzylated polyurethanes based on ethylene glycol and 4-methyl-1,3-phenylene di-isocyanate[36].

Analogues of the polyurethanes

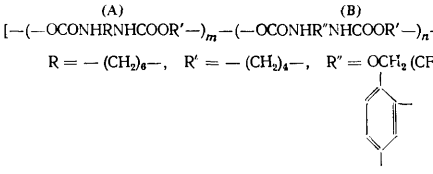
$$[-OCO(CH_2)_nOOCNH(CH_2)_6NH-]_x \qquad (4)$$

($n = 4-6$) in which 2–4 methylene groups have been replaced by difluoromethylene groups, in either or both di-isocyanate and glycol units, have been examined thermographically[37–41]. The introduction of fluorine atoms into one of the components results in anomalous melting, with two extrema on the fusion peak of the thermogram obtained when the polyurethane is heated. Such anomaly depends on the previous history of the specimen, and is due to the polymorphism of the crystalline phase, as with polyurethanes based on glycols containing oxygen in the chain. The ability to form a polymorphic crystalline structure diminishes as the number of difluoromethylene groups introduced into the chain decreases. When glycol and di-isocyanate components contain the same number of difluoromethylene groups, the resulting polyurethane exhibits no tendency to polymorphism. Conformational changes in the chain due to the sequence of difluoromethylene units are held responsible for the polymorphism of fluorinated aliphatic polyurethanes.

Fluorinated aromatic polyurethanes and their unfluorinated analogues of general formula

both crystallise poorly[42]. Those based on an aliphatic di-isocyanate exhibit the greatest tendency to crystallise. With an aromatic di-isocyanate the polyurethane has a higher melting point. Thus those obtained from hexamethylene, 4-methyl-1,3-phenylene, and methane-*pp'*-diphenylene di-isocyanates melt at 188, 190, and 222°C respectively, the corresponding glass points being 42, 47, and 49°C. It is significant that two glass points—as with the polyurethane from methane-*pp'*-diphenylene di-isocyanate and triethylene glycol[35]—are not observed here, which indicates that the introduction of a benzene ring into the glycol unit leads not only to an increase in the general rigidity of the polyurethane chain but also to a "levelling out" of the mobilities of di-isocyanate and glycol units. Probably this is responsible also for some tendency to crystallise shown by these polyurethanes based on aromatic di-isocyanates and glycols.

Formula (5) shows fluorine introduced into the benzene ring of the glycol unit, which should not affect the thermodynamic flexibility of the polyurethane chain. However, both the melting points and the crystallinity of all three types of fluorinated aromatic polyurethanes are lower than those of their unfluorinated analogues. The explanation is that the replacement of hydrogen by fluorine atoms leads to weakening of interchain interaction and of the tendency to associate at the fluorinated benzene rings. This is evidenced by the fall in the glass point of a polyurethane based on an aliphatic di-isocyanate when fluorine is introduced into the benzene ring of the glycol unit. However, the introduction of fluorine into polyurethanes based on an aromatic di-isocyanate, in which its benzene rings are also able to associate, does not affect the glass point of the polyurethane.



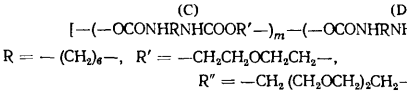
The above results indicate that, depending on the previous thermal, mechanical, etc. history of linear homopolyurethanes based on the lower glycols, their structure and physicochemical properties are predetermined by the chemical structure of the whole polymer chain. This implies that the main method of regulating the properties of polyurethanes of this type is, as before, to vary the chemical structure of the chains, not their physical structure.

## 2. Linear Copolyurethanes‡

Copolyurethanes of the simplest type are obtained from two di-isocyanates and one glycol or from two glycols and one di-isocyanate. They can be regarded as binary

‡ The term *copolyurethane* indicates that one of the initial constituents (di-isocyanate or glycol) comprises more than one component.

copolymers, in which units of two initial homopolyurethanes can be distinguished. Three types of random binary copolyurethanes have now been obtained, differing in their property–composition diagrams[41,43–47]. An example of the first type is based on tetramethylene glycol, hexamethylene di-isocyanate, and a fluorinated aromatic di-isocyanate having a structure resembling that of 4-methyl-1,3-phenylene di-isocyanate but with the methyl group replaced by a polyfluoroalkoxyl[45]. The chemical structure of this copolyurethane-I can be represented by the formula



(6)

containing two kinds of units—4,6-polyurethane (A) and a polyurethane based on tetramethylene glycol and the fluorinated di-isocyanate (B)—corresponding to the initial homopolyurethanes. The latter, in contrast to 4,6-polyurethane, cannot crystallise. Thus copolyurethane-I contains units capable (A) and incapable (B) of crystallising. Thermographic examination has shown that the introduction of non-crystallising units causes the crytallisation and melting points of copolyurethane-I to fall and lowers the heats of crystallisation and fusion[45]. The reason is the diminished ability of the copolymer to crystallise with increase in the proportion of non-crystallising units, with a consequent lower degree of crystallinity and the formation of a less perfect crystal structure: copolyurethane-I containing >50 mole % of non-crystallising units is amorphous. This phenomenon leads to anomalous variation of the density of the copolymers, which increases linearly with the content of fluorinated units only for the amorphous copolymers. This is because the density is determined over the initial composition range (<50 mole % of non-crystallising units) by competition between two processes: the introduction of fluorinated units tends to increase the density by the substitution of fluorine atoms, but tends to diminish the density by disrupting the crystalline phase of the crystallising units (4,6-polyurethane).

Flory's equation for random binary copolymers comprising crystallising and non-crystallising units was applied to the depression of the melting point of copolyurethane-I. The calculated melting point was closely similar to the experimental value only for low contents of the non-crystallising units, but was above the latter at higher contents. Such anomaly is attributed to the presence in the non-crystallising units of long polyfluoroalkoxy-groups, which act as an internal plasticiser and intensify the general irregularity of the copolyurethane-I chains.

A copolyurethane of the same type is obtained from triethylene glycol with hexamethylene and methane-*pp*′-diphenylene di-isocyanates[47]. The initial homopolyurethanes are the crystallisable polyurethane-3 and the amorphous polyurethane-F3 (see Section I). In this case the melting point and the crystallinity of the copolyurethane also fall with increase in the proportion of non-crystallising units, but the copolymer becomes completely amorphous only when the content reaches 80 mole %. This provides further conformation that polyfluoroalkoxy-groups do indeed intensify the general irregularity of the copolyurethane-I chain.

An example of the second type of random binary copolymers is copolyurethane-II based on di- and triethylene glycols with hexamethylene di-isocyanate, whose chemical structure can be represented by the formula[43,44,46]

(7)

which shows that the initial homopolyurethanes are the above polyurethane-2 and polyurethane-3 (units C and D respectively). In contrast to copolyurethane-I, both kinds of units in copolyurethane-II are able to crystallise. Infrared spectroscopy and X-ray diffraction reveal a crystal structure identical with that of one of the initial homopolyurethanes. Transition from one type of structure to another is observed when the copolyurethane-II contains 60 mole % of C units. The composition dependence of the melting point contains a "eutectic minimum" at intermediate compositions, but no eutectic—mixture of crystals of the initial homopolyurethanes—is present. The occurrence of the eutectic minimum is due to the appearance of a less perfect crystal structure, owing to disruption of the regularity in the alternation of urethane groups that is necessary to produce a perfect crystal structure in polyurethanes of this type. The copolyurethanes, like the initial homopolyurethanes, are capable of a polymorphic crystal structure, but this ability diminishes with the transition to an equimolecular copolyurethane-II composition. Structural investigations have shown that the polymorphic transitions in the copolymer and in the initial homopolymers are a consequence of conformational changes in the chain, which may involve both the urethane group and the glycol unit. Thermographic and structural examination of mixtures of the initial homopolyurethanes crystallised together has shown that they are not isomorphous and cannot cocrystallise.

The copolyurethane obtained from hexamethylene di-isocyanate and mixtures of ethylene and hexaethylene glycols is of the same type[48]. Both kinds of units are also capable of crystallising, and their melting point also falls as the equimolecular composition of the copolymer is approached. Yet several mechanical properties of the copolyurethane vary irregularly, which can be attributed to the absence of a random or nearly random distribution of glycol units and the presence of long sequences (blocks) of the same glycol units in the chain. This may be due to a difference in the conditions of preparation of the copolyurethane[49].

Binary copolyurethanes of the third type may have the chemical structure[41]

(8)

As with copolyurethane-II, the initial homopolyurethanes of copolyurethane-III can crystallise, but they are isomorphous and able to form a combined crystal structure. Further, the composition dependence of the melting point does not pass through a "eutectic minimum", but is linear, owing to isomorphism. Another difference is that the tendency to form a polymorphic crystal structure inherent in a fluorinated homopolyurethane is not suppressed by the introduction of units of the second homopolyurethane, and a polymorphic structure appears even when the copolyurethane-III contains 70 mole % of the unfluorinated homopolyurethane.

A series of copolyurethanes based on hexamethylene di-isocyanate and mixtures of glycols of general formula $HO[C_2H_4O]_nH$ ($n = 1-4$, 6) (copolyurethane-M) had a constant mean concentration of hydroxy-groups in the mixture equal to their concentration in triethylene glycol [27,49-51], so that the empirical formula of the copolymers corresponded to formula (3) with $n$ adopting simultaneously all the above values. The properties of these copolyurethanes are compared with those of polyurethane-3, since they possess the same concentration of urethane groups, and differ only in the distribution of the latter in the chain. As in the case of copolyurethane-II, on passing from polyurethane-3 to copolyurethane-M not only the tendency to crystallise but also the ability to form a polymorphic crystal structure diminishes. The structure of copolyurethane-M containing 60% and 70% of triethylene glycol in the initial glycol mixture is identical with that of polyurethane based on triethylene glycol (polyurethane-3). Copolyurethanes having about the same contents of different glycols may have different types of structures depending on the conditions of crystallisation (from different solvents). The glass point of copolyurethane-M, in contrast to those of the initial homopolyurethanes, is determined not only by the concentration of urethane groups but also by their distribution in the chain. The temperature range of the glass transition also becomes wider, owing to the expansion of the spectrum of relaxation times resulting from differences in the mobility of individual chain segments caused by the irregular distribution of urethane groups in these copolyurethanes. Enthalpies and entropies of fusion as well as crystallinities have been determined for copolyurethanes-M. As in the cases of polyurethanes-4 and -6, the contribution of urethane groups to the entropy of fusion of the copolyurethanes identical in structure with polyurethane-3 has been estimated: they lower the entropy of fusion of the crystalline phase as in the other cases, the observed decrease being similar in magnitude to that of NHCOO groups in polyurethanes-4 and -6, and of NHCO groups in polyamides.

The data given on the structure and properties of linear polyurethanes obtained from the lower glycols indicate that their relation to the chemical structure of the chain is governed by the same laws as with other types of thermoplastic polymers capable of specific interactions (e.g. polyamides). Nevertheless, results for various random copolyurethanes obtained from multicomponent initial constituents suggest that the structure and properties of thermoplastic polyurethanes can be controlled extremely effectively by varying not only the chemical structure and nature of the initial constituents but also the distribution in the chain of polar—primarily urethane—groups, which determine the regularity of intermolecular hydrogen bonds in polyurethanes of this type.

## III. POLYURETHANES BASED ON OLIGOMERIC GLYCOLS

### 1. Cross-linked Polyurethanes

Increasing the molecular weight of the glycol constituents of polyurethanes while chemically cross-linking their chains leads to a qualitatively new type of polymeric materials—elastomers (rubbers)—which have been the subject of many studies, mainly on their strength, elastic, and other operating properties. Since most of this information has been summarised in monographs, reviews, and symposia [1,3,4,52-54], we shall discuss here only some of the main conclusions that can now be reached concerning the relation between the chemical constitution of cross-linked elastomers and their structure and physicochemical properties.

Cross-linked polyurethane elastomers are characterised by the alternation in their macromolecules of oligomeric blocks differing in flexibility and nature, as well as rigid di-isocyanate units, and the presence of various polar functional groups capable of forming various types of physical cross-links and transverse chemical bonds, etc. All this combined determines the macroscopic properties of the polyurethanes (glass point, temperature and range of phase transitions in crystallisable polymers, mechanical and other properties). As a consequence, the three-dimensional network in cross-linked polyurethanes is formed by both chemical cross-links and physical (hydrogen) bonds [1,3,4], and the structure of the effective three-dimensional framework, together with other parameters, acquires especial importance [1]. The most convenient procedure in estimating the contributions of individual parameters to the variation in the properties of cross-linked polyurethanes is to study successively the initial components (oligoglycols), intermediate products in the synthesis (linear polyurethanes), and the final cross-linked polyurethanes, as has been done in several studies [2,55-58].

Blocks of oligomeric glycols have the predominant role in determining the structure and properties of polyurethanes derived from them. Thermodynamic analysis and structural investigations have shown [56-59] that the ability of these polymers to crystallise is determined by the corresponding ability of the oligomeric blocks, and increases with the molecular mass of the latter. The crystal structure appearing both in linear and in cross-linked polyurethanes is identical with that of the oligoglycol blocks and their high-polymer homologues, but is less perfect, since the di-isocyanate units—and in cross-linked polyurethanes also branch points of the chemical network with adjacent units—act as defects in the crystal lattice. Formation of a crystalline phase in cross-linked polyurethanes is responsible for the development of properties inherent in energy-elastic materials [2,60,61], but the action of temperature or mechanical stresses breaks down this phase and restores to the polyurethanes the properties characteristic of entropy-elastic materials.

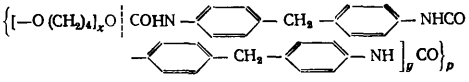
An abrupt rise in the glass point is observed on passing to polyurethanes only from oligoglycols (oligoethers) comprising polar chains, as a consequence of the formation of a secondary physical network diminishing their kinetic flexibility [1,2]. In cross-linked polyetherurethanes the glass point (like that of linear polyurethanes, largely determined by the thermodynamic flexibility of the chain) depends mainly not on the frequency of chemical cross-linking but on the concentration of urethane groups forming branch points of the physical network. Indeed, calculation of effective and chemical densities of cross-linking for polyurethanes based on oligoethers showed that physical links constitute about 80% of the total three-dimensional network, whereas the corresponding proportion in cross-linked polyurethanes based on carbon-chain oligoglycols is 10–30% [63].

With oligomeric blocks of the same molecular mass, the same di-isocyanate structure, and the same degree of chemical cross-linking the fall in the glass point of the polyurethanes with decrease in the polarity of the oligomeric blocks is accompanied by extension of the temperature range of vitrification, owing to a change in the character of the intermolecular bonds in the polymers.

Application of the theory of the free volume to vitrification of the initial oligoethers and the resulting polyurethanes established[58,64] that the macromolecules of polyurethanes based on oligoesters are thermodynamically more flexible than those based on oligoethers, but kinetically less flexible. The high thermodynamic flexibility of oligoester blocks is due to the great mobility of the secondary physical network formed, so that the latter readily rearranges under the influence of temperature or mechanical stress[1]. The presence in polyetherurethanes of a dense physical network capable of structural reorganisation influences also the thermodynamics of their deformation: in contrast to ordinary rubbers, the deformation of polyetherurethane elastomers is accompanied not only by a decrease in entropy but also by a change in internal energy[61,65,66].

The dominant role of glycol blocks in determining structure and properties is indicated by the fact that the flexibility of the molecules in polyurethane networks is due not only to the formation of long sequences of relatively short oligomeric chains but also the intrinsic flexibility of the oligomeric blocks. The cleavage and redistribution of secondary physical bonds in amorphous polyesterurethane elastomers, which occur under the influence of temperature and mechanical stress, are then a consequence of the preservation of oligoester blocks of high thermodynamic flexibility (mobility) even after their introduction into the polyurethane[2]. The high mobility of the secondary network in polyesterurethanes suggests an analogy between these polymers and the thixotropic structures studied in colloid chemistry[1,67].

Polyurethanes based on oligoglycols and individual di-isocyanates can be regarded as block copolymers, but the individual properties of the di-isocyanate units do not develop in the polyurethane, owing to their small size and the small fraction of the volume of the polymer that they occupy.



## 2. Segmented Polyurethanes

The introduction into the chain not only of oligomeric glycols but also of lower glycols or other bifunctional compounds (diamines, hydrazine, dihydrazides of dicarboxylic acids, etc.) leads to the formation of polyurethanes that, being linear or weakly cross-linked, develop under certain conditions the properties of elastomers, but at high temperatures or under the influence of solvents behave as ordinary thermoplastic polymers (polymeric materials).[1,68-73] Since the oligoglycol blocks are accompanied in the chain by relatively long sequences (segments, blocks) comprising di-isocyanate units and lower functional units, these polymers are usually termed *segmented polyurethanes*. The term "block copolyurethanes" is also fully applicable, but these compounds differ from traditional block copolymers (butadiene–styrene copolymers, etc.) in the relative smallness of the blocks, whose molecular mass reaches only a few thousands, so that the number of them in the chain is far larger. Since segmented polyurethanes have the properties both of thermoplasts and of elastomers, they have been termed *thermoplastic elastomers* (*thermoelastoplasts*).

During recent years quite a large number of studies have been published on segmented polyurethanes, concerned with their fine and supermolecular structure[71,74-93], their thermal and thermomechanical behaviour[94-110], and their physicochemical and physicomechanical properties[111-128]. The latter are related to the chemical constitution and to the supermolecular structure present in segmented polyurethanes.

### (*a*) Structure

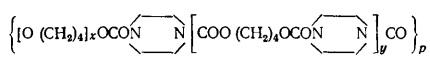
The chemical structure of segmented polyurethanes can be demonstrated by that based on an oligo-oxytetramethylene glycol, methane-*pp'*-diphenylene di-isocyanate, and tetramethylene glycol (chain lengthener)

(9)

one of the most thoroughly studied examples. Two types of blocks can be distinguished (separated by the broken line)—flexible (oligether) and rigid, comprising di-isocyanate and lower glycol (chain lengthener) units—the first of which exhibit relatively weak intermolecular interactions and are responsible for the elasticity of the system, whereas the second ensure strong intermolecular interactions in the chain, the total effect of which may be comparable with that of cross-linking of the chains by chemical bonds[129]. Investigation of intermolecular links, primarily hydrogen bonds, therefore becomes especially important in segmented polyurethanes. An additional reason is that both the concentration and the distribution of hydrogen bonds should depend significantly not only on the chemical structure of the blocks but also on the length of the rigid blocks—the values of $y$ in formula (9)—as well as their proportion and distribution in the chain.

Information on chemical bonds, including hydrogen bonds, and physical interactions in polyurethanes has already been summarised[1]. Different types of hydrogen bonds may be formed in polyetherurethanes, involving either urethane or ether groups of the oligoether blocks. The type of hydrogen bond is largely determined by the concentration of urethane groups in the chain, increase in which results in hydrogen bonds formed predominantly between urethane groups. Fresh information on hydrogen bonds in polyurethanes has been obtained by the quantitative infrared spectroscopy of segmented polyetherurethane[77-81]. Examination of the efficiency of hydrogen-bonding in polymers based on methane-*pp'*-diphenylene di-isocyanate, tetramethylene glycol, and an oligo-oxytetramethylene glycol—formula (9)—or an oligo(tetramethylene adipate) of molecular mass 1000 has shown that almost all the NH groups in the urethane groups are hydrogen-bonded, with only about 60% bound to urethane carbonyls, and the remaining 40% to ethereal oxygen. Qualitatively similar results have been obtained for polyurethanes based on either oligoethers or oligoesters. A considerable number of hydrogen bonds between NH groups and ethereal oxygen in flexible chain segments are found in polyetherurethanes based on 2- and 4-methyl-1,3-phenylene di-isocyanates[81].

Whereas the presence of hydrogen bonds between urethane groups indicates the association of rigid blocks to form rigid domains[69], a high content of hydrogen bonds involving ethereal oxygen is evidence that segregation of rigid blocks in segmented polyurethanes does not (may not) go to completion. This may indicate that such bonds are formed at the boundary between the rigid domains and the flexible medium (matrix) formed by the oligoether blocks. Consequently, the spectral investigations of segmented polyurethanes are not inconsistent with



the conclusion that phase separation takes place in these polyurethanes, as in traditional block copolymers[68]. This is confirmed also by an investigation of the infrared dichroism of segmented polyurethanes[78], but in this case the regions of rigid urethane blocks and those of flexible oligoether blocks partly overlap.

X-Ray investigations have also been made[71,82-85,89] of the physical structure of the cross-links in segmented polyurethanes based on methane-*pp'*-diphenylene di-iso cyanate, an oligoether and an oligoester, and various chain lengtheners (tetramethylene glycol, ethylenediamine, hydrazine), both initially and after considerable deformation. The diffraction patterns of initial specimens containing hydrazine as lengthener show, besides a broad amorphous halo, a weak reflection with an interplanar spacing of 12 Å, which is a consequence of intermolecular packing of urethane segments[71]. Stretching the specimen by 200 to 300% results predominantly slanting orientation of rigid segments, while flexible segments are oriented in the direction of deformation. Further stretching leads to reorientation of rigid blocks. Heat-treatment in turn results in almost complete disorientation of flexible blocks, but does not affect the orientation of rigid blocks.

Furthermore, structural differences may be observed in stretched polyurethanes depending on the structure of both flexible and rigid blocks. The differences in intensity of scattering of X-rays by various segmented polyurethanes are attributed to different degrees of aggregation of the rigid blocks[83]. Rigid urethane domains constructed from methane-*pp'*-diphenylene di-isocyanate and tetramethylene glycol units[85] possess a lamellar structure, with mean distances of 100–200 Å between their centres. Both X-ray and spectral studies indicate that the rigid segments of segmented polyurethanes form isolated domains within a rubberlike matrix of flexible blocks.

Electron microscopy of segmented polyurethanes also indicates a two-phase structure[88]. They are micro-heterogeneous two-phase systems with rigid domains of size 30–100 Å. The micrographs suggest that the domains are three-dimensional.

Structural investigation of the polyurethane[87,88]

(10)

from which hydrogen bonds should evidently be absent, also indicates the presence of domains. Furthermore, such segmented polyurethanes, with a narrow range of lengths of flexible blocks and a different (definite) length of rigid blocks, may contain structural formations ("superstructures" or "superdomain structures") substantially larger than the domains. These stable structural formations, which may extent to 1 μm, are revealed by the scattering of polarised light. Although they resemble spherulites, the pattern of scattering is somewhat different. The nature of these structures is related to the possible crystallisation of rigid chain segments, since flexible segments do not crystallise in the undeformed state. This indicates that the appearance of a domain structure in segmented polyurethanes is not a consequence solely of the presence in the rigid blocks of polar groups capable of forming hydrogen bonds. Phase separation in segmented polyurethanes, as in traditional block copolymers, is predetermined also by the limited compatibility of different blocks in the chain, differing in nature and flexibility.

(*b*) Thermal and thermomechanical behaviour

Both the chemical constitution and the structure of segmented polyurethanes govern also their thermal and thermomechanical behaviour. Calorimetric, differential thermal, dilatometric, thermomechanical, and other studies indicate that segmented polyurethanes undergo a multiplicity of temperature transitions, due to the occurrence of various processes. Thermal transitions have been investigated[95] in a segmented polyurethane based on an oligoethylene glycol adipate, tetramethylene glycol, and various di-isocyanates (methane-*pp'*-diphenylene, tolylene, etc.), in which several thermal transitions have been detected, three of which can usefully be distinguished. Thus a transition in the region of −40°C is due to the segmental mobility of units of the oligoether block, i.e. its vitrification, as in cross-linked polyurethanes based on the above adipate[1]. The temperature of this transition in the polyurethane is higher than the glass point of the initial oligoether. Yet the glass point varies little with the structure of the di-isocyanate units in polyurethanes, with the exception of tolylene di-isocyanate, which may raise the glass point of a segmented polyurethane.

The other two transitions, observed around 70–80° and 150–180°C, depend on the structure of the rigid blocks and represent processes occurring in the micro-regions formed by them. The higher glass point and somewhat lower temperatures of the high-temperature transitions in the polyurethane based on tolylene di-isocyanate are attributed to the diminished segregation of rigid blocks due to the large number of bonds formed between them and the oligoether blocks. Hence interaction between rigid and flexible blocks may lead to disordering of the rigid domains, resulting in depression of the transition temperatures characterising these domains. It was also concluded that rigid segments may achieve a high degree of order, but the high-temperature transition points in segmented polyurethanes are lower than those for the initial rigid blocks owing to their small proportion in the polyurethane or low percentage crystallinity resulting from their copolymerisation with flexible blocks or from branching. However, cases are possible in which the degree of order in the rigid domains is so great that the high-temperature transition point in the segmented polyurethane is almost identical with that in the initial rigid block.

The glass point in a segmented polyurethane can be lowered[96] by increasing the chain length of flexible blocks, shortening rigid blocks, replacing aromatic by aliphatic urethane units, and restricting the intermolecular interactions of flexible blocks. The introduction into a segmented polyurethane of oligoether blocks having a wide molecular-mass distribution leads in turn to widening of the temperature range of vitrification and crystallisation of the polyurethane (flexible blocks)[97].

Calorimetric investigations have been made on segmented polyurethanes obtained from various oligoethers—oligo-oxypropylene glycol, oligo-oxytetramethylene glycol, oligo(ethylene butylene glycol adipate)—varying in molecular mass, methane-*pp'*-diphenylene di-isocyanate, and tetramethylene glycol[101]. The concentration of urethane groups was controlled by varying the content of lower glycol units in the chain. As with cross-linked polyurethane elastomers[1], the glass points of these polymers depend on the total concentration of urethane groups in the chain, but this relation becomes less marked with increase in the molecular mass of the oligoether block.

In addition to the low-temperature vitrification, a high-temperature transition develops at 110–120°C, whose character depends on the length of the rigid block. It was suggested that this latter transition was due to the dissociation of hydrogen bonds between rigid blocks, caused by "thermal perturbation of adjacent polyether segments of the chain" [101].

Three thermal transitions have been revealed by thermographic and thermomechanical studies of segmented polyurethanes (polyurethane semicarbazides) [99,108] prepared from methane-*pp'*-diphenylene di-isocyanate, oligoethers (oligo-oxytetramethylene glycol, oligo-oxypropylene glycol), and chain lengtheners (hydrazine, adipo- and isophthalo-dihydrazines). The first transition occurs between −25 and −55°C depending on the chemical structure and the molecular mass of the oligoether block, as well as on the concentration of urethane groups, and is due to the segmental mobility of the oligoether blocks. The third transition, which begins around 70°C and is diffuse in character, represents the breakdown of association complexes formed from rigid blocks (devitrification of rigid blocks). The second transition occurs in the region of 25°C, and is probably due to dissociation of bonds between oligoether and rigid (di-isocyanate–lengthener–di-isocyanate) blocks. In a segmented polyurethane [100] having longer blocks capable of crystallisation the latter two transitions correspond to higher temperatures (50–100 and 140–200°C); in addition a new transition appears in the range 200–300°C, caused by the melting of paracrystalline ordered domains constructed from rigid blocks.

Thermal transitions and thermomechanical behaviour have been investigated also in segmented polyurethanes [103] obtained from 2- and 4-methyl-1,3-phenylene di-isocyanates, differing also in the proportions of the initial components and the previous history of the test specimens. Polyurethanes obtained from the symmetrical di-isocyanate crystallise; those containing the unsymmetrical 4-methyl-1,3-phenylene di-isocyanate unit are amorphous. Three temperature transitions are observed depending on the structure of the di-isocyanate unit, the composition of the segmented polyurethane, and the previous thermal history. The transition in the range 20–80°C is attributed to dissociation of bonds between loosely packed domains of rigid blocks, and that above 150°C to fusion of crystalline formations of rigid blocks.

Thermomechanical and structural investigations of segmented polyurethanes based on oligoethers and oligoesters, methane-*pp'*-diphenylene di-isocyanate, and aliphatic diamines $NH_2[CH_2]_xNH_2$ ($x$ = 0, 2–6) have established [106] that preliminary softening takes place at 60–70°C in specimens from diamines having $x$ = 3, 5, which is attributed to interaction between phases formed by flexible and rigid blocks, leading to some mutual dissolution. The softening temperature of the polyurethanes varies from 130 to 190°C with change in $x$ from 0 to 6. Softening temperatures are in all cases lower for polyurethanes containing oligomeric ester blocks than for segmented polyurethanes based on oligoethers. Small-angle scattering of X-rays shows that the softening temperature rises with increasing degree of isolation of rigid blocks. Varying the number of methylene groups in a segmented polyurethane alters the degree of aggregation of rigid blocks, although the content of urethane and urea groups remains the same. The aggregation of rigid blocks involves the formation of hydrogen bonds between functional groups in the blocks, which is governed by the number of methylene groups in the diamine unit. Aggregates of rigid segments act as an active filler or as branch points in the three-dimensional network of the segmented polyurethane.

The temperature of annealing has a complicated influence on transitions in and the structure of a segmented polyurethane [98]. It is concluded that annealing results in two types of microstructural changes: homogenisation of the system of hydrogen bonds includes the observed increase in order; and conversion into an ordered structure (perhaps microcrystalline) may involve reorientation of the domain structure. The effect of quenching (amorphisation) on thermal behaviour has been demonstrated in a thermographic investigation of a segmented polyurethane based on an oligo-oxytetramethylene glycol, hexamethylene di-isocyanate, and diethylene glycol [108]. Six temperature transitions were observed, associated with vitrification, crystallisation, and fusion of microregions formed by blocks of differing rigidity. The polar nature of the blocks leads to interaction between microregions differing in rigidity, which affects the transition temperatures. Nevertheless, the melting point of a rigid block remains almost unchanged after introduction into a polyurethane. This agrees well with an earlier conclusion [95] that a high degree of order may be possible in rigid domains.

Investigation of a polyurethane based on an oligobutylene glycol adipate, hexamethylene di-isocyanate, and an aliphatic (tetramethylene glycol) and an arylated chain lengthener has revealed [109] that the previous thermal history has a significant influence on the thermomechanical behaviour and other properties of segmented polyurethanes. The structure and the properties of these polymers depend on their state of phase aggregation, which depends both on the structure of the rigid blocks (governed by that of the chain lengtheners) and on the previous thermal history of the copolyurethane. The polyurethane based on the aliphatic lengthener exhibits considerable residual elongations, which are attributed to orientation crystallisation on stretching. The rather lower values found with aromatic lengtheners are consistent with the smaller tendency to crystallise shown by the resulting blocks than by those based on tetramethylene glycol.

Investigations on segmented polyurethanes [110] in which the chain lengtheners contain either non-polar or polar substituents have shown that increase in the polarity of a rigid block is accompanied not only by the regular rise in the flow point owing to the breakdown of rigid domains but also by a fall in the glass point of the flexible oligoether blocks. This phenomenon is attributed to an increase in the degree of segregation of rigid blocks with increase in their polarity.

Study of the thermal behaviour of the above segmented polyurethane devoid of hydrogen bonds (based on piperazine—formula 10) revealed [94] the properties of cross-linked elastomers over a wide temperature range, but at high temperatures this polymer melts, and can be processed by the methods used for plastics and fibres. Their three-dimensional network is formed by the association (crystallisation) of rigid blocks bound by intermolecular bonds. It is concluded that the flexible blocks act as a diluent and do not mix with the rigid blocks.

A multiplicity of transitions in segmented polyurethanes has been detected in an investigation of their relaxation properties by dynamic, mechanical [111,116,117], and dielectric [125–127] methods. Thus two principal transitions have been observed [111], corresponding to the glass points of

oligoether and rigid blocks (containing urethane groups). Several transitions corresponding to the movement of various groups in the blocks have also been found. All relaxation transitions depend on the molecular mass and the content of rigid blocks, as well as on the previous thermal history. Increasing the molecular mass of the rigid block leads to the formation of a semicrystalline material. Relaxation mechanisms in segmented polyurethanes depend not only on the crystallinity but also on the nature of the domain structure. The properties of segmented polyurethanes from oligoethers are determined by both the size and the structure of the rigid blocks [112,117]. In the case of a polyurethane having a non-polar flexible block the glass point of the latter is in turn independent of the nature and the concentration of the rigid urethane blocks [116].

Investigation of the influence of block dimensions and molecular-mass distribution on the properties of a segmented polyurethane shows [123] that a narrower distribution of rigid blocks gives a higher elastic modulus in the region of the plateau. The reason is that the domains formed in such a polyurethane are more perfect that those in a polyurethane having a wider molecular-mass distribution.

(*c*) Orientation and deformation behaviour

Application of infrared dichroism to orientation processes in segmented polyurethanes containing [90,91] and devoid of [92,93] hydrogen bonds reveals two different mechanisms of orientation for crystalline and amorphous segments formed by rigid blocks. In amorphous segments such blocks are oriented in the direction of stretching at small deformations. The orientation of crystalline segments takes place in two stages, the first of which consists in positive orientation of crystalline regions as a whole, leading to negative orientation of the blocks. In the second stage the primary crystalline segments break down, and the blocks are packed in microregions parallel to the stretching force. Segmented polyurethanes containing no hydrogen bonds exhibit enhanced deformability of rigid blocks and hysteresis in comparison with the hydrogen-bonded segmented polyurethanes. This difference applies to the decrease in energy of intersegmental bonds and the increase in crystallinity of the rigid blocks. Calorimetric examination of the stretching of segmented polyurethanes from crystallisable and non-crystallisable oligoethers indicates [119] in turn that mainly the flexible blocks are deformed when the polyurethane is stretched. Comparison of the energy of the probable hydrogen bonds with the quantity of heat evolved on stretching shows that these bonds are completely realised in the undeformed state. Crystallisation occurs in some polyurethanes even at small deformations, as is confirmed by X-ray diffraction. If the chain structure permits crystallisation, large residual deformations may be observed, which become reversible on subsequent heating.

Investigation of the structure of initial and stretched fibres of a segmented polyurethane showed [74] that orientation drawing is accompanied by a transition of flexible blocks from an unordered (amorphous) state to an ordered (crystalline) state. During drawing the chains slide over one another until the strong dipole–dipole interaction between rigid blocks inhibits such slippage. It was concluded that the deformed polyurethane contained an oriented supermolecular structure, whose character depended on the chemical structure and on the conditions of fibre formation. The influence of temperature and the previous history of stretching on molecular orientation in various blocks in a segmented polyurethane has also been examined [130]. A two-phase model is suggested for interpreting the morphology of polyurethane. It envisages two regions—one containing urethane blocks, and the other flexible oligoether blocks—which are semi-continuous and mutually overlapping. Those having a high elastic modulus, containing aromatic urethane units, reinforce the flexible phase. Since these phases are interpenetrating, both are deformed when stress is applied. On removal of the load, the flexible regions relax, whereas the rigid regions remain plastically deformed. Other investigations on the orientation of rigid and flexible blocks [131] are consistent with a model in which a segmented polyurethane consists of hydrogen-bonded crystallites formed by rigid blocks, which are distributed in a matrix of flexible blocks.

Several studies have been made of the optical [114,118] and mechanical [118,120–122] properties of various segmented polyurethanes. The optical behaviour on deformation [114] indicates a segregated spherical structure comparable with that observed by electron microscopy in hydrocarbon block copolymers. Investigation of the optical and mechanical properties of various segmented polyurethanes containing optically anisotropic regions of size 50–200 $\mu$m, as well as spherulitic structures, has shown that both the anisotropy of their distribution and the mechanical properties of these polyurethanes are functions of composition. Some specimens are deformed with formation of a neck and the appearance of small hump on the stretching curve, and others have a curve characteristic of elastomers; the moduli of elasticity also differ. Such variation in mechanical properties is attributed to the formation of different domain structures, which explain also the low-temperature deformability of the segmented polyurethane obtained from an oligo-oxytetramethylene glycol, methane-*pp'*-diphenylene di-isocyanate, and isophthalodihydrazide [121]. The mechanism is assumed to resemble that of the large low-temperature deformations developed for crystalline polypropylene [132]. However, the deformation is due in this case to the slippage not of units of the supermolecular (spherulitic) structure but of domains or their units formed by rigid blocks. Hence the structural features of segmented polyurethanes govern also their typical orientation and deformation behaviour.

Thus, in spite of some ambiguity and occasionally contradictions in the results of individual investigations, there are nevertheless grounds for reaching definite conclusions on the structure and properties of segmented polyurethanes. Like hydrocarbon block copolymers, these materials possess a two-phase structure. Rigid domains, made up of rigid blocks, are distributed in a medium (matrix) of flexible oligomeric (oligoethereal) blocks and act as branch points of a physical network or as an active thinner. In the present case, however, the rigid domains are usually hydrogen-bonded and may possess a crystalline (semicrystalline) structure, depending on the chemical structure, the molecular mass and its distribution, and other properties of the rigid blocks determining their degree of segregation. The polar nature of blocks differing in rigidity and the presence in them of functional groups capable of specific interaction prevent the segregation of rigid blocks and favour the appearance of "transition" (mutually overlapping) regions. However, the presence in rigid blocks of polar groups capable of forming hydrogen bonds and other physical interactions is not the only factor responsible for the domain structure in segmented polyurethanes. As in hydrocarbon block copolymers, separation into phases is

due also to the limited compatibility of blocks differing in structure and rigidity. Segmented polyurethanes can be regarded as microheterogeneous systems.

### 3. Segmented Polyetherurethanes

The term "segmented polyetherurethanes" can also be applied in most cases to the polyurethanes discussed above (Section III, 2), but we have decided to use it for copolyurethanes whose chains contain two kinds of oligoether blocks, usually differing either in ability to crystallise or in flexibility, and linked by a di-isocyanate (lengthener). The general formula of such a polymer can be written

$$(-A-OCONHRNHCOO-)_{1-n}-(-B-OCONHRNHCOO-)_n \qquad (11)$$

in which A and B are segments (blocks) of different oligoethers, and R is part of the di-isocyanate unit. Several studies of these products [124,133-142] have examined such aspects as the influence on structure and properties of the chemical constitution, molecular mass, molecular-mass distribution, mole fraction, etc. of various oligoether blocks. Several properties of these polyetherurethanes have already been surveyed [1].

Study of the properties of segmented polyetherurethanes [134] prepared from an oligoethylene glycol adipate, an oligo-*p*-phenylenebisethylene glycol adipate, and hexamethylene di-isocyanate with different molar proportions of the blocks and different molecular masses of the acrylated oligoether established that each block could crystallise as a separate phase. The ability to form a crystalline phase decreases as the oligoether block becomes smaller. Polyetherurethanes with roughly the same number of blocks of each kind exhibit the smallest tendency to crystallise, which is responsible for their highest elastic properties. The increase in the content of urethane groups resulting from decrease in the length of the block raises the glass and melting points of homopolyurethanes of comparable molecular mass. The crystallinity of a segmented polyetherurethane is usually due to crystallisation of the oligoether block present in excess [133]. The glass and melting points of segmented polyetherurethanes are largely determined by the structure and the molar content of the oligoether blocks.

Investigation of segmented polyetherurethanes with crystallising blocks of oligo-*o*-phenylenebisethylene glycol adipate and amorphous blocks of oligo(diethylene glycol adipate) suggested [135] that the primary units of the spherulitic structures were formed only by crystallising blocks. Blocks of the amorphous component chemically combined with them, also present in the spherulite, were arranged on the periphery of the primary crystalline structures, acting as an interstructural plasticiser. Crystallisation processes taking place with time then result not in a rise but in a fall in the glass point, since crystallisation is accompanied by accumulation of the interstructural component in the spherulites. An analogous fall in glass point has been observed in other investigations of segmented polyetherurethanes containing crystallising and non-crystallising oligoether blocks [136-138], which indicates that during crystallisation the non-crystallising block forms a separate phase with its own inherent properties.

Thermographic investigations of a segmented polyetherurethane obtained from oligo-oxytetramethylene glycols of various molecular masses and an oligoethylene glycol sebacate have shown [140,142] that crystallisation occurs predominantly in the latter, but when the first block is sufficiently long both may crystallise. These polyetherurethanes exhibit two separate melting ranges, that at lower temperatures due merely to weakening of the "physical network" (fusion of the crystalline phase comprising oligo-oxytetramethylene glycol blocks) with a corresponding change in elastic properties, whereas the higher-temperature range (melting of the crystalline phase of oligoethylene glycol sebacate blocks) represents transition of the polyurethane to a state of viscous flow. The flow point of segmented polyetherurethanes can be raised by introducing tetramethylene glycol units into their chain, so that the concentration of urethane groups is increased, with an increase in branch points of the physical network. Strictly speaking, such modification of properties leads to the formation of a kind of "hybrid" segmented polyurethane, between the above segmented polyurethanes and segmented polyetherurethanes, since sequences of di-isocyanate and tetramethylene glycol units are produced (formation of a rigid block). Investigation of the structure of an analogous segmented polyetherurethane but with oligo-oxytetramethylene glycol blocks differing in polydispersity indicates [124] that the properties of these polymers are determined mainly by the structure and the properties of the crystalline phase, and to a less extent by the structure of the more flexible block. However, the most labile, easily reorganised crystal structure should be more readily achieved in copolymers with mobile fragments of the more flexible block. This should apply also to segmented polyetherurethanes with greater polydispersity of the oligo-oxytetramethylene glycol blocks, in which the network of physical bonds formed by the urethane group is most imperfect and labile.

Thus the above results for segmented polyetherurethanes indicate that they also can be included among thermoelastoplasts, but the crystalline structure produced in them, acting as branch points of the physical network, cannot provide adequate thermal and physicomechanical constants. This makes it necessary to introduce also lower glycols, which increase the concentration of urethane groups in the chain and localise them in separate microregions (domains). Strictly speaking, we return to the above segmented polyurethanes with two kinds of flexible oligoether blocks in their chains.

# Gas-chromatographic Analysis of Unstable Inorganic and Organoelement Compounds

N.T.Ivanova and L.A.Frangulyan

The present state of the gas-chromatographic analysis of unstable and reactive substances if reviewed and described systematically in terms of the characteristic reactions of such compounds, such as hydrolysis, oxidation, thermal and catalytic degradation, and isomerisation. The requirements which must be met by the carrier gas, the solid carrier, and the stationary phase in the analysis of these compounds are discussed together with the characteristics of the qualitative analyses, as well as the apparatus employed.
The bibliography includes 218 references.

## I. INTRODUCTION

Gas-chromatography is the most universal method for the solution of various analytical problems. However, the application of the usual version of gas chromatography in the analysis of unstable substances is impossible owing to the high reactivity of the compounds analysed. In the analysis of such substances, it is therefore necessary to carry out methodological modifications involving the elimination of the causes responsible for these reactions or the latter must be carried out either before injection into the column or in the column.

One of the trends in the development of gas chromatography is the development of special methods whereby gas chromatography can be used to analyse unstable compounds.

Several reviews have been published on chromatographic analysis, which include, in particular, data on the analysis of relatively unstable compounds[1-4]. However, they mainly describe isolated data for specific classes of substances combined because of the similarity of their molecular structures. We thought it most useful to give a systematic account of the gas-chromatographic analysis of unstable compounds on the basis of their characteristic reactions, such as hydrolysis, oxidation, thermal and catalytic degradation, and isomerisation.

In order to prevent the above reactions in chromatographic analysis, it is necessary to take special precautions in the preparation of the carrier gas and in the selection of the solid carrier, the stationary phase, the apparatus, etc. In the first place, more stringent requirements must be met by the carrier gas as regards its nature and purity, in particular its content of oxygen and moisture. In the analysis of unstable compounds, much attention is devoted to the selection of the solid carrier on the basis of diatomite and polytetrafluoroethylene. The structures and properties of solid carriers have been described in detail[5]. On the other hand, the choice of the carrier in the analysis of readily hydrolysable, oxidisable, and thermally and catalytically active compounds has its own characteristic features. Important properties of the carrier are its specific surface, mechanical strength, surface pH, and adsorption and catalytic activities. Its chemical properties (acidity or alkalinity) to a large extent determine the error in qualitative or quantitative analysis. In order to eliminate the chemical, catalytic, or adsorption activity of the carrier, it is modified by thermal, acid, or alkaline treatment, by coating the surface with a continuous film of an inert material, by deactivating the adsorption-active centres as a result of the introduction of small amounts of adsorption-active additives, and by chemical conversion of the polar hydroxy-groups into non-polar groups. Inert polymeric sorbents based on Teflon are used successfully.

In the first place, the mobile phase should be incapable of dissolving oxygen, should be chemically inert, with respect to the substances analysed, and should be hydrophobic. Specific requirements in the analysis of compounds of the type under consideration must be met by the material of the column, the metering device, and the detector, and the conditions during analysis. In order to prevent the decomposition of thermally unstable compounds, the percentage impregnation of the mobile phase is low and use is made of solid carriers with small surface areas, vacuum, low temperature, short columns, and high carrier gas flow rates. In many cases the instability of certain compounds makes it possible to analyse them on the basis of the stable products of their characteristic reactions; the reactions are carried out in the column or before injection into the latter (the method of reaction chromatography). Stable compounds in unstable products are analysed by the same method involving a preliminary reaction with the unstable compound in order to remove it and subsequent separation of the stable compounds.

The gas-chromatographic study of the reactions of unstable substances (hydrolysis, oxidation, isomerisation, etc.) constitutes a separate problem and is not discussed in this review.

## II. ANALYSIS OF READILY HYDROLYSABLE SUBSTANCES

One of the large groups of substances which are analysed by gas chromatography are those which can be hydrolysed. These include metal chlorides, chlorosilanes and organochlorosilanes, boron, hydrides, chlorine, bromine, and iodine fluorides, and alkylated derivatives of boron, aluminium, beryllium, and gallium. The following reactions may be quoted as examples of hydrolysis:

$$BCl_3 + 3H_2O \rightarrow 3HCl + H_3BO_3,$$
$$BHCl_2 + 3H_2O \rightarrow 2HCl + H_2 + H_3BO_3,$$
$$SiCl_4 + 2H_2O \rightarrow SiO_2 + 4HCl.$$

Evidently hydrolysis results in the evolution of gaseous substances (such as HCl and $H_2$) and solid products (silicon dioxide and boric acid). The occurrence of such reactions cannot be allowed in gas-chromatographic analysis, because, on the one hand, it distorts the quantitative result and, on the other hand, leads to corrosion of the apparatus (HCl) and the formation of a solid deposit which blocks the metering device, the detector, and the connecting capillaries. Furthermore, the formation of a solid deposit on the stationary phase impairs the separation and alters the chromatographic characteristics of the substances analysed.

Numerous studies have been devoted to the direct gas-chromatographic analysis of readily hydrolysable substances. The first publications on this problem appeared in 1957–1960[6,7] and subsequently their number greatly increased[8–45]. Table 1 presents the fundamental groups of substances which are readily hydrolysable. Direct gas-chromatographic quantitative analysis of compounds of this type requires careful drying of the carrier gas until its water content is such that it does not affect the analytical results. The drying agents employed in gas chromatography are listed in Table 2, which shows that the best drying effect is achieved in the presence of phosphorus pentoxide. Furthermore, moisture is removed by condensing water vapour at the temperature of liquid nitrogen. In the majority of studies involving the analysis of readily hydrolysable substances, drying is achieved with a combination of drying systems. Thus, in the analysis of inorganic hydrides[46,47], the carrier gas (nitrogen) was dried by being passed through a system of five series-connected columns filled with granulated copper, KSK silica gel, activated granulated alumina, type 5 Å molecular sieve, and a liquid eutectic mixture of sodium and potassium. After passage through the system, up to $8 \times 10^{-5}$% of water remained in the nitrogen. However, in another investigation[7] oxygen-free nitrogen for the analysis of boron hydrides was dried with magnesium perchlorate alone, the drying effect being regarded as sufficient.

In the analysis of inorganic corrosive gases, the drying agents employed were 5 Å molecular sieve (nickel column 12.5 mm in diameter and 107 cm long) subjected to preliminary activation by heat treatment (at 300–325°C, and a residual pressure less than 1 mmHg) for 2 h. The authors[48] claim that such activation makes it possible to employ the drying agent without reactivation for several months, and that the water content in the gas is reduced to $< 5 \times 10^{-4}$%. A gas-chromatographic method has also been proposed for the determination of residual moisture in the carrier gas by condensing water at −78°C and then removing it by reaction with calcium hydride with determination of the oxygen formed. The drying capacities of KSK silica gel, Anhydrone, 5 Å and 4 Å molecular sieves, and phosphorus pentoxide have been tested[49]. The maximum attainable drying effect has been achieved, for example, in the drying of chlorosilanes with the aid of phosphorus pentoxide ($5 \times 10^{-3}$ mg litre$^{-1}$). In order to increase the period during which the $P_2O_5$ column is serviceable (the $P_2O_5$ is deposited on lumps of pumice), some other drying agent must be placed before this column: molecular sieves, Anhydrone, or silica gel. In some investigations[50,51], three columns (100 cm long and 40 mm in diameter), made of glass and filled with 5 Å molecular sieve, were used as the drying train. The moisture content in the nitrogen emerging from the chromatographic column was less than $5 \times 10^{-4}$ mole %, which is permissible for the analysis of germanium tetrachloride and trichlorosilane.

Table 1. Conditions in the gas-chromatographic analysis of readily hydrolysable substances.

| Substance analysed | Carriers and stationary phases | Carrier gas and requirements which it must meet | Detector | Refs. |
|---|---|---|---|---|
| Boron hydrides | Celite 545, Chromosorb W, Chromaton N, Embacel, liquid paraffin, tricresyl phosphate, Octoyl S, silicone oil 702, OV-17, SE-30, E-301, OV-1, Apiezon L | helium and nitrogen: oxygen content not more than $1 \times 10^{-3}$ mg litre$^{-1}$ | katharometer, flame-photometric detector | 6-13 |
| Metal chlorides, $BCl_3$, $SiCl_4$, $SnCl_4$, $TiCl_4$, $PCl_3$, $TaCl_5$, $NbCl_5$ | Celite 545, Teflon, Chromosorb AW-HMDS, graphite heated in a stream of $Cl_2$, Sterchamol, silicone oils, DC-703, DC-550, XE-60, Kel-F, Apiezon L, saturated n-alkanes, paraffin, $BiCl_3$–$PbCl_2$ eutectic mixture | helium, nitrogen, and hydrogen with a water content up to $1 \times 10^{-3}$ mg litre$^{-1}$ | katharometer, thermionic detector, electron capture detector | |
| Chlorosilanes and organochlorosilanes | infusorial earth, tiles, Celite 545, INZ-600, Sterchamol, treated DMDXC, Spherochrome, Chromaton NWA, nitrobenzene, benzophenone, liquid paraffin, diethyl- and dibutyl phthalates, tricresyl phosphate, silicone oils NF-M50150, DC-703, PFMS-4, F-169, FS-16, OE-4178, SF-96, DC-LS, K-3-0295, SKTFT-50, and E-301 | helium and nitrogen, argon with a water content up to $1 \times 10^{-3}$ mg litre$^{-1}$ | electrical conductivity detection, katharometer, flame-ionisation detector | 23-36 |
| Corrosive inorganic gases | PTFE, solid Kel-F polymer, silica gel, NaF, LiF, liquid Kel-F, oil. dimethyl galcarbonic ether of triethylene glycol, chlorofluorohydrocarbons | helium, nitrogen, and argon | nickel katharometer, thermistors coated with Teflon | 37-45 |

Thus specially activated 5 Å molecular sieve and phosphorus pentoxide may be regarded as the most effective drying agents in the analysis of readily hydrolysable compounds. The degree of drying of the carrier gas can be usefully inferred from the chromatograms of readily hydrolysable products, for example trichlorosilane.[52] When moisture is present in amounts exceeding $5 \times 10^{-4}$ mole %, two peaks due to trichlorosilane and its hydrolysis product (hydrogen chloride) appear on the chromatogram. When the degree of drying was inadequate, the sorbent was additionally dried by passing trichlorosilane vapour through the column.

In the drying of the carrier gas, account must be taken of the tendency for the moisture content in the carrier gas–sorbent system to reach equilibrium. The dew point in the carrier gas does not therefore characterise the moisture content of the system as a whole, which is the most important parameter.

We shall now consider a number of drying procedures. Thus, in order to prevent the decomposition of boron trichlorides in the chromatograph, the sample injection system is coated with Teflon and the connections between the latter, the column, and the detector are made of Teflon tubes [15]. The carrier gas is carefully dried by means of a molecular sieve and a trap cooled with a mixture of acetone and ice and is treated with 1% of boron trichloride†.

Table 2. Comparison of the drying capacities of various substances.

| Drying agent | Residual concentration of water vapour at 25°C, mg litre$^{-1}$ |
|---|---|
| Fused $CaCl_2$ | 0.36 |
| Granulated $CaCl_2$ | 0.14–0.25 |
| $Al_2O_3$ | 0.03 |
| $Mg(ClO_4)_2.3H_2O$ | 0.002 |
| Anhydrous $Mg(ClO_4)_2$ | 0.0005 |
| Molecular sieves | 0.0005 |
| Phosphorus pentoxide | 0.000025 |

In many cases the gas system of the chromatograph is dried by substances more readily hydrolysable than the compound analysed. For example, before the analysis of dichloro-(β-cyanoethyl)methylsilane, trichlorosilane or silicon tetrachloride are introduced several times into the apparatus after the column has been flushed with dry helium [35]. Alkylated boron derivatives are analysed after the entire system has been flushed with the carrier gas at 150°C and above, with subsequent repeated passage of boranes through the column [53]. On the other hand, in the analysis of readily hydrolysable compounds, for example, boron trichloride, the final drying is carried out using the compound analysed [54,55].

A scheme with circulation of the carrier gas [56] is of interest. The authors showed that the passage of 1.5 litres of the carrier gas (containing water at a concentration of $1 \times 10^{-4}$%) through the column at a rate of 50 ml min$^{-1}$ causes the decomposition of 0.002 ml of the bisisopropyl benzenechromium specimen. On the other hand, circulation of the carrier gas makes it possible to reduce its moisture content by its interaction with the first portion of the substance chromatographed. The employment of stepwise chromatography in the analysis of readily hydrolysable substances is also of considerable interest. In this case, hydrolysis does not affect the results of the quantitative analysis [52].

†We believe that the cooling of the carrier gas described above is not a rational procedure, because the drying capacity of molecular sieves is extremely high and there is a possibility of the formation of a mist in the trap, which would prevent the complete drying of the carrier gas.

As already mentioned, special requirements must be met by the solid carrier in the analysis of readily hydrolysable and corrosive compounds. In the first place, it is necessary to remove physically adsorbed moisture, which leads to the instantaneous hydrolysis of the substances analysed. However, drying should not remove the water which is used to deactivate the active centres of the carrier [57]. Thus it has been noted‡ that, in the analysis of boron trichloride on Celite (Chromaton) subjected to preliminary vacuum drying at 300°C, boron trichloride undergoes complete irreversible adsorption. The HCl peak is not then observed, which indicates the absence of moisture from both the system and the solid carrier. On the other hand, partial removal of water from the active centres of the solid carrier led to a sharp increase of the retention time of boron trichloride (the peak remained asymmetric). In the drying of the solid carrier, it is therefore necessary to select optimum conditions.

Various methods are used to eliminate the adsorption activity of the carrier. Together with the generally accepted procedures described above, the most effective method for modifying the solid carrier involves its treatment with the substances analysed. In the analysis of primary amines, the preliminary steps involve the repeated admission of the mixture analysed, after which quantitative analysis becomes possible [58]. A study of the influence of irreversible adsorption on the analysis of 1-butanol showed that the error in the determination of 1-butanol decreases appreciably with the increase of the number of successive analyses. If the strongly adsorbed compounds are then desorbed by heating the solid carrier in a stream of carrier gas, saturation is again necessary in the subsequent analyses [59].

The INZ-600 carrier modified by chloromethylsilanes has been used in the analysis of readily hydrolysable chlorosilanes and organochlorosilanes. It was shown that the best modifying agent is dichlorodimethylsilane. [52,60–62] Boron trichloride has been analysed on non-modified Celite 545. [55] In subsequent studies, additional treatment of the solid carrier with boron trichloride proved to be necessary in order to obtain reproducible quantitative results. The method of treatment was as follows: the solid carrier was dried *in vacuo* at 200°C for 3 h, after which it was treated with boron trichloride vapour for 1 h, freed from the trichloride which failed to be adsorbed on the surface by a stream of dry carrier gas, and the stationary phase was deposited (avoiding contact with air). Fig. 1 presents two chromatograms for boron trichloride obtained on untreated and treated carriers.

The solid carrier is also modified when substances of a similar type are introduced into the carrier gas. It is recommended that, in the analysis of amines, a volatile amine or ammonia be added to the carrier gas [63]. In another investigation [15], 1% of boron trichloride was added to the carrier gas in order to achieve additional drying. In this case, boron trichloride probably also behaves as a modifying agent in relation to the carrier surface.

It is claimed [64] that diatomite carriers such as Celite 545 and Chromosorb are unsuitable for the analysis of hydrogen chloride and chlorine even after they have been washed with acid. Further studies showed that this view is

‡N. I. Ivanova, L. D. Prigozhina, S. V. Syavtsillo, G. V. Avdonin, and L. A. Frangulyan, "Protsessy v Khromatograficheskikh Konokakh" (Processes in Chromatographic Columns), Karpov Physicochemical Institute, Moscow, 1975, No. 26, p. 65.

invalid[65-69]. However, the usual silanised diatomite carriers do not always permit the separation of corrosive mixtures. Carriers based on polymeric materials, a major proportion of which have a hydrophobic surface and low adsorption and catalytic activities, are used to separate such mixtures. Carriers based on polytetrafluoroethylene[5], which is manufactured in the USSR under the names Ftoroplast, Polykhrom-1, and Polykhrom-2, have found extensive applications. Outside the USSR, analogous materials are manufactured under the names Teflon (USA), Fluon (England), Algoflon (Italy), Hostaflon (German Federal Republic), and Soreflon (France). Methods have been described[70] for the preparation of an effective Teflon carrier (Polykhrom-1 and Polykhrom-2) and it has been shown that they can be used for the separation of phosphorus, silicon, germanium, strontium, titanium, and arsenic halides and oxide halides. PTFE type carriers are also used for the analysis of corrosive inorganic gases (chlorine fluorides, chlorine oxide fluoride, hydrogen fluoride, hydrogen chloride, and chlorine)[71-75].

Mainly gas–liquid chromatography is used for the analysis of readily hydrolysable compounds. Gas–adsorption chromatography (GAC) has been applied in only a few studies. Graphite, heated beforehand in a stream of chlorine and then evacuated, is used in the analysis of metal chlorides[18]. Studies have shown[76-78] that GAC employing Carbochromes and Silochromes is the best method for the separation of structural and steric isomers of organic derivatives of Group IVB elements. Studies have been made on the analysis of reactive substances on a graphitised carbon black[79]. Furthermore, artificial diamond has been used as the solid carrier for the analysis of hydrogen fluoride, hydrogen chloride, fluorine, and chlorine trifluoride [80], while the alkali metal fluorides KF, RbF, and CsF have been used for the separation of $SF_4$, $SOF_2$, $COF_2$, and $SO_2F_2$.[81]

In the analysis of readily hydrolysable unstable substances, the stationary phase must not be hygroscopic and must not contain hydroxy-groups; it must be thermally stable under the conditions of the gas-chromatographic experiment and must not react with the compounds analysed. Before being deposited on the solid carrier, the stationary phase is dried. In the analysis of chloromethylsilanes, the stationary phase was subjected to preliminary distillation from phosphorus pentoxide and stored over anhydrous sodium sulphate[82]. The high-boiling liquids employed as stationary phases are dried by evacuation at appropriate temperatures. Nitrobenzene was used as the stationary phase in early studies on the analysis of chlorosilanes and organochlorosilanes[23-29,81-83]. However, despite the satisfactory selectivity of this phase in relation to chlorosilanes, it is highly volatile (b.p. 210°C); it can be used only at room temperature and for a short time, since the separating capacity of the column is impaired as the stationary phase is carried away.

Stationary phases based on organosilicon liquids, which are hydrophobic, thermally stable, and exhibit different polarities depending on the nature of their organic group, began to be used to an increasing extent[25-35,84,85]. Alkyl-, aryl-, and fluorine-containing liquid polysiloxanes were tested as stationary phases for the analysis of organochlorosilanes. It was shown that the separating capacity in relation to chromomethylsilanes increases with the polarity of the stationary phase. Liquids containing fluorinated groups, for example the FS-16 liquid, exhibit a high selectivity. In terms of selectivity, the FS-16 liquid is close to organic stationary phases such as diethyl and dibutyl phthalates. The PFMS-4 and PFMS-6 liquids as well as silicone rubbers and elastomers are used in the analysis of more high-boiling organochlorosilanes. Silicone oil 703 has been employed to analyse boron trichloride, diborane, dichloroborane, and monochlorodiborane, while glycols, the Apiezon grease, phthalates, sulphides, and phosphates reacted with these compounds[54].

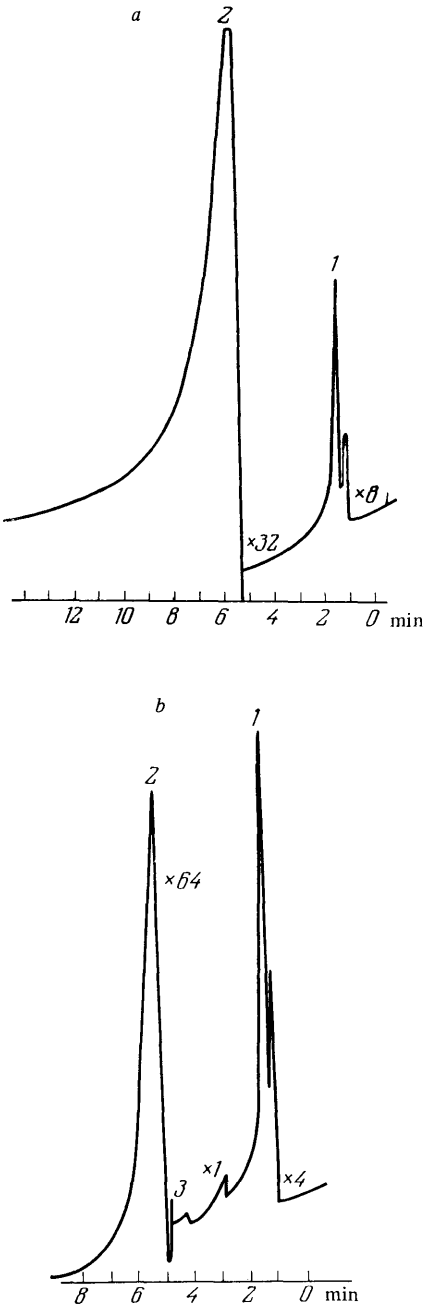

**Figure 1.** The chromatogram of $BCl_3$ on untreated (*a*) and $BCl_3$-treated (*b*) Chromaton N: 1) HCl; 2) $BCl_3$; 3) $COCl_2$.

**Table 3.** The interaction of hydrides with water and oxygen.

| Group in Periodic System | Element | Interaction with water | | Interaction with oxygen | |
|---|---|---|---|---|---|
| | | nature of interaction | example of reaction | nature of interaction | example of reaction |
| III, IV | B, Si | decomposition with evolution of $H_2$ | $SiH_4 + 4H_2O \rightarrow 4H_2 + Si(OH)_4$ | explosive decomposition | $SiH_4 + 2O_2 \rightarrow SiO_2 + 2H_2O$ |
| IV, V | Sn, Sb, P, As, Ge | does not react | — | quiet oxidation | $4AsH_3 + 6O_2 \rightarrow 2As_2O_3 + 6H_2O$ |
| V | N | addition of $H^+$ ions | $NH_3 + H_2O \rightleftarrows H_4^+ + OH^-$ | — | — |
| VI | O, S, Se, Te | weak oxidative dissociation | $H_2S \rightleftarrows H^+ + HS^-$ | weak interaction | $2H_2Se + 3O_2 \rightarrow 2SeO_2 + 2H_2O$ |
| VII | F, Cl, Br, I | vigorous acid dissociation | $HCl \rightleftarrows H^+ + Cl^-$ | — | — |

Only a few studies have been made on the analysis of the very readily hydrolysable boron trichloride and extremely contradictory results have been obtained.

Some authors believe [86] that boron trichloride is bound in an involatile complex with PMS-100 which conflicts with the results of other investigations [54,87,88] where liquid polyorganosiloxanes were used as the stationary phases in the analysis of this compound. The authors of this review showed that the hydrophobic properties and lack of reactivity of liquid silicones permitted the employment of these compounds, such as VKZh-94, PMS-100, and E-301, for the analysis of boron trichloride, boron hydrides, and alkylated boron derivatives§. Readily hydrolysable boron hydrides have been analysed in most cases on silicone stationary phases [6-13]. It has been shown that liquids containing unsaturated compounds and hydroxy-compounds cannot be used as stationary phases.

However, despite the careful selection of the stationary phase and its preparation, analysis cannot be achieved immediately. The above procedure, involving the drying of the system by passing the most readily hydrolysable component through it before analysis, is applicable also in the final drying of the stationary phase. Apart from the generally adopted silicone stationary phases [22,87,88], the $BiCl_3$–$PbCl_2$ eutectic mixture, melting at 217°C, has been used in the analysis of metal chlorides and for the separation of titanium tetrachloride and antimony trichloride.

Thus the assortment of stationary phases for the analysis of readily hydrolysable substances is limited. For this reason, their selection for the analysis of various groups of substances is highly specific.

## III. THE USE OF HYDROLYTIC REACTIONS FOR ANALYTICAL PURPOSES

Hydrolytic reactions can be used in the analysis of readily hydrolysable compounds for the following purposes: (1) when a direct determination is impossible; (2) in the detection of non-hydrolysable substances which do not exhibit corrosion activity; (3) in order to increase sensitivity by employing detectors selective in relation to the hydrolysis products.

The hydrolytic reaction is employed in the analysis of organometallic derivatives of Group I–IV elements (organolithium, organosodium, organopotassium, organomagnesium, organocalcium, and organoaluminium compounds) in order to convert these substances into stable volatile compounds, which are then subjected to gas-chromatographic analysis. Thus vinyl-lithium was determined on the basis of its hydrolysis product—ethylene [89]. The hydrolytic reaction has been used for the analysis of organopotassium, organolithium, and organosodium compounds [90-95]. In the analysis of complexes of phenylcalcium and *m*-tolylcalcium iodides with dioxan and of phenylcalcium in tetrahydrofuran (THF) solution, their hydrolysis products ($C_6H_6$ and $C_6H_5CH_3$) were analysed by gas–liquid chromatography [96]. Ethylmagnesium iodide was hydrolysed by phosphoric acid in the reactor and the gaseous reaction products were then injected into the chromatographic column [97].

Different versions of the analysis of trialkylaluminium compounds, based on their reaction with hydroxy-compounds, which leads to the formation of the corresponding hydrocarbons, have been described [98]. Rapid analysis of $C_1$–$C_5$ aluminium and zinc alkyls has been achieved on the basis of their gaseous hydrolysis product [99,100]. A method has been proposed for the determination of (iso-$OC_4H_9$)Al(iso-$C_4H_9$)$_2$ and (iso-$OC_4H_9$)$_2$Al(iso-$C_4H_9$) in tri-isobutylaluminium on the basis of the hydrolysis product—the alcohol [101]. Alkylaluminium derivatives have also been analysed using their hydrolysis products [102,103].

Since substances containing active hydrogen are hydrolysed, quantitative gas-chromatographic determination of, for example, B–H and Si–H bonds is possible on this basis. A rapid method for the quantitative determination of the total content of B–H bonds in chloroboranes and boron hydrides, based on the hydrolysis of these substances followed by the detection of hydrogen with a thermistor-based thermal conductivity detector, has been developed [104]:

$$BHCl_2 + 3H_2O \rightarrow B(OH)_3 + 2HCl + H_2,$$
$$B_2H_5Cl + 6H_2O \rightarrow 2B(OH)_3 + HCl + 5H_2,$$
$$B_2H_6 + 3HOH \rightarrow 2B(OH)_3 + 3H_2 \quad \text{etc.}$$

A method has been described for the determination of hydride hydrogen in boron compounds and of hydroxyl hydrogen in alcohols [105]. Si–H bonds are determined by the gas-chromatographic estimation of hydrogen after the hydrolysis of the substances in the presence of KOH. [106]

Diborane and dichloroborane have been determined in hydrogen, nitrogen, and boron trichloride using hydrolytic reactions [107]. The same report [107] describes the apparatus and experimental technique. Furthermore, there is a possibility of reactions with the HCl hydrolysis products. Hydrogen chloride mixed with acetylene and methylene chloride was determined on the basis of the $CO_2$ formed via the reaction [108]

$$HCl + NaHCO_3 \rightarrow NaCl + H_2O + CO_2.$$

§N. T. Ivanova, L. D. Prigozhina, S. V. Syavtsillo, G. V. Avdonin, and P. A. Frangulyan, Symposium, "Uspekhi Gazovoi Khromatografii" (Advances in Gas Chromatography), Kazan, 1975, No. IV, Part 1, p. 75.

The same reaction can be carried out with the hydrogen chloride evolved after the hydrolysis of the corresponding compounds and the reaction mechanism can be represented as follows:

$$CO_2 \xrightarrow[\text{catalyst}]{H_2,\ T} CH_4.$$

This makes it possible to improve the sensitivity of the determination by using the more sensitive flame-ionisation detector [109].

In the analysis of readily hydrolysable reactive substances, the problem arises of the determination of stable organic and inorganic impurities. The determination of the impurities requires the employment of highly sensitive detectors, or concentration of the impurities, or reactions must be carried out with the impurities in order to improve the sensitivity of the analysis. When highly sensitive ionisation detectors such as the thermionic detector (TID), the electron capture detector (ECD), and the flame-ionisation detector (FID) are used, the entry of the main organoelement derivative into the detector is prevented, since this puts it out of order. Thus microimpurities consisting of chlorinated hydrocarbons of the methane series have been determined in boron trichloride using a thermionic detector after binding $BCl_3$ into a complex with diphenylamine, which was deposited (in an amount corresponding to 20%) on the INZ-600 carrier. [110] Certain organic chloroderivatives and inorganic substances have been determined in boron trichloride with the aid of a thermionic detector also after their binding into involatile complexes [86]. Using the ability of arsenic trichloride to form a complex with tricresyl phosphate, its organic impurities were determined with the aid of a flame-ionisation detector. Chromosorb W with 15% of tricresyl phosphate was placed in the initial section of the column, while the rest of the column was filled with Chromosorb, containing 10% of PEG-400. [111] In addition, a method is used where the main substance is removed after emerging from the column and before reaching the detector. $CCl_4$, $C_6Cl_6$, $C_2H_5Cl$, and $C_2H_4Cl_2$ impurities in arsenic trichloride have been determined with the aid of a flame-ionisation detector, $AsCl_3$ being removed before reaching the detector [112].

## IV. ANALYSIS OF READILY OXIDISABLE SUBSTANCES

The next group of substances which must be analysed by gas chromatography comprises those which are oxidised by atmospheric oxygen. They include boron, silicon, phosphorus, arsenic, tellurium, and selenium hydrides as well as alkyl derivatives of boron, aluminium, gallium, and silicon. However, the majority of oxidisable substances are also capable of interacting with water to some extent. Table 3 presents examples of the interaction of hydrides with water and oxygen.

The oxidation reaction proceeds with formation of water and the solid metal oxide, i.e. with decomposition of the substance. Special precautions are therefore necessary in the chromatographic analysis of certain substances in order to prevent the oxidation reaction. In gas-chromatographic analysis, the products may be oxidised by the oxygen contained in the carrier gas, adsorbed on the solid carrier, and dissolved in the stationary phase. Furthermore, the products may also be oxidised outside the chromatograph at the instant of the removal and injection of the sample. The gases produced by the USSR industry and used as carrier gases, namely helium, nitrogen, and argon, contain the oxygen impurity in amounts of 0.001 to 0.003, 0.1–1, and 0.003–0.4% respectively. For a valid analysis, one must therefore select a carrier gas with the minimum oxygen content and, when necessary, additional elimination of oxygen must be carried out.

In the analysis of silicon, germanium, arsenic, and phosphorus hydrides, the carrier gas was freed from moisture and oxygen by means of a system [46] comprising granulated copper, KSK silica gel, active granulated alumina, 5 Å molecular sieves, and the sodium-potassium eutectic mixture. This made it possible to eliminate oxygen from nitrogen down to $1 \times 10^{-3}$%. It is noteworthy that in most instances substances with a tendency towards being oxidised are also hydrolysed. For this reason, a system of drying and oxygen-removing columns is used as a rule. In another study [47], the authors thought that the elimination of oxygen in a granulated copper column alone was sufficient for the analysis of silicon, germanium, phosphorus, and arsenic hydrides.

It has been shown that the removal of the oxygen impurity from technical helium is necessary, since the presence of oxygen (0.003%) lowers the sensitivity of the determination of phosphine approximately by an order of magnitude. Oxygen must be removed from helium at 300°C on a column 1 m long and 3 cm in diameter and filled with a granulated chromium–nickel catalyst. The catalyst was reduced beforehand in a stream of hydrogen until the complete elimination of the water evolved. Table 4 presents the results of the calibration of the chromatograph by Lovelock's method against phosphine with and without the removal of oxygen from helium. It is seen that the area of the peak corresponding to the same concentration of phosphine (0.08%) is almost ten times greater when helium is additionally freed from oxygen. Evidently the lower the concentration of the substance, the more harmful the presence of oxygen in the carrier gas; this is particularly the case in the analysis of impurities. With the aid of such purification, it has been possible to achieve a sensitivity in relation to arsine (by the direct method) of $5 \times 10^{-3}$%.

Furthermore, it has been suggested that MnO, obtained from manganese acetate, be used for the absorption of oxygen from the gas stream [113]. According to the authors, this makes it possible to reduce the concentration of oxygen in nitrogen to $10^{-7}$%.

Table 4. The influence of the elimination of oxygen from the carrier gas on the analytical results.

| Calc. concn. of phosphine, % | Phosphine peak areas, cm² | |
|---|---|---|
| | with elimination of $O_2$ | without elemination |
| 3.87 | 38.4 | 28.6 |
| 2.38 | 23.8 | 15.5 |
| 1.51 | 15.2 | 8.6 |
| 0.77 | 7.6 | 2.38 |
| 0.28 | 2.88 | 0.35 |
| 0.16 | 1.54 | 0.16 |
| 0.08 | 0.81 | 0.08 |

However, the carrier gas always contains some residual oxygen. In order to prevent the reaction or reduce the percentage decomposition of the substance analysed, the method involving a decrease of contact time is used. Thus nitrogen freed from oxygen and moisture, a column 50 cm long at 34.5°C, and Celite 545 with 30% of silicone 702 were used in the separation of boron hydrides ranging from $B_2$ to $B_5$. [7] By passing the separated

components through the chromatographic column again, it was established that the compounds $B_2H_6$, $B_4H_{10}$, and $B_5H_9$ are not decomposed at all under the conditions of the analysis, while $B_5H_{11}$ decomposes to the extent of 10% during each pass through the column. We believe that drying with Anhydrone, suggested in the above investigation for the analysis of boron hydrides, is inadequate, and this may be the reason for the decomposition of $B_5H_{11}$.

The scheme involving the circulation of the carrier gas discussed in the preceding section is of undoubted interest also for the elimination of oxygen from the carrier gas [56]. The carrier gas is freed from oxygen following the injection of the first samples containing the readily oxidisable compounds to be analysed. The reactivities of such substances are not the same and an individual approach to the selection of drying agents and of the oxygen-elimination system is therefore necessary [114,115].

In the analysis of boron trialkyls, attention was drawn to their extremely high reactivity in relation to moisture and oxygen, which necessitated the "complete" absence of the latter [114,115]. However, it is known that trimethylboron is resistant to water and is not oxidised in air and that triethylboron and tripropylboron are less steadily hydrolysed than boron hydrides and triethyl aluminium [116]. One of the authors of the present review [117] tested the influence of the removal of oxygen from the carrier gas by the chromium–nickel catalyst on the decomposition of triethylboron. The experiments demonstrated a slight change in the results of the analysis for the main product (97.0% with elimination of oxygen and 96.9% without). The "complete absence" of oxygen and moisture is therefore not obligatory in the analysis of boron alkyls. The use of technical helium dried over phosphorus pentoxide without additional elimination of oxygen is quite feasible.

Table 5. Conditions in the chromatographic analysis of oxidisable substances.

| Substances analysed | Carriers and stationary phases | Carrier gas and requirements which it must meet | Detector | References |
|---|---|---|---|---|
| Boron, silicon, germanium, phosphorus, arsenic, selenium, tellurium, and tin hydrides | Celite, Chromosorb W, Embacel, liquid silicones Apiezones, BAU charcoal, Polysorb-1 | helium, nitrogen, and argon freed from $H_2O$ and $O_2$ to within $1 \times 10^{-3}$% | katharometer, FID PPD | 6,10,13,46,47,53, 79,113,117,118, 121–124 |
| Alkylated boron, aluminium, gallium, tin, and silicon derivatives | refractory brick, Polychrom-1, Kieselguhr, Stercha-mol, Celite, liquid silicones | ditto | katharometer | 113–116 |

The requirements which must be met by the solid carrier in the analysis of substances showing a tendency towards both hydrolysis and oxidation (boron hydrides, alkylated derivatives of boron, aluminium, and gallium, and silicon hydrides), on the one hand, and substances which can only be oxidised (phosphorus, arsenic, tellurium, and selenium hydrides), on the other, are different. In the former case, apart from the drying procedures described in the previous section, the carrier must be degassed in order to remove physically adsorbed oxygen. Furthermore, the impurities in the solid carrier can serve as oxidation catalysts. In the analysis of such products, one therefore uses as a rule solid carriers such as Celite 545 [9], Embacel [10,11], and Chromosorb W. [12,13] In the latter case, one can use gas-adsorption chromatography. Thus the adsorption of silicon, arsenic, germanium, and phosphorus hydrides on BAU activated charcoal has been investigated [118,119] in the temperature range from 0° to 100°C, and it was shown that the substances do not decompose in this temperature range and undergo physical adsorption. This justified the employment of BAU charcoal as the adsorbent in the analysis of the above hydrides.

A necessary condition for the employment of gas-adsorption chromatography is careful elimination of adsorbed oxygen from the adsorbent by evacuation at high temperatures, and careful removal of oxygen from the carrier gas in order to prevent the adsorption of oxygen on the solid carrier. In one investigation [79], graphitised carbon black was subjected to a preliminary treatment with hydrogen at 1000°C. This process should have limited the number of active centres formed by the surface oxygen complexes which are always present on the surface of adsorbents. In this case, the carbon black behaves as an inert carrier.

Readily oxidisable substances are separated on polymeric sorbents. Polysorb-1 has been used to determine arsine and phosphine in the effluent gases from phosphorus furnaces and as impurities in acetylene [120,121]. The requirements which must be met by the stationary phase are analogous to those mentioned previously and, in addition, the stationary phase must not dissolve oxygen. The method of preparation involves vacuum heat treatment followed by stabilisation of the column. Mainly liquid silicones and Apiezon are recommended as the stationary phases for the analysis of readily oxidisable substances [10,12,13,53,113,122–124].

In certain cases, the oxidation of the main substance does not interfere with the analysis, for example in the determination of stable non-oxidisable impurities in a readily oxidisable compound. Thus, in the determination of hydrocarbons in arsine [125], the mixture was passed through a tube containing copper heated to 130°C, where arsine was bound and the impurities were then separated on a chromatographic column and detected with the aid of a flame-ionisation detector. In addition, one sometimes uses the method where the main reactive substance is removed before entering the detector [126], and stable impurities are detected. The impurities are also concentrated by employing two columns, where silicon, boron, or germanium hydrides are separated in the first column from the organic impurities, which are collected in a cooled trap and then separated on the second column: the hydrides are removed and subjected to thermal decomposition [127].

Table 5 presents the conditions necessary for the chromatographic analysis of oxidisable substances.

## V. ANALYSIS OF SUBSTANCES CAPABLE OF THERMAL AND CATALYTIC DEGRADATION AND ISOMERISATION

Chromatographic analysis of substances showing a tendency towards thermal and catalytic degradation is possible when a number of conditions preventing the occurrence of such reactions are maintained. These include the employment of reduced evaporator, column, and detector temperatures, the use of inert and catalytically inactive solid carriers and stationary phases, careful

selection of the material for the metering device and column, and purity of the carrier gas. The requirements which must be met by the carrier gas are similar to those described above. In contrast to the hydrolytic and oxidation reactions, which are as a rule instantaneous, the catalytic and thermal degradation and isomerisation reactions take place over a period of time. In the analysis of such substances it is therefore important to bear in mind the duration of the analysis.

The gas-chromatographic method has been used in the analysis of thermally unstable substances. Dichloroborane and monochlorodiborane are known to decompose at room temperature [128]. In the separation of a mixture of dichloroborane, monochlorodiborane, hydrogen chloride, boron trichloride, and hydrogen, a temperature of 0°C, and a column 10 mm long and 6 mm in diameter filled with Chromosorb W containing a silicone oil as the stationary phase were therefore used. It has been suggested [107] that diborane and dichloroborane be determined in hydrogen, nitrogen, and boron trichloride below 0°C. The hydrogen–diborane or hydrogen–dichloroborane–boron trichloride sample is directed to a column 25 cm long, filled with quartz sand, and cooled to −173°C, where diborane (or boron trichloride–dichloroborane) condenses, while hydrogen does not and passes subsequently through the hydrolysis column (molecular sieves treated with ethanol) and is detected. The condensation column is then warmed and the diborane (or boron trichloride–dichloroborane) sample is directed to the hydrolysis column, where it decomposes with evolution of hydrogen, which passes to the detector. This permitted the determination of diborane and dichloroborane with a high sensitivity.

The metal carbonyls $Fe(CO)_5$, $Ni(CO)_4$, $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ are readily oxidised and thermally unstable. However, at a reduced temperature and when the percentage impregnation of the stationary phase was low, it was possible to analyse them by gas–liquid chromatography. A column 2 m long and 6 mm in diameter, filled with molybdenum glass containing 0.5% of liquid polymethylethylsiloxane (VKZh-94), was used at 30°C for the analysis of iron pentacarbonyl and nickel tetracarbonyl, boiling at 102° and 42°C respectively [129]. Chromium, molybdenum, and tungsten carbonyls were separated at 76°C on a 3 m × 3 mm column filled with 10% of 1,2,3-tris-2-cyanoethoxypropane on diazolide [130].

As a rule thermally unstable substances undergo hydrolysis and oxidation at the same time. Their chromatographic analysis therefore requires a combined approach involving precautions against both hydrolysis and oxidation. Substances of this kind include alkylated derivatives of boron, aluminium, and gallium. The possibility of using gas-chromatographic analysis for the investigation of catalytic exchange reactions between boron trialkyls and for the determination of the rates of these reactions has been demonstrated [53,114]. This was achieved by employing high carrier gas flow rates. At relatively low temperatures, boron alkyls are known to split off olefins via the reaction

$$R_2BCH_2CH_2R' \rightarrow BR_2H + CH_2 = CHR' \ .$$

The selection of the temperature of the metering device and the column is therefore very important in the analysis of these substances. It is claimed [37] that the above reaction does not play a significant role in gas-chromatographic analysis. The authors of the present review [117] determined the maximum permissible evaporator temperature, which is 100°C for tripropylboron (B.p. 160°C) and 80°C for triethylboron (B.p. 96°C). The analysis of these substances is carried out under programmed conditions. Methyldiboranes have been determined at 0°C. [131]

Not only temperature parameters but also the selection of the solid carrier and its treatment are important for substances undergoing thermal and catalytic degradation and polymerisation. A gas-chromatographic method has been proposed for the analysis of dichloro-(β-cyanoethyl)-methylsilane, which boils at 210°C and is extremely reactive, being readily hydrolysed by water and polymerising at elevated temperatures and in the presence of a number of metals [35]. In order to prevent the decomposition of the substance, a glass tube was inserted into the metallic metering device of the chromatograph, which was responsible for the non-reproducibility of the chromatograms obtained, in such a way that its end entered the initial section of the chromatographic column; the temperature of the metering device did not exceed 150°C, because decomposition was observed already at 180°C. Before analysis, the column was flushed with the dry carrier gas at 200°C for 2 h and the sorbent was then additionally dried by introducing several trichlorosilane samples in succession; the column was stabilised by injecting samples of the substance to be analysed.

A direct gas-chromatographic method for the analysis of triethylaluminium and triethylgallium, which are also readily oxidised and thermally unstable, has been proposed [132]. The boiling point of triethylaluminium is 186.6°C and it begins to decompose in an inert atmosphere already at 120–125°C. The authors propose a method for the removal and injection of these substances into the chromatograph without coming into contact with air, but do not indicate the range of evaporator temperatures and do not quote quantitative data, which precludes an assessment of the reliability of this procedure. In most studies, reaction chromatography is used for the analysis of organoaluminium compounds [99–103].

The fundamental conditions in the selection of the solid carriers are its complete catalytic inertness, the employment of modifying carriers [133], and the stabilisation of the sorbent by passing through the column compounds resembling those to be analysed. Thus, in the analysis of bisethylbenzenemolybdenum, the column was first modified by passing bisarene complexes of chromium through it, 3–5 analyses were carried out, and the column was then modified [134].

An interesting procedure has been proposed for the analysis of organophosphorus compounds, which tend to isomerise [135]. An isomerisation inhibitor was added to the stationary phase, which permitted the gas-chromatographic analysis of these substances. The separation of dichloroborane and monochlorideborane [54] at 40°C on a column filled with Chromosorb containing 30% of n-hexadecane, saturated with boron trichloride, is based on the same principle. Since it was known that dichloroborane and monochlorodiborane are most stable in the presence of boron trichloride, the saturation of the stationary phase by the latter made it possible to achieve the separation [54].

A decrease of the resonance time of the unstable substance in the column should undoubtedly improve the results results of the chromatographic analysis. A study has been made [136] of the influence of the solid carrier, of the percentage content of the stationary phase and its nature, and of the residence time of the sample in the column (i.e. the carrier gas flow rate) on the separation of the isopropylphenyl hydroperoxide. It was shown that tricresyl phosphate (TCP), which has the smallest acid number, is the best stationary phase; common salt and silanised Chromosorb W were used as the solid carriers and it was

shown that the degree of decomposition diminishes with increase of the percentage of the stationary phase and with the carrier gas flow rate. Conditions were selected on the basis of the percentage decomposition for the separation of a mixture of isopropylbenzene, acetophenone, and isopropylphenyl hydroperoxide. Glass columns, high carrier gas flow rates, and low temperatures are as a rule employed in the analysis of hydroperoxides. Thus *n*-butyl hydroperoxide was isolated on a glass column (Celite with 30% of dinonyl phthalate) at 40–60°C and a helium flow rate of 120 ml $min^{-1}$, the sample being injected directly into the column[137]. A mixture containing isopropylphenyl hydroperoxide was analysed on Chromosorb treated with dichlorodimethylsilane (DCDMS) with 1.5% of TCP at 80°C; after preliminary flushing of the column for 8 h at 100°C and the injection of 15–16 hydroperoxide samples into the chromatograph, the decomposition of isopropylphenyl hydroperoxide was not observed[138]. Ethylphenyl hydroperoxide was analysed on Chromaton treated with DCDMS containing 5% of poly(ethylene glycol) (PEG) distearate at a nitrogen flow rate of 210 ml $min^{-1}$.[139]

We considered specially the procedures used in the analysis of organic peroxides which are thermally and catalytically unstable, since analogous methods are used in the analysis of organoelement compounds. For example GLC analysis of alkylmercury derivatives showed that RHgX and $R_2Hg$ are effectively separated on glass and metallic columns when the sample size is $10^{-5}$ g; when the sample size is reduced to $10^{-8}$ g, RHgX decomposes on a steel column[140]. Similar experiments showed that stable MgHgX peaks may be obtained by increasing the mass of the chromatographed sample[141]. To prevent a long residence time of the unstable hydrides in the column, a short column (40 cm long, containing Celite with 30% of silicone 702) was used in a study of the pyrolysis of diborane[7].

## VI. IDENTIFICATION OF UNSTABLE COMPOUNDS AND QUANTITATIVE INTERPRETATION OF CHROMATOGRAMS

Several methods are available for the identification of compounds. They include identification on the basis of chromatographic parameters, i.e. the determination of the dependence of the retention time on the nature of the substance and the determination of the relation between the retention volume and the number of similar groups or atoms (analogously to the relations observed in homologous series of organic compounds), preparative isolation followed by the employment of physicochemical methods of analysis, and chromato-mass-spectrometry. The use of chromatographic relations (the dependence of the retention volume on the number of atoms and on the boiling point) is difficult, because a high reliability of the analysis requires the determination of the retention volume in stationary phases of different polarities and at different temperatures. However, this is not always possible, since the number of stationary phases and the feasible temperature ranges are limited in the analysis of unstable substances. Furthermore, the extremely high reactivity of the products may distort the measured retention volumes when the sample interacts with the solid carrier and the material of the column.

However, attempts to find relations which would assist in the identification of substances of this kind have been made. For example, the behaviour of alkoxychlorosilanes $Cl_nSi(OR)_{4-n}$ (where $n$ = 1, 2, 3, or 4 and R = Me, Et, Pr, or Bu) at 50–90°, 80–120°, 150–190°, and 160–200°C respectively has been studied by GLC on 1 m × 3 mm columns filled with different weakly polar and polar stationary phases on Resorb and Hexasorb[142,143]. When the fluorosilicone FS-16 was used as the stationary phase, a linear relation was obtained between the heats of solution and boiling points of alkoxychlorosilanes, which may be used for the identification of these compounds. The retention indices of alkyl-, aryl-, akylaryl-, and chloroaryl-chlorosilanes have been determined[144,145] and it has been shown that the indices for substances on a non-polar stationary phase are satisfactorily correlated with their boiling points. The retention volumes of decaborane and its 1- and 2-halogeno-substituted derivatives $B_{10}H_{13}X$, where X = Cl, Br, or I, have been determined at 141°, 151°, and 161°C.[146] Using these data and the specific retention volumes of pentadecane and eicosane, the retention indices were calculated. The sorbent employed was Chromosorb W with 3% of silicone oil QF-1. It was shown that Carbowax 20 M, polyesters, and unsaturated compounds react with the substances analysed.

The retention indices of boron hydrides ranging from $B_2$ to $B_{10}$ have been calculated for a column with 6% OV-17 on Chromosorb. It was found that the indices vary approximately linearly with the number of boron atoms in the boron hydride molecules, which made it possible to identify hexaborane in the mixture, the result being subsequently confirmed mass-spectrometrically[12]. Linear relations have been obtained between the logarithm of the absolute retention volume ($\lg V_g^{abs}$) and the number of atoms in silicon hydrides from $Si_2$ to $Si_6$ and between the logarithm of the relative retention volume ($\lg V_g^{rel}$) and the number of germanium atoms in germanium hydrides and silicogermanes[147]. The data for metal chlorides are contradictory. Thus it has been found[148] that the variation of $\lg V_g^{abs}$ with the boiling points of Si–Ti tetrachlorides is non-linear, while other workers[149,150] obtained a linear relation between $\lg V_g^{abs}$ for metal tetrachlorides and the reciprocal of the absolute column temperature ($1/T$), the boiling point, and the molecular refraction. There are also contradictory data for organotin compounds. It was found in a study of the chromatographic properties of $Me_4Sn$, $Et_4Sn$, and $Bu_4Sn$ on eight stationary phases that the dependence of $\lg V_g$ on $1/T$ and the number of carbon atoms in the molecule is linear[151], while another investigation[152] demonstrated a non-linear variation of $\lg V_g$ for compounds of the type $R_4Sn$ with the total number of carbon atoms.

Since the temperature and the stationary phase cannot always be varied in the analysis of unstable compounds, which is necessary in qualitative analysis, the preparative isolation of the unknown compounds followed by their identification by infrared spectroscopy, mass-spectrometry, etc. is the most reliable procedure. Comparative chromatography combined with infrared spectroscopic analysis of the compounds isolated has been used to identify admixtures in dichlorodiphenylsilane and trichlorophenylsilane[153]. Certain compounds, obtained in the direct synthesis of chloromethylsilanes, were identified by preparative gas chromatography followed by the study of their physicochemical constants, elemental composition, and infrared spectra[154]. Chromato-mass-spectrometry has been used to identify trialkylboranes[155] and boron hydrides[156].

The specificity of the chromatographic analysis of unstable compounds is also reflected in the quantitative interpretation of the chromatograms. The method of absolute calibration, normalisation without the introduction of calibration coefficients, and, more rarely, the internal standard method are used in quantitative analysis. When an absolute calibration is carried out, it is necessary to prepare artificial mixtures. For substances with high vapour pressures and boiling points up to 100°C, a vacuum system for the preparation of the calibration mixture is used. This procedure, proposed for the preparation of a calibration mixture of nickel and iron carbonyls [129], can be modified as a function of the reactivity of the product. A similar system can be made wholly from glass and metallic taps can be replaced by glass and Teflon taps[50,51]. Provision can be made for several flasks at once, in which the calibration mixtures are prepared. For substances with a tendency towards oxidation accompanied by explosion, the mixtures are usually prepared in metallic cylinders, their composition being followed from the pressure. Naturally the material of the cylinder should not react with the mixture. Finally, the exponential dilution method proposed by Lovelock [157] is used for the calibration.

In the calibration of sulphur compounds, a method is used which combines permeability and exponential dilution. It has been shown that the application of the exponential dilution method alone with injection of the sample into the vessel from a syringe does not yield a result with an error less than 5%. [158] On the other hand, the combination of the two methods results in a relative standard deviation not exceeding 1%. When calibration mixtures of readily hydrolysable compounds are prepared, there is a risk of an error due to their hydrolysis during the preparation of the mixture. In the study of the possibility of calculating low concentrations of readily hydrolysable chloromethyl- and chlorophenyl-silanes by a normalisation method without calibration coefficients, the errors were determined and the limits of the applicability of the method were found [159]. It was shown that, in the analysis of trichloromethylsilane (TCMS) microimpurities in chlorodimethylsilane (CDMS) up to a content of 0.75%, the systematic absolute error associated with failure to take into account the coefficients does not exceed 0.10%, which implies that, in the analysis of commercial organosilicon monomers containing 98–99% of the main substance, the concentrations of the impurities may be calculated with adequate accuracy by the normalisation method without taking into account calibration coefficients. Calculations by the normalisation method from the areas without the use of calibration coefficients have been employed by various investigators in the analysis of chlorosilanes [31], dichloro(β-cyanoethyl)methylsilane [15], alkylated boron derivatives, and boron trichloride [117].

In the absolute calibration of readily hydrolysable substances, it is possible to suppress the hydrolysis of the admixture, having prepared its calibration mixture with a more readily hydrolysable substance. This is particularly important in the determination of microimpurities. Thus mixtures of $SiCl_4$ and boron trichloride containing between 0.01 and 0.08% $SiCl_4$ have been prepared and the analytical error was about 10 rel.%. The absolute calibration method has been used in the analysis of mixtures of phosphorus, $PCl_3$, $POCl_3$, and $PSCl_3$ [160] (the relative error of the determination varied in the range ±6%), in the analysis of alkylchlorosilanes and chloroalkyl derivatives [161], and in the analysis of chloromethylsilanes [29,162].

The internal standard method is more rarely used in the analysis of reactive substances owing to the difficulty of selecting an internal standard and of its introduction into the mixture. As examples of the application of the internal standard method, we shall only quote studies [34,163] where ether was used as the internal standard in the analysis of chloromethylsilanes (analytical error 2%) and the study where trichloro-*n*-propylsilane chlorination products were analysed using trichloro-*n*-propylsilane as the internal standard. We believe that the employment of a substance having a similar structure and properties as the internal standard is more justified.

In order to obtain accurate quantitative results, it is desirable to use a density detector, which does not require calibration, for the analysis of unstable substances with different molecular weights. Corrosive halogen gases have been analysed quantitatively by means of a Martin nickel densitometer [164].

One should also note that, using the capacity of reactive substances for interaction with some other substance or their thermal instability, in the analysis of such substances one can carry out the reaction beyond the column and before the detector in order to detect the inert substance or the inert mixture in the detector and to calibrate the apparatus with respect to the reaction products. In the experiments on the analysis of volatile inorganic hydrides of a number of Group IV–VI elements ($SiH_4$, $GeH_4$, $AsH_3$, $PH_3$, $H_2S$, etc.), the furnace (10 to 15 cm long and 1.5 cm in diameter) was placed beyond the chromatographic column in order to decompose the hydrides to hydrogen at 1000°C. [46] This enabled the authors to increase the sensitivity of the determination and also to avoid (under the conditions of complete conversion) the calibration of the apparatus with respect to the hydrides, using hydrogen for this purpose. The apparatus was calibrated similarly after the decomposition of chlorophenylsilanes [165,166]. Using the hydrolysis of chlorosilanes to HCl and carrying it out before the detector with subsequent conversion into $CO_2$ via the reaction $HCl + NaHCO_3 = NaCl + H_2O + CO_2$, it is also possible to calibrate the apparatus with respect to the stable carbon dioxide instead of the readily hydrolysable substances. A method has been proposed [37] for the analysis of $F_2$, ClF, $ClF_3$, and $ClF_5$ on the basis of the products of their reaction with silicon, which results in the formation of $SiF_4$ and $Cl_2$ ($Si + 2F_2 \rightarrow SiF_4$; $Si + 4ClF \rightarrow SiF_4 + 2Cl_2$, etc.).

This is of interest also from the standpoint of quantitative interpretation, since calibration with respect to one component undoubtedly gives rise to a smaller error than calibration with respect to four different components (naturally provided that one can be certain that all the reactions go to completion). Iron carbonyls have been detected [167] by a flame-ionisation detector after conversion via the mechanism $Fe(CO)_5 \xrightarrow{T} Fe + 5CO$ and the transformation of CO into methane; after the decomposition in the column, organolead compounds were passed through a tube with a nickel catalyst and the methane formed in the presence of the catalyst from the substances separated was detected [168]. In all the instances described, the calibration procedure is simplified and can be carried out with a high accuracy, but the chromatographic set up becomes much more complex, requiring the calculation (or selection) of optimum reactor parameters and careful monitoring of the reaction conditions.

## VII. CHARACTERISTICS OF THE APPARATUS USED IN THE ANALYSIS OF UNSTABLE COMPOUNDS

Analysis of readily hydrolysable, corrosive, and toxic compounds imposes additional requirements on the materials of the metering devices and it is also essential to protect the injected sample from the surrounding medium.

There is no universal metering device in chromatography; there are several possibilities for the metering of various types of samples, from which the optimum procedure must be selected. The most widely used materials for the construction of sample injection systems and metering in chromatographic analysis of the compounds under consideration are Teflon, polyethylene, glass, nickel, stainless steel, and Monel metal.

Metering by means of a syringe, whereby samples ranging from several millilitres can be injected depending on the design, is simple and fairly reliable. The possibility of using a microsyringe for the metering of corrosive readily hydrolysable compounds depends on the materials used for its construction and design solutions ensuring a fully hermetic seal. Syringes produced by U.S. and East German (GDR) firms to a large extent meet these requirements, being used, in particular, in the metering of organometallic compounds [169,170].

In the analysis of extremely reactive and toxic compounds, the authors of the present review¶ used a hermetically sealed syringe having a volume up to 10 μl with a Teflon piston, isolated from the external medium and ensuring the localisation of the sample in case of accidental breakage of the glass cylinder.

A system consisting of a glass 50 ml nitrogen-flushed cuvette with two outlets has been proposed for the removal of samples which must not be allowed to come into contact with air, for example those of organic compounds of certain metals [169]. After the insertion of the needle into the cuvette through the stopper, nitrogen was passed through the syringe until the product was collected, which ensured that the sample was preserved in the syringe until its injection into the evaporator of the chromatograph. During the transfer of the syringe to the chromatograph, the needle of the former remained inserted in an elastic stopper, which prevented its contact with air. The sample was injected with simultaneous piercing of both the stopper on the needle and the rubber membrane on the chromatograph inlet unit. A similar procedure to ensure a hermetic seal on the syringe needle was used when liquid alkylated boron [53], aluminium, and gallium [132] derivatives and dichloro-(β-cyanoethyl)methylsilane [35] were injected into the chromatograph. Triethylboron and tripropylboron were sampled in an inert atmosphere or in a stream of an inert gas [117]. One of the varieties of metering device for the injection of liquid and solid samples has been described by Wong and Schwartz [171].

In the removal of gaseous samples, vacuum sample removal and sample injection systems are used in most instances. One of such systems has been used in the analysis of trichlorosilane, germanium tetrachloride, and arsenic, phosphorus, germanium, and silicon hydrides [46,50,51]; an analogous system, with slight modifications, has been employed in the analysis of fluorine and chlorine fluorides [37,38], alkylated boron derivatives [53], and metal carbonyls [129]. Various systems made of glass, incorporating multiway taps and metering reservoirs [172-174], including experiments *in vacuo* at residual pressures down to $10^{-3}$ mmHg, are used in the analysis of many corrosive inorganic gases, for example nitrogen oxides, HCl, and fluorine compounds (other than HF) [175-177]. Precautions are taken to eliminate a sealing grease by employing glass and Teflon taps [50]. Samples ranging from several millilitres [175] to $10^{-5}$ mole have been metered with the aid of such systems [177]. Samples of readily hydrolysable corrosive and toxic substances, such as, for example, organochlorosilanes, boron hydrides, and boron and silicon chlorides, are frequently introduced into the chromatograph by means of breakable glass bulbs.

A device has been proposed [178] for the injection of very small samples (0.001–10 mole) of gases of vapours by means of a sealed glass tube, the upper, breakable part of which is made in the form of a hemisphere with a drawn out portion, where it can be sealed off. The sealed tube constitutes the lower part of an outer Pyrex tube (with an internal diameter of 15 mm and a polished inner surface) which is fitted onto the cylindrical shell of the Teflon metering device into which the carrier gas is supplied via a capillary. When the capillary comes into contact with the upper part of the sealed tube, the latter is broken and the sample is blown out by the stream of carrier gas via a side arm of the metering device directly into the chromatograph. The hermetically sealed bulb metering device, in which a sealed glass bulb with the sample of the test substance was placed, has been used in the analysis of organochlorosilanes, boron trichloride, and other products [179]. The metering device is joined directly to the evaporator of the chromatograph. The bulb is broken by a rod activated at a distance by an electromagnet; the sample is then introduced into the evaporator by the stream of carrier gas. The metering device is freed from glass fragments via a special aperture after 25–30 analyses.

The metering systems in which glass is used are unsuitable for the injection of samples containing hydrogen fluoride and highly toxic substances. Furthermore, in the removal of samples from systems under an excess pressure, glass is unsuitable because of its low mechanical strength. A metallic metering tap made of a corrosion-resistant material with a Teflon seal makes it possible to inject samples of reactive and highly toxic gases from the cylinder, provision being made for the flushing of the tap and the connecting tube by a dry inert gas with the aid of a system of valves [107]. The removal of the sample directly from the technological line can be achieved similarly, provided that conditions permit it. For the cyclic injection of liquid hydrolysable substances, particularly into an industrial chromatograph, a slide-valve metering device with a pneumatic actuator was developed; in it, a stainless steel plate is made to move through a definite cycle by means of the pneumatic device [180]. The plate, moving between stationary PTFE plates, causes the injection of the sample into the column or its flushing with the carrier gas as it allows appropriate channels to be connected. A similar system was also used in the metering of metal chlorides and phosphorus compounds [181,182].

Methods for the injection of samples by special gas tube systems and blocking devices, permitting the alteration of the direction of the stream of the carrier gas and the injection of the sample directly into the chromatograph, have been described in a number of studies [48,54,183-186]. Thus, a system consisting of sections of polyethylene capillary tubes 0.38 mm in diameter and blocking devices have been used to meter mixtures of chlorine and hydrogen fluoride [185]. Tubes were connected by nickel capillaries to a T-shaped socket made of Monel metal. In order to alter the direction of the gas streams, the tubes were closed by

¶See the footnote to p. 175.

clamping them to a solid plate by means of five bronze screws. Metallic or Teflon washers between the screw and the tube protected the latter from being crushed. By opening and closing the tubes to the gas stream in different combinations, it is possible to achieve in succession the passage of the carrier gas through a by-pass into the chromatograph with simultaneous removal of the sample into the metering reservoir, its isolation, and injection into the column. The size of the dose is determined by the length of the corresponding section of the polyethylene tube (the dose is $6.5 \times 10^{-3}$ mm for a tube 50 mm long).

A system acting on a similar principle has been proposed for the removal *in vacuo* of samples of corrosive halogen-containing gases from the technological stream[48]. The gas streams are controlled by glandless needle valves made of bronze with nickel-plated inner surfaces. The gas system is welded using a silver solder. Such valves remain effective for 12–18 months of continuous operation according to the authors, after which the system is completely renewed. One of the varieties of the systems described with cut-off valves, controlled by compressed air, has been used for the injection of samples of mixtures of chlorofluoroalkanes with uranium hexafluoride. The materials used for their preparation were nickel, Monel metal, and Teflon[186]. The latter systems have definite advantages over multiway taps and slide-valve metering devices from the standpoint of reliability of operation and the hermetic seal, although their control requires a large number of operations.

In many instances, particularly in the industrial control of a technological process, the sample removed must be transported over a certain distance for its chromatographic analysis. It is then necessary to employ samplers which ensure that the sample is representative, is preserved, and can be injected into the chromatograph. A version of a 10 ml sampler, made of Teflon, for sulphur-containing gases ($H_2S$, $SO_2$, etc.) has been described[187]. A transportable sampler has been proposed† for corrosive, toxic, and readily hydrolysable gaseous media in which the volume of the working chamber is 250 $cm^3$ (Fig. 2). The device makes it possible to remove a sample from gaseous systems under an excess pressure or under the conditions of rarefaction. The Teflon shell of the sampler is clamped together with an elastic membrane between Textolite flanges. The membrane is connected to a plunger with a rigid centre and is moved by a guide screw with a handle, located in a guide bracket. The sampler tube is connected to the shut-off valve by a polyethylene capillary. Samples containing compounds capable of diffusing through Teflon are removed by a modified sampler with a stainless steel bellows replacing the membrane unit.

The choice of column materials is as a rule preceded by a careful analysis of their behaviour under various conditions[188]. For example, Teflon is completely inert and can be used in the separation of any substances, including HCl, HF, etc., but the temperature must not exceed 200°C. Like Teflon, glass and quartz are not catalytically active, while metallic columns can exhibit catalytic effects, particularly at high temperatures, and the sorption phenomena on their surfaces are manifested to a greater extent than for glass and Teflon. The disadvantages of metallic columns are compensated by their high resistance to heat, optimum thermal conductivity, and the technological ease of their manufacture. Thus the choice of column material depends on the nature of the substance analysed, the conditions of the analysis, and the technology of the column manufacture. Despite its disadvantages, glass is in many cases the only material suitable for the preparation of columns used in the analysis of chemically unstable compounds. For example, studies carried out with copper, stainless steel, Teflon, and glass on the chromatographic analysis of mixtures of nitrogen dioxide and air showed that materials other than glass cannot be used because of sorption on the column surface[189]. Nor could glass columns be replaced in the analysis of admixtures of hydrogen chloride, chlorine[172,190], halogenohydrocarbons[173], organic derivatives of boron, beryllium, aluminium, phosphorus, zinc, and tin[169], and phosphates, amines, and triazides[191], and in the determination of organic chloro-impurities in germanium tetrachloride and hydrocarbons[50,51]. The replacement of Teflon columns by glass columns in the analysis of tetraethyl pyrophosphate decomposition products increased the sensitivity of the determination by a factor of five[192].

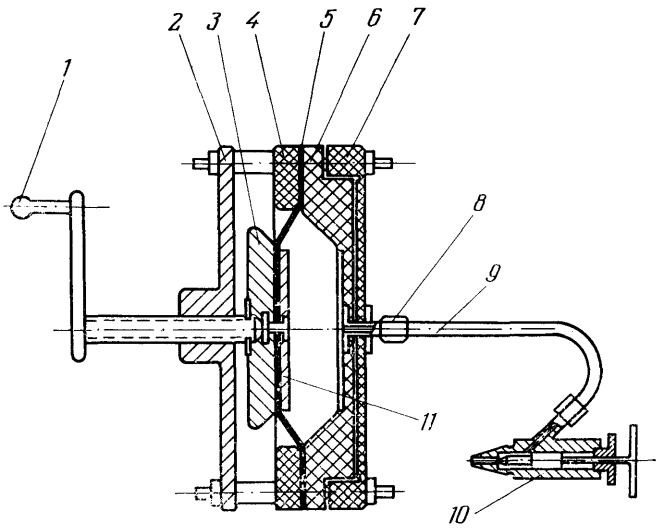

Figure 2. Gas sampler: 1) guide screw; 2) bracket; 3) plunger; 4) and 7) flanges; 5) membrane; 6) shell; 8) tube; 9) capillary; 10) valve; 11) rigid centre.

Monel metal and nickel columns are used as a rule in the chromatographic analysis of halogen and interhalogen compounds as well as metal fluorides and chlorides[40,181,184,193,194]. However, in most cases the columns are made of stainless steel in view of its ready availability and lower cost compared with nickel and Monel metal. In particular, stainless steel columns have been used in the analysis of arsenic and phosphorus hydrides, organic chloro- and bromo-compounds, and organic compounds of phosphorus, tin, and many other elements[170].

In view of the great inertness of zirconium oxides, they have been suggested as coatings for the inner walls of gas connectors and chromatographic columns to be used in the analysis of corrosive substances. For this purpose, the zirconium components are etched with oxidising solutions and kept in moist $CO_2$ at 450°C. The last process can be carried out directly in the chromatograph by passing

†See the NIITEKhIM Information Bulletin No. 2, Moscow, 1972.

through it moist $CO_2$ instead of the carrier gas [195]. The high stability and complete chemical inertness of the resulting protective film have been noted. Teflon is widely used as a material for chromatographic columns, particularly for the analysis of xenon fluoride [183], the halogens and their binary compounds [196], inorganic halogen compounds [185], hydrogen sulphides, and many sulphur compounds [187].

The problems of the detection of reactive compounds have been partly considered by Brazhnikov [197], who noted that, when the application of gas chromatography is extended from the analysis of hydrocarbons to the analysis of inorganic and organic compounds with a high reactivity, a new approach is needed for the solution of the problem of the detection of these compounds, particularly when a high sensitivity must be ensured. The detection of such compounds frequently requires both universal and selective detectors, which must be made of corrosion-resistant materials. The protection of sensor elements requires particular attention.

The thermal conductivity detector was one of the first to be used for the analysis of reactive gaseous mixtures. Many corrosive inorganic acids, certain alkylated compounds, metal chlorides, etc, have been analysed with its aid. Thus the concentration of nitrogen dioxide in air with a detection threshold of $10^{-4}$ vol. % [189] and MeGaCl, $Me_2AlCl$, $H_2$, and $CH_4$ admixtures in trimethylgallium [198] have been determined and mixtures of chlorine with chlorine, uranium, bromine, and xenon fluorides (with a lower detection limit of 0.1 vol.%), halogens and their compounds [38,40,48,183,193,196,199,200], chlorosilanes and organochlorosilanes [52,201], inorganic chlorides, and organometallic compounds [160,182,202] have been analysed using a katharometer. In order to achieve the maximum sensitivity of the katharometer, helium or hydrogen are used as the carrier gas [202], although some investigators prefer air or Freon-12. [194]

The sensor elements of the detector are mainly made of a tungsten coil with a high mechanical strength. However, tungsten is readily oxidised by traces of oxygen at high filament temperatures and is susceptible to the influence of corrosive media. To improve the stability of the sensor elements, they are gold-plated or coated with Teflon [40,181,182,200]. Although the coating of the filament with Teflon lowers the sensitivity of the detector by a factor of approximately four, its high stability in corrosive media is thereby ensured. Gold plating does not have a significant influence on the sensitivity of the detector. Platinum coils react with fluorides and are also decomposed in the presence of aluminium, gallium, and zirconium chlorides [18]. Nickel wire sensor elements have been used in the detection of chlorine and bromine chlorides, hydrogen fluoride, and fluorine, the shell of the katharometer being made of stainless steel or glass [38,183,193,196,199]. In the determination of microimpurities in $Me_3Ga$ at concentrations of $2 \times 10^{-3}$ wt.%, the detector shell was made of tantalum [198]. Thus the use of the katharometer as a rule permits the chromatographic analysis of a wide variety of reactive compounds over a wide range of concentrations, provided that materials are suitably chosen for the manufacture of its elements and special protective precautions are taken.

However, the use of extremely expensive and scarce helium and the permanent contact between the sensor element and the compounds analysed preclude the improvement of the sensitivity of the analysis when the katharometer is employed. The density detector, in which nitrogen or argon are used as the carrier gas, is free from these disadvantages. Furthermore in the analysis of substances containing components with known molecular weights, the calibration plot for the chromatograph can be calculated, which greatly facilitates work with unstable compounds. According to the literature, the density detector has been used most successfully for the analysis of organochlorosilanes [180,203-205], a sensitivity of $3.1 \times 10^3$ mV ml $mg^{-1}$ being achieved, which is approximately two orders of magnitude higher than the sensitivity of the katharometer using nitrogen as the carrier gas and an order of magnitude lower than for the katharometer with helium as the carrier gas. This detector is recommended as the most suitable for the analysis of organosilicon monomers [205].

An industrial chromatograph with a density detector has been developed [180] and used for the analysis of admixtures in a stream of organochlorosilanes at concentrations of 0.1%, the detection threshold being $10^{-3}$–$10^{-4}$ vol.%. A densitometer with argon as the carrier gas has also been used to detect HF, $H_2O$, and $SiF_4$,[206] $ClF_3$, $AsF_5$, $Cl_2$, $Br_2F_5$, etc. and in the determination of molecular weights of a number of compounds [186,193,207]; it has been employed [193] together with the katharometer [193], and in the analysis of mixtures of aluminium, gallium, niobium, and zirconium chlorides it replaced successfully the katharometer, the platinum coils of which disintegrated in the substances analysed [18].

Organochlorine and organofluorine compounds, alkylchlorosilanes, organometallic compounds, and other extremely reactive compounds [52,208-212] have been analysed with the aid of the flame-ionisation detector (FID), this type of detector being used in many instances in conjunction with selective detectors—thermionic and flame-photometric [170,213,214] (in the analysis of organometallic compounds and arsenic and phosphorus hydrides). For example, organochlorine impurities in HCl at concentrations of $(1–1.5) \times 10^{-4}$ wt.% have been determined with the aid of the flame-ionisation detector [172]; alkylchlorosilanes have been detected with a sensitivity threshold of $10^{-3}$ vol.%, which is lower by a factor of 40–50 than the sensitivity threshold of the katharometer with helium as a carrier gas in relation to these compounds [52]. However, it has been noted that the operation of the flame-ionisation detector in the analysis of alkylchlorosilanes is unreliable owing to the deposition of the decomposition products ($SiO_2$ and rust) on the electrodes.

Analysis of inorganic halogen compounds with the aid of the flame-ionisation detector is of definite interest [185]. The detector was designed in such a way that the carrier gas was introduced directly into the hydrogen flame, which significantly enhanced ionisation. The choice of the design and the selection of the positions of the electrodes ensured the optimum stability and sensitivity of the detector under the given conditions, amounting to 40.8–77.2 ml mV$\mu$ $g^{-1}$ for halogens, which is much superior to the sensitivity with respect to benzene (1310 ml mV$\mu$ $g^{-1}$) but considerably inferior to the sensitivity of the densitometer (approximately 3 ml mV$\mu$ $g^{-1}$). The authors preferred the flame-ionisation detector to the katharometer and the densitometer because the latter could not be used in combination with capillary columns. Experience gained in use showed the high stability of the platinum electrodes of the flame-ionisation detector with respect to corrosion, while the burner was corroded after prolonged use. The high linear dynamic detection range ($10^7$–$10^8$), the low sensitivity to variations in the carrier gas flow rate, pressure, and temperature, the possibility of detecting many classes of compounds, the degradation of highly toxic substances on

combustion, and other advantages have to a large extent favoured the wide-scale employment of the flame-ionisation detector in chromatographic analysis. However, the deposition of degradation products in the detector in the analysis of unstable compounds, which increase the detector noise, and the lack of sensitivity to certain compounds (chlorosilanes, nitrogen oxides, ammonia, and other compounds without carbon or with a low carbon content) hinder its use for the analysis of the compounds considered in the present review.

In contrast to the katharometer, the densitometer, and the flame ionisation detector, the electron capture detector (ECD) and the thermionic detector are selective. For example, the electron capture detector has proved to be the most suitable for the analysis of organometallic compounds in small amounts ($3 \times 10^{-4}$ mole $s^{-1}$), inorganic chlorides[181], and volatile fluorine compounds[184]. $1.5 \times 10^{-6}$% $SiCl_4$, $10^{-7}$% $PCl_3$ in $POCl_3$, and $10^{-4}$% of $PSCl_3$ in $PCl_3$ have been determined with the aid of the electron capture detector. In the analysis of admixtures in compounds which do not capture electrons, the electron capture detector is combined with the katharometer[181]. Analysis of reactive gases requires the protection of radioactive sources. The source may be exposed to an additional stream of an inert gas[181] or a special closed source may be used[184].

The thermionic detector (TID) has been known mainly as the detector most sensitive to compounds containing halogens and (particularly) phosphorus. Organochlorine impurities in germanium tetrachloride have been determined with its aid, the sensitivity being $8 \times 10^{-6}$–$5 \times 10^{-4}$ mole %, which exceeds by 1–2 orders of magnitude the sensitivity of the flame-ionisation detector[50], and the impurities in trichlorosilane have been determined with a sensitivity of $1 \times 10^{-4}$–$5 \times 10^{-2}$ mole %[43]; the possibility of the chromatographic determination of organochlorosilanes with a sensitivity threshold of $10^{-5}$% has been demonstrated[215]. Studies on the sensitivity of the thermionic detector, fitted in a "Khrom-35" chromatograph, to organochlorosilanes and alkylated tin and lead compounds showed that the sensitivity is a maximum when caesium salts are used as the ion source[216]. The detector readings are then positive in relation to silicon compounds and negative in relation to tin and lead compounds. The sensitivity of the thermionic detector giving positive readings diminishes in the sequence P > Si > Br > Cl, while for negative readings it increases in the sequence Pb < S < Sn. The thermionic detector has been used also in the analysis of boron compounds[217]. It has been established that, in order to achieve the stable operation of the detector, it is necessary to increase the temperature of the flame, which led to the employment of the refractory PbCl salt, since, under the conditions used in the analysis of boron compounds, the sensitivity of the detector depends much more on the hydrogen flow rate than, for example, in the case of phosphorus compounds.

The thermionic detector has been used in many cases in combination with other types of detector. When it was combined with the flame-ionisation detector, a sensitivity of $8 \times 10^{-7}$–$2 \times 10^{-10}$ g $s^{-1}$ was achieved in the analysis of phosphorus and arsenic hydrides, organochlorine and organoboron compounds, and organic derivatives of tin and phosphorus[170]. Both detectors were mounted in the same shell made of glass. In the analysis of phosphates and nitrogen-containing phosphorus compounds, the joint employment of the thermionic and thermal conductivity detectors is recommended[191].

However, together with its high selectivity, mention must be made of the comparatively short linear range of the response of the thermionic detector (up to $10^3$), which limits its scope for the determination of concentrations over a wide range. The most serious disadvantage of the sodium thermionic detector is its low stability, caused largely by the quality of the alkali metal salt, which evaporates in the burner flame; for this reason, surface ionisation thermionic detectors are preferable, despite their somewhat lower sensitivity.

The flame-photometric emission detector (PPD) is also selective, and its selectivity may be varied within fairly wide limits by altering the wavelength and the width of the transmission band. The problems of the application of such a detector in the detection of a wide variety of corrosive organic and inorganic compounds have been examined[197]. Mention may be made of the use of the flame-photometric detector for the analysis of boron hydrides with a detection limit of 0.7 ng[13,156] and also the possibility of determining sulphur compounds in amounts of $10^{-7}$%.[187] Like other selective detectors, the flame-photometric detector can be usefully employed in combination with, for example, the flame-ionisation detector in the analysis of organic compounds of phosphorus, tin, lead, and certain nitrogen compounds[213,214,218].

The examples considered above demonstrate the wide scope of the applications of various detectors for the chromatographic analysis of a wide range of organic and inorganic compounds with high reactivities. The wide variety of requirements which must be met by the analytical method and the sensitivity of the analysis, the operational and design features of the apparatus, the wide variety of classes of compounds analysed, and the conditions used in the analyses preclude unambiguous recommendations in the present review concerning the usefulness of a particular detector in the analysis of a specific compound. The necessary choice and combination of the optimum separation and detection systems in each individual case enable the investigator to make the correct choice of the method for the solution of the problem facing him; this is possible only after a careful preliminary study of the apparatus and of the mechanisms of the reactions occurring during separation and possible side processes.

# Kinetics of Chemical Reactions Initiated by Hot Atoms

L.P.Firsova

A general account is given of modern ideas on the kinetics of hot-atom reactions and the fundamental postulates of the phenomenological theories, namely the Wolfgang-Estrup "kinetic theory" of hot-atom reactions and Porter's theory of the "integral reaction probability" are described. The physicochemical models of elastic and non-elastic collisions used for the solution of the Boltzmann integrodifferential equations and of the stochastic equations in Porter's theory are examined. The fundamental formulae describing the probabilities or yields of chemical reactions initiated by hot atoms in relation to the energy distribution functions of hot species are presented and a brief account is given of the methods and the results of the application of the phenomenological theories in the interpretation of the results of experiments involving hot atoms in nuclear reactions, photochemical studies, etc.
The bibliography includes 96 references.

## I. KINETIC EQUATIONS IN THE CHEMISTRY OF HOT ATOMS

Chemical processes involving high-energy atoms or ions under the conditions of a non-uniform distribution of these species in time and space and a non-Maxwellian energy distribution of "hot" atoms or ions are widely investigated at the present time. The chemical reactions of hot atoms are of interest in connection with the high efficiency of the collisions, the dominant role of high-energy processes, and the possibility of carrying out new types of reactions. Hot atoms or ions are obtained as a result of radiation-chemical, plasma-chemical, or nuclear transformations in chemical accelerators, in photochemical reactions, in shock waves, and in cold flames. Extensive experimental data have accumulated on the yield of products in processes involving hot atoms[1-3]. During the last decade, there has been intense development of theoretical ideas about the kinetics of reactions of hot species, mainly in two directions, the first of which is associated with the study of the dynamics of the collisions of hot atoms leading to their cooling and chemical capture[4]. The second led to the establishment of phenomenological theories describing the yield of products as a function of the cross-sections of various elastic and non-elastic collisions and also the energy distribution functions of hot atoms[5,6]. Among these, the most productive have been the "kinetic theory" of hot-atom reactions proposed by Wolfgang and Estrup[7,8] and the theory of the "integral reaction probability" developed by Porter[9]. In the present review, attention has been concentrated on the fundamental postulates of the above phenomenological theories and on the results of their application in the analysis of numerous experimental data on the chemistry of recoil atoms.

## 1. Transport Equations in the Kinetics of Hot-atom Reactions

The nature of the chemical reaction of a species (atom or ion) with the target material depends on the parameters for the species at the instant of reaction and on the properties of the medium at the point of interaction, which depend in their turn on the previous history of both the given hot species and the entire set of species bombarding the target as well as the previous history of the target material. In systems where high-energy species are introduced, relaxation processes and chemical reactions are indissolubly linked. In a rigorous study of kinetic relations, it is therefore necessary to take into account the set of processes involving high-energy species:

(1) elastic and non-elastic scattering of the species and the penetration, caused by these processes, of the species into the bulk of the target with establishment of a definite spatial distribution and retardation of the species accompanied by the establishment of a definite energy distribution (taking into account both the kinetic energy and the energies of vibrational, rotational, electronic, etc. excitation);

(2) the escape of species from the boundaries of the target and their absorption by the material of the target owing to chemical reactions or retention in various types of traps;

(3) the recombination reactions of the bombarding species.

The relaxation processes of hot species are accompanied by the transfer of their excess energy to the target material with subsequent microscopic and macroscopic transformations. Such transformations include the change in the internal state of the target molecules and in their chemical energy, ionisation, dissociation, and other chemical reactions, as well as the atomisation of the surface layers, heating, and other primary radiation effects. The primary radiation processes also include the displacement and dislodgement of atoms from the crystal lattice; the dislodgement of secondary high-energy species in a system where the target contains atoms equivalent to those used in the bombardment may be regarded as the development of a cascade process. Together with the primary radiation-induced transformations, there is a possibility of secondary transformations, in particular chemical reactions of the bombarding species with the product of the radiation-induced decomposition and reactions of unstable primary products with one another or with the molecules of the target material.

The distribution of the bombarding species in space, time, and with respect to energy and their absorption are determined by the large number of random collisions leading to the above processes. The macroscopic effects, for example the release of the products of the capture of hot species or their retention in the bombarded target, are treated in hot-atom chemistry on the basis of the study of single collisions and their properties. The main task in theoretical hot-atom chemistry involves the determination of the probabilities of reactions involving hot atoms and of the reaction rates or rate constants with the aid of one of the equivalent kinetic equations, for example:

$$P = \int p_r(E) \cdot n(E)\,\mathrm{d}E\,,$$
$$k = \int \sigma_r(E) n(E) v\,\mathrm{d}E \Big/ \int n(E)\,\mathrm{d}E\,, \qquad (I.1)$$
$$R = \int \Sigma_r(E) \cdot \varphi(E)\,\mathrm{d}E,$$

where $P$, $k$, and $R$ are the probability, rate constant, and the rate of the chemical reaction respectively, $p_r(E)$ the probability of reaction on collision of an atom having the energy $E$ with the target, $n(E)\mathrm{d}E$ the number of collisions of hot atoms in the range $E-E+\mathrm{d}E$, $\Sigma_r(E)$ the reaction cross-section of the species for the energy $E$ or velocity $v(E)$, $\sigma_r(E)$ the reaction microsection, and $\varphi(E)$ the flux of species with the energy $E$.

In contrast to traditional kinetics, in hot-atom chemistry the above problems have to be solved for species having a non-equilibrium non-Maxwellian distribution, determined by their initial energy, their mass, the retarding capacity of the medium, its reactivity, etc. One of the fundamental problems in the theory of chemical reactions initiated by hot atoms is therefore associated with the search for the distribution functions of the reacting species with respect to energies or velocities and internal states, or their distribution functions within the bulk of the target. In theoretical models describing the chemical effects of hot atoms, particular attention has been concentrated at the present time on the energy distribution of the retarding species in spatially homogeneous cases[5-9], and in addition on the spatial distribution of species under spatially inhomogeneous conditions.

Models used to describe the chemical effects of recoil atoms are described in the first place in the present review, since this field has now been developed fairly extensively. A characteristic feature of the models is their spatial restriction by independent factors with a homogeneous distribution of the sources of hot species in an infinite medium, account being taken only of the energy distribution of the recoil atoms or, more precisely, of their distribution with respect to kinetic energy.

The kinetics of non-equilibrium chemical hot-atom processes may be based on the Boltzmann, Pauli, or Liouville equations[11,12]. It has been pointed out that[11] the difficulty of the solution of the Liouville equations, the inapplicability of the Boltzmann equations to three-particle processes, and the obscure nature of the problem of the uniqueness of the solutions of these equations in the general case necessitate the hypothesis that the Pauli equation is the most promising for the description of the kinetics of non-equilibrium processes; this equation is particularly convenient in numerical methods of calculation.

However, mainly the Boltzmann integrodifferential equations have been used hitherto in hot-atom chemistry. A rigorous treatment taking into account the various effects accompanying the bombardment of targets by high-energy species requires the solution of integrodifferential transport equations with many independent variables (three spatial coordinates, two variables defining the direction of motion, and the energy and time variables). The problem is complicated by the fact that, if it is necessary to take into account secondary effects, the equations become non-linear.

The neglect of secondary processes is quite valid for low flux intensities of the bombarding species and small integral fluxes. If, in addition, one disregards the internal degrees of freedom, i.e. the colliding species are assumed to be material points, or the collision cross-sections and other quantities are averaged with respect to internal states (taking into account the statistical weights), then the behaviour of the entire set of species in a scattering and absorbing medium can be described on the basis of the laws of conservation of matter and energy by linear equations with independent variables: the radius-vector $\boldsymbol{r}$, the time $t$, the solid angle $\Omega$, the energy $E$, or the velocity $v$.

The set of bombarding species may be characterised by the differential density or the differential vector flux; these quantities are linked by the equation $\rho(r, \Omega, E)v = \varphi(r, \Omega, E)$. The change in differential density or flux must depend on the ratio of the supply and loss of species in the region of phase space characterised by the quantities $r$, $\Omega$, $E$. The supply is determined by independent sources, atom migration chain processes, and the scattering of species from neighbouring regions. The loss may occur as a result of slipping of the species from the external boundaries of the target, scattering, and capture by chemical or physical traps.

In many instances, one can disregard atom migration chain processes, whereupon the change in the differential density of species or the differential vector flux in the volume element $dV$ with the energy of the species in the range $dE$ and the direction of motion in the solid angle $d\Omega$ is defined by the following factors:

(1) the density of the sources $S(r, \Omega, E)$;

(2) the loss of species from the given volume element $\Omega \cdot \mathrm{grad}\varphi(r, \Omega, E)dV d\Omega dE$;

(3) the losses on scattering and absorption $\Sigma_t \cdot \varphi(r, \Omega, E)dV d\Omega dE$ ($\Sigma_t = \Sigma_S + \Sigma_r$, where $\Sigma_r$ is the absorption cross-section and $\Sigma_S$ the scattering cross-section);

(4) the increment in the number of species as a result of displacement or scattering from neighbouring regions of phase space with the coordinates $(r, \Omega', E')$:

$$\int_{4\pi}\int_{0}^{\infty} \Sigma_s(\Omega', \Omega; E', E) \cdot \varphi(r, \Omega', E')\, d\Omega\, dE\, dV\, d\Omega'\, dE',$$

where $\Sigma_S(\Omega', \Omega; E', E)d\Omega\, dE$ is the scattering cross-section of the species with the energy $E'$ and the direction of motion $\Omega'$, the direction of motion becoming $\Omega$ (in the range $\Omega - \Omega + d\Omega$) and the energy becoming $E$ (in the range $E - E + dE$) after the collision. Hence the change in the differential density or the differential flux of the species must obey the equation

$$\frac{\partial \rho(r, \Omega, E)}{\partial t} = \frac{1}{v}\frac{\partial \varphi(r, \Omega, E)}{\partial t} = S(r, \Omega, E) - \Omega \cdot \mathrm{grad}\varphi(r, \Omega, E) + \int_{4\pi}\int_{0}^{\infty} \Sigma_s(\Omega', \Omega, E', E) \times \varphi(r, \Omega', E')\, d\Omega'\, dE' - \Sigma_t(E) \cdot \varphi(r, \Omega, E). \quad (I.2)$$

The rate of formation of recoil atoms may be assumed to be constant, except over long periods, where the loss of parent nuclei as a result of the reactions involving the formation of recoil atoms becomes significant. The constancy of the strength of the source of hot species makes it possible to treat the problem of the determination of $\rho(r, \Omega, E)$ or $\varphi(r, \Omega, E)$ as stationary, if one excludes from consideration also the region of very short times during which nearly stationary energy or spatial distributions of the species are established. This makes it possible to formulate the transport equation for hot species in the following way:

$$\Omega \cdot \mathrm{grad}\varphi(r, \Omega, E) + \Sigma_t(E) \cdot \varphi(r, \Omega, E) = S(r, \Omega, E) + \int_{4\pi}\int_{0}^{\infty} \Sigma_s(\Omega', \Omega; E', E)\varphi(r, \Omega', E')\, d\Omega'\, dE'. \quad (I.3)$$

If the target is isotropic and is so large compared with the paths traversed by the hot species before retardation in the region of chemical interaction and compared with the diffusion paths that it can be regarded as infinite and the boundary effects may be neglected, in particular the loss of species as a result of recoil or diffusion, one may eliminate from Eqn.(I.3) all spatial variables and average with respect to directions of motions quantities such as, for example, the scattering cross-sections. Under these conditions, the transport equation (I.3) may be reduced to the form:

$$\Sigma_t(E) \cdot \varphi(E) = S(E) + \int_{0}^{\infty} \Sigma_s(E', E) \cdot \varphi(E')\, dE', \quad (I.4)$$

where $\varphi(E)$ is the flux of species with the energy $E$ and $\Sigma_S(E', E)$ the scattering cross-section with a change of energy from $E'$ to a value in the range $E - E + dE$. Eqn. (I.4) is the initial equation for many specific forms of kinetic expressions in the chemistry of recoil atoms uniformly distributed within the space of infinite isotropic targets. In the case of recoil atoms, one usually operates with the density of the collisions of hot atoms with the atoms or molecules of the target and not with the fluxes of hot species. The collision density $\psi(E)$, i.e. the number of species colliding per unit volume per unit time, is related to the flux by the expression $\psi(E) = \varphi(E) \cdot \Sigma_t(E)$.

Evidently Eqn.(I.4) for the density of collisions can be written in the form:

$$\psi(E) = S(E) + \int_{0}^{\infty} \frac{\Sigma_s(E', E)}{\Sigma_s(E') + \Sigma_r(E')} \psi(E')\, dE'. \quad (I.5)$$

The applicability of Eqn.(I.5) is based not only on the stationary nature of the sources and $\psi(E)$, but also on the absence of non-uniformity in the spatial distribution of hot species due to the homogeneity of the distribution of the sources, the isotropic nature of the medium, and the large size of the target.

In order to obtain analytical solutions of equations of type (I.5), additional conditions are introduced in the chemistry of recoil atoms which vary as a function of the characteristics of the models proposed by a particular investigator. It is usually assumed that elastic collisions with the free atoms of the target at rest are of fundamental importance. For fairly high energies of hot atoms (recoil atoms usually have identical initial energies greatly exceeding the upper limit of the energy range of the chemical reactions), neglect of the thermal motions of the target atoms and the effects due to their chemical bonds cannot give rise to significant errors, but neglect of inelastic scattering can entail appreciable errors. However, in the range of energies not exceeding $E = (m_1/8m_e)I^*$ (where $I^*$ is the ionisation potential and $m_e$ and $m_1$ are the masses of the electron and the hot atom), the energy losses in inelastic collisions, particularly in electronic excitation and ionisation, are small. The above hypotheses make it possible to simplify the expression relating $\Sigma_S(E')$ and $\Sigma_S(E', E)$.

Suppose that $g(E', E)dE$ is the probability that the species with the energy $E'$ acquires after collision an energy in the range $E - E + dE$. Evidently $\Sigma_S(E', E) = \Sigma_S(E') \cdot g(E', E)$. Substitution of $\Sigma_S(E', E)$ in Eqn.(I.5) leads to the expression

$$\psi(E) = S(E) + \int_{E}^{E/\alpha} \frac{\Sigma_s(E')}{\Sigma_s(E') + \Sigma_r(E')} \psi(E')\, g(E', E)\, dE'. \quad (I.6)$$

The integration limits are determined by the quantities $\alpha = [(m - m_1)/(m + m_1)]^2$ which depend on the masses of the hot atom ($m$) and the target atoms ($m_1$). If $\alpha = 0$ or $\alpha \neq 0$ but $\alpha E_0 < E$, then the upper integration limit may be assumed equal to $E_0$; in other instances, the upper limit is $E/\alpha$. Eqn.(I.6) makes it possible to take into account the change in collision density as a result of the "erosion" of the species from the energy spectrum in chemical processes, since it includes the reaction cross-sections $\Sigma_r(E)$. If the ratio $\Sigma_S(E')/[\Sigma_S(E') + \Sigma_r(E')]$ is expressed in the form $1 - \Sigma_r(E')/[\Sigma_S(E') + \Sigma_r(E')] = 1 - p_r(E')$,

where $p_r(E)$ is the probability of chemical reaction on collision of the recoil atom having the energy $E$, then it follows from Eqn.(I.6) that

$$\psi(E)=S(E)+\int_{E}^{E/\alpha}[1-p_r(E')]\cdot\psi(E')\cdot g(E', E)\,dE'. \quad (I.7)$$

For identical initial energies of all the recoil atoms, the source function of the hot species $S(E)$ can be written in the form $S(E)=S_0\delta(E_0, E)$, where $\delta(E_0, E)$ is the delta-function. Thus, for all $E\neq E_0$, the function $S(E)$ is zero. When $\Sigma_r(E)=0$, we have $p_r(E)=0$ and Eqn.(I.7) becomes

$$\psi(E)=S(E)+\int_{E}^{E/\alpha}\psi(E')\cdot g(E', E)\,dE'. \quad (I.8)$$

The quantities $g(E', E)$ may be estimated on the basis of the laws of mechanics[13-15]. The quantities $G(E', E)=\int_{\alpha E'}^{E} g(E', E'')dE''$, characterising the probability that the species having the energy $E'$ before collision have an energy in the range $E-0$ after collision, are estimated similarly. If the scattering is isotropic, then we have for $E'>E>\alpha E'$

$$g(E', E)=\frac{1}{E'(1-\alpha)} \quad (I.9)$$

$$G(E', E)=\frac{E-\alpha E'}{E'(1-\alpha)}. \quad (I.10)$$

Using the value of $g(E', E)$ obtained, Eqns.(I.7) and (I.8) for elastic isotropic collisions may be transformed into

$$\psi(E)=S(E)+\frac{1}{1-\alpha}\int_{E}^{E/\alpha}\psi(E')\frac{dE'}{E'} \quad (I.11)$$

$$\psi(E)=S(E)+\frac{1}{1-\alpha}\int_{E}^{E/\alpha}[1-p_r(E')]\psi(E')\frac{dE'}{E'}. \quad (I.12)$$

Eqn.(I.11) has a simple asymptotic solution. The collision densities for energies less then $E_0$ are defined by the approximate expression

$$\psi_0(E)=S_0/\xi E, \quad (I.13)$$

where $\xi$ is the average logarithmic energy loss in the collision. $\psi_0(E)$ can be regarded as the asymptotic solution of Eqn.(I.11) not only for billiard collisions but also for any elastic collisions, provided that account it taken of the dependence of $g(E', E)$, $G(E', E)$, and $\xi$ on the form of the interaction potential. The asymptotic solution shows that, for any elastic collisions characterised by a spherically symmetrical potential, the collision density function decreases with increase of $E$; the nature of $\psi_0(E)$ depends on the form of the interaction potential through the function $\xi(E, \alpha)$.[16-21] In the general case, the average logarithmic energy loss in the collision can be represented by the formula

$$\xi=\overline{\ln\frac{E'}{E}}=\int_{\alpha E'}^{E'}\ln\frac{E'}{E}\cdot g(E', E)\,dE. \quad (I.14)$$

For the hard-core interaction potential, we have

$$\xi_{hs}=1+\frac{\alpha}{1-\alpha}\ln\alpha. \quad (I.15)$$

In a mixture of moderators, $\bar{\xi}=\sum_i f_i\xi_i$, where $f_i=\sigma_{si}N_i/\sum_j\sigma_{sj}N_j$ ($N_j$ is the mole fraction of the component $j$) is the fraction of the collisions of the hot atoms with the component $i$ and $\xi_i$ is determined by the potential of the interaction of the hot atoms with the atoms $i$.

In non-absorbing systems, the asymptotic solution of equations of type (I.8) for sources with an arbitrary distribution spectrum (for example in $\beta$-decomposition) in terms of collision density is

$$\psi_0(E)=S(E)+\frac{1}{\xi E}\int_{E_{min}}^{E_{max}}S(E')\,dE', \quad (I.16)$$

where $E_{max}$ is the maximum energy of the recoil atoms in the spectrum. For energies less than the minimum value, we have in the spectrum

$$\psi_0(E)=S_0/\zeta E, \quad (I.17)$$

where $S_0=\int_{E_{min}}^{E_{max}}S(E')dE'$. If the non-absorbing medium contains a mixture of moderating atoms, then Eqn.(I.11) can be written as follows:

$$\psi(E)=S(E)+\sum_i\int_{E}^{E/\alpha_i}f_i\psi(E')\frac{dE'}{E'(1-\alpha_i)}. \quad (I.18)$$

If the ratio $\sigma_{si}/\sum_j\sigma_{sj}$ is independent of the energy, the asymptotic solution of Eqn.(I.18) for a monochromatic source is

$$\psi_0(E)=S_0/\bar{\xi}E. \quad (I.19)$$

In the general case, considerable mathematical difficulties arise in the solution of Eqn.(I.7) for absorbing systems. An exact and fairly simple analytical solution is available only for $\alpha=0$, when there are no oscillations in the collision density near the sources and the upper integration limit, involving in the general case the variable $E$, is replaced by $E_0$. For a monochromatic source and $E\ll E_0$, the asymptotic solution is

$$\psi_0(E)=\frac{S_0}{E}[1-p_r(E_0)]\exp\left[-\int_{E}^{E_0}\frac{p_r(E')}{E'}dE'\right]. \quad (I.20)$$

In the $\beta$-decomposition, where the recoil atoms have a definite distribution with respect to $E_0$, it is particularly important to obtain a solution of Eqn.(I.7) for an arbitrary source $S(E)$. The solution is

$$\psi_0(E)=S(E)+\frac{1}{E}\int_{E}^{E_{max}}[1-p_r(E')]S(E')\cdot\exp\left[-\int_{E}^{E'}p_r(E'')\frac{dE''}{E''}\right]dE. \quad (I.21)$$

Solutions (I.20) and (I.21) show that, owing to "erosion" during absorption, the flux of hot species increases more slowly with decrease of the energy than would be expected from the $1/E$ law. In particular, if the ratio $\Sigma_s(E)/\Sigma_r(E)$ is independent of the energy and close to $C$, the flux for low energies is proportional to $E^{-C/(1+C)}$; the corresponding collision density is

$$\psi(E)\propto\frac{S_0}{\xi E^{\frac{C}{1+C}}}. \quad (I.22)$$

In those cases where $\alpha\neq 0$, fairly complex relations were obtained in the solution of equations (I.7) and (I.12).[22] Instead of complex solutions, one can employ in many instances simple Wigner and Fermi approximations[23].

Their use is possible, firstly, when the initial energy of the species is fairly high and the absorption region with the boundaries $E_1$ and $E_2$ lies considerably lower and, secondly, when absorption leads to a weak perturbation of the spectrum of hot species. This corresponds to a very weak absorption when $\Sigma_r < \Sigma_s$ or to absorption due to strong but well resolved resonances; the width of the resonances should then be small compared with the values of $\ln(1/\alpha)$ and the distances between the individual resonances should greatly exceed $\ln(1/\alpha)$. When the above conditions are fulfilled, one can neglect non-asymptotic oscillations near the sources of hot species and also near the absorption zone, which may be regarded as a negative source with possible non-asymptotic oscillations, and an approximate solution may be used. The solution is of the form

$$\psi_0(E) = q(E)/\xi E, \tag{I.23}$$

where $q(E)$ is the retardation density, i.e. the number of species retarded per $cm^3$ per second down to energies below $E$. In the general case, the following expression is valid for $q(E)$:

$$q(E) = \int_E^{E/\alpha} [1 - p_r(E')] \cdot \psi(E') \cdot G(E', E)\, dE'. \tag{I.24}$$

In non-absorbing media, $q(E) = S_0$ for a monochromatic source and $q(E) = \int_E^{E_{max}} S(E')dE'$ for an arbitrary source. In absorbing media with $\alpha = 0$, we have

$$q(E) = S_0[1 - p_r(E_0)] \exp\left[-\int_E^{E_0} \frac{p_r(E')}{E'} dE'\right] = S_0 p(E) \tag{I.25}$$

for a monochromatic source and

$$q(E) = \int_E^{E_0} S(E')[1 - p_r(E')] \exp\left[-\int_E^{E'} \frac{p_r(E'')}{E''} dE''\right] dE' \tag{I.26}$$

for an arbitrary source. Here $p(E)$ is the probability of avoiding capture in the retardation process until the attainment of the specified energy. In terms of the Wigner–Fermi approximation, we obtain the following expression for absorbing systems with $\alpha \neq 0$ and a monochromatic source when $p_r(E_0) \simeq 0$:

$$q(E) = S_0 p(E) = S_0 \exp\left[-\int_E^{E_0} \frac{p_r(E')}{\xi E'} dE'\right]. \tag{I.27}$$

The chemical effects of the recoil atoms can be described also in terms of other approximations obtained in neutron physics. In particular, for a flux subjected to only a slight perturbation under conditions where the cross-section $\Sigma_r$ varies only slightly with the energy, one can probably employ the Goertzel–Greuling approximation[24], according to which the following expression is valid for $p(E)$:

$$p(E) = \exp\left[-\int_E^{E_0} \frac{\Sigma_r}{\xi\Sigma_s + \gamma\Sigma_r} \frac{dE'}{E'}\right], \tag{I.28}$$

where $\gamma = 1 - \alpha \ln^2(1/\alpha)/2(1-\alpha)\xi$; for example, when $\Sigma_r(E) \sim E^{1/2}$, $\Sigma_s(E) = \text{const.}$, and $E_0 \to \infty$, we have

$$p(E) = \left[1 + \frac{\gamma}{\xi} \frac{\Sigma_r(E)}{\Sigma_s}\right]^{-2/\gamma}.$$

For an absorbing medium containing the components $j$, each of which may be involved in chemical reactions, the solutions of equations of type (I.7) for $\psi(E)$ are formulated as follows in terms of the Wigner–Fermi approximation:

$$\psi_0(E) = \frac{S_0}{\xi E} \exp\left[-\sum_j \int_E^{E_0} \frac{f_j p_{rj}(E')}{\xi E'} dE'\right]. \tag{I.29}$$

Many investigators of hot-atom chemistry also use the quantities $n(E)$ as functions characterising the distribution of species with respect to energy, together with the collision density $\psi(E)$ and the flux of the species $\varphi(E) = [1/\Sigma_t(E)]\psi(E)$; $n(E)dE$ is the number of collisions of the hot atom in the range from $E$ to $E + dE$. If the source of recoil atoms is monochromatic, then $n(E) = \psi(E)/S_0$. Transport equations and their solutions of the same types as those quoted previously for $\psi(E)$ and $\varphi(E)$ are valid for $n(E)$. One may also note that the velocity $v$ or the lethargy $\ln(E_0/E)$ may be used as variables instead of $E$.

## 2. Porter's Equations for the Integral Probability of Hot-atom Reactions

Equations analogous to Eqns. (I.7) or (I.8) can be obtained by the direct determination of the probability of the transfer of a specified energy in the elementary collision step[9,25]. The method led to the creation of Porter's phenomenological theory of the "integral reaction probability"[9,26], which is particularly interesting because it makes it possible to take into account the thermal motion of the molecules or atoms of the bombarded targets, at least in numerical computer calculations. Evidently the probability that a hot atom with the energy $E'$ retains the energy $E$ after the first collision can be represented as the ratio of the differential cross-section $\Sigma_s(E', E)$ to the sum of the average cross-sections $\Sigma_s(E')$ and $\Sigma_r(E')$; the cross-sections are averaged taking into account the distribution functions for the relative velocities of the colliding species $v_{rel}$; they can also be averaged taking into account the energy (for example Maxwellian) distribution of the target species. Then, for a particular angle $\gamma$ between the vectors of the velocities $v_1$ and $v$, we have

$$g_1(E', E) = \frac{\int \Sigma_s(E', E, v_1, \gamma) \cdot v_{rel} \cdot \Omega(E', v_{rel})\, dv_{rel}}{\int [\Sigma_s(v_{rel}) + \Sigma_r(v_{rel})]\, v_{rel} \cdot \Omega(E', v_{rel})\, dv_{rel}}, \tag{I.30}$$

where $\Omega(E', v_{rel})$ can be determined in terms of Eqn. (II.35) (see below) when the target has a Maxwellian spectrum. For arbitrary cross-sections, $g_1(E', E)$ may be calculated numerically; in the case of an elastic isotropic collision with species at rest and in many other specific instances, an analytical determination of $g_1(E', E)$ is possible (see subsection 1 of this Section)

It is also evident that the following expressions are valid for the analogous probabilities for two, three, and $n$ collisions:

$$g_n(E', E) = \int_0^{\infty} g_{n-1}(E', E') \cdot g_1(E'', E)\, dE''. \tag{I.30a}$$

For a monoenergetic source, we have

$$g_0(E', E) = \delta(E', E). \tag{I.30b}$$

The average number of collisions of the species in the energy range $E - E + dE$, when the first collision occurs for the energy $E'$, can be determined in terms of $g_n(E', E)$ as follows:

$$n(E', E)\, dE = \sum_n g_n(E', E)\, dE. \tag{I.31}$$

Substitution of Eqns. (I.30a) and (I.30b) in (I.31) yields

$$n(E', E)=\delta(E', E)+\int_0^\infty n(E', E'')g_1(E'', E)\,dE''. \quad (I.32)$$

If it is assumed that $p_r(E) = \Sigma_r(E)/\Sigma_t(E)$ and $g(E', E) = \Sigma_s(E', E)/\Sigma_s(E')$, it follows from Eqn. (I.30) that

$$g_1(E', E)=[1-p_r(E')]\cdot g(E', E). \quad (I.33)$$

Then

$$n(E', E)=\delta(E', E)+\int_0^\infty [1-p_r(E'')]\cdot g(E'', E)\cdot n(E', E')\,dE''. \quad (I.34)$$

Thus an expression analogous to Eqn. (I.7) is obtained for the function $n(E', E)$.

The solution of transport equations for the flux of the species, the collision density, the retardation density, or another equivalent distribution function of hot species opens a pathway for solving the problem of the determination for the rates and probabilities of the reactions or their yields and also to the analysis of parametric relations governing the above quantities. However, the estimation of the distribution function of hot species with respect to energy is not obligatory for the determination of the probability of the chemical reaction [9,27-30].

If the probability of the chemical interaction in the $n$th collision of the hot atom $P_n(E')$ is introduced, then evidently the probability of chemical stabilisation is defined as follows when account is taken of all the collisions for $E'$:

$$P(E')=\sum_n P_n(E'). \quad (I.35)$$

However, it is also evident that

$$P_n(E')=\int_{E_1}^{E_0} g_{n-1}(E', E)\,p_r(E)\,dE. \quad (I.36)$$

Substitution of Eqn. (I.36) in Eqn. (I.35) and transformations of $P_n(E)$ analogous to those performed for $g_n(E', E)$ (see above) lead to the expression

$$P(E')=p_r(E')+[1-p_r(E')]\int_{E_1}^{E'} g(E', E)P(E)\,dE. \quad (I.37)$$

For isotropic scattering and $\alpha = 0$, Eqn. (I.37) becomes

$$P(E')=\bar{p}_r(E)+\frac{1-p_r(E')}{E'}\int_{E_1}^{E'} P(E)\,dE. \quad (I.38)$$

The solution of Eqn. (I.38) yields

$$P(E')=1-[1-p_r(E')]\exp\left[-\int_{E_1}^{E'} p_r(E)\frac{dE}{E}\right]. \quad (I.39)$$

For anisotropic scattering, mainly at small angles, or for isotropic scattering and $\alpha$ close to unity, one obtains

$$P(E')=1-\exp\left\{-\int_{E_1}^{E'}\frac{p_r(E')\,dE'}{E'[1-p_r(E')]\int_0^{E'} g(E', E)(1-E/E')\,dE}\right\}. \quad (I.40)$$

The solution (I.39) is the same as the value obtained under analogous conditions in the determination of $P$ in terms of the distribution functions with respect to energy. In the general case, Eqn. (I.37) can be solved for $P$ by numerical, in particular iterative, methods, and $p_r(E)$ constitutes the first approximation [9,26,31].

For systems containing several components ($i$, $z$) involved in several types of reactions ($j$, $x$), $P(E)$ is defined by the equation

$$P_{ix}(E')=f_i(E')p_{rix}(E')+\int_0^\infty H(E', E)\cdot P_{ix}(E)\,dE, \quad (I.41)$$

where

$$H(E', E)=\sum_{z=1}^{N_r} f_z(E')\left[1-\sum_{j=1}^{\rho_z} p_{rzj}(E')\right]g_z(E', E)+\sum_{z=1}^{N_m} f_z(E')g_z(E', E),$$

$N_m$ is the number of moderators, $N_r$ the number of reactants, $\rho_z$ the number of reaction channels for the component $z$, and $p_{rix}$ the probability of a reaction of type $x$ with the component $i$. The method for the numerical solution of Eqns. (I.37) and (I.41) has been examined [31] with a quantum-mechanical description of elastic scattering.

Thus, without resorting to a preliminary determination of the distribution functions for the energy in terms of Boltzmann equations, one can obtain from the equations for the integral reaction probability in terms of analogous approximations (at least the simplest approximations) expressions relating the probability of chemical reactions to functions and parameters such as $p_r(E)$, $g(E', E)$, and $E_0$. However, this does not imply that the energy distribution functions of different species are no longer of any interest in hot-atom chemistry. Their determination is important, since, firstly, fairly well developed methods are now available for the solution of the Boltzmann equations, i.e. for the determination of the corresponding distribution functions and, secondly, the parametric relations found from the distribution functions, in particular the variation of $n(E)$ and $\psi(E)$ with the initial recoil energy and with the concentration of moderators, may reflect the corresponding parametric relations for the probability of chemical reactions.

The application of the stochastic method to the solution of non-stationary problems made it possible to obtain a number of kinetic equations describing the behaviour in time of the energy distribution function of the hot atoms [32]. For a stochastic description of time variations, it is important that the lifetime of the hot atom ($t$) is proportional to the number of its collisions ($n$) and the average time interval between them ($\tau$): $t = n\tau$; $dt \simeq (n+1)\tau - n\tau = \tau$. In the general case, Keizer [33] describes the variation of the density of hot atoms involved in the reactions by kinetic equations with a quasi-rate constant $k(t)$. If only a small proportion of the collisions lead to chemical absorption and $k(t) < \tau^{-1}$, the distribution is stationary. Under stationary conditions, the change in the number of hot atoms ($n$) and the yield of products ($R_i$) are described by the simple equation $R_i = k_i n/\sum_i k_i$ and $dn/dt = \sum_i k_i n$, where $k_i$ is inversely proportional to $\tau$. Thus, in the case of stationary distributions, the absorption of hot species is described by pseudofirst-order equations and the reaction rate constants have been shown [33] to correspond to an effective temperature $T^*$ determined by the parameters of the energy distributions of the hot species. The following expression has been obtained for light atoms ($m \ll m_i$) and the average energy of chemical reactions $\langle\epsilon\rangle_r$:

$$k=C(T^*)^{-3/2}\exp\left[\frac{\langle\epsilon\rangle_r}{k_B T^*}\right], \quad (I.42)$$

where the constant $C$ may depend on the temperature of the surrounding medium. It is significant that, depending on the reactivity of the system, the effective temperature $T^*$ may be close to the temperature of the target or higher.

## II. THE APPLICATION OF KINETIC EQUATIONS IN THE CHEMISTRY OF RECOIL ATOMS

### 1. Kinetic Relations for Elastic Isotropic Scattering

The kinetics of recoil atoms were first described by Libby [34] and Miller and Dodson [35,36]. Apart from the hypotheses about the isotropic nature of the medium, the elastic billiard collisions with atoms at rest, etc., the hypothesis of a definite role of the energy of the reaction cell or the liquid cage ($\epsilon$) in chemical stabilisation has been used to estimate the probability of the retention of hot atoms. The model postulates additional conditions for the formation of a stable chemical bond in reactions involving substitution by recoil atoms: the energy transmitted to the atom displaced from the molecule must exceed the energy of its chemical bond ($\nu$); the recoil atom must then have an energy $E < \epsilon$. Under these conditions, the probability of retention is defined as follows:

$$P = \frac{\int_{\nu}^{E_0} f_i \psi(E) \frac{\varepsilon}{E} \mathrm{d}E}{\sum_i \int_{\nu/\alpha_i}^{E_0} f_i \psi(E) \frac{\nu - \alpha_i E}{E(1-\alpha_i)} \mathrm{d}E} . \qquad \text{(II.1)}$$

In order to determine $\psi(E)$, one can employ methods examined previously. The form of the solution (II.1) depends on $\nu$, $\alpha$, and $E_0$. Analysis of the solutions obtained led to the conclusion that the probability of the chemical stabilisation of hot atoms is independent of their initial energy in all cases except those where account must be taken of collisions for $\alpha \neq 0$ when $\alpha E_0 < \nu$. The expressions obtained by Miller and Dodson also define the form of the dependence of the retention of hot atoms on the composition of two-component systems. It is significant that $P(E) \propto R$ increases in the presence of a second component having atoms with masses different from $m$ (Fig.1).

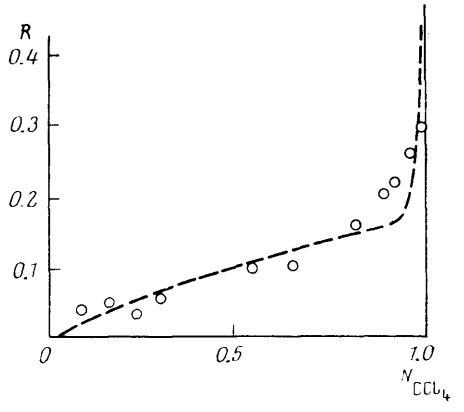

Figure 1. Variation of the yield of labelled $CCl_4$ with its mole fraction in a mixture with benzene; dashed curve—calculation; circles—experiment.

The characteristic features of the Miller–Dodson model are its applicability for relatively low recoil energies; their are no limitations on $E_0$ of the kind which occur in other models.

Postulates analogous to those put forward by Miller and coworkers [35,36] have been used by Capron and Oshima [37]. Analysis of the probability of retention for different ratios of $E_0$, $\epsilon$, and $\nu$ led them to the conclusion that the dependence of $R$ on $E_0$ may be manifested only for low initial energies and $\alpha \neq 0$ (Fig. 2). A similar method for the estimation of $R$ was subsequently developed by Nesmeyanov and Borisov [38].

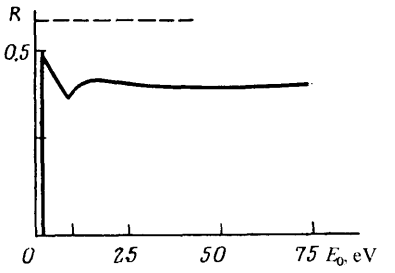

Figure 2. Variation of the yields of substitution products with the initial energy of hot atoms; continuous curve—$\alpha = 0.5$; dashed line—$\alpha = 0$.

Considerable progress in the theoretical interpretation of experimental results in the chemistry of recoil atoms has been achieved as a result of studies by Wolfgang and Estrup [7,8]. The "kinetic theory" of hot-atom reactions developed by these investigators is based mainly on the hypotheses used previously [35,36], but only instances with fairly high initial energies (exceeding the upper threshold for chemical reactions) were considered for a weak perturbation of the particle flux by chemical "erosion" [23]. It was assumed that, without reacting chemically, the recoil atoms undergo repeated elastic scattering and are retarded to energies below $\alpha^3 E_0$ or $E_2$. When the above conditions are fulfilled for weakly absorbing media, one can adopt the Wigner–Fermi approximation, according to which the solution of the transport equation for the values of $n(E)$ used by Wolfgang and Estrup can be formulated as follows:

$$n(E) = \frac{1}{\xi E} \exp\left[ -\sum_I \int_E^{E_2} f_I \frac{p_{rI}(E')}{\xi E'} \mathrm{d}E' \right] . \qquad \text{(II.2)}$$

Substitution of the values of $n(E)$ obtained in equations of type (I.1) yields

$$P = \sum_I \int_{E_1}^{E_2} f_I \frac{p_{rI}(E)}{\xi E} \cdot \exp\left[ -\sum_I \int_E^{E_2} \frac{f_I p_{rI}(E')}{\xi E'} \mathrm{d}E' \right] \mathrm{d}E . \qquad \text{(II.3)}$$

The Wolfgang–Estrup approximation, corresponding to small perturbations of the flux of hot atoms as a result of chemical absorption or the presence of sources, holds more exactly the lower the value of $E$ compared with $E_0$ and the greater the difference between $E$ and the resonance absorption energies. The accuracy of the determination of $P$ increases with decreased reactivity of the medium, characterised by the quantity $\int f p_r(E) n(E) \mathrm{d}E$. In the derivation of Eqn. (II.3), it was assumed that $f$ and $\xi$ are independent of energy; this condition is fulfilled fairly reliably for $f$. Although $\sigma_{sj}$ is a function of energy, the

variation of the ratio $\sigma_{sj}N_j/\sum_j \sigma_{sj}N_j = f_j$ with the energy may be neglected. The hypothesis of the constancy of $\xi$ is fulfilled only in specific instances, for example for isotropic scattering or when $g(E', E) \propto (1/E').\Phi(E/E')$. This limits the region of applicability of the kinetic theory and can lead to significant errors in the determination of the probability of chemical reactions when the methods of kinetic analysis based on this model are used.

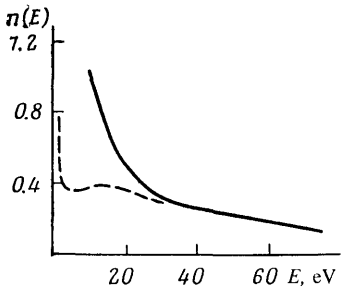

Figure 3. Variation of the number of collisions $n(E)$ in inert systems (continuous curve) and in chemical absorption of hot atoms (dashed curve).

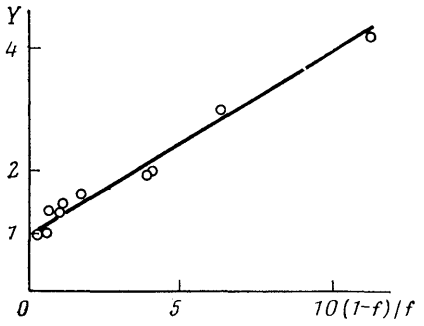

Figure 4. Variation of $y = [-1/\ln(1 - P)]$ in the $He-C_3H_8$ system with $(1 - f)/f$.

It follows from Eqn. (II.2) that, in the range of energies $E_2 \geqslant E$, the collision density corresponding to the specified energy $E$ decreases owing to the chemical reactions and the curves describing the collision density may have extrema, which are particularly distinct in the absence of moderators (Fig. 3).[39] In the Wolfgang–Estrup approximation for systems where the values of $p_r(E)$ or $f$ are significant for only one component (for example, in mixtures with an inert moderator or in the presence of small amounts of added scavengers), the probability of the retention of hot atoms is described by the equation

$$P = 1 - \exp\left[-\frac{fI}{\xi}\right] = \frac{f}{\xi}I - \frac{f^2}{\xi^2}K + \frac{f^3}{\xi^3}L - \ldots \qquad \text{(II.4)}$$

Similar equations can be obtained for the probabilities of the formation of the individual products $P_i$. The terms of the series (II.4) have the coefficients

$$A_{nl} = \frac{1}{n!}\int_{E_1}^{E_2} \frac{p_{rj}(E)}{E}\left[\int_{E}^{E_2} \frac{\sum_j p_{rj}(E')}{E'}\,dE'\right]^n dE, \qquad \text{(II.5)}$$

where $A_{0i} = I_i$, $A_{1i} = K_i$, $A_{2i} = L_i$, etc.[40] Since the series converges rapidly, primarily because of the smallness of $(f/\xi)^{n+1}$, there is no necessity to take into account more than two–three terms of the expansion.

The quantity $I_j$ characterises the integral probability of the formation of the product $j$ in the range of energies $E_2 - E_1$ and reflects the form of the excitation function $p_{rj}(E)$. In the simplest case with a weak energy dependence of $p_r(E)$ we have $\bar{p}_r = I/\ln(E_2/E_1)$ over the entire $E_2 - E_1$ range. The yield of the chemical reaction is not only a function of the probability of the reaction on collision with the species having the energy $E$, but is also determined by the probability that the hot atom is not absorbed in the process involving retardation until the attainment of the energy $E$. The terms of the series (II.5) containing $K$, $L$, etc. take into account the weakening of the flux of hot atoms owing to their absorption in the range $E_2 - E$. The role of such correction terms is particularly marked in the estimation of the yield of products formed in the lower range of the energy spectrum. The quantities $K$ or $L$ yield information about the energy ranges where the values of $p_r(E)$ are non-zero (see below).

Equations of type (II.1)–(II.5) constitute the basis of the kinetic analysis (of the first and second kind) of the experimental data whereby a systematic treatment of a wide range of results can be achieved using several simple parameters ($I$, $K$, and $\xi_r$), measured in units of $\xi_m$ (the subscripts $r$ and $m$ refer to the reactant and the moderator). For mixtures containing an inert moderator in addition to the reacting component, where $\xi = f_r\xi_r + (1 - f_r).\xi_m$, it follows from Eqn. (II.4) that

$$-\frac{1}{\ln(1-P)} = \frac{\xi_r}{I} + \frac{\xi_m}{I}\frac{1-f_r}{f_r}. \qquad \text{(II.6)}$$

When the relation between $-[1/\ln(1 - P)]$ and $(1 - f_r)/f_r$ (Fig. 4), involving the experimental yields of hot-atom reactions, is linear, Eqn. (II.6) can be used to estimate $I$ and $\xi_r$, as well as $\xi_{m_1}/\xi_{m_2}$.[8,41,42] According to the kinetic theory, in mixtures with different moderators the following expression is valid for the ratio of the yields of products $i$ and $j$:

$$\frac{I_i/\xi_{m_1}}{I_j/\xi_{m_1}} = \frac{I_i/\xi_{m_2}}{I_j/\xi_{m_2}} \qquad \text{(II.7)}$$

although the quantities $I_i$, expressed in units of $\xi_{m_1}$ or $\xi_{m_2}$, are different. The equation

$$\frac{\xi P_i}{f_r} = I_i - \frac{f_r}{\xi}K_i, \qquad \text{(II.8)}$$

which is a corollary of Eqn. (II.4), makes it possible to determine $I_i$ and $K_i$ from the corresponding experimental linear relations (Fig. 5). Estimates of the $K_i$ in individual cases[40,43,44] permit conclusions concerning the energy ranges within which various products are formed. According to Baker et al.[43], $F_i = 1 + (\frac{1}{2}I_i^2 - K_i)/[I_i(I - I_i)]$ is a criterion for the estimation of the energy ranges. If reactions (A) have a non-zero value of $p_r(E)$ in the energy range wholly above the corresponding range for reactions (B), then $K_{A,min} = \frac{1}{2}I_A^2$ and $F_A = 1$. When the energy

ranges are the same, $K_A = \frac{1}{2}I_A(I_A + I_B)$ and $F_A = 0.5$. If the energy range for reactions (A) is below that for reactions (B), then $K_{A,max} = I_A I_B + \frac{1}{2}I_A^2$ and $F_A = 0$. Methods for the comparison of the energy ranges for competing processes have been developed by Urch and coworkers[40, 44,45]. The quantities $F^* = (K - I^2/2)/(K_{max} - I^2/2)$, where $F_i^* = (K_i - I_i^2/2)/(K_{i,max} - I_i^2/2)$, varying in the range from 0 to 1, may be used as the principal criterion; all the intermediate values should correspond to overlapping energy ranges; when $F_A^* = 0$, the energy range for reactions (A) is higher than for reactions (B); when $F_A^* = 1$, the energies for which $p_{rA}(E) > 0$ lie below the corresponding energies for reactions (B).

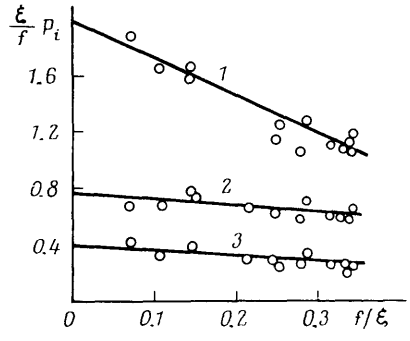

Figure 5. Variation of the probability functions for the formation of labelled products ($\xi/fP_i$) with the composition of the $He-C_3H_8$ mixture ($f/\xi$): 1) HT; 2) $C_3H_7T$; 3) remaining products.

The development of methods for kinetic analysis has led to a number of important conclusions for the interpretation of the results of experiments on the stabilisation of recoil atoms in binary and more complex systems. The prospects for the application of the first approximations of the kinetic theory in the analysis of experimental data for binary mixtures of weak or strong absorbers with $p_{rz}(E) = Cp_{ry}(E)$ and $P_y/P_z = f_y/C.f_z$ were examined by Wolfgang[8], who demonstrated the possibility of estimating $\xi_y/I_y$, $\xi_z/I_z$, and $\xi_y/\xi_z$. Differentiation of the equations obtained by Wolfgang with respect to $N$ ($N$ is the mole fraction of component $y$), assuming that $\bar{p}_r = I/\ln(E_2/E_1)$, showed that the second derivatives $\partial^2 P_z/\partial N^2$ and $\partial^2 P_y/\partial N^2$ may be non-zero.[46-49] Thus the possibility of the deviation of the yields in binary systems from additivity when $\xi_z \neq \xi_y$ or $p_{ry} \neq p_{rz}$ has been established by the analysis of the second derivatives. The causes of the deviations from additivity are evident; for example, the introduction of component $z$ with $\xi_z < \xi_y$ causes an increase of the number of collisions in the range $E_2-E_1$, which leads to an increase of $P_y$.

Since systems containing an inert moderator and a radical acceptor in addition to the reactant are most frequently investigated experimentally in hot-atom chemistry, kinetic analysis of three-component systems is of greatest interest. Methods have now been developed for correcting the results of kinetic analysis to allow for the characteristics of the third component (R).[50-54] For mixtures where this component also fulfills effectively the functions of a moderator, the kinetic analysis can be performed using equations of the type

$$-\frac{1}{\ln(1-P)} = \frac{\xi_r}{I} + \frac{\xi_m}{I}\,\frac{f_m + \frac{\xi_R}{\xi_m}f_R}{f_r}. \qquad (II.9)$$

The presence of a scavenger may also affect the results of the kinetic analysis if the scavenger interacts chemically with the recoil atoms in the hot region[51-54]. Under these conditions, the role of the scavenger is determined by the derivatives $dP/df_R = -f_r K'/\xi^2$, $dP_i/df_R = -f_r K_i'/\xi^2$, or $Y_i = (1/\xi)(df_R/dN_R)(K_i'/I_i)$. $Y_i$ characterises the overlapping of the excitation functions for reactions with the scavenger and the reactant, leading to the formation of the product $i$. The role of the competing scavenger is particularly marked when it is present in large amounts or in the presence of large amounts of a relatively ineffective moderator, where the number of collisions in the hot region is large[51,53]. It follows from Malcolme-Lawes' results[53] that in such cases one can write for $f_r \ll 1$

$$P = 1 - \exp\left(-\frac{f_r}{\xi}I - \frac{f_r f_R K'}{\xi^2}\right),$$
$$P_i = \frac{f_r}{\xi}I_i\left(1 - \frac{f_R}{f_r}K_i'\right), \qquad (II.10)$$

where

$$K' = \int_{E_1}^{E_2} p_r(E)\left(\int_{E'}^{E_2}\frac{p_R(E'')}{E''}dE''\right)dE';$$
$$K_i' = \int_{E_1}^{E_2}\frac{p_r(E')}{E'}\left(\int_{E'}^{E_2}\frac{p_{Ri}(E'')}{E''}dE''\right)dE'.$$

The equations obtained may be used to correct the results of a kinetic analysis which does not allow for the influence of radical acceptors on the yields of hot-atom reactions:

$$I_i = I_{i0} + f_R K_i',$$
$$K_i = K_{i0} + (\xi_r - 1)f_R K_i', \qquad (II.11)$$
$$\frac{\xi_r}{I} = \frac{\xi_{r0}}{I_0}$$

(the subscript zero refers to the results before correction).

Analysis of experimental data based on the kinetic theory led to a deeper understanding of the specific features of hot-atom reactions, their parameters, mechanisms, and kinetics. Without considering in detail the results thus obtained, which have been discussed in a number of reviews[1,2,5,55], we may note that kinetic analysis has yielded proof of the dependence of the quantities $\xi_r$ and $\xi_r/\xi_m$ on the energies of hot species and molecular structure[56]; evidence has also been obtained for a complex mechanism of the action of inert gas moderators, which are involved not only in the relaxation processes of hot atoms, but also in the deactivation of the excited products and their dissociation in collisions[57-60]. Interpretation of the experimental data on the basis of the kinetic theory yielded information about the nature of the excitation functions, about the relation between the energy ranges where the excitation functions for various reactions are significant[44,45], and about the relative widths of the energy ranges for reactions in the presence of various moderators[51]. The problem of the involvement of radical acceptors in hot-atom reactions[53,54] and a number of problems concerning the mechanisms of such reactions and the reactivity of various compounds[45] have been solved using the methods of kinetic analysis.

Thus the possibility of employing the approximate Wolfgang–Estrup model and the fruitfulness of methods of kinetic analysis in the interpretation of experimental results, obtained in the first place for gaseous systems, have thus been confirmed. At the same time, the limits of the applicability of the kinetic theory and its disadvantages were discovered in the course of developing methods for kinetic analysis and their employment. Thus it has been shown that the linear relations between $1/\ln(1-P)$ and $(1-f_r)/f_r$ or between $\xi P_i/f_r$ and $f_r/\xi$ do not constitute a reliable criterion of the correspondence of the model to real systems. According to Malcolme-Lawes and Urch[61], the above relations hold even if the fundamental conditions for the applicability of the Wolfgang–Estrup theory are not fulfilled. Not all the *a priori* conclusions of the theory have been confirmed experimentally. In particular, in contrast to the expected Eqn. (II.7), the following experimental relation has been found for the reactions involving the abstraction and substitution of hydrogen by hot tritium atoms[62–64]:

$$\frac{I_{HT}/\xi_{He}}{I_{RT}/\xi_{He}} > \frac{I_{HT}/\xi_{Ne}}{I_{RT}/\xi_{Ne}}.$$

The majority of the above contradictions arise because the Wolfgang–Estrup model does not take into account the anisotropic scattering and the corresponding $\xi(E)$ relation or the complexity and the many-sided nature of the action of moderators and scavengers and the influence of secondary processes.

Model calculations using the Monte Carlo method and computers have been very important in determining the limits of the applicability of the kinetic theory and of the physical significance of the kinetic parameters obtained in kinetic analysis ($I$, $K$, $\xi_r$).[54,61,65,66]. The simulation of the behaviour of recoil atoms is based on the hypothesis put forward by Wolfgang and Estrup concerning elastic scattering, which makes it possible to assume an equal-probability distribution of energy losses in the range from zero to $E_0[1-\exp(-2\xi)]$. Thus, by selecting the random numbers $u_i$, it is possible to determine the energy of the hot atom after the $i$th elastic collision: $E_i = E_{i-1} \cdot \exp(-2\xi u_i)$. On the other hand, simulation by the Monte Carlo method makes it possible to introduce into computational schemes new postulates concerning the nature of not only the $p_r(E)$ relation but also $\xi_m(E)$ or $\xi_r(E)$; in particular, a Gaussian function has been used: $p_{ri}(E) = h_i \exp[-(E-a_i)^2/c_i^2]$. Methods of kinetic analysis, whereby the quantities $P$, $I$, and $K$ can be estimated for the specified parameters $p_r(E)$, $\xi_r(E)$, $\xi_m(E)$, etc. were subsequently applied to the results of the numerical calculation of the probability of chemical reactions in terms of the fraction of absorbed species[61]. The calculations showed that, for low and even considerable reactivities of the components but with values of $\xi$ which are constant in the energy range investigated, the kinetic analysis based on the Wolfgang system is justified. The parameters $\xi_r$, $I$, and $K$ obtained by this procedure reflect (the first two less satisfactorily) the physical properties of the test objects, in particular the excitation functions. If $\xi_r$ and $\xi_m$ vary but their ratio remains constant in the experimental energy range, the results of the kinetic analysis require a complex interpretation. If $\xi_m/\xi_r$ varies in the energy zone of hot-atom reactions, the employment of the Wolfgang methods leads to erroneous results. The reliability of the estimates of the kinetic parameters depends also on the degree of overlapping of the energy ranges of different chemical reactions. The overlapping of the function $p_{ri}(E)$ has a particularly strong effect on the values of $K_i$; the distortion of the $K_i$ data becomes more pronounced with increase of $\xi_r$. The simulation data showed that one of the fundamental conditions for the improvement of the kinetic theory is allowance for the variation of $\xi$ with the energy $E$.

Summarising the discussion of the application of methods of kinetic analysis, one must consider several of the most significant factors which are bound to determine the further development of theoretical studies in hot-atom chemistry.

1. The Wolfgang–Estrup model does not take into account the thermal motion of the species of the medium and is valid only for atoms with a high initial energy ($E_0 > E_2$); the extension of the application of kinetic analysis to the description of photochemical, radiation-chemical, etc. phenomena requires the removal of the above limitations.

2. The improvement of the kinetic theory and of kinetic analysis should lead to the description of the relaxation processes of the excited products of hot-atom reactions, which were not considered in the Wolfgang–Estrup theory.

3. The results of kinetic analysis depend greatly on the values of $\xi$. The postulate of isotropic scattering, characterised by the quantity $\xi_{is}$, which is independent of the energy of the hot species, does not satisfy the conditions in real systems. The Wolfgang–Estrup model does not take into account two factors, namely the occurrence of non-elastic relaxing collisions and elastic but anisotropic collisions with small energy losses per collision. The role of the non-elastic scattering component is particularly marked for polyatomic molecules, since to a first approximation the contribution of non-elastic collisions is determined by the ratio $M/(M+m)$ ($M$ is the mass of the molecule). However at the present time there is no adequately developed theory whereby one could take into account non-elastic collisions in analytical solutions of transport equations for hot atoms; the yield of the products of hot-atom reactions has not been analysed taking into account the non-elastic scattering component. The attempts to estimate the values of $\xi$ for complex polyatomic molecules have not been successful either. When two polar postulates are adopted, namely that the molecules can be regarded as collections of individual atoms or that the molecules are involved in collisions as simple particles with mass $M$, the calculated values of $\xi$ do not agree with experimental data. For *a priori* estimates of the energy loss in non-elastic collisions of hot atoms, one of the most promising procedures is the method of statistical tests[61,66] and the analytical approach via estimates of the stopping power of the medium has also proved useful[67]. Considerable difficulties still arise also when an attempt is made to take into account the scattering anisotropy; they are associated both with the determination of the form of the functions $\xi(E)$ and with the solution of transport equations for arbitrary $\xi(E)$.

## 2. Kinetic Relations in the Anisotropic Scattering of Hot Atoms

It is known from the physics of atomic collisions[18] that the degree of asymmetry of scattering depends on the energy of the colliding species. Thus in the region of high energies, atomic collisions are of the strongly anisotropic Rutherford type but, as the energy falls below $E_A = (13.6)^2[(m+m_1)/m]Z_1Z\sqrt{Z_1^{2/3}+Z^{2/3}}$, they can be described approximately in terms of the hard-core potential and $\xi_{is}$. In the region of low energies of the chemical interaction, the elastic component of scattering is

again characterised by an appreciable anisotropy and "soft" potentials. The change in interaction potential should lead to the corresponding changes in $g(E', E)$ and $\xi(E)$. The softer the potential, the lower the value of $\xi$. As a consequence of this, an increase in anisotropy increases the number of collisions of the atom in the specified energy range and a change in the energy spectrum of the species and in the yield of the hot-atom reactions. Thus the necessity to take into account the anisotropy of scattering in hot-atom chemistry is evident.

The main tasks in hot-atom chemistry are as follows: 1. The search for the form of the functions $\xi(E)$. Since there are reliable methods for estimating $\xi_{is}$, it is important for hot-atom chemistry to find relations between $\xi$ and $\xi_{is}$. 2. Determination of the nature of the variation of the ratio $\xi_i(E)/\xi_j(E)$ with the energy, since simulation by the method of statistical tests has shown that, when $\xi_m/\xi_r$ varies with the energy, kinetic analysis leads to considerable errors in the determination of the kinetic parameters[68,69]. 3. Solution of the transport equations and the equations for the probability of chemical reactions for specified $\xi(E)$ or $g(E', E)$. 4. Determination of the nature of the variation with the energy of $\varphi(E)$, $n(E)$, or $\Lambda(E) = E.n(E)$ for specified $\xi(E)$. In particular, the test of the possibility of using for non-absorbing or weakly absorbing media asymptotic values of distribution functions of the species energy and the functions $\Lambda(E)$, which are characterised by the strongest dependence on $\xi(E)$, since $\Lambda_0 \propto 1/\xi$.[70,71]

The nature of the variation of $\xi$ with the energy is determined by the form of the interaction potential between the colliding species. For example, the level of anisotropy for the potential $U(r) = ar^{-s}$ depends on the value of $s$:[68]

$$\xi(E) = C(1-\alpha)\left[E\frac{m_1}{m_1+m}\right]^{\frac{2-s}{s(s-1)}},$$

where

$$C \propto A^{2/s}\int_0^\infty \sin^2\frac{1}{2}\,[\sigma(\rho)]\,\rho\,d\rho$$

($\rho$ is the target parameter and $\sigma$ the scattering micro-cross-section). When $s \to \infty$, the scattering is isotropic; the case where $s = 1$ corresponds to Coulombic scattering with maximum anisotropy; for many types of interaction with not unduly large or not unduly small energies, the values of $s$ are in the range 9–12; when $s \gg 2$, the $\xi$ depend relatively little on the energy. It is significant that the ratios $\xi_{m_1}/\xi_{m_2}$ depend little on the energy and are determined mainly by the ratio of the masses of the colliding species. Thus, for $U(r) = Ar^{-s}$ and the combined potential $U(r) = A_1r^{-s_1} + A_2r^{-s_2}$ under the conditions of preferential forward scattering, i.e. for low values of $s$, we have $\xi_{m_1}/\xi_{m_2} \simeq (1-\alpha_1)/(1-\alpha_2)$; when $s \to \infty$, i.e. for the hard-core-potential, we have

$$\xi_{m_1}/\xi_{m_2} = (1-\alpha_2)(1-\alpha_1+\alpha_1\ln\alpha_1)/(1-\alpha_1)(1-\alpha_2+\alpha_2\ln\alpha_2).$$

Estrup[72] was one of the first to draw attention to the necessity to consider the anisotropy of scattering in kinetic analysis. He found[72] that, when $(1-\alpha)/(1+\alpha) < 1$, then $\xi \simeq \xi_{is}.\pi r_0^2/\sigma_S(E)$, where $r_0$ is the distance of closest approach of the species in head-on collisions and $\sigma_S$ is the scattering cross-section; for $\alpha$ close to zero, the best approximation is $\xi \simeq [\pi r_0^2/\sigma_S(E)][\xi_{is} - \kappa(\alpha)\gamma^{-1} + c(\gamma)]$. Special methods were developed for estimating $\gamma$, $\kappa$, $c$, and $\sigma_S$. Calculations and analysis of the dependence of the quantities determining $\xi$ on the energy led Estrup to the conclusion that the energy variation of $\xi$ becomes weaker with increase of the kinetic energy of hot atoms (Fig. 6). Numerical calculations showed that, for collisions of T atoms with He, $D_2$, and $CH_4$, the ratios $\xi/\xi_{is}$ are respectively 0.09, 0.12, and 0.33. In the T + He + $CH_4$ system, the values of $I$ proved to be an order of magnitude smaller than those of $I_{is}$.

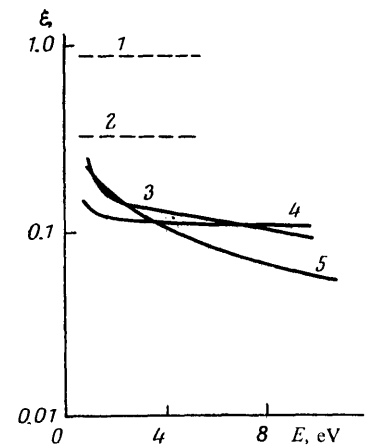

Figure 6. Variation of $\xi = \ln(E/E_0)$ with the kinetic energy of the recoil tritium atoms for isotropic ($\xi_{is}$) and anisotropic ($\xi$) elastic scattering: 1) $\xi_{is}$ in the He–$D_2$ system; 2) $\xi_{is}$ in $CH_4$; 3) $\xi$ in $D_2$; 4) $\xi$ in $CH_4$; 5) $\xi$ in He.

Gordus and coworkers[70,71] also examined elastic anisotropic scattering under the conditions of spherically symmetrical soft potentials, for which one can assume that $\xi = \xi_{is} - b([1-\alpha^2)/2 + \alpha\ln\alpha]$. If the coefficients $b$ are independent of the energy, i.e. $b = 1/(1-\alpha)^2$, then in all cases with $g(E', E) \propto (1/E')\Phi(E/E')$ the values of $\xi$ remain unchanged as $E$ is varied and are determined only by the values of $\alpha$ and $b$. If $b = 1/E(1-\alpha)^2$, the anisotropy is appreciable only for low values of $E$, and $\xi$ increases with increase of the kinetic energy of hot atoms, approaching $\xi_{is}$.

Numerical calculations have been made of $n(E)$ and $\Lambda(E)$ under the conditions of weak absorption. They showed that the greatest differences between the calculated values of $\Lambda(E)$ and the asymptotic values of $\Lambda_0(E) = 1/\xi$ for a constant $b$ correspond to the region where $E/E_0 > \alpha$. With decrease of $\alpha$, the difference between the asymptotic values and the results of the numerical solution of transport equations taking into account the scattering anisotropy becomes smoothed out; when $\alpha = 0$, the values of $\Lambda(E)$ are close to the asymptotic values for any $E$. According to Gordus and coworkers[70,71], the use of the asymptotic values of $n(E)$ or $\psi(E)$ in calculations of the probability of chemical reactions should not lead to appreciable errors; for tritium atoms, the errors should not exceed 50% (Fig. 7).

Analytical solutions have been obtained[73-79] to transport equations for soft potentials of the type $U(r) = Ar^{-s}$ and the following values of $g(E', E)$:

$$g(E', E) = \frac{1}{E'} b\left(E', \frac{E}{E'}\right) \text{ when } E' \geqslant E \geqslant \gamma E';$$

$$g(E', E) = [a(E')/E'] \Phi\left(\frac{E}{E'}\right) \text{ when } \gamma E' \geqslant E \geqslant \alpha E';$$

$g(E', E) = 0$ in the remainder of the energy range; here $\gamma = (1 + \mu^2 + 2\mu \cos\theta_c)/(1 + \mu)^2$, $\mu = m_1/m$, and $\theta_c$ is the critical scattering angle.

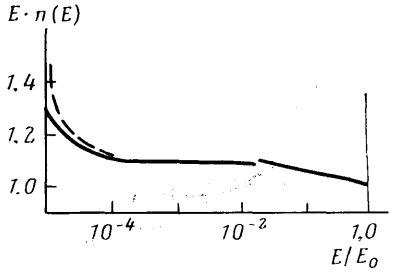

Figure 7. Variation of $E.n(E)$ with $E/E_0$ for $E_0 = 2.5 \times 10^5$ eV; $\alpha = 0.02$; $b = 1/E.(1 - \alpha)^2$; continuous curve—$E.n(E) = \Lambda(E)$; dashed curve—$E.n(E) = 1/\xi = \Lambda_0$.

In non-absorbing systems where $\gamma = 1$ and $a(E) = 1$ and the differential cross-sections are independent of $E$ for any scattering angle, Eqn.(I.8) has the solution $\psi(E') = S_0/E'\zeta$; when $\gamma \neq 1$, the solution is $\psi(E') = S_0/E'\zeta a(E')$, where

$$\zeta = \int_{\gamma}^{1} \ln\frac{E}{E'} \cdot \frac{b(E, E'/E)}{a(E)} d\left(\frac{E'}{E}\right) + \int_{\alpha}^{\gamma} \ln\frac{E}{E'} \Phi\left(\frac{E'}{E}\right) d\left(\frac{E'}{E}\right).$$

Comparison of the solution obtained with the asymptotic solution showed that $\xi \simeq \zeta a(E')$. Taking into account the nature of the variation of $a(E)$ with the energy for $\Sigma_s(E) = CE^{-1(s^{-1})}$, Felder and Kostin[73] found that $\psi(E) = S_0/\zeta E^{\beta}$, where $\beta = 1 - 2/s + 1/(s - 1)$.

For reactive systems, where $\Sigma_s(E) > \Sigma_r(E) > 0$ and $\Sigma_r(E)/\Sigma_s(E) = B$, Felder and Kostin[73] examined a solution of a transport equation of type (I.7) with $g(E', E) = (1/E').\Phi(E/E')$. In this case, they used as the solution the expression $\psi(E') = C(E')^{\beta}$, the values of $\beta$ being found from the equation

$$B = \int_0^1 \Phi\left(\frac{E'}{E}\right)[(E'/E)^{\beta-1} - 1] d\left(\frac{E'}{E}\right). \qquad \text{(II.12)}$$

For an arbitrary form of $\Phi(E'/E)$, the values of $\beta$ are found numerically; when $\Phi(E'/E) = (n + 1)(E'/E)^n$, the analytical solution $\beta = [B + 1/(n - 1)]^{-1} - n$ was obtained. For isotropic scattering, $n$ should be zero, an increase of $n$ corresponding to an increase of the scattering anisotropy.

According to Felder and Kostin[73], $\psi(E) = C/E^{1/(B+1)}$ is obtained for isotropic scattering in absorbing media when $\Sigma_r(E)/\Sigma_s(E) = B > 0$. Consequently in absorbing media $\psi(E)$ varies with energy less markedly than in the absence of chemical capture. The energy spectrum is smoothed out as a result of the "erosion" of low-energy species in chemical reactions. In the most general case, where $n \neq 0$ and $B \neq 0$, an increase of $n$, corresponding to an increase of anisotropy, leads to a decrease of $\beta$ compared with its values in isotropic scattering; this promotes the smoothing of the species distribution functions with respect to energy. This conclusion has a simple physical interpretation. When energy transfer in small portions predominates, the hot atom undergoes a greater number of collisions in the specified energy range, which leads to an increased probability of its absorption in this range before it is retarded with attainment of lower energies.

Asymptotic solutions for $\psi(E)$ have been obtained[74-76,79] in the most general cases of multicomponent absorbing systems, taking into account the influence of secondary high-energy species on the yield of hot-atom reactions. When account is taken of secondary displaced atoms in isotropic scattering in chemically inert systems, we have $\psi(E) \propto 1/E^2$ [instead of $\psi(E) \propto 1/E$].[75]

When absorbing systems were considered and a number of additional conditions were introduced {the potential is not unduly soft, $s > 6$, $\Sigma_r(E)/\Sigma_s(E) = B(E)$, $B(E)/a(E) = D$, $p_r(E) = B(E)/[1 + B(E)]$ and $E < E_2 < E_0$}, Felder[77] obtained the following solutions:

$$P_0 = D^2\left[1 - \left(\frac{E_1}{E_2}\right)^{1-\beta}\right] \Big/ \zeta\zeta_\beta(1 - \beta)^2; \qquad \text{(II.13)}$$

$$P_1 = 1 - \left(\frac{E_1}{E_2}\right)^{D/\zeta} \text{ when } \mu \gg 1 \text{ or } \mu \ll 1; \qquad \text{(II.14)}$$

$$P_2 = 1 - \left(\frac{E_1}{E_2}\right)^{D/\zeta} \cdot \left(\frac{1 + CDE_2^n}{1 + CDE_1^n}\right)^{D/n\zeta} \text{ when } a(E) = CE^n;\ n = \frac{1}{s-1} - \frac{2}{s}; \qquad \text{(II.15)}$$

$$P_3 = 1 - \left(\frac{E_1}{E_2}\right)^{D/\zeta(1+CD)} \text{ when } a(E) = C, \qquad \text{(II.16)}$$

where the quantities $\beta$, $\zeta$, and $\zeta_\beta$ are defined as follows:

$$\zeta = \int_0^1 \lg\frac{E}{E'} \cdot \Phi\left(\frac{E'}{E}\right) d\left(\frac{E'}{E}\right); \quad \zeta_\beta = -\int_0^1 \left(\frac{E'}{E}\right)^{\beta-1} \lg\frac{E'}{E} \cdot \Phi\left(\frac{E'}{E}\right) d\left(\frac{E'}{E}\right); \qquad \text{(II.17)}$$

$$\int_0^1 \left(\frac{E'}{F}\right)^{\beta-1} \cdot \Phi\left(\frac{E'}{E}\right) d\left(\frac{E'}{E}\right) = 1 + D.$$

Together with calculations based on Eqns.(II.13)–(II.16), numerical solutions were also obtained to transport equations for Felder's model taking into account the scattering anisotropy. Comparison of the results of the numerical calculation ($P$) with the calculations by Eqns.(II.13)–(II.16) did not reveal significant differences between $P$ and $P_0$. Thus, for $\mu = 1$, $E_2 = 100$, $E_1 = 25$ eV, $s = 12$, and $D = 0.2$, the values of $P$ and $P_0$ differed by 2.8%; for $\mu = 0.01$, they were indistinguishable. The maximum differences between $P$ and $P_1$ were of the order of 0.5% for $\mu = 0.01$ and approximately 10–15% for $\mu = 0.2$. Comparison of the values of $P$ with $P_2$ and $P_3$ revealed a satisfactory agreement, particularly for $P$ and $P_3$. The differences did not exceed 3–4% for $\mu = 0.01$, 10–15% for $\mu = 0.2$, and 20–25% for $\mu = 1$.

The results of the calculations were also compared with those obtained in terms of the Wolfgang–Estrup approximation. The comparison showed that the accuracy of the simple kinetic approximation increases with increase in the difference between the masses of hot and thermal atoms and with increase in the "hardness" of the potential for low values of $p_r(E)$ or for narrow well resolved resonances in absorption.

Interesting results, characterising the influence of the scattering asymmetry on $\psi$ and $P$, were obtained by Porter

and Kunt [80]. Numerical calculations using stochastic equations yielded the values of $P$ for three different elastic particle scattering models. Model A corresponds to isotropic collisions and model B presupposes anisotropic scattering with $g(E', E) = 2(\zeta - \alpha)/E'(1 - \alpha)^2$. Model C corresponds to anisotropic scattering with $g(E', E) = a/E'(1 - \alpha)$ for $bE' > E > \alpha E'$ or $g(E', E) = [a/E'(1-\alpha)] + 2(1 - a).(\zeta - b)/E'(1 - b)^2$ for $bE' < E < E'$, where $\zeta = E/E'$. The coefficients $a$ and $b$ were fitted by quantum-mechanical calculations. For all the models $g(E', E) \propto \Phi(E/E')/E'$, where $\xi$ is independent of the energy of hot atoms, and $\xi(C) < \xi(B) < \xi(A)$.

Numerical calculations have shown that model C gives the optimum values of $P$, in good agreement with the experimental yields of the stabilisation products of tritium recoil atoms in hydrogen or deuterium. For all the models investigated, an increase is observed in the probability of reactions as a result of an increase in $\Sigma_r(E)$ in the range 0–20 eV; in the range 20–100 eV, the values of $P$ varied only slightly, broad maxima being observed in the vicinity of 20 eV. Porter and Kunt [80] showed that calculation by Eqn. (I.41) and by the Wolfgang–Estrup formulae yields different results; $P_C < P_{W-E}$ for model C and $P_{A,B} > P_{W-E}$ for models A and B. In calculations for mixtures, the deviations were proportional to the content of the reactive component. The errors for $H_2$ are greater then for $D_2$, which is consistent with $\Sigma_r$; it is known that $p_r(H_2) > p_r(D_2)$. However, one must note that the discrepancies between the results are small and comparable to the experimental errors in the determination of the yields of reactions initiated by hot atoms; they do not exceed several per cent.

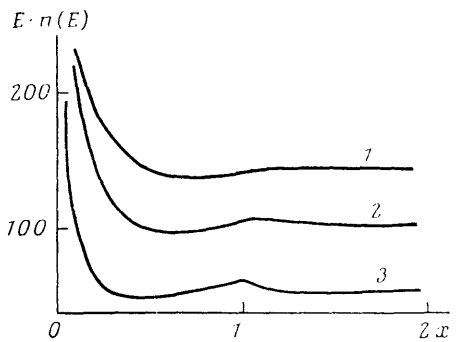

**Figure 8.** Variation of $E.n(E)$ with $x = \ln(E/E_0)/\ln\alpha$ for $E_0 = 10^5$ eV, $\alpha = 0.8882$, and different interaction potentials: 1) $U(r) = 10^2/r^6$; 2) $U(r) = 10^2/r^{12} \pm 10^2/r^6$; 3) $U(r) = 10^2/r^{12}$.

The series of studies designed to improve the kinetic models in hot-atom chemistry was continued by Baer and Amiel [16,17,27,28,41,69]. In the main, they used the postulates discussed previously, but, in the description of elastic scattering processes, they used the combined Lennard–Jones potential $U(r) = A_1/r^{s_1} + A_2/r^{s_2}$ (where $s_1 > s_2$) in addition to the hard-core potential and $U(r) = Ar^{-s}$. The combined potential makes it possible to describe both the short-range forces of the Coulombic repulsion of the nuclei of the colliding species and the long-range polarisation forces giving rise to repulsion or attraction. The Lennard–Jones potential also ensures flexibility in the description of the elastic scattering of species over a wide range of energies. However, methods have not yet been found whereby one can obtain an analytical solution for $g(E', E)$ or equivalent functions for a two-term potential. Numerical computer calculations were therefore made [16,17] of the quantities $g(E', E)$, $n(E)$, and $\Lambda(E)$.

The numerical calculations for $n(E)$ and $\Lambda(x)$, where $x = \ln(E/E_0)/\ln\alpha$ for one-term and two-term potentials, showed that $n(E)$ increases with decrease of the energy; the asymptotic values of $\Lambda_0(E)$ and $n_0(E)$ are attained rapidly, particularly for small $\alpha$ and $s$. For high energies ($E_0 > 1$ KeV), different values of $\Lambda(x)$ were obtained for one- and two-term potentials, the values of $\Lambda(x)$ for the two-term potential depending only slightly on the sign of $A_2$, i.e. on whether the second long-range term characterises repulsion or attraction. For low initial energies, the long-range terms with $A_2 > 0$ completely swamps the short-range term; when $A_2 < 0$, the values of $\Lambda(x)$ are lower than for the one-term potential or the potential with $A_2 > 0$ (Fig. 8).

The results of Amiel and Baer's calculations [16,17] indicate also a series of regularities in the variation of $\Lambda(x)$. It was shown that the variation of $\Lambda(x)$ with the coefficients $A$ and $E_0$ is characterised by the equation

$$\frac{\Lambda^{(2)}(x)}{\Lambda^{(1)}(x)} = \left[\frac{A^{(2)}}{A^{(1)}}\right]^{\frac{2}{s(s-1)}} \left[\frac{E_0^{(2)}}{E_0^{(1)}}\right]^{\frac{s-2}{s(s-1)}}. \qquad \text{(II.18)}$$

Thus the variation of $\Lambda(x)$ with $A$ and $E_0$ becomes weaker as $s$ increases. The greater the difference between the masses of the colliding species the greater the value of $\alpha$ and the greater the sensitivity of $\Lambda(x)$ to changes in any scattering parameters.

The problem of the analytical description of $\Lambda(E)$ was solved by Baer [17] for a modified two-term potential $U + \Delta U$, where $U(r) = A'/r^s$ for $R < r < \infty$ and $U(r) \to \infty$ for $0 < r < R$. These conditions reflect the swamping of the short-range term by the long-range term for low energies, i.e. make it possible to retain the principal advantages of the combined potentials but at the same time significantly simplify the analytical solutions for $G(E', E)$, $\Lambda(E)$, or $\psi(E)$. Without considering their derivation in detail, we shall merely quote Baer's expressions:

$$\psi(E) = \frac{C}{E}\left(\frac{E_{1,2}}{E}\right)^{\frac{1}{s-1}} \left\{1 + \frac{E_1}{E}\sum_{l=0}^{\infty}\frac{4(s-1)}{(2l+3)\cdot[(2l+s)^2-1]} - \right.$$

$$\left. - \frac{2(s+1)}{s(s-1)}\cdot\left(\frac{\gamma_s^2\pi}{2}\right)^{\frac{1}{s}}\cdot\frac{(1-\alpha)\cdot(E_1/E)^{\frac{s+1}{s}}}{1 - s(1-\alpha^{\frac{2s+1}{s}})/[(2s+1)\cdot(1-\alpha)]}\cdot\left(\frac{E_1}{E}\right)^{\frac{s+1}{s}}\right\}, \qquad \text{(II.19)}$$

where $R$ is the sum of the radii of the colliding species and $C = S_0/\xi$ is;

$$E_1 = AR^{-s};\quad E_{1,2} = \frac{m\pi}{2\hbar^2}\lambda_s^{s-1}\left(\frac{A'}{R^{s-1}}\right)^2;$$

$$A' = A\frac{m_1}{m_1 + m};\quad \gamma_s = \frac{\Gamma(s/2 + 1/2)}{\Gamma(s/2)};$$

$$\lambda_s = \sin\left(\frac{\pi}{2}\frac{s-3}{s-1}\right)\cdot\Gamma\left(\frac{s-3}{s-1}\right)\cdot\left[\frac{\Gamma(s/2-1/2)}{\Gamma(s/2)}\right]^{\frac{2}{s-1}};\quad \Gamma\left(\frac{s}{2}\right)\ldots\text{— gamma functions.}$$

It is noteworthy that the above expression is an asymptotic solution valid to within $E_1/E$.

Baer's treatment corresponds to the subdivision of the entire energy range into three sections: $0 < E < E_1$, where the interaction is described by the soft potential $U(r) = A/r^s$, $E_1 < E < E_{1,2}$, where a soft two-term potential also operates, and $E < E_{1,2}$, where the interaction is described by a hard-core potential.

3. Kinetic Equations Taking into Account Non-elastic Scattering and the Stopping Power of the Medium

Apart from those already discussed, Thomsen's model [67] is applicable in the case of a marked scattering anisotropy with small angles predominating. In this model, as in those already examined, no account is taken of thermal motion and the chemical bonds formed by the atoms in the target, the model being restricted to stationary conditions. Limitations are also imposed on the reactivity of the target, but, in contrast to other workers, Thomsen postulates a model whereby one can take into account, together with elastic anisotropic scattering by the nuclei, also electronic retardation, which is particularly significant for high energies. The relaxation processes are characterised in Thomsen's model by the stopping powers $-\mathrm{d}E/\mathrm{d}l$ and not the quantities $g(E', E)$ or $G(E', E)$. This is fairly correct if the moderation process can be regarded as continuous, if the energy losses in the collision $\Delta E$ are small compared with the energies of the hot species, if small scattering angles predominate, and if the masses of the colliding species differ markedly. The introduction of the stopping power as the main characteristic of the moderation processes has many other advantages. Firstly, satisfactory approximations are now available for estimates of $-\mathrm{d}E/\mathrm{d}l$ corresponding to different scattering mechanisms. Secondly, the introduction of the stopping power makes it possible to include the loss of bombarding species from targets with limited volumes, which extends the scope of the model.

Thomsen defines the probability of hot-atom reactions over the entire energy range by the formula

$$P = 1 - \exp \int_0^{E_0} \frac{\Sigma_r(E)\,\mathrm{d}E}{\mathrm{d}E/\mathrm{d}l}, \qquad \text{(II.20)}$$

which permits the determination of $\Sigma_r$ from the known yield of the chemical reaction and the stopping power of the medium. For low absorption cross-sections, when $P(E_0) \ll 1$, it follows from Eqn. (II.20) that

$$P \simeq -\int_0^{E_0} \frac{\Sigma_r(E)\,\mathrm{d}E}{\mathrm{d}E/\mathrm{d}l}. \qquad \text{(II.21)}$$

Thomsen expresses the energy distribution function $\rho(E)\mathrm{d}E$, the number of species per unit volume with the energy $E$ in the range $\mathrm{d}E$, by the product of the function of the source $S(E_0)$, the residence time of the species in the given energy range $\mathrm{d}E$, and the probability of the attainment of this range without absorption. Then

$$\rho(E_0, E)\,\mathrm{d}E = S_0(E_0) \exp\left[\int_0^{E_0} \frac{\Sigma_r(E')\,\mathrm{d}E'}{\mathrm{d}E'/\mathrm{d}l}\right] \mathrm{d}t, \qquad \text{(II.22)}$$

where $\mathrm{d}E$ and $\mathrm{d}t$ are related by the equation

$$-\mathrm{d}E = \left(\frac{\mathrm{d}E}{\mathrm{d}l}\right) \sqrt{\frac{2E}{m}}\,\mathrm{d}t.$$

It also follows from Eqn. (II.22) that, for a monochromatic source in weakly absorbing media, we have

$$\rho(E_0, E) = -\frac{S_0}{\mathrm{d}E/\mathrm{d}l} \sqrt{\frac{m}{2E}} \exp\left[\int_E^{E_0} \frac{\Sigma_r(E')\,\mathrm{d}E'}{\mathrm{d}E'/\mathrm{d}l}\right]. \qquad \text{(II.23)}$$

The functions $\rho(E)$ are related in the following way to the density of chemically active collisions:

$$\psi_r(E) = S_0 \frac{\Sigma_r(E)}{-\mathrm{d}E/\mathrm{d}l} = \rho(E)\,\Sigma_r(E) \sqrt{\frac{2E}{m}}. \qquad \text{(II.24)}$$

It is significant that the stopping powers are additive quantities and $-\mathrm{d}E/\mathrm{d}l = \sum_i N_i \Sigma_{\mathrm{st},i}(E)$, $\Sigma_{\mathrm{st}}$ being the stopping cross-section equal to the sum of the stopping cross-sections in collisions with electrons ($\Sigma_{s,e}$) and with atomic nuclei ($\Sigma_{s,n}$). Thus the introduction of $-\mathrm{d}E/\mathrm{d}l$ facilitates allowance for non-elastic collisions in estimating the quantities $\psi_r(E)$. Thomsen also examined the cases where moderation cannot be described as a continuous process and account must be taken of the discrete nature of the energy transfer, but $\Delta E \ll E$.

Comparison of the expressions obtained for the energy distribution functions and the probabilities of chemical reactions with the solutions of the transport equations for hard-core collisions and anisotropic scattering with $U(r) = Ar^{-s}$, which were discussed previously, led Thomsen to the conclusion that the formulae which he recommended give a fairly correct description of the characteristics of the distribution of hot species with respect to energy in weakly absorbing systems, but the values of $\psi(E)$ obtained from Thomsen's approximate formulae differ from the earlier asympotic solutions of the transport equations. For isotropic collisions, Eqn. (II.24) leads to $\psi_0(E) = 2S_0/(1-\alpha)E$, in contrast to $\psi_0(E) = S_0/\xi E$. The ratio of Thomsen's solution ($\nu$) to the asymptotic solution for a hard-core potential is $2\xi/(1-\alpha)$; for $U(r) = Ar^{-s}$, the following expression is valid for $\nu$:

$$\nu(s, \alpha) = s + [(s-1)/(1-\alpha)] \lg \alpha + (s-1)\cdot(1-\alpha)^{1/s-1} \cdot \int_0^{(1-\alpha)} \chi^{1-1/s} \frac{\mathrm{d}\chi}{1-\chi},$$

where $\chi = N_1\Sigma_{\mathrm{st},1}(N_1\Sigma_{\mathrm{st},1} + N_2\Sigma_{\mathrm{st},2})^{-1}$ for a mixture of two components.

Evidently the values of $\nu$ depend on the ratio of the masses of the colliding species and on the parameters of the potential ($s$) (Fig. 9).

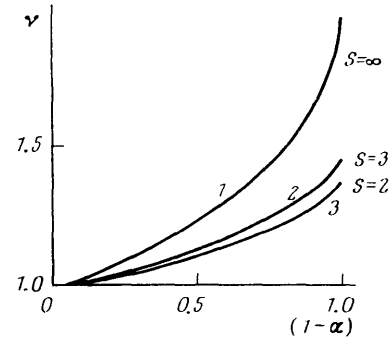

Figure 9. Variation with $\alpha$ of the ratio of the approximate and asymptotic solutions ($\nu$) for the interaction potential $U(r) \propto r^{-s}$: 1) for isotropic scattering; 2) for $s = 3$; 3) for $s = 2$.

In describing relaxation processes, Malerich and Spicer [81] took into account the energy losses in non-elastic collisions accompanied by the dissociation of the molecules of the medium. As a result of such collisions, hot atoms can lose a considerable fraction of their energy in the region of relatively low energies close to the range $E_2 - E_1$.

If the collisions with hot atoms lead to a transition of the molecules of component $z$ from the internal state $i$ to the state $f$ with $\Delta E_{zi\to f}$, then

$$g_z(E', E) = \frac{2\int_0^{2\pi} \sigma_{zi\to f}(V, \zeta, \eta)\, d\eta}{(1-\alpha_z)E'\left[1-\left(\frac{m+m_z}{m_z E'}\right)\Delta E_{zi\to f}\right]^{1/2}\Sigma_{sz}(E')} + \frac{4\pi\sigma_{zi=f}(V, \zeta)}{(1-\alpha_z)E'\Sigma_{sz}(E')}, \quad \text{(II.25)}$$

where $V$ is the relative velocity, $\eta$ and $\zeta$ are scattering angles, and

$$E = E' - \frac{1-\alpha_z}{2}E'\left[1-\left(1-\frac{m+m_z}{m_z E'}\Delta E_{zi\to f}\right)^{1/2}\cos\zeta\right] - \frac{m_z}{m+m_z}\Delta E_{zi\to f}. \quad \text{(II.26)}$$

For the non-elastic scattering component, $g_{zi\to f} = 0$ over the entire energy range, except

$$\frac{1}{2\alpha}(t - \sqrt{t^2-4\alpha s^2}) \leqslant E' \leqslant \frac{1}{2\alpha}(t + \sqrt{t^2-4\alpha s^2}),$$

where

$$s = E + \frac{m_z}{m_z+m}\Delta E_{dis}; \quad t = (1+\alpha_z)s - \frac{(1-\alpha_z)^2}{4}\cdot\frac{m_z+m}{m_z}\cdot\Delta E_{dis}.$$

For the non-elastic scattering component in the energy range of non-zero values, $g_{zi\to f}$, is described by the formula

$$g_{zi\to f}(E', E) = \frac{\Sigma_{z\,dis}(E')}{\Sigma_{sz}(E')(1-\alpha_z)E'\left[1-\frac{m_z+m}{m_z E'}\Delta E_{dis}\right]^{1/2}}. \quad \text{(II.27)}$$

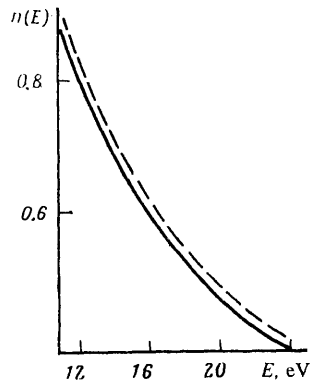

Figure 10. Variation of the asymptotic value of $n_0(E)$ with the energy; dashed curve—with allowance for dissociation; continuous curve—without allowance for dissociation (for isotropic scattering of tritium atoms by deuterium).

The limits of the energy range of non-zero values $g_{zi\to f}$ are determined by the solution of Eqn. (II.26) for the limiting scattering angles $\zeta = 0$ and $\zeta = \pi$. The minimum energy transferred in a non-elastic collision is determined by the value of $\Delta E_{dis}$ which has been set equal [81] to $E_b$; the quantity $\Delta E_{z,dis}$ was calculated by the method of trajectories. For the elastic scattering component, it was assumed [81] that $g_{zi=f}(E', E)$ in the range $E \leqslant E' \leqslant E/\alpha$ is given by the expression $g_{zi=f} = \Sigma_{s,is}/[(1-\alpha_z)\cdot\Sigma_{sz}(E')\cdot E']$. Numerical calculations of $\psi(E)$ and $P$ using the above equations for $g_{zi=f}$ and $g_{zi\to f}$ showed that, for non-elastic energy losses in dissociation, the density of collisions in the region of chemical interaction is lower than for elastic isotropic scattering (Fig. 10). In the region of low energies close to the dissociation threshold, the energy losses in the non-elastic collisions considered have a smaller effect.

## 4. Kinetic Relations Taking Account of the Relaxation of Hot Products

In the solution of transport equations, the relaxation of the hot molecules formed on chemical capture of hot atoms and having an excess kinetic or internal energy ($E_t$ or $E_i$), which makes possible dissociation and other reactions of the primary products, may be taken into account if the probability of the formation of the stable product $p_r(E)$ is represented as follows [68]:

$$p_r(E) = p_c(E) - f'q_r(E) - (1-f')q_m(E), \quad \text{(II.28)}$$

where $p_c(E)$ is the probability of the formation of the product with different sets of $E_t$ and $E_i$, $q_m(E)$ and $q_r(E)$ are the probabilities of the decomposition of the hot molecules in collisions with the moderator or the reactant respectively, and $f'$ is the fraction of the collisions of hot product molecules with reactant molecules. Then, in solutions of type (II.4), we have

$$I(E) = I_0(E) - f'I_r(E) - (1-f')I_m(E); \quad \text{(II.29)}$$

$$\text{when } I_0(E') = \int_0^{E'} p_c(E)\frac{dE}{E} \text{ we have } I_r(E') = \int_0^{E'} q_r(E)\frac{dE}{E};$$

$$I_m(E') = \int_0^{E'} q_m(E)\frac{dE}{E}.$$

Hence

$$P(E) = 1 - \exp\left\{-\frac{f}{\xi}[I_0 - f'I_r - (1-f')I_m]\right\}$$

$$[-\ln(1-P)]^{-1} = \left(\xi_r + \xi_m\frac{1-f}{f}\right)\Big/[I_0 - f'I_r + (1-f')I_m]. \quad \text{(II.30)}$$

The results obtained are important for the interpretation of the experimental data on the non-additivity of the yields in mixtures when the deviations from additivity may be caused by processes involving energy transfer from the primary excited products to the surrounding medium. In particular, it has been shown that, when the probability of the decomposition of the primary products depends on the medium, the variation of $[-\ln(1-P)]^{-1}$ with $(1-f)/f$ when $I_r \neq I_m$ may be non-linear (Fig. 11). However, for low values of $P(E)$, $f$, and $f'$, it follows from Eqn. (II.30) that

$$P^{-1} = I_0^{-1}\frac{\xi_r + \xi_m[(1-f)/f]}{1 - I_m/I_0}. \quad \text{(II.31)}$$

Eqns. (II.31) permit the estimation of the lifetimes of the hot products, since the ratios $(\xi_{m_1}/\xi_{m_2})(I_0 - I_{m_2})/(I_0 - I_{m_1})$ or $(I_0 - I_{m_2})/(I_0 - I_{m_1})$ may be determined from the experimental data for different energy acceptors.

The application of the Monte Carlo method in combination with a novel approach to the problem of describing the relaxation of hot products by binary collisions in the presence of a fraction of stabilised molecules varied by the pressure in the gas system enabled Smith et al. [82] to propose a new method for estimating the parameters of the energy distribution functions of species.

## 5. Kinetic Equations and Their Solutions taking into Account the Thermal Motion of the Molecules of the Target

In the studies examined previously, it was postulated that the thermal motion of the species of the target may be neglected, which is valid only for $E \gg k_B T$. In a series of studies by Kostin and coworkers [83-86] an attempt was made to take into account thermal motion under conditions where the initial energy of the epithermal species is low. Such conditions are encountered in plasma-chemical, radiation-chemical, and photo-chemical studies and in the investigation of chemical reactions in chemical accelerators, in flames, and with recoil atoms in many nuclear decomposition schemes. When account is taken of thermal effects in systems with non-Maxwellised atoms, the conservation equation should contain terms describing elastic collisions involving both a decrease and an increase of the energy of the atom. Under stationary conditions in the source of epithermal species $S(E)$, the conservation equation can be written similarly to Eqn. (I.5). Evidently, when $\Sigma_r \gg \Sigma_s$, the atoms react until there is a significant change in the energy and density of the hot species $\rho(E) \propto S(E)/p_r(E)$. If the medium is chemically inert and the power of the source is low, the species entering from outside attain equilibrium with the surrounding medium, acquiring a Maxwellian distribution corresponding to the target temperature; then

$$n(E) \propto M(E) = \frac{E^{1/2}}{(k_B T)^{3/2}} \exp\left(-\frac{E}{k_B T}\right).$$

When $p_r(E) \neq 0$, the distribution of the bombarding atoms with respect to energy is non-Maxwellian: $\rho(E) \propto M(E) \cdot L(E)$, where $L(E)$ is a correction factor.

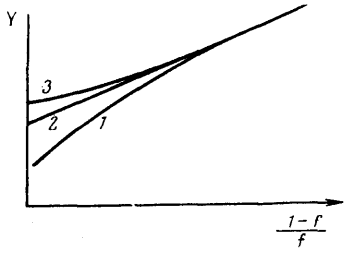

Figure 11. Variation of $Y = -[\ln(1-P)]^{-1}$ with $(1-f)/f$: 1) $I_m > I_r$; 2) $I_m = I_r$; 3) $I_m < I_r$.

The following equation was obtained for this factor on the basis of the principle of detailed balance:

$$[p_s^*(E') + p_r^*(E')] \cdot L(E') = \int_0^\infty g^*(E', E) \cdot L(E)\,dE + S(E')/M(E'), \quad \text{(II.32)}$$

where $p_s^*(E')$, $g^*(E', E)$, and $p_r^*(E')$ are the corresponding probabilities that the atom with the energy $E'$ will be scattered in unit time, will have energy in the range $E-(E+dE)$, and will react chemically.

In a few instances it is possible to convert the integral equation (II.32) into a differential form, which has a solution, by expanding $L(E)$ in Taylor's series. Thus, for small energy changes during scattering, when the scattering anisotropy is marked and there is a large difference between the masses of the colliding species, Eqn. (II.32) gave

$$\frac{1}{2} R_2(E') \frac{d^2 L}{(dE')^2} + R_1(E') \frac{dL}{dE'} + \frac{S(E')}{M(E')} = p_r^*(E') \cdot L(E'), \quad \text{(II.33)}$$

where

$$R_1(E') = \int_0^\infty (E-E') \cdot g^*(E', E)\,dE \text{ and } R_2(E') = \int_0^\infty (E-E')^2 \cdot g^*(E', E)\,dE$$

characterise the average and mean square energies transferred. For reactions with low activation energies, where $\Sigma_r$, $\Sigma_r/\Sigma_s$, and the mean cosine of the scattering angle depend little on the energy, the solution of Eqn. (II.33) assumes the following form for $\epsilon_T^{-1}(m/m_1) < 1$:

$$L(\varepsilon_T) = \text{const}\left[1 + \frac{1}{2} a\varepsilon_T + \ldots + \frac{(a)_n \varepsilon_T^n}{(2)_n \cdot n!}\right], \quad \text{(II.34)}$$

where

$$\varepsilon_T = E/k_B T; \quad a = \Sigma_r \Big/ \left[2\frac{m}{m_1}\Sigma_s(1-\langle\cos\theta\rangle)\right] \text{ and } (a)_n = a(a+1) \times (a+2)\ldots(a+n-1).$$

The solution is valid for $\epsilon_0 > 1$. If, $\epsilon_0 > \epsilon_T > 1$, then

$$L(\varepsilon_T) \propto e^{\varepsilon_T} \varepsilon_T^{a-2}; \quad \psi(\varepsilon_T) = \varepsilon_T e^{-\varepsilon_T} L(\varepsilon_T) \sim \varepsilon_T^{a-1}$$

Thus the greater the value of $a$ for a higher reactivity of the material of the target, the slower the decrease of the collision density with increase of $E$. In non-absorbing systems with $a = 0$, we obtain $\psi(E) \propto 1/\epsilon_T$. Analysis of the solutions leads to the conclusion that, in specimens containing a moderator and a radical acceptor in addition to the reactant and when the reactions have different activation energies, the ratio of the yields of the products of different chemical processes can vary with target temperature (Fig. 12), but only slightly—in the region of very low or very high temperatures.

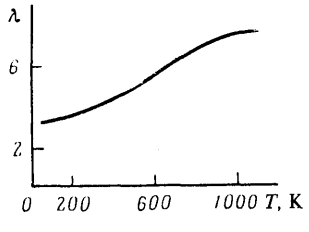

Figure 12. Variation of the ratio of the yields of the primary hot reactions to the yields of the reactions with radical acceptors ($\lambda$) as a function of target temperature ($E_0 = 2.5$ eV; $E_{thresh} = 0.3$ eV; $m_2/m_1 = 1$).

When account is taken of thermal effects, difficulties arise in many instances also in the numerical solution of Eqn. (II.32). In order to facilitate the solution, the function $g^*(E', E)$ is written in the form of a sum of $g_a$ and $g_b$, where $g_a(E', E) > g_b(E', E)$ for small energy transfers and $g_a(E', E) < g_b(E', E)$ for large transfers. This procedure makes it possible to employ instead of Eqn. (II.32) approximate equations which can be solved numerically [86].

The non-stationary problem with allowance for thermal effects has also been solved numerically [87]. For this

purpose, use was made of the transport equation with the correction factors $L(E, t)$ or $L(\epsilon, \tau)$, where $\tau = v_p t/l_s$, $\epsilon = \sqrt{E/k_B T}$, $v_p = \sqrt{2k_B T/m}$, and $l_s$ is the length of the free path of hot atoms before collision with the moderator. Calculation showed that the values of $L(\epsilon, \tau)$ are almost constant over a wide range of thermal velocities already for $\tau > 2$ (Fig. 13).

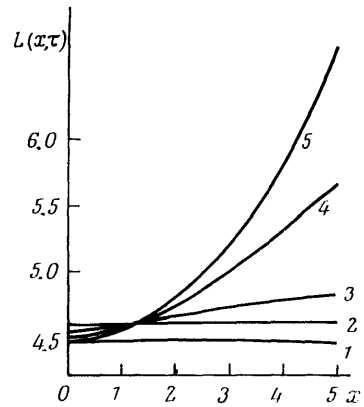

Figure 13. Variation of the correction factor $L(x, \tau)$ with the dimensionless velocity of thermalised species $x = (E/k_B T)^{1/2}$: 1) $\tau \to \infty$; 2) $\tau = 6.0$; 3) $\tau = 2.0$; 4) $\tau = 0.5$; 6) $\tau = 0$.

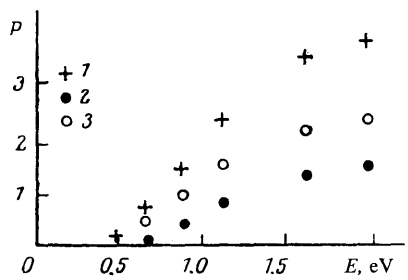

Figure 14. Variation with the energy of the integral probability $P$ of reactions involving the abstraction of deuterium atoms by photolytic H atoms: 1) $C_4D_{10}$; 2) $C_4D_6H_4$; 3) $C_4D_{10}-C_4D_6H_4$).

The kinetic theory of hot-atom reactions has been used successfully to interpret experimental data in photochemistry [88-95]. Thus the variation of the integral probabilities with energy, the threshold energies, and reaction cross-sections have been determined [92] for processes involving the abstraction of deuterium atoms from primary and secondary C–D bonds in deuterobutanes by hot photolytic hydrogen atoms (Figs. 14 and 15). Similar data were obtained from the analysis of the yields of $H_2$ in the interaction of photolytic H atoms with HBr. [93] The kinetic analysis of the photochemical data was performed taking into account the thermal motion of the target molecules; for this purpose, a function (Fig. 16) [92] characterising the kinetic energy distribution ($E_{rel}$) of colliding target species, having a Maxwellian distribution with respect to velocity at the temperature $T$, and of hot atoms with the energy $E$ [90] was introduced into the equations for the estimation of the integral reaction probabilities and the density or number of collisions:

$$\Omega(E_{rel}, E)\,dE_{rel} = \frac{1}{2\mu}\sqrt{\frac{mm_1}{\pi k_B TE}}\cdot\left\{\exp\left[-\frac{m_1}{2k_B T}\left(\sqrt{\frac{2E}{m}}-\sqrt{\frac{2E}{\mu}}\right)^2\right]-\right.$$
$$\left.-\exp\left[-\frac{m_1}{2k_B T}\left(\sqrt{\frac{2E}{m}}+\sqrt{\frac{2E}{\mu}}\right)^2\right]\right\}, \qquad (II.35)$$

where $\mu$ is the reduced mass.

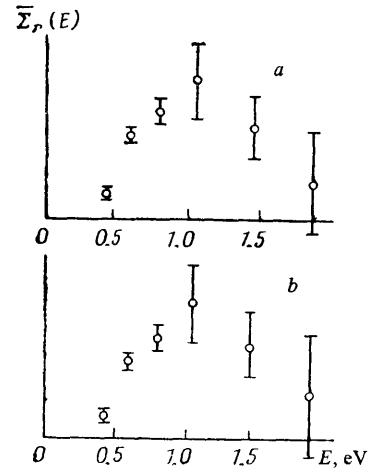

Figure 15. The cross-section of the reaction involving the abstraction of deuterium atoms by photolytic H atoms from a secondary C–D bond in $C_4D_{10}$: *a*) $U(r)_{H-Xe} \propto r^{-7}$; *b*) $U(r)_{H-Xe} \propto r^{-4}$.

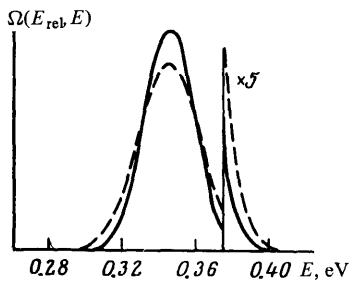

Figure 16. Variation with the energy of the function $\Omega(E_{rel}, E)$ for photolytic H atoms with $E_0 = 0.35$ eV in $C_4D_{10}$; continuous curve—at 229 K; dashed curve—at 323 K.

In systems where allowance for the thermal motion of molecules is necessary, i.e. for small initial energies of the hot atoms, close to non-zero values of $p_r(E)$ and $T > 0$ K, the following equations are valid:

$$n(E_{rel})\,dE_{rel} = \left[\int_0^\infty n(E)\cdot\Omega(E, E_{rel})\,dE\right]dE_{rel}, \qquad (II.36)$$

$$\Sigma_t(E) = \int_0^\infty \Sigma_t(E_{rel})\cdot\Omega(E_{rel}, E)\,dE_{rel}.$$

In this case, equations of type (I.1) for the probabilities of chemical reactions in mixtures containing considerable amounts of the moderator can be written in the form

$$P = \int_{E_1}^{E_2} \frac{\Sigma_r(E_{rel})}{\Sigma_{t,r}(E_{rel})} \int_0^\infty n_m(E) \frac{\Sigma_{t,r}(E)}{\Sigma_{t,m}(E)} \Omega(E, E_{rel})\, dE \cdot dE_{rel} \quad (II.37)$$

In estimating $n(E)$, Gann and coworkers [90-94] used different versions of the asymptotic solutions ($E \ll E_0$) where the average fractions of the transferred energy, in particular $\epsilon_{is} = \langle E' - E \rangle / E' = 2\mu/(m + m_1)$, were substituted for $\xi$ when $m_1 \gg m$. When account is taken of the thermal motion of the target molecules during isotropic scattering, we have

$$\bar{\varepsilon}_{is} = \frac{2\mu}{m + m_1}\left(1 - \frac{3}{2}\frac{k_B T}{E}\right);$$

then

$$n_0(E) \simeq \frac{1}{\bar{\varepsilon}_{is} E} = \frac{m + m_1}{2\mu E}\left(1 - \frac{3}{2}\frac{k_B T}{E}\right)^{-1}. \quad (II.38)$$

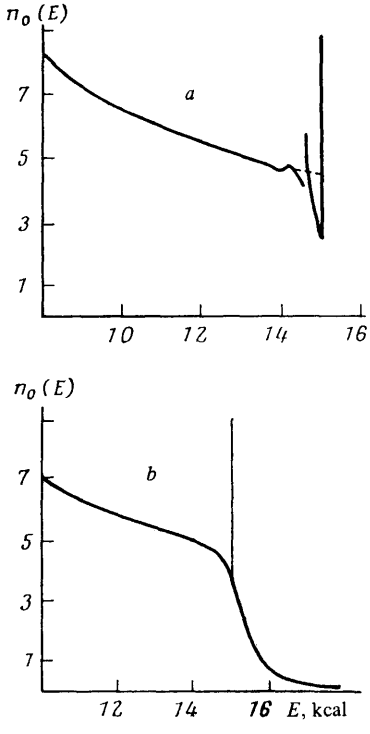

**Figure 17.** Variation with the energy of the asymptotic value of $n_0(E)$ for the hard-core potential of the scattering of photolytic H atoms ($E_0 = 15$ kcal) in xenon: *a*) at 0 K; *b*) at 273 K.

For an interaction described by potentials other than the hard-core potential, for example $U(r) = Ar^{-s}$ or the Lennard–Jones potential in the range where $E < 0.93E_0$, we have

$$\bar{\varepsilon}(E) = \frac{2\mu}{m_1 + m}\left(1 - \frac{3}{2}\frac{k_B T}{E}\right)\frac{Q(E)}{\Sigma_t(E)},$$

where $Q(E) = \int_0^\infty Q(E_{rel})\Omega(E_{rel}, E)dE_{rel}$. In the general case, $Q(E_{rel})$, the moment of the transport cross-section, is found by graphical integration [96]. The expression

$$n_0(E) \simeq \text{const} \cdot E^{-\left(1-\frac{s}{2}+\frac{1}{s-1}\right)}\left(1 - \frac{3}{2}\frac{k_B T}{E}\right)^{-1} \quad (II.39)$$

was obtained for $U(r) = Ar^{-s}$.

Calculation of $n_0(E)$ by the above methods led to the following conclusions: (1) when $T \gg 0$ K, there are collisions in the region where $E > E_0$ (Fig. 17), the oscillations in $n(E)$ in the vicinity of $E_0$ being smoothed out under these conditions. 2. The form of the function $n_0(E)$ depends only slightly on the form of the interaction potential. 3. For the Lennard–Jones potential, the decrease of the collision density near $E_0$ is manifested less markedly than for the hard-core potential. The width at the half height level of the tail portion of the function $n_0(E)$ increases appreciably with increase of the target temperature (Figs. 18 and 19). The width of the distribution with respect to relative energy can be large even for $E_0 > k_B T$, since the relative energies are in the range $E_{max} - E_{min}$; $\Delta E \propto \mu\sqrt{k_B T E/mm_1}$.

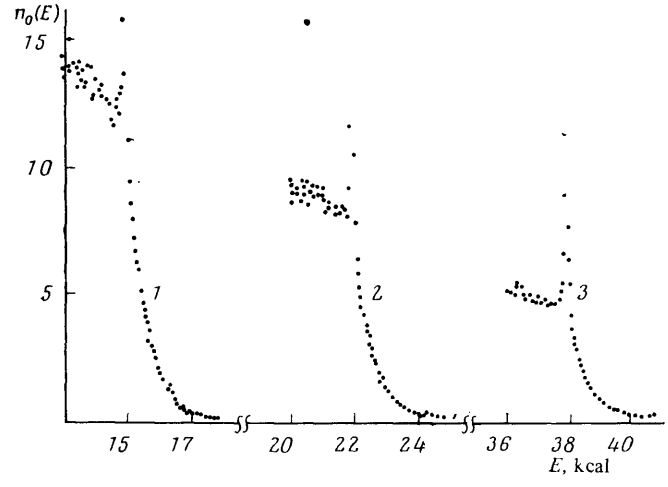

Figure 18. Variation of the asymptotic value of $n_0(E)$ for the Lennard–Jones potential in the H–Xe system ($E$ = 273 K) as a function of the energy of the photolytic H atoms (kcal): 1) 15; 2) 22; 3) 38.

Numerical solutions of the Boltzmann equation for the collision density were also obtained by Kupperman et al. [88] with the analogous function $\Omega(E, E_{rel})$ and $g(E', E)$ expressed in terms of the normalised Gaussian function. It was assumed that the flux of hot species is fairly small and does not affect the thermal distribution of the target molecules.

In conclusion of the review of data on the analytical and numerical solutions of kinetic equations in relation to the distribution functions of hot species with respect to energy or the probabilities of the chemical reactions initiated by them, we shall specify the most important of the results obtained. For energies below the initial values, the particle distribution functions with respect to energy $\psi(E)$, $n(E)$, and $\varphi(E)$, etc. attain asymptotic values. The asymptotic values increase with decrease of the energy $E$.

In the vicinity of sources, more precisely for $E = \alpha E_0$, the distribution functions undergo a discontinuity and in the vicinity of $\alpha^3 E_0 < E < E_0$ they exhibit oscillations.

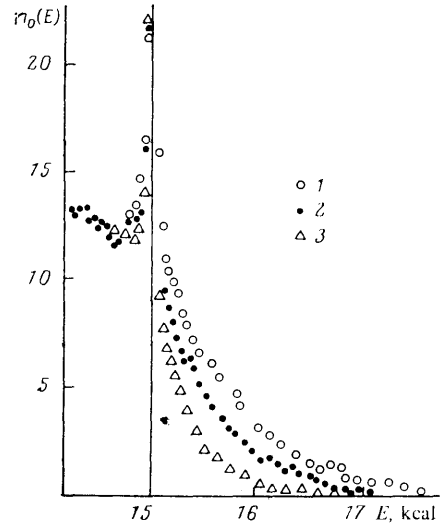

Figure 19. Variation of the asymptotic value of $n_0(E)$ for the Lennard–Jones potential of the scattering of photolytic H atoms ($E_0 = 15$ kcal) in xenon as a function of temperature (K): 1) 373; 2) 273; 3) 173.

In non-absorbing media, the asymptotic value of the collision density is inversely proportional to the energy $\psi_0(E) = S_0/E\xi(E)$. For initial energies of the species $E_0$ comparable to the energy of the thermal motion of target atoms and molecules, the asymptotic value of the collision density is inversely proportional to the energy normalised with respect to $k_B T$, i.e. $\psi_0(\epsilon_T) \propto 1/\epsilon_T$, where $\epsilon_T = E/k_B T$. The rate of attainment of asymptotic values is determined mainly by the ratio of the masses of the hot atom and target species and also by the parameters of the interaction potentials. For elastic isotropic collisions, the asymptotic value of $\psi_0(E)$ can be used in the region where $E < \xi_{is} E_0$. For elastic anisotropic scattering, for example for potentials of the type $U(r) = Ar^{-s}$ or $U(r) = A_1 r^{-s_1} + A_2 r^{-s_2}$, the rate of attainment of the asymptotic value is particularly large for small values of $s$ and $\alpha$, i.e. for similar masses of the colliding species. Analytical criteria of the applicability of $\psi_0(E)$ for arbitrary potentials are unknown. For individual types of potentials, the results of numerical calculations are available, showing that, for example, for $U(r) = Ar^{-s}$ with $s < 10$ and $\alpha < 0.8$, the asymptotic value of the collision density is attained already when $\ln(E/E_0)/\ln\alpha \geq 1$.

When hot species are retarded as a result of elastic collisions, the distribution functions show a general tendency to increase with decrease of the energy. However, the detailed variation of the change in $\psi_0(E)$ or $\psi(E)$ is determined by the average logarithmic energy losses and their variation with $E$. The values of $\xi_{is}$ are constant over the entire range of energies of the elastic isotropic collisions. For anisotropic scattering, the values of $\xi$ may remain constant as $E$ varies, for example when $g(E', E) \propto 1/E'\Phi(E, E')$, but they can also vary with the energy. Since small scattering angles predominate in elastic and anisotropic collisions, it follows that $\xi_{is} > \xi$ and $\psi_{0,is}(E) < \psi_0(E)$. The decrease of $\xi(E)$ with decrease of $E$ leads to a weakening of the dependence of the asymptotic values of the distribution functions on the energy. For example, for $U(r) = Ar^{-s}$, the collision density is inversely proportional to $E^\beta$, where $\beta = 1 - 2/s + (s-1)^{-1} \leq 1$ ($\beta = 1$ when $s = 2$, $\beta = 0.83$ when $s = 4$, etc.).

The asymptotic values of the collision densities and the equivalent distribution functions depend only slightly on the initial energy of the hot species if $E_0 \gg E$. The nature of this dependence is likewise determined by the parameters of the interaction potentials. Thus, for $U(r) = Ar^{-s}$, the ratio of the asymptotic values of $\psi_0(E, E_0^{(2)})/\psi_0(E, E_0^{(1)})$ is proportional to $[E_0^{(2)}/E_0^{(1)}]^{s - 2/s(s-1)}$; consequently, for fairly large values of $s$ and in the case of the hard-core potential, $\psi_0(E)$ is almost independent of $E_0$ for $E \ll E_0$.

In absorbing media, the distribution functions for hot particles with respect to energy have the same qualitative features as in inert moderators. They too can have discontinuities at $E = \alpha E_0$ and can exhibit oscillations in the vicinity of sources of hot species and intense chemical absorption zones, which may be regarded as negative sources. The distribution functions in the reactive systems likewise have asymptotic solutions in the regions of energies remote from the sources or the intense chemical reaction zones. The values of $\psi_0(E_0)$ in absorbing media also decrease with increase of $E$. However, those of $\psi_0(E)$ in reactive media take into account the "erosion" of the hot species from the spectrum by chemical reactions. The "erosion" has a particularly marked influence on the region of low energies. For a weak perturbation of the particle flux (see above), the asymptotic solutions of the transport equations taking into account the "erosion" have a form formally identical with that of solutions for inert moderators: $\psi_0(E) = q(E)/E\xi(E)$.

The use of asymptotic distribution functions in the calculation of the probability of chemical reactions does not lead to major errors. The results are in this case more accurate the further away is $E_0$ from the energy range of the reactions. The accuracy of the determination of $P$ in terms of asymptotic distribution functions increases with decrease of $\alpha$ and also with decrease of the reactivity of the components, i.e. with decrease of $\int f p_r(E).n(E)dE$.

In weakly absorbing systems, $q = S_0 p(E)$, i.e. it contains the correction factor $p(E)$, characterising the probability of avoiding capture during the moderation process until the attainment of the specified energy $E$. Evidently, the appearance of the correction factor dependent on $E$ may alter the variation of the distribution functions with energy in a chemically reactive medium compared with an inert medium. Interpretation of the resonance integral $p(E)$ shows that the overall tendency should be towards the smoothing out of the dependence of $\psi_0(E)$ on the energy.

Owing to "erosion" as a result of the chemical absorption of hot species, the flux or density of collisions increases more slowly with decrease of the energy than predicted by the $1/E$ law even for $\xi = \text{const}$. This is shown most clearly by the exact solutions of the transport equations for $\alpha = 0$ and for the ratio $\Sigma_s(E)/\Sigma_r(E) = c$ independent of the energy. Under these conditions, $\psi(E) \propto E^{-c/(1+c)}$; thus, with increase of the reactivity of the system owing to the decrease of $c$, the collision density changes with the energy less markedly. This general tendency persists for approximate solutions under the

conditions of appreciably different masses of the colliding species, when $\alpha \neq 0$, regardless of the potential used to describe the scattering processes and whether or not the scattering is isotropic or anisotropic. The smoothing out of the variation of the distribution functions with energy is characteristic also of the energy range where account must be taken of the thermal motion of the target species. In certain specific instances, the asymptotic value of $\psi_0(\epsilon_T)$ is inversely proportional to $\epsilon_T^{(1-a)}$. The values of $a$ are proportional to the ratio $\Sigma_r(E)/\Sigma_s(E)$ and characterise the reactivity of the medium. The higher the reactivity of the material of the target, the larger the value of $a$ and the correspondingly less marked the dependence of $\psi_0(\epsilon_T)$ on the energy.

The anisotropy of scattering for values of $\xi_{anis}$ dependent on the energy promotes, as in non-absorbing systems, a further smoothing out of the energy spectrum and a slower variation with the energy of the asymptotic values of the distribution functions. Whereas $\psi(E) \propto E^{-c/(1+c)}$ for retardation as a result of elastic isotropic scattering, we have $\psi_0(E) \propto E^{-\beta}$ for anisotropic scattering and $|\beta| < |c/(1+c)|$. The softer the potential of the elastic interaction, the smaller the value of $\xi_{anis}$ and the greater the number of collisions per unit energy. This leads to an increase of the overall probability of chemical capture owing to the large number of collisions for the same probability of a single collision.

The asymptotic values of the distribution functions in absorbing systems depend only slightly on the initial energy of the hot species if $E \ll E_0$. This is evident, since the values of $\psi_0(E)$ undistorted by chemical absorption (in non-absorbing systems) depend only slightly on $E_0$ and the probability of avoiding capture following retardation to $E$ is almost independent of $E_0$ when $E_2 < E_0$. Accordingly, the probability of chemical reactions for $E_2 < E_0$ may be expected to depend only slightly on $E_0$. This conclusion follows from the stochastic definition of the probability of chemical reactions of hot atoms in terms of Porter's formulae.

For mixtures of inert moderators, $\psi_0(E) \propto 1/\bar{\xi}E$, where $\bar{\xi} = \sum_i f_i\xi_i = \sum_i (N_i\sigma_{si}/\sum_j N_j\sigma_{sj})\xi_i$. The dependence of $\bar{\xi}$ on the mole fraction of the components determines to a large extent the nature of the corresponding variation of the collision densities and probabilities and yields of hot reactions in binary and more complex systems. The simplest linear relations, for example between $-1/\ln(1-P)$ and $(1-f_r)/f_r$, describe the yields of chemical reactions in mixtures of the reactive components with inert moderators. Similar simple relations have been obtained also for mixtures containing, apart from the moderator, two reactants with low chemical reaction cross-sections, for mixtures of the moderator and two strong absorbers with $p_{rz}(E) = \text{const.}p_{ry}(E)$, and for mixtures of two reactants. Comparison of the above relations with the experimental data for kinetic analysis made it possible to obtain much information about the nature of the processes involving hot atoms.

In conclusions, one should note that the characteristics of the parametric relations involving distribution functions with respect to energy and the probabilities of chemical reactions, obtained by solving Boltzmann equations, agree with the results of calculations based on stochastic schemes.

# Niobates and Tantalates of Tervalent Elements

A.M.Sych and A.M.Golub

The types of compounds in the $A_2O_3$–$B_2O_5$ systems, where A = the *p*-, *d*-, and *f*-elements of Group III, the *p*-elements of Group V, and the *d*-elements of the fourth period in the tervalent state and B = Nb or Ta, are considered. An analysis of the methods of making the niobates and tantalates is given, their structure is described, and their physicochemical and electrophysical properties are reviewed. Special attention has been paid to the description of the rare-earth element metaniobates, which exhibit the properties of electrets, and of the compounds of composition $ABO_4$ (A = Sb, Bi; and B = Nb, Ta), which belong to a new group of ferroelectrics. Bibliography of 147 references.

## I. INTRODUCTION

Niobates and tantalates of various metals are widely used in contemporary technology. They are usually used as the pure compounds or as components of solid solutions, which exhibit ferro-, piezo-, and pyro-electric, electro-optical, and other properties[1-3]. Materials based on them are employed in the production of ceramic generators of ultrasound, sound pickups, piezoelectric microphones and telephones, strain gauges, hydroacoustic collectors (receivers) of energy, laser crystals, etc.[3]

The development of the newest technology and the consequent requirement for new materials has aroused exceptional interest in the niobates and tantalates of tervalent metals. The successful combination of various physical properties with chemical inertness, high resistance to heat and moisture, and mechanical strength puts the niobates and tantalates of the tervalent metals among the most important materials of the new technology. Thus the rare-earth element (r.e.e.) orthoniobates of composition $RNbO_4$, activated with $Nd^{3+}$ ions, serve as materials for lasers[4]. Antimony and bismuth orthoniobates and orthotantalates of composition $ABO_4$ have ferroelectric properties, which are successfully combined with high pyro- and piezo-sensitivity[5]. The metaniobates $R(NbO_3)_3$ can be used as ceramic electrets[6,7]. The niobates and tantalates of composition $RBO_4$ (where R = Y, La, or Nd) with fergusonite structure are antiferroelectrics with a high Curie temperature[8,9].

The number of papers dealing with the preparation and investigation of the properties of niobates and tantalates began to increase sharply after 1960. However, the results obtained have not yet been systematically examined, although there have been monographs[1,2] which deal with a limited set of problems on the preparation and certain properties of the niobates and tantalates of tervalent elements.

The present paper systematically examines the results on the methods of preparation, crystal-chemistry, and certain physicochemical and electrophysical properties of the niobates and tantalates of tervalent elements. Of the many types of compound among the niobates and tantalates we will consider only the simple compounds of the $A_2O_3$–$B_2O_5$ binary systems, where B is Nb or Ta, and will not deal in detail with mixed niobates and tantalates, that is, the compounds formed in the $M_2O$–$A_2O_3$–$B_2O_5$ systems and also the so-called aquoniobates and aquotantalates formed in the $A_2O_3$–$B_2O_5$–$H_2O$ system. Special attention is paid to the most important inorganic materials of contemporary technology, the r.e.e., Sb, and Bi niobates and tantalates.

The niobates and tantalates of tervalent metals can be regarded as salts of hypothetical niobic and tantalic acids, namely, the ortho-salts $ABO_4$ as derivatives of the ortho-acids $H_3BO_4$ ($3H_2O.B_2O_5$), the meta-salts $A(BO_3)_3$ as derivatives of the meta-acids $HBO_3$ ($H_2O.B_2O_5$), and finally, many polyniobates and polytantalates $A_nB_mO_{2.5m+1.5n}$ (for example, $ANb_5O_{14}$, $ANb_{11}O_{29}$, $A_2Nb_{12}O_{33}$, $A_2Ta_{12}O_{33}$) as salts of the acids $nH_2O.mB_2O_5$.

Depending on the chemical nature of element A, it is desirable to consider the niobates and tantalates by dividing them into the following classes: (a) the niobates and tantalates of the Group III *p*-elements (Al, Ga, In, Tl); (b) the niobates and tantalates of the Group III *d*- and *f*-elements (r.e.e.); (c) the niobates and tantalates of the Group V *p*-elements (Sb and Bi); (d) the niobates and tantalates of the fourth period *d*-elements (Ti, V, Cr, and Fe).

## II. TYPES OF COMPOUND

### 1. ALUMINIUM, GALLIUM, INDIUM, AND THALLIUM NIOBATES AND TANTALATES

Table 1 shows the niobates and tantalates of the metals of the aluminium subgroup known at present. The orthoniobates and orthotantalates of composition $ABO_4$ (known for all the elements except thallium) are characteristic. Aluminium orthotantalate $AlTaO_4$ is encountered in nature as the mineral simpsonite[28]. The existence of metaniobates and metatantalates of composition $A(BO_3)_3$ has been established reliably only for thallium[26,27]. There are reports of the preparation of the aquometaniobates $Al(NbO_3)_3.nH_2O$[20,29,30] and $In(NbO_3)_3.nH_2O$.[25]

The compounds in the $Al_2O_3$–$Nb_2O_5$ system (Fig. 1) have been studied most completely; apart from $AlNbO_4$, the existence of the polyniobates $AlNb_{11}O_{29}$ and $AlNb_{49}O_{124}$ has been found[12,21]. There have also been reports of the existence in this system of the compounds $AlNb_9O_{24}$,[14] $AlNb_{25}O_{64}$,[14] and $AlNb_{29}O_{74}$.[16]

**Table 1.** Niobates and tantalates of the *p*-elements of Group III and methods of making them.

| B | Al | | Ga | | In | | Tl | |
|---|---|---|---|---|---|---|---|---|
| | composition | method of preparation* | composition | method of preparation* | composition | method of preparation* | method | method of preparation* |
| Nb | $AlNbO_4$ [10–13] | T[10–13,18], CO[20] | $GaNbO_4$ [13,21,22] | T[13,21,22] | $InNbO_4$ [13,22,24] | T[13,22,24], CO[25] | — | — |

| | $AlNb_{11}O_{29}$ [11–17] | T[11–17] | $GaNb_{11}O_{29}$ [21] | T[21] | | | $Tl_4Nb_6O_{21}$ [26] | T[26] |
| | $AlNb_{25}O_{64}$ [14] | T[14] | — | — | | | | |
| | $AlNb_{29}O_{74}$ [16] | T[16] | $GaNb_{29}O_{74}$ [16] | T[16] | | | | |
| | $AlNb_{49}O_{124}$ [13,17] | T[13,17] | $GaNb_{49}O_{124}$ [21] | T[21] | | | | |
| Ta | $AlTaO_4$ [11,13] | T[11,13,19] | $GaTaO_4$ [13,23] | T[13,19,23] | $InTaO_4$ [13,24] | T[13,24] | — | — |
| | | | | | | | $TlTa_3O_9$ [27] | CO[27] |
| | | | | | | | $Tl_4Ta_6O_{21}$ [27] | CO[27] |

T = solid-phase preparation by heating mixture of oxides; CO = coprecipitation of the components from solutions.

Note. In this table and in subsequent tables all superscripts are reference numbers.

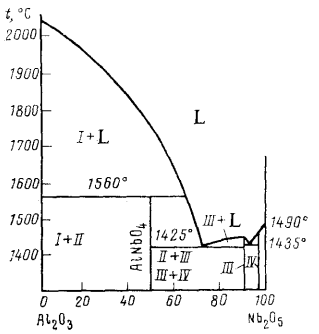

**Figure 1.** Equilibrium diagram of the $Al_2O_3$–$Nb_2O_5$ system[12]: *I* = $Al_2O_3$; *II* = $AlNbO_4$; *III* = $AlNb_{11}O_{29}$; *IV* = $Nb_2O_5$.

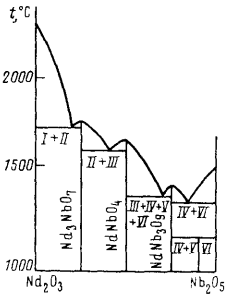

**Figure 2.** Equilibrium diagram of the $Nd_2O_3$–$Nb_2O_5$ system[59]. *I* = $Nd_2O_3$; *II* = $Nd_3NbO_7$; *III* = $NdNbO_4$; *IV* = $NdNb_3O_9$; *V* = $Nd_2Nb_{12}O_{33}$; *VI* = $Nb_2O_5$.

## 2. R.E.E. NIOBATES AND TANTALATES

In considering the niobates and tantalates of the Group III *d*- and *f*-elements it is desirable to isolate into separate groups Sc and Y compounds, compounds of the cerium-subgroup lanthanides (La, Ce, Pr, Nd, Sm, and Eu), and those of the yttrium-subgroup lanthanides (Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu). The many types of niobates and tantalates of these subgroups of metals are shown in Table 2, from which it is clear that compounds $ABO_4$ are known for all the r.e.e. Compounds of this composition are widely encountered in nature as the minerals fergusonite[83] ($YNbO_4$) and formanite ($YTaO_4$).

The compounds $A_3NbO_7$ and $A_3TaO_7$ are also known for all the r.e.e. However, the niobates $A_3NbO_7$ of the yttrium-subgroup elements have been obtained only for Gd,[38] Dy,[38] and Ho,[78] whereas tantalates of analogous composition are known for all the elements. The metaniobates $RNb_3O_9$ have been described only for the lanthanides of the cerium subgroup. The elements with ionic radius < 0.80 Å apparently cannot form compounds of this type. However, metatitanates $RTa_3O_9$ have been obtained for almost all the r.e.e. Since the r.e.e. metaniobates and metatantalates have the structure of perovskite $ABO_3$, their formula is best represented as $Ln_{1/3}NbO_3$ and $R_{1/3}TaO_3$.

The formation of pentaniobates of composition $LnNb_5O_{14}$ has been shown for La, Ce, Pr, Nd, and Eu[56–58] but such compounds are not formed for the other elements. There is no information about r.e.e. pentatantalates. Dodecaniobates $Ln_2Nb_{12}O_{33}$ (Ln = La, Ce, Pr, and Nd)[45,59] and dodecatantalates $Ln_2Ta_{12}O_{33}$ (Ln = La, Nd)[37,61] have been described only for the elements of the cerium subgroup.

For tantalum, the compounds $LnTa_7O_{19}$ are also known[38,41], being formed throughout the entire series of lanthanides except for Yb and Lu.[41] The equilibrium diagrams in the $Ln_2O_3$–$Nb_2O_5$ and $Ln_2O_3$–$Ta_2O_5$ systems have not been studied systematically. As an example, Fig. 2 gives the equilibrium diagram of the $Nb_2O_5$–$Nd_2O_3$ system as an example. The existence of the compounds $Nd_3NbO_7$, $NdNbO_4$, $NdNb_3O_9$, and $Nd_2Nb_{12}O_{33}$ has been observed.

| | — | — | $LnNb_5O_{14}$ [50,56—58] | T[57] | — | — |
| | — | — | $Ln_2Nb_{12}O_{33}$ [49,59] | T[49,59], CO[59] | — | — |
| Ta | $ATaO_4$ [13,31,34,35,39] | T[13,31,34,35,39] | $LnTaO_4$ [13,31,53,60—66] | T[13,31,49,53,60—63], CO[65,66] | $LnTaO_4$ [13,62,63,80—82] | T[13,62,80—82], CO[63] |
| | $A_3TaO_7$ [38] | T[38] | $Ln_3TaO_7$ [31,38,44,61,63] | T[31,38,49,61,63] | $Ln_3TaO_7$ [38,63] | T[38,63] |
| | $ATa_3O_9$ [40] | T[40] | $LnTa_3O_9$ [40,55,61,63,66] | T[41,40,55,61,63] | $LnTa_3O_9$ [40,55,63] | T[40,55,63] |
| | — | — | $Ln_2Ta_{12}O_{33}$ [49,61] | T[49,61] | — | — |
| | $ATa_7O_{19}$ [41] | T[41], CO[41] | $LnTa_7O_{19}$ [41,57] | T[41,57], CO[41] | $LnTa_7O_{19}$ [41] | T[41], CO[41] |

*T = solid-phase preparation by heating mixtures of oxides; CO = coprecipitation of the components from solutions; Kp = crystallisation from solution in a melt; Ch = preparation of single crystals after Czochralski.

Even a simple list of the types of compounds of the elements of subgroup IIIa shows that (unlike the niobates) the tantalates exist in a large number of varieties. This is especially noticeable for Sc, Y, and the yttrium subgroup of lanthanides.

## 3. ANTIMONY AND BISMUTH NIOBATES AND TANTALATES

The minerals stibiocolumbite $SbNbO_4$, stibiotantalite $SbTaO_4$, and bismutotantalite $BiTaO_4$,[83] are encountered in nature, and these compounds have been prepared under laboratory conditions only comparatively recently[13,84-93], evidently owing to the volatility of the oxides $Sb_2O_3$ and $Bi_2O_3$ above 650–700°C.

**Table 3.** Antimony and bismuth niobates and tantalates and methods for making them.

| B | Sb | | Bi | |
|---|---|---|---|---|
| | composition | method of preparation | composition | method of preparation |
| Nb | $SbNbO_4$ [13,84—87]; $SbNb_3O_9$ [90] | T[13,84,85], H[86,95—97], CO[87]; T[90] | $BiNbO_4$ [84,88,89] | T[84,88,89], H[98], CO[98] |
| | | | — | — |
| | | | $Bi_3Nb_3O_{15}$ [89] | T[89] |
| | | | $Bi_8Nb_{18}O_{63}$ [89] | T[89] |
| | | | $BiNb_5O_{14}$ [89] | T[89] |
| | | | $Bi_3Nb_{17}O_{47}$ [92] | T[89] |
| Ta | $SbTaO$[84—85,91] | T[84—85], H[96], CO[147] | $BiTaO_4$ [84,88] | T[84,88], H[98], CO[147] |

*T = solid-phase preparation by heating mixtures of oxides; CO = coprecipitation of the components from solutions; H = hydrothermal preparation.

Special interest in the Sb and Bi niobates and tantalates was aroused recently owing to the observation of ferroelectric properties in the mineral stibiotantalite[5] and the synthetic $ABO_4$ (where A = Sb or Bi, B = Nb or Ta)[94]. Table 3 gives the types of antimony and bismuth compounds. The most characteristic compounds are the orthoniobates and orthotantalates $ABO_4$. For antimony, the compound $SbNb_3O_9$ is also known[90].

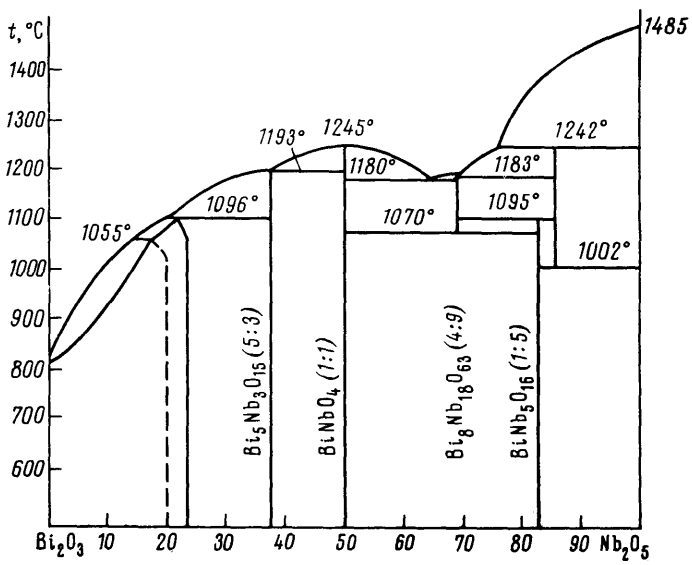

Figure 3. Equilibrium diagram of the $Bi_2O_3$–$Nb_2O_5$ system[89].

Fig. 3 gives the equilibrium diagram of the $Bi_2O_3$–$Nb_2O_5$ system. Formation of the compounds $BiNbO_4$, $Bi_5Nb_3O_{15}$, $Bi_8Nb_{18}O_{63}$, and $BiNb_5O_{14}$ has been reported[89].

Nothing has been published on the existence of Sb and Bi tantalates of a composition other than $ABO_4$.

## 4. NIOBATES AND TANTALATES OF THE *d*-METALS OF GROUPS IV–VIII

Of all the *d*-elements of periods IV and V which can exist in the tervalent state, only Ti, V, Cr, Mn, Fe, and Rh are known to have niobates and tantalates. Table 4 shows that in addition to the compounds of type $ABO_4$ several polyniobates have also been described[17,103].

Information is also available about the existence of the orthoniobates $TiNbO_4$,[13] $VNbO_4$,[13] $MnNbO_4$,[81] $RhNbO_4$,[13,18] and the orthotantalates $TiTaO_4$,[13] $VTaO_4$,[13] and $RhTaO_4$.[13,18] The possibility of the formation of iron hexatantalate $Fe_8(Ta_6O_{19})_3.44H_2O$ has also been suggested[105].

Table 4. Chromium and iron niobates and tantalates and methods for making them.

*T = solid-phase preparation by heating mixtures of oxides; TRG = transport reactions from the gas phase with formation of single crystals.

## III. PREPARATION OF NIOBATES AND TANTALATES OF TERVALENT ELEMENTS

Almost all the methods of making inorganic materials are used for obtaining niobates and tantalates of tervalent elements but the following are those used most widely: (1) solid-phase synthesis (T); (2) coprecipitation of the components from solutions followed by heating of the precipitate (CO); (3) hydrothermal synthesis (H). Tables 1–4 give information about the use of the various methods for making the niobates and tantalates.

### 1. SOLID-PHASE SYNTHESIS

Solid-phase synthesis (in other words, the ceramic method) which consists in the high-temperature heating of a mechanical mixture of the components, has been widely used for every niobate and tantalate of a tervalent element (Tables 1–4).

The starting materials in the solid-phase synthesis of niobates and tantalates are usually mixtures of the corresponding oxides. Much more rarely, a mixture of the oxides $Nb_2O_5$ ($Ta_2O_5$) with the carbonates, oxalates, nitrates, or other thermally unstable salts of the tervalent metal is used. Since the mechanism of solid-phase reactions depends mainly on the phase composition of the initial mixture, the latter also determines the temperature at which the mixture is heated.

We give below some examples of solid-phase synthesis. Thus for the preparation of $R_3NbO_7$, where R = La, Nd, Sm, Gd, Dy, Sc, and Y the oxides $R_2O_3$ and $Nb_2O_5$ are mixed in the necessary ratio and heated as tablets for 2 h at 1000°C. Then the mixture was pressed again and heated for 2 h at 1400°C. The tablets were then homogenised by being heated rapidly to 1800°C.[38] The r.e.e. and also V, Cr, Fe, and Rh orthoniobates were made analogously at 1250°C and the orthotantalates of the same elements at 1350°C.[13] The La, Ce, Pr, and Nd metaniobates and also the La, Ce, Pr, Nd, Sm, Gd, Dy, and Y metatantalates are obtained by heating mixtures of the oxides to 1450–1500°C.[40] Afonskii and Neiman[61] obtained the tantalates $LaTaO_4$, $La_3TaO_7$, $LaTa_3O_9$, and $La_2Ta_{12}O_{33}$ at lower temperatures (1300–1500°C).

A comparison of the results shows that different investigators give different temperatures for the preparation of the same compound. This is because the solid-phase reaction can be carried out over some range of temperatures higher than the temperature for the start of interaction between the initial oxides. Actually, in an investigation[72] of the interaction of a mixture of the oxides $La_2O_3$ and $Nb_2O_5$ the effect due to the formation of lanthanum orthoniobate $LaNbO_4$ is observed at 1190°C. $LaNbO_4$ has been prepared by various investigators at 1250–1300°C[52] and even 1600°C.[71] It seems that the reaction temperature depends on the duration of the sintering, which determines the completeness of the interaction of the initial substances. The tervalent metal tantalates are almost always prepared at higher temperatures than the niobates.

When one of the oxides in the solid-phase synthesis is volatile (for example, $Sb_2O_3$ and $Bi_2O_3$), then the niobates and tantalates are prepared in a closed volume. For example, to make antimony orthoniobate the mixture of oxides was first heated at 820°C for 2 h. After this, the material was sealed in a platinum tube and heated at 905°C for 16 h, then at 1000°C for 1 h, and at 1103°C for 14 h.[84]

The mechanism of the solid-phase processes has been studied repeatedly. The simplest compounds $ABO_4$ are evidently formed in a single stage[50,60]. The compounds $Ln_3NbO_7$ are formed in stages. The example of $Eu_3NbO_7$ showed[50] that initially (in the temperature range up to 1100°C) $EuNbO_4$ is formed and then further addition of $Eu_2O_3$ is observed at 1300°C.

The mechanism of formation of cerium metaniobate $CeNb_3O_9$ can, according to Godina and coworkers[51], be represented by the following processes:

$$Ce_2O_3 \cdot n\,H_2O + Nb_2O_5 \cdot n\,H_2O \xrightarrow{850^\circ} CeNbO_4\ (\text{cub.}) + Nb_2O_5\ (T\text{-form}),$$
$$CeNbO_4 + Nb_2O_5 \xrightarrow{1000\text{–}1100^\circ} CeNb_3O_9.$$

Kiparisov and coworkers[50] think that the formation of europium metaniobate $EuNb_3O_9$ takes place by the reaction:

$$EuNb_5O_{14} \xrightarrow{1500^\circ} EuNb_3O_9 + Nb_2O_5.$$

The scheme of formation of dodecaniobates (for example, $Ce_2Nb_{12}O_{33}$) postulates the formation of the intermediate phases $CeNbO_4$ and $CeNb_3O_9$.[51]

The kinetics of interaction of $Sc_2O_3$ and $Y_2O_3$ with $Nb_2O_5$ have been studied[32,35], also those of $Y_2O_3$, $Sm_2O_3$, $Eu_2O_3$, and $Gd_2O_3$ with $Ta_2O_5$.[35,62] The activation energy is 48.3 kcal mole$^{-1}$ for the formation of $ScNbO_4$,[32] 56.8 kcal mole$^{-1}$ for $YNbO_4$,[35] and 42.3 kcal mole$^{-1}$ for $YTaO_4$.[35]

As noted above, the solid-phase synthesis can be carried out over a rather wide range of temperatures, which allows the various polymorphic configurations of the niobates and tantalates to be investigated[53,71]. However, the ceramic method has significant drawbacks, which reduce the effectiveness and make it unpromising in practice. These drawbacks are: (a) the heterogeneity of the product; (b) the purity of the product being inadequate; (c) the low stoichiometry of the components; (d) the comparatively high synthesis temperatures. The duration of the process is also characteristic of this method, several days sometimes being required for homogeneity to be attained and the reaction to be complete; higher synthesis temperatures lead to the high energy capacity of the method.

## 2. COPRECIPITATION OF THE COMPONENTS FROM SOLUTIONS

The precipitation of the components from solutions can be brought about by mixing aqueous solutions of the niobates $KNbO_3$, $K_3NbO_4$, and $K_8Nb_6O_{19}$ or tantalates $K_8Ta_6O_{19}$ with solutions of tervalent metal salts. In addition, a version of the preparation in which hydroxides are precipitated by the action of ammonia on a mixture of a solution of $NbCl_5$ ($TaCl_5$) and a salt of the metal, the compound of which is being made. $(NH_4)_2CO_3$ can also be used as precipitant. In both instances the precipitate was heated to the crystallisation temperature of the corresponding niobate or tantalate.

Soluble orthoniobates were used as starting materials for obtaining the orthoniobates $AlNbO_4$,[20] $InNbO_4$,[25] $YNbO_4$,[42] and $ScNbO_4$.[43] Aluminium[20,29,30] and indium[25] aquometaniobates have been made by this method.

The mechanism of the precipitation of Al, In, Y, and Sc ortho- and meta-niobates when aqueous solutions of the corresponding potassium niobates and salts of the metals being precipitated are mixed has been studied[20,25,42,43]. Orthoniobates of these metals are precipitated on reaching the ratio A : Nb = 1 : 1, which corresponds to pH 6–7. Metaniobates are precipitated when the ratio in the solution is A : Nb = 1 : 3.

Clearly, this version of the coprecipitation method requires the preliminary preparation of water-soluble niobates and tantalates, which somewhat reduces its effectiveness. A second version of the preparation, which uses the coprecipitation of the components in the form of hydroxides is evidently more effective, since it can be used for making the niobates and tantalates of any composition and it employs readily available reagents.

R.e.e. orthoniobates[36] and the tantalates $Tl_4Ta_6O_{21}$ and $TlTa_3O_9$[27] were obtained by using aqueous solutions. Since aqueous solutions of niobium and tantalum are unstable, a method using precipitation of the components from non-aqueous solutions is receiving greater attention. Thus, in making lanthanide orthoniobates $LnNbO_4$ (La, Ce, Pr, Nd),[67,68] the metaniobates $LnNb_3O_9$ (La, Pr, Nd, Sm),[6,51] the niobates $Ln_3NbO_7$ (La, Pr, Nd)[54] and $Ln_2Nb_{12}O_{33}$ (La, Ce, Pr, Nd),[59] and also bismuth orthoniobate $BiNbO_4$,[93] coprecipitation of the niobium and tervalent element hydroxides was carried out from alcoholic solutions.

Despite the rather wide use of coprecipitation for making niobates and tantalates, the mechanism of the process itself has still been studied insufficiently. There appear to be two possibilities: one is linked with the high dispersion of the coprecipitated components, the other, with the formation of contact compounds between the solid phases being coprecipitated[106]. Whereas the heat treatment of the material formed in the first instance gives some reduction of the crystallisation temperature of the final products as compared with the ceramic method, in the second instance the formation of crystalline compounds takes place at an appreciably lower temperature than in the sintering of the oxides.

The mechanism of the formation of the compounds during coprecipitation has been studied for only certain examples[6,67,87,93]. Chemical interaction of the components has been observed in the coprecipitation of Nd and Nb from aqueous alcoholic solutions. The precipitate obtained contained up to 60% combined Nd. In this instance hydroxoniobates of the type

$$Ln[NbO_{3-x/2}(OH)_x]_3 \cdot nH_2O,$$

where $x = 0–6$, are probably formed. Analogous results were obtained in studies of the formation of Ce, Pr, Nd,[67] Sb,[87] and Bi[93] orthoniobates.

There have been considerably more papers on the chemical reaction of the coprecipitated hydroxides of niobium or tantalum and a tervalent element during heating. However, they relate mainly to the processes taking place with participation of r.e.e. hydroxides[51,54,59,65,73,74,77] and, as noted above, only two studies concern the reaction of coprecipitated niobium and antimony or bismuth hydroxides[87,93]. In all these investigations it was found that when coprecipitated hydroxides are heated niobates (or tantalates) are formed without the intermediate production of the free oxides[6,51,59,93]. Usually, the crystallisation temperature is 300–500 K below the synthesis temperature in ceramic technology. This reduction in the temperature of preparation of the compounds is a principal advantage of the method of coprecipitation of the components from solution.

The observed decrease in the temperature of formation of niobates and tantalates when the coprecipitation method is used is often explained by the Hedvall effect, that is, the increase in the activity of the components during the thermal decomposition (dehydration) of hydroxides or salts. However, on taking into account the fact of chemical interaction between the components even at the moment of precipitation, it is thought[6,93,106] that the formation of intermediate compounds of the hydroxoniobate type, which are converted into niobates at comparatively low temperatures can also be responsible for the reduction in the synthesis temperature. The absence of individual oxides during the heating of the coprecipitated components suggests the impossibility of relating the mechanism of formation of the niobates and tantalates to simple interaction of oxides of increased activity.

In conclusion, it must be mentioned that in addition to the decrease in the synthesis temperature the coprecipitation method allows products of high homogeneity to be obtained. The purity of the compounds prepared by this method is usually higher than the purity of the initial solutions. These advantages make the method irreplaceable in the need to obtain homogeneous, high-purity materials with well reproducible properties.

## 3. HYDROTHERMAL SYNTHESIS

Crystallisation from solution at elevated pressures and temperatures has been used as a method of preparation only for antimony[86,96] and bismuth[98] orthoniobates and orthotantalates of composition $ABO_4$. The crystallisation was carried out in batch autoclaves. The starting materials were $Sb_2O_3$, $Bi_2O_3$, $Nb_2O_5$, and $Ta_2O_5$. The main parameters of the crystallisation process are: temperature 500–650°C, temperature rise up the height of the autoclave 15–65 K, coefficient of filling 0.6–0.65. Sych and coworkers[87,93] started from polycrystalline $SbNbO_4$ and $BiNbO_4$ with the aim of increasing the yield of single crystals; the recrystallisation of $SbNbO_4$ and $BiNbO_4$ took place at 500–560°C and a temperature gradient of 1.0–2.5 K $cm^{-1}$ up the height of the autoclave.

## IV. CRYSTAL-CHEMISTRY OF NIOBATES AND TANTALATES OF TERVALENT ELEMENTS

The structures of tantalates and niobates of the same composition type are usually similar, but in certain instances they are not completely isostructural.

1. NIOBATES AND TANTALATES OF THE GROUP III *p*-ELEMENTS

Little is known about the crystal-chemistry of the aluminium, gallium, indium, and thallium niobates and tantalates. Only the $ANbO_4$ (A = Al, Ga, In), $InTaO_4$, and $ANb_{11}O_{29}$ have been investigated by X-ray diffraction. According to Pedersen[75], $AlNbO_4$ is monoclinic, space group $C2/m$. The number of formula units $AlNbO_4$ in the unit cell is $Z = 4$. The monoclinic lattice parameters are: $a = 12.13$, $b = 3.726$, $c = 6.46$ Å, $\beta = 107.2°$. However, Burdese and Lucco[76] state that $AlNbO_4$ is orthorhombic with $a = 6.17$, $b = 7.38$, $c = 8.4$ Å, $Z = 6$, $\rho_{expt} = 4.5$, $\rho_{X\text{-ray}} = 4.15$ g cm$^{-3}$.

Gallium orthoniobate $GaNbO_4$ is monoclinic[21,107] with $a = 15.22$, $b = 3.75$, $c = 8.07$ Å, $\beta = 141.5°$;[21] it does not undergo any polymorphic transformations up to the melting point (1480°C).[22]

The compounds $InNbO_4$ and $InTaO_4$ are isostructural and of the wolframite type[13,24], space group $P2/c$, $Z = 2$. The $InNbO_4$ monoclinic lattice parameters[13] are: $a = 4.843$, $b = 5.773$, $c = 5.140$ Å, $\beta = 91.140°$, $\rho_{expt} = 6.22$, $\rho_{X\text{-ray}} = 6.28$ g cm$^{-3}$.

The compounds $AlNb_{11}O_{29}$ and $GaNb_{11}O_{29}$ are monoclinic[15,16]. The lattice parameters of $GaNb_{11}O_{29}$ are[16]: $a = 15.35$, $b = 3.82$, $c = 20.91$ Å, $\beta = 113°26'$. Other investigators[16,21] have reported the existence also of an orthorhombic modification of $GaNb_{11}O_{29}$ with lattice parameters: $a = 28.67$, $b = 3.813$, $c = 20.58$ Å.

Table 5. Lattice parameters of the r.e.e. orthoniobates[13].

| Compound | *a*, Å | *b*, Å | *c*, Å | β | *Z* | $\rho_{expt}$, g cm$^{-3}$ | $\rho_{X\text{-ray}}$, g cm$^{-3}$ |
|---|---|---|---|---|---|---|---|
| $LaNbO_4$ | 5.565 | 11.528 | 5.201 | 94°40′ | 4 | 5.82 | 5.909 |
| $CeNbO_4$ | 5.539 | 11.415 | 5.165 | 94°33′ | 4 | 6.04 | 6.061 |
| $PrNbO_4$ | 5.499 | 11.342 | 5.137 | 94°34′ | 4 | 6.10 | 6.170 |
| $NdNbO_4$ | 5.468 | 11.282 | 5.144 | 94°32′ | 4 | 6.31 | 6.324 |
| $SmNbO_4$ | 5.417 | 11.166 | 5.117 | 94°40′ | 4 | 6.61 | 6.616 |
| $EuNbO_4$ | 5.393 | 11.133 | 5.113 | 94°35′ | 4 | 6.67 | 6.705 |
| $GdNbO_4$ | 5.371 | 11.090 | 5.107 | 94°37′ | 4 | 6.80 | 6.882 |

| $DyNbO_4$ | 5.320 | 11.000 | 5.074 | 94°34′ | 4 | 7.12 | 7.168 |
| $HoNbO_4$ | 5.298 | 10.957 | 5.068 | 94°29′ | 4 | 7.15 | 7.167 |
| $ErNbO_4$ | 5.280 | 10.914 | 5.064 | 94°29′ | 4 | 7.30 | 7.400 |
| $TmNbO_4$ | 5.262 | 10.876 | 5.049 | 94°31′ | 4 | 7.51 | 7.517 |
| $YbNbO_4$ | 5.237 | 10.842 | 5.043 | 94°47′ | 4 | 7.56 | 7.677 |
| $LuNbO_4$ | 5.293 | 10.043 | 5.065 | 94°32′ | 4 | 7.69 | 7.756 |
| $YNbO_4$ | 5.293 | 10.943 | 5.065 | 94°32′ | 4 | 5.53 | 5.583 |
| $ScNbO_4$ | 4.818 | 5.655 | 5.101 | 88°25′ | 2 | 4.76 | 4.817 |

2. NIOBATES AND TANTALATES OF THE GROUP III *d*- AND *f*-ELEMENTS

This section considers the structural features of the compounds $RBO_4$, $R_{1/3}BO_3$, $R_3BO_7$, and $RB_5O_{14}$. Information about the crystal-chemistry of the other niobates and tantalates is extremely limited or completely non-existent.

A. Orthoniobates and Orthotantalates of Composition $ABO_4$

The r.e.e. (with the exception of Sc) orthoniobates of composition $RNbO_4$ have a fergusonite structure at room temperature[13,50,53,108]. As Table 5 shows, as the ionic radius of the lanthanide in $LnNbO_4$ is reduced there is a regular decrease in the monoclinic lattice parameters, the parameters *a* and *c* falling linearly from La to Eu and from Gd to Lu, with a pronounced break at $EuNbO_4$ (Fig. 4). The lattice parameters of $YNbO_4$ do not fit into this regularity. It seems that the dimensions of the $RNbO_4$ unit cell are affected not only by the ionic radius of the cation but also by the fraction of the covalent bond A–O, which decreases appreciably on going from Sc to Y and La.

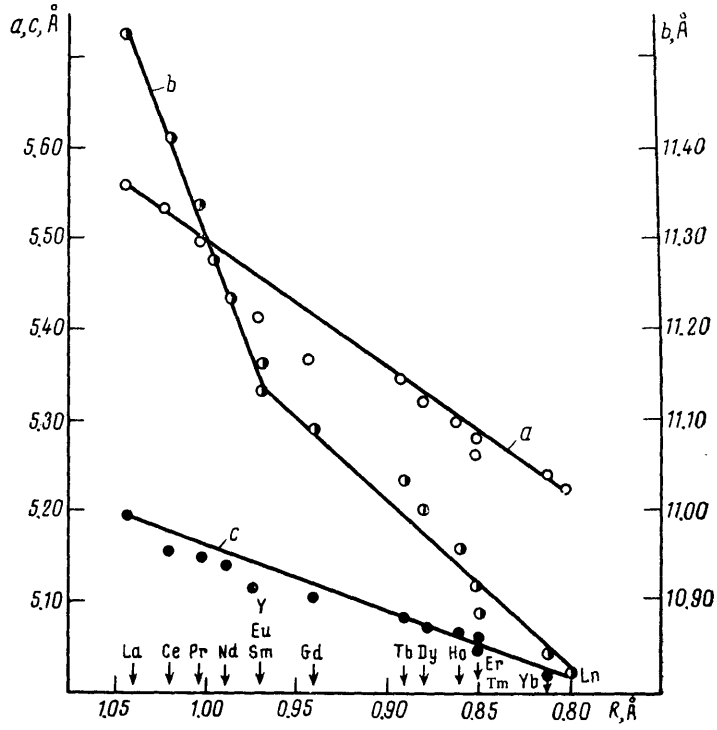

Figure 4. Variation of the lattice parameters of the r.e.e. orthoniobates[13] with the radius of the r.e.e. ion[116].

The orthotantalates $LnTaO_4$, where Ln = Nd–Lu, and $YTaO_4$ also crystallise in a monoclinic lattice of the fergusonite type[13,109,110] (Table 6). As for the orthoniobates, there is a linear increase in the size of the monoclinic cells of the $LnTaO_4$ as the ionic radius of the lanthanide is increased.

The $ABO_4$ crystal structure of fergusonite type is a distorted scheelite structure[45,111]. The Nb (or Ta) atoms are situated within several distorted tetrahedra of oxygen atoms. The r.e.e. atoms have coordination number 8 and are also surrounded by oxygen atoms[45,108,111]. All 16 oxygen atoms in the $LnNbO_4$ unit cell ($Z = 4$) occupy positions with general symmetry ($C_1$) and the Ln and Nb atoms are situated at points with site symmetry $C_2$.

It has been reported[112] that the X-ray diffraction pattern of $YTaO_4$ can be indexed in a basocentric monoclinic unit cell with $a = 6.978$, $b = 10.930$, $c = 5.323$ Å, $\beta = 133°50'$. Probable space group: $C2/c$ or $Cc$.

B. Isomorphism of the Compounds $ABO_4$ with Fergusonite Structure

When compounds of the $RNbO_4$ (R = Y, Ln) or $RTaO_4$ (R = Y, Nd–Lu) type are heated their monoclinic cell is converted into a tetragonal one (scheelite structure)[45,53]. The transformation is reversible, takes place in stages, has a "shear" nature[45], and is accompanied by a gradual change in the lattice parameters, which is accelerated close to the transformation temperature[109]. During such a transformation the parameters $a$ and $c$ of the monoclinic cell become equal to the parameter $a$ of the tetragonal, and the parameter $b$ of the monoclinic cell is changed to the parameter $c$ of the tetragonal cell[53].

Table 6. Lattice parameters of the r.e.e. orthotantalates.

| Compound | $a$, Å | $b$, Å | $c$, Å | β | $Z$ | $\rho_{expt}$, g cm$^{-3}$ | $\rho_{X\text{-ray}}$, g cm$^{-3}$ |
|---|---|---|---|---|---|---|---|
| $LaTaO_4$ [13] | 7.651 | 5.577 | 7.823 | 101°31′ | — | — | — |
| $NdTaO_4$ [13] | 5.514 | 11.237 | 5.114 | 95°42′ | 4 | 8.12 | 8.199 |
| $SmTaO_4$ [13] | 5.455 | 11.137 | 5.091 | 95°44′ | 4 | 8.47 | 8.548 |
| $EuTaO_4$ [13] | 5.428 | 11.103 | 5.087 | 95°44′ | 4 | 8.60 | 8.644 |
| $GdTaO_4$ [13] | 5.405 | 11.063 | 5.084 | 95°35′ | 4 | 8.76 | 8.830 |
| $TbTaO_4$ [13] | 5.382 | 11.022 | 5.068 | 95°40′ | 4 | 8.82 | 8.967 |
| $DyTaO_4$ [13] | 5.354 | 10.974 | 5.061 | 95°43′ | 4 | 8.97 | 9.147 |
| $HoTaO_4$ [13] | 5.329 | 10.935 | 5.056 | 95°32′ | 4 | 9.25 | 9.284 |
| $ErTaO_4$ [13] | 5.306 | 10.893 | 5.042 | 95°44′ | 4 | 9.27 | 9.443 |
| $TmTaO_4$ [86] | 5.053 | 10.82 | 5.243 | 95°11′ | 4 | — | — |
| $YbTaO_4$ [82] | 5.035 | 10.82 | 5.23 | 84°22′ | 4 | — | — |
| $LuTaO_4$ [82] | 5.03 | 10.78 | 5.25 | 84°22′ | 4 | — | — |
| $YTaO_4$ [13] | 5.239 | 10.893 | 5.056 | 95°31′ | 4 | 7.56 | 7.592 |
| $ScTaO_4$ [13] | 4.809 | 5.670 | 5.118 | 88°20′ | 4 | 6.84 | 6.802 |

The temperature of the transformation into the scheelite structure for the orthoniobates is 500–800°C. Usually the temperature for the appearance of the tetragonal phase increases with decrease in the atomic radius of the r.e.e., that is, in the order La–Lu. It is significantly higher for the tantalates than for the niobates[109]. A high-temperature form has not been observed for the Tm, Yb, and Lu tantalates[109].

During the growing of single crystals of the r.e.e. orthoniobates and orthotantalates the formation of a third polymorphic modification of the $ABO_4$ compounds was observed[113,114]. The monoclinic lattice parameters (example, $YTaO_4$)[114] are: $a = 5.292$; $b = 5.451$, $c = 5.110$ Å, $\beta = 96.44°$, $Z = 2$. In the structure of this modification of $YTaO_4$ the Ta atoms are at the centre of a distorted $TaO_4$ tetrahedron (Ta–O distance = 1.94–2.03 Å) and the Y atoms are at the centre of a distorted cube (Y–O distance = 2.25–2.42 Å).

C. The Orthotantalates $LnTaO_4$ (Ln = La, Ce, Pr)

The La, Ce, and Pr orthotantalates are not isostructural with the corresponding orthoniobates. $LaTaO_4$ is monoclinic, space group $P2_1/c$.[115] The Ta atoms are situated close to the centres of distorted octahedra, and the Ta–O distance varies within the limits 1.91–2.05 Å (mean distance 2.00 Å). The octahedra are linked at the vertices and form an infinite (in two-dimensions) corrugated layer. Each octahedron has four vertices in common with four neighbouring octahedra, the layers being separated from those similar in configuration to them by layers of La atoms, which have eightfold coordination, the eight La–O distances lying within the range 2.40–2.84 Å.[115] Fig. 5 shows a fragment of the $LaTaO_4$ structure.

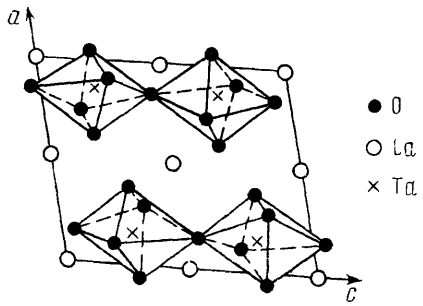

Figure 5. Fragment of the $LaTaO_4$ structure projected on [010].

Scandium orthoniobate and orthotantalate are monoclinic[53] (Tables 5 and 6). Their structure shows greater similarity with the wolframite structure[32,53] than with the fergusonite structure, which seems to be due to the appreciable difference between the size of the $Sc^{3+}$ ion and those of the other r.e.e. ions.

D. R.e.e. Metaniobates and Metatantalates

All the r.e.e. metaniobates and metatantalates have a perovskite $ABO_3$ structure[40,55,110,117] and their formulae are usually written as $R_{1/3}BO_3$. Whereas the metatantalates $R_{1/3}TaO_3$ are known for almost all the r.e.e., metaniobates have been obtained only for La, Ce, Pr, Nd, and Eu.

The lanthanide metaniobates are orthorhombic; the La, Ce, Gd, Dy, Ho, Eu, and Y metatantalates are tetragonal; Pr, Nd, and Tb metatantalates are orthorhombic, and Yb metatantalate is monoclinic (Table 7). The lattice parameters and unit-cell volume[40,55] of the metaniobates $Ln_{1/3}NbO_3$ and metatantalates $R_{1/3}TaO_3$ fall regularly with increase in the atomic number of the lanthanide.

Since the metaniobates with perovskite structure are known only for the metals of the cerium subgroup, the very existence of compounds of composition $A_{1/3}BO_3$ depends in a definite manner on the size of the r.e.e. cation. As Table 8 shows, metaniobates with the perovskite structure can exist at Goldschmidt stability factors $\leqslant 0.9$. Therefore the metaniobates of Fe, Cr, Sc, and other 3*d*- or *p*-metals with perovskite structure can hardly be obtained. Nevertheless the hitherto unknown $Bi_{1/3}TaO_3$ should be stable. The lower limit of the stability factor for the metatantalates of composition $A_{1/3}TaO_3$ should be somewhat lower than for the niobates and seems to be 0.83–0.84.

The structure for the metaniobates and metatantalates of composition $R_{1/3}BO_3$ has been determined for $La_{1/3}NbO_3$ [55] and $La_{1/3}TaO_3$, [55,117] and also $Y_{1/3}TaO_3$. [117] All the compounds have a perovskite structure, $P4/mmm$. [55,117] However, unlike the ideal structure of perovskite, for the compounds $A_{1/3}BO_3$ only one-third of the sites in the A sublattice can be occupied and the remaining two-thirds of the sites remain vacant.

Table 7. Lattice parameters of the metaniobates and metatantalates $A_{1/3}BO_3$.

| Compound | Symmetry | Lattice parameters | | | | |
|---|---|---|---|---|---|---|
| | | *a*, Å | *b*, Å | *c*, Å | *V*, Å³ | *Z* |

| $Y_{1/3}TaO_3$ [55] | tetr. | 3.824 | — | 7.758 | 113.5 | 2 |

* $\beta = 91.6°$

An increase in the lattice parameter along the *c* axis by a factor of two in comparison with the initial perovskite cell is characteristic for all the compounds. This doubling is due to the alternation of the empty layers with the layers two-thirds filled with atoms A. The atoms A are distributed statistically in two-thirds filled cubo-octahedra. The sometimes suggested [118] doubling of the lattice parameters also along axes *a* and *b*, which for the composition $Ln_{1/3}NbO_3$ requires $Z = 8$, can hardly be correct.

The niobium and tantalum atoms are surrounded by six oxygen atoms, which are situated at the vertices of an almost regular $NbO_6$ (or $TaO_6$) octahedron. The structure and interatomic distances for $Ln_{1/3}NbO_3$ are given in Fig. 6. Clearly the distance Nb–O (or Ta–O) in the r.e.e. metaniobates and metatantalates differs from the B–O distance in the ideal perovskite. This is due to some displacement of the Nb (Ta) atom along the *c* axis. Similar structural features are characteristic for ferroelectrics of the oxygen-octahedral type, for example, $BaTiO_3$, $KNbO_3$, etc. [119]

## E. Niobates and Tantalates of Composition $A_3BO_7$

The niobates of composition $A_3BO_7$ belong to three structural groups, depending upon the nature of the r.e.e. and the temperature. The La, Nd, and Sm niobates, which form the first group, are orthorhombic, weberite structure type [38], space group $Pncm$. [120,121] $Eu_3NbO_7$ and $Gd_3NbO_7$, which belong to the second structural group, are monoclinic, space group $P2/m$. [122] All the niobates $R_3NbO_7$ (R = Dy–Lu, Y, Sc) of the third group are cubic, fluorite type [120–122]—according to other investigators [38], pyrochlore type.

Table 8. Relation between the ionic radius and stability factor for certain niobates of composition $A_{1/3}NbO_3$ with a perovskite structure.

| Element A | Ionic radius, $r_A$, Å | Stability factor, *t* | Compound |
|---|---|---|---|
| La | 1.04 | 0.924 | $La_{1/3}NbO_3$ [40,55] |
| Nd | 0.99 | 0.907 | $Nd_{1/3}NbO_3$ [40,45] |
| Sm | 0.97 | 0.900 | unknown |
| Eu | 0,97 | 0.900 | $Eu_{1/3}NbO_3$ [50] |
| Gd | 0,94 | 0.888 | unknown |
| Lu | 0,80 | 0.835 | unknown |
| Y | 0,97 | 0.900 | unknown |
| Sc | 0.83 | 0.844 | unknown |
| Bi | 1,20 | 0.988 | unknown |
| Sb | 0,90 | 0.874 | $Sb(NbO_3)_3$ structure $PbNb_2O_6$ [90] |
| Fe | 0.67 | 0.785 | unknown |
| Al | 0,57 | 0.744 | unknown |
| Ga | 0,62 | 0.765 | unknown |
| In | 0.92 | 0.883 | unknown |

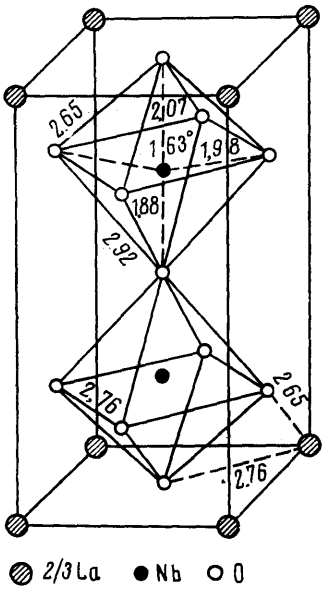

**Figure 6.** Unit cell of $La_{1/3}NbO_3$. [55]

Table 9 gives the lattice parameters of the compounds $R_3NbO_7$. With increase in the atomic radius of the r.e.e. the fluorite lattice parameter increases. The niobates $Ln_3NbO_7$ of the first and second groups undergo polymorphic transformations above 1300°C with change to a stable fluorite cubic structure [121,122] (Table 9).

The tantalates of composition $R_3TaO_7$ (where R = La, Nd, Sm, Gd, Dy, Y, and Sc) are cubic[38]. However, Rooksby and White[38] could not find any difference between the disordered fluorite structure and the ordered pyrochlore structure. According to Romashov and coworkers[110] the $R_3TaO_7$ (R varies from Sm to Lu and Y) have a pyrochlore structure. The lattice parameters change regularly along the lanthanide series.

**Table 9.** Lattice parameters of certain niobates and tantalates $R_3BO_7$.

| Compound | Symmetry | Lattice parameters | | | | Structure type* | Polymorphic transformation |
|---|---|---|---|---|---|---|---|
| | | a, Å | b, Å | c, Å | β | | |
| $La_3NbO_7$ [38] | o-rh. | 7.84 | 10.86 | 7.70 | — | | W $\xrightarrow{1300°}$ F[122] |
| $Nd_3NbO_7$ [38] | o-rh. | 7.66 | 10.98 | 7.70 | — | W | W $\xrightarrow{1300°}$ F[122] |

| $Sc_3TaO_7$ [38] | cub. | 4.88 (F); 9,66 (P) | — | — | — | F,P | — |

*W = weberite; F = fluorite; P = pyrochlore.

## F. Niobates and Tantalates of Composition $LnB_5O_{14}$

According to Badiot[58] the pentaniobates $LnNb_5O_{14}$ (Ln = La, Ce, Pr, and Nd) are orthorhombic, the lattice parameters for $LaNb_5O_{14}$ being: $a = 20.12$, $b = 12.42$, $c = 7.74$ Å, $Z = 8$, space group $C_{2V}^9$. The tantalates $RTa_5O_{14}$ (R = La, Ce, Nd, Pr, Sm, Dy, Tm, and Y) have an orthorhombic basocentric lattice, corresponding to a distorted $ReO_3$ structure[124]. The lattice parameters for $LaTa_5O_{14}$ are: $a = 17.56$, $b = 16.98$, $c = 3.851$ Å. According to Ferguson[111], $LaTa_5O_{14}$ is not isostructural with $LaNb_5O_{14}$, despite Iyer and Smith's claim[55].

## 3. CRYSTAL-CHEMISTRY OF THE ANTIMONY AND BISMUTH NIOBATES AND TANTALATES

According to Roth and Waring[84] compounds of composition $ABO_4$ (A = Sb or Bi; B = Nb or Ta) at room temperature are isostructural and have the same structure as the natural mineral cervatite $SbSbO_4$,[91] stibiocolumbite (Sb, Bi)(Nb, Ta)$O_6$, or bismutotantalite (Bi, Sb)(Ta, Nb)$O_4$.[125]

Table 10 gives the orthorhombic lattice parameters. X-ray diffraction investigation of $SbTaO_4$ [13,91] and $SbNbO_4$,[13,85] as examples, indicated the space group of the $ABO_4$: $Pna2_1 = C_{2V}^9$, $Z = 4$. The $SbTaO_4$ structure is shown in Fig. 7. It is characteristic of an octahedral environment for the atoms Nb and Ta. The atoms Sb and Bi also have a coordination number of 6. Fig. 8 gives the bond lengths in the $SbNbO_4$ structure[85]. The $NbO_6$ and $TaO_6$ octahedra form toothed chains. The monolayers of $BO_6$ octahedra are separate in the $z$ direction. The ions A occupy the vacancies between the $BO_6$ octahedra.

**Table 10.** Lattice parameters of antimony and bismuth orthotantalates and orthoniobates[84].

| Compound | a, Å | b, Å | c, Å | Z | $\rho_{expt}$, g cm$^{-3}$ | $\rho_{X\text{-ray}}$, g cm$^{-3}$ |
|---|---|---|---|---|---|---|
| $SbNbO_4$ | 4.929 | 11.797 | 5.559 | 4 | 5.75[87] | 5.79 |
| $BiNbO_4$ | 4.980 | 11.709 | 5.675 | 4 | 7.37[93] | 7,34 |
| $SbTaO_4$ | 4,911 | 11.814 | 5.535 | 4 | 7,57[147] | 7.65 |
| $BiTaO_4$ | 4.957 | 11,763 | 5.633 | 4 | 9.26[147] | 9,22 |

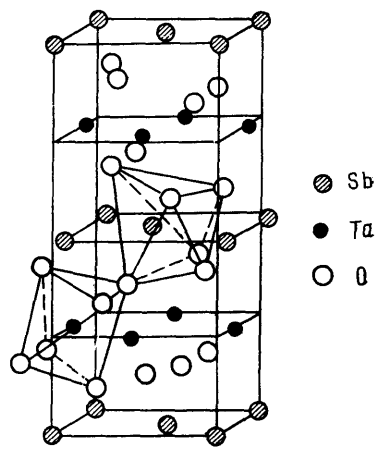

**Figure 7.** Structure of antimony orthotantalate $SbTaO_4$.[91]

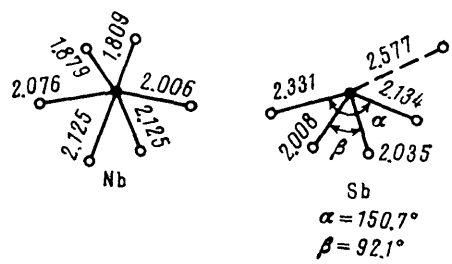

**Figure 8.** Lengths of the Nb–O and Sb–O bonds and valence angles in the $SbNbO_4$ structure[85].

According to Popolitov and coworkers[98] the orthorhombic single crystals of $BiNbO_4$ and $BiTaO_4$ prepared under hydrothermal conditions have the centrosymmetric space group $D_{2h}^6 = Pnna$.

In addition to the orthorhombic modification $\alpha$-$ABO_4$ a high-temperature modification $\beta$-$ABO_4$ is characteristic

for bismuth orthoniobate and orthotantalate. The triclinic high-temperature modification for $BiNbO_4$ and $BiTaO_4$ was first obtained by heating mixtures of $Bi_2O_3$ and $Nb_2O_5$ [or $Ta_2O_5$ (Ed. of Translation)] in air at 1100–1200°C.[88] $\alpha$-$BiNbO_4$ and $\alpha$-$BiTaO_4$ are irreversibly converted into the triclinic $\beta$-modification when heated to 1020° and 900°C respectively[84,89].

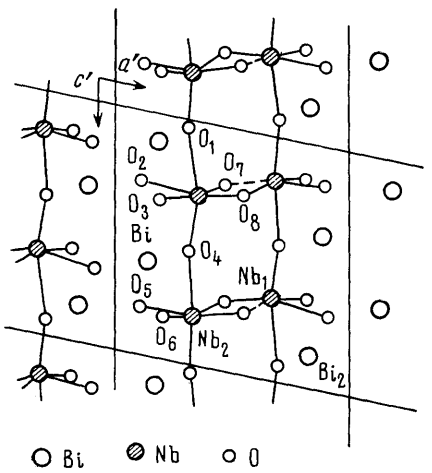

Figure 9. Projection of the $\beta$-$BiNbO_4$ structure on [010].[126]

The lattice parameters of the triclinic $\beta$-$BiBO_4$ are[88]:

| | a, Å | b, Å | c, Å | α | β | γ |
|---|---|---|---|---|---|---|
| $\beta$-$BiNbO_4$ | 7.61 | 5.53 | 7.91 | 83.99° | 74.43° | 82.15° |
| $\beta$-$BiTaO_4$ | 7.62 | 5.58 | 7.77 | 89.92° | 77.12° | 96.45° |

The space group of $\beta$-$BiNbO_4$ is[126]: $P1$, $Z = 4$.

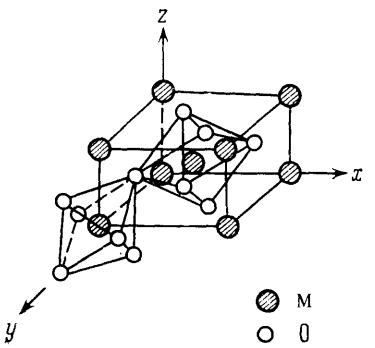

Figure 10. Rutile structure for compounds of the $ABO_4$ type (A = Ti, V, Cr, or Fe).

The structure of $\beta$-$BiNbO_4$ [126,127] (Fig. 9) consists of corrugated lattices constructed from $NbO_6$ octahedra parallel to the plane $oc$. Each octahedron is connected by vertices with four other octahedra. The $NbO_6$ lattices are maintained by Bi atoms. The Bi atoms have a coordination number of eight. The Bi polyhedron is a distorted tetragonal antiprism. The Bi–O distance is in the range 2.105–3.017 and the Nb–O distance in the range 1.803–2.313 Å.

$SbNb_3O_9$ is orthorhombic with lattice parameters $a$ = 17.635, $b$ = 3.968, $c$ = 17.219 Å. The structure is analogous with the ferroelectric $PbNb_2O_6$, $Z = 10$.[90] The compound $Bi_3Nb_{17}O_{47}$ has the structure of a tungsten "bronze".[37,128] The orthorhombic lattice parameters are: $a$ = 12.516, $b$ = 37.14, $c$ = 3.922 Å, $Z = 2$. Space group $Pba2$. Some of the niobium atoms have coordination number 7. The coordination polyhedron is a pentagonal bipyramid. The remaining 8 niobium atoms are arranged in octahedra. The Nb–O distance is 1.48–2.46 Å.[92]

## 4. CRYSTAL-CHEMISTRY OF THE *d*-ELEMENT NIOBATES AND TANTALATES

### Compounds of Composition $ABO_4$ (A = Ti, V, Cr, Fe)

The orthoniobates and orthotantalates of composition $ABO_4$ crystallise according to rutile type[13,18,129]. The $TiO_2$ rutile structure is tetragonal, space group $D_{2h}^{14}$ [$D_{4h}^{14}$? (Ed. of Translation)]. The number of formula units for $TiO_2$ is $Z = 2$; that for $ABO_4$ is $Z = 1$. The lattice parameters of the compounds of composition $ABO_4$ are $a$ = 4.6, $c$ = 3.0 Å (Table 11). Fig. 10 shows the $ABO_4$ structure. Atoms A and B are arranged randomly in the cell of the double oxide[13,129] and have coordination number 6, occupying identical positions.

Table 11. Lattice parameters of the *d*-element orthoniobates and orthotantalates with a rutile structure.

| Compound | a, Å | c, Å | $\rho_{X\text{-ray}}$, g cm$^{-3}$ | $\rho_{expt}$, g cm$^{-3}$ |
|---|---|---|---|---|
| $TiNbO_4$ [13] | 4.712 | 2.996 | 5.100 | 5.01 |
| $VNbO_4$ [13] | 4.681 | 3.033 | 5.194 | 5.13 |
| $CrNbO_4$ [18] | 4.635 | 3.005 | — | — |
| $FeNbO_4$ [18] | 4.68 | 3.05 | — | — |
| $TiTaO_4$ [129] | 4.645 | 3.020 | — | — |
| $VTaO_4$ [129] | 4.667 | 3.047 | — | — |
| $CrTaO_4$ [129] | 4.638 | 3.018 | — | — |
| $FeTaO_4$ [129] | 4.679 | 3.047 | — | — |
| $TiO_2$ [130] | 4.594 | 2.959 | — | — |

For iron orthoniobate $FeNbO_4$, in addition to the tetragonal form mentioned there are another two polymorphic modifications—monoclinic and orthorhombic[131]. Roth and Waring[132] think that the low-temperature modification, stable up to 1085°C, is monoclinic, space group $P2_1/a$. The lattice parameters are $a$ = 5.001, $b$ = 5.620, $c$ = 4.653 Å, $\beta$ = 90°16′. The orthorhombic phase ($a$ = 5.005, $b$ = 5.613, $c$ = 4.647 Å) is stable from 1085° to 1380°C. The rutile modification exists from 1380°C up to the melting point (~ 1475°C).[132] Conversion of the low-temperature rutile modification into the high-temperature orthorhombic modification, with wolframite structure, is observed for iron orthotantalate $FeTaO_4$. The lattice parameters are $a$ = 4.63, $b$ = 5.64, $c$ = 5.04 Å.[133]

The above crystallographic results show that the niobates and tantalates of tervalent elements form two structural groups: with tetrahedral and octahedral environment of the Nb or Ta. Tetrahedral coordination is encountered only in the orthoniobates and orthotantalates $ABO_4$. However, even for this composition it is not the only possibility. Isolated $BO_4^{3-}$ tetrahedra exist only in the r.e.e. orthoniobates and (in part) orthotantalates (except for La, Ce, and Pr) with the fergusonite structure, which has many features in common with the scheelite structure. The remaining tervalent metal niobates and tantalates for which structural results have been published are compounds of octahedral type.

A comparison of the available results shows that the change from tetrahedral to octahedral configuration even in the series of $ABO_4$ compounds is not determined by the increase in the ionic radius of the r.e.e. This transformation is usually due to the change in the nature of the A–O bond and the competition of the A atoms with the Nb(Ta) atoms for possession by the oxide ligands.

The niobates and tantalates of tervalent metals with an octahedral configuration crystallise according to the $LaTaO_4$ type, perovskite, cervantite, or rutile. In all these structures the $BO_6$ octahedra are usually connected by their vertices with the formation of two-dimensional or three-dimensional skeletons, unlike the fergusonite structure with isolated $BO_4^{3-}$ tetrahedra.

Table 12. Interplanar spacings (Å) in niobates and tantalates with octahedral coordination.

| Structure type | $(B-O)_{min}$ | | $(B-O)_{max}$ | | $(B-O)_{av}$ | |
|---|---|---|---|---|---|---|
| | Nb–O | Ta–O | Nb–O | Ta–O | Nb–O | Ta–O |
| $LnTaO_4$ | — | 1.91 | — | 2.05 | — | 2.00 |
| Perovskite ($La_{1/3}BO_3$) | 1.88 | 1.90 | 2.07 | 2.06 | 1.98 | 1.98 |
| Cervantite ($SbBO_4$) | 1.81 | 2.06 | 2.07 | 2.09 | 2.00 | 2.09 |
| Rutile ($ATaO_4$) | — | 1.95 | — | 2.04 | — | 2.00 |
| Mean value (B–O) | 1.85 | 1.95 | 2.07 | 2.07 | 1.99 | 2.01 |

The B–O interatomic distances in the compounds of octahedral type according to the available information are given in Table 12. A regular dependence of the B–O distances on the nature of the metal A is not observed. The Ta–O distance is somewhat greater than the Nb–O distance. The mean interatomic B–O distances in the octahedral compounds (2.00 Å) is greater than the mean B–O distance in the tetrahedral compounds (1.77–1.78 Å for scheelite). Distortion of the octahedron is observed in all the compounds of octahedral type, the shortest bond always being *trans* to the longest B–O bond (cf. Figs. 6 and 8). This fact can be due to the displacement of the Nb (Ta) atom from the centre of the octahedron along one of the fourth-order axes. These structural features are known to facilitate the production of a spontaneously polarised state in tantalates, niobates and molybdates of a series of *s*- and *p*-elements.

## V. PROPERTIES OF NIOBATES AND TANTALATES OF TERVALENT METALS

### 1. PHYSICOCHEMICAL PROPERTIES

The information about the chemical stability and solubility of the niobates and tantalates of tervalent metals is disconnected. However, the available information suggests that all the compounds considered have high chemical stability. Both the niobates and tantalates are almost insoluble in water. For example, when the r.e.e. tantalates were treated with boiling water for 10 h there was no change in the structure of the compound, and r.e.e. ions could not be detected in the water[63].

The niobates and tantalates do not react with dilute HCl, $HNO_3$, $HClO_4$, $H_3PO_4$ or solutions of alkalis. However, when heated with concentrated acids or alkalis they are partly decomposed, and in hot $H_2SO_4$ some of the niobates and tantalates[63] can decompose completely. They also dissolve in hydrofluoric acid.

Niobates and tantalates are also highly resistant towards solutions of organic acids, and to many molten salts and metals. The niobates and tantalates are stable also towards moderate heating. Thus the r.e.e. (except Eu) orthoniobates are not reduced in an atmosphere of hydrogen at 1100–1200°C.[134] Under the same conditions $EuNbO_4$ is reduced to the metaniobate with perovskite structure ($a$ = 3.95 Å)[134].

### 2. MELTING POINTS

Tables 13 and 14 give the melting points of the niobates and tantalates of some tervalent metals. As might be expected, the tantalates melt at a higher temperature than the corresponding niobates.

Table 13. Melting points of certain niobates of tervalent metals, °C.

| Element A | $ANbO_4$ | $A_{1/3}NbO_3$ | $A_3NbO_7$ | Other compounds |
|---|---|---|---|---|
| Al | 1560[12] | — | — | — |
| Ga | 1450[22] | — | — | — |
| In | 1740[22] | — | — | — |
| Sc | 1950[32] | — | — | — |
| Y | 2000[77] | — | — | — |
| La | 1620[48] | 1460[48] | 1760[48] | $La_2Nb_{12}O_{33}$—1330[59] |
| Ce | 1660[48] | 1480[48] | 1790[48] | $Ce_2Nb_{12}O_{33}$—1350[59] |
| Pr | 1720[48] | 1550[48] | 1800[48] | — |
| Sb | 1160[87] | — | — | — |
| Bi | 1245[59] | — | — | — |

Another obvious regularity is observed for the r.e.e. niobates and tantalates. With increase in the molar ratio A : B in the compounds, that is, in the series $AB_3O_9$–$ABO_4$–$A_3BO_7$, the melting points of the compounds of a single element A increase (Tables 13 and 14). The compounds of composition $A_3BO_7$, which contain the greatest possible proportion of tervalent metal, have the highest melting point. A tendency towards an increase in the melting points of the compounds in the series La–Lu is not observed. The melting points for all types of compound undergo a jump at gadolinium and they reach a maximum for the La–Lu series.

## 3. ELECTROPHYSICAL PROPERTIES

As noted above, in most of the niobates and tantalates the $NbO_6$ (or $TaO_6$) octahedra are usually distorted owing to the displacement of the B atoms from the centres of the octahedra. This is characteristic of many ferroelectrics, for example, $KNbO_3$, $KTaO_3$, $PbNb_2O_6$, the antiferroelectric $NaNbO_3$, the piezoelectrics $Sr_xBa_{1-x}Nb_2O_6$, and other commercially important niobates and tantalates[119].

**Table 14.** Melting points of certain r.e.e. tantalates[63], °C.

| Element A | $ATaO_4$ | $A_{1/3}TaO_3$ | $A_3TaO_7$ | Element A | $ATaO_4$ | $A_{1/3}TaO_3$ | $A_3TaO_7$ |
|---|---|---|---|---|---|---|---|
| Y | 2100 | 1920 | 2380 | Tb | 1980 | 1820 | 2230 |
| La | 1860 | 1780 | 1960 | Dy | 2030 | 1820 | 2270 |
| Ce | 1890 | — | — | Ho | 2010 | 1835 | 2270 |
| Pr | 1845 | 1750 | 1990 | Er | 2010 | 1810 | 2360 |
| Nd | 1825 | 1820 | 1980 | Tm | 1990 | 1770 | 2260 |
| Sm | 1930 | 1810 | 2050 | Yb | 2030 | 1780 | 2360 |
| Eu | 1830 | 1805 | 2000 | Lu | 1980 | 1760 | 2340 |
| Gd | 2050 | 1840 | 2280 | | | | |

### A. Al, Ga, and In Niobates and Tantalates

Manakov and coworkers[135] were the first to study the dielectric properties of the $Al_2O_3$–$Nb_2O_5$ system. Ionic conductivity was observed for the entire composition region. As the temperature is raised (100–1600°C) in the $Al_2O_3$–$Nb_2O_5$ system the curve of electrical conductivity $\sigma$ against temperature shows an inflection characteristic of ionic conduction, and this inflection corresponds to the melting point[135].

The curves showing the temperature dependence of $\epsilon$ and $\sigma$ for the $Al_2O_3$–$Nb_2O_5$ and $Ga_2O_3$–$Nb_2O_5$ systems have anomalies characteristic of ferroelectric materials close to the Curie point. The most pronounced maximum on the curve of $\epsilon$ against temperature is observed at the composition $Al_2O_3 : Nb_2O_5 = 1 : 5$. However, the absence of a hysteresis loop did not confirm the hypothesis of ferroelectric properties for these materials[31,107]. The dielectric properties of ceramic specimens of $AlNbO_4$ and $GaNbO_4$ have also been studied[20,136]. The variation of $\epsilon$ and tan $\delta$ with the temperature for all the specimens agrees with the temperature dependence of electrical conductivity. It is therefore thought[20] that the inflections on the above curves are due to relaxation processes.

Anomalies in the dielectric properties have not been observed for Al and Ga tantalates[31]. Their dielectric constant is much less than for the corresponding niobates in the temperature range up to 350°C.

### B. Niobates and Tantalates of Scandium Subgroup Elements

(1) Orthoniobates of composition $RNbO_4$. The electrical properties of compounds of the type $ABO_4$ have been studied only for $YNbO_4$,[9,42] $NdNbO_4$,[6,137] $GdNbO_4$,[137] and $HoNbO_4$,[9] and for $LaNbO_4$, $YbNbO_4$, $YTaO_4$, and $YbTaO_4$.[8] These r.e.e. orthoniobates are antiferroelectrics with a rather high Curie temperature (500–830°C)[8,9]. The Curie temperature is inversely proportional to the radius of cation A and lies in the range 500–730°C for $ABO_4$, where A = Y, La, Yb.[8]

The dielectric constant and slope of the dielectric loss vary slightly up to 160°C.[42] When the temperature is raised further there is an increase in $\epsilon$ and tan $\delta$;[8,137] the curves have a characteristic inflection at the Curie point (Fig. 11). The reciprocal of the dielectric constant $1/\epsilon$ is a linear function of temperature, which agrees with the Curie law[137]. The electrical conductivities $\sigma$ of the $LnNbO_4$ (Ln = Nd, Gd) also increase with the temperature[6,137]. Above 130°C for $NdNbO_4$ and 230°C for $GdNbO_4$ lg $\sigma$ varies linearly with $1/T$.[137] The $NdNbO_4$ and $GdNbO_4$ exhibit *n* type conduction.[137]

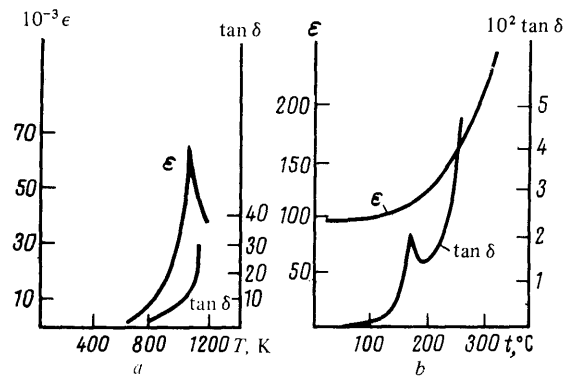

**Figure 11.** Variation of the dielectric constant $\epsilon$ and slope of the dielectric loss tan $\delta$ with temperature: *a*) $NdNbO_4$;[137] *b*) $Nd_{1/3}NbO_3$.[138]

(2) Metaniobates of composition $Ln_{1/3}NbO_3$. The niobium compounds of oxygen-octahedral type of composition $MNbO_3$ (M = K or Na) with perovskite structure usually exhibit ferroelectric or antiferroelectric properties[119]. This very feature is responsible for the more detailed study of the dielectric properties of the r.e.e. metaniobates.[6,7,133,138].

On the curves for the temperature dependence of $\epsilon$ and tan $\delta$ for $Ln_{1/3}NbO_3$ there are distinct inflections[31,138] which allow them to be associated with a phase transformation (Fig. 11). However, neither the shape nor the size of these maxima are characteristic of ferroelectrics[138] but seem to be characteristic of relaxation[6,138]. The latter is explained by the ordered alternation of filled layers and vacancies in the A sublattice[138].

The electrical conductivity $\sigma$ of the r.e.e. metaniobates is similar, as regards absolute value and temperature dependence, to that for the orthoniobates[6]. All the metaniobates exhibit an ability to accumulate a large residual charge[6,7]. The existence of residual charges capable of being retained for a long time (up to 1–5 years) and the reversal of the sign of the charge shows the $Ln_{1/3}NbO_3$ to possess electret properties, this being connected with the residual polarisation of the specimens. The residual charge of the r.e.e. metaniobates[6] (Table 15) usually exceeds that for the other known ceramic electrets, for example, those based on titanates[139], consequently materials based on r.e.e. metaniobates are interesting not only as electrets but also as low-power sources of current.

C. Antimony and Bismuth Niobates and Tantalates

The detailed study of the dielectric properties of the antimony and bismuth orthoniobates and orthotantalates of composition $ABO_4$ with cervantite structure began after the discovery in 1970 that the natural mineral stibiotantalite $(Sb,Bi)(Ta,Nb)O_4$ exhibits ferroelectric properties[5,140]. Later on, ferroelectric properties were also observed in synthetic specimens of $SbNbO_4$ [87,96,97] and $SbTaO_4$.[95,96] Phase transformations, the nature of which is still disputed, are shown clearly on the curves of $\epsilon$ and $\tan\delta$ against temperature (Fig. 12). Some investigators[86,87,97] identify the phase transformation at 410°C with the Curie temperature, that is, with a change from a spontaneously polarised state into a pyroelectric phase. These results agree with the Curie temperature of $T_C = 410°C$ for the natural mineral stibiotantalite[5].

Table 15. Residual charge of certain ceramic electrets.

| Composition | $\epsilon$ | $P$, C cm$^{-2}$ | Composition | $\epsilon$ | $P$, C cm$^{-2}$ |
|---|---|---|---|---|---|
| $La_{1/3}NbO_3$ | 200 | $(4.5-8)\cdot10^{-4}$ | $MgTiO_3$ | 15 | $1.3\cdot10^{-7}$ |
| $Pr_{1/3}NbO_3$ | 70 | $(3-5)\cdot10^{-5}$ | $CaTiO_3$ | 150 | $1.0\cdot10^{-7}$ |
| $Nd_{1/3}NbO_3$ | 50 | $(1-2.5)\cdot10^{-5}$ | | | |

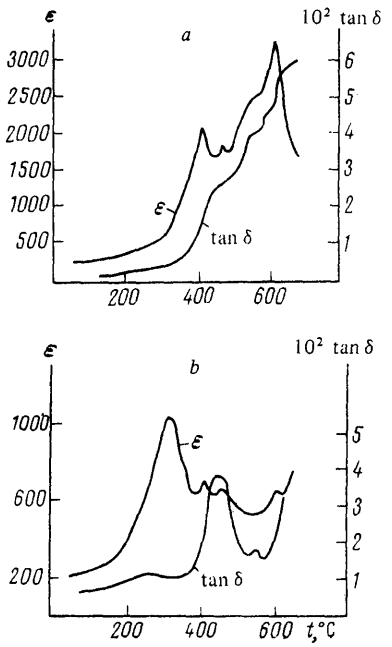

**Figure 12.** Variation of the dielectric constant $\epsilon$ and of the slope of the dielectric loss $\tan\delta$ with temperature[96]: *a*) $SbNbO_4$; *b*) $SbTaO_4$.

Combined studies of single-crystalline ceramic specimens of $ABO_4$ showed[94,96,98] that the Curie point lies at temperatures higher than thought earlier, namely $T_C = 600°C$ for $SbNbO_4$, 605°C for $SbTaO_4$. Below the Curie point they have an antiferromagnetic phase, but Ivanova and coworkers[96] think that ferroelectric properties appear at 400–410°C. The compounds $BiNbO_4$ and $BiTaO_4$ are antiferroelectrics with $T_C = 570°C$.[98]

The existence of a spontaneously-polarised state in the compounds $ABO_4$ agrees with the appearance of pyro- and piezo-electric properties. The hydrostatic piezo-modulus $d_h$ at room temperature is $8\times10^6$ cgse units for $SbNbO_4$. The combination of this $d_h$ with low dielectric constant shows the high piezoelectric sensitivity of $SbNbO_4$ in relation to omnidirectional pressure[86].

In addition, the high resistance to heat and moisture, the chemical inertness, and the mechanical strength of the antimony and bismuth niobates and tantalates will facilitate their wide use in various branches of technology.

D. Niobates and Tantalates of the 3*d*-Metals

Among the niobates and tantalates of the 3*d*-metals, the dielectric properties of the Ti, V, Cr, and Fe orthotantalates[141] and orthoniobates[142] have been studied.

The temperature dependence of the electrical conductivity of $ATaO_4$ [141,143,144] and $FeNbO_4$ [145] has been investigated. All the compounds exhibit electron conductivity. An insignificant fraction of an ionic component appears only at 1000°C. The temperature dependence of the conductivity of the $ATaO_4$ is of a semiconductor nature[144].

It has also been shown that the $ANbO_4$ (where A is Ti, V, Cr, or Fe) are semiconductors with a narrow forbidden gap[142]. The mechanism for the establishment of electrical conductivity and its nature have been discussed from the standpoint of ideas about the formation of the chemical bond in the $ATaO_4$.[141,143] Study of the temperature dependence of the dielectric constant $\epsilon$ has shown that $TiTaO_4$, $VTaO_4$, $CrTaO_4$, and $FeTaO_4$ are ferroelectrics[141,146].

# New Advances in Catalysis by Ion-exchange Resins

N.G.Polyanskii and V.K.Sapozhnikov

Current research on the general problems, methods and theory of catalysis by ion-exchange resins as well as new advances in its application in hydrolytic, hydration, and dehydration reactions, the synthesis of esters, alkylation, polymerisation, isomerisation, and condensation are surveyed.
The bibliography includes 276 references.

CONTENTS

I. General problems of catalysis by ion-exchange resins 226
II. Experimental methods 229
III. Kinetics of reactions catalysed by ion-exchange resins 232
IV. A brief description of the application of various ion-exchange resins as catalysts of reactions of organic compounds 237

This review is a continuation and logical development of previous publications by one of the authors[1,2], which appeared in 1962 and 1970. Reviews on the applications of ion-exchange resins as catalysts of various organic reactions[3-5] and narrowly specialist review articles on hydration[6], condensation[7,8], and esterification[9] reactions were published somewhat later; the literature references cover publications mainly after 1970. This review surveys the literature on catalysis by ion-exchange resins up to February 1976.

## I. GENERAL PROBLEMS OF CATALYSIS BY ION-EXCHANGE RESINS

The catalytic functions of ion-exchange resins and other similar substances reduce to the formation of reactive intermediate complexes either by the addition of the mobile ions (counterions) of the polymers to the molecules of one of the reactants or by the protonation of the electron-donating atoms of the active groups. Since there is no ion exchange either at this or subsequent reaction stages up to the formation of the final product, it is desirable to replace the established term "ion-exchange catalysis"[2,10] by "catalysis by ion-exchangers"[11].

Recent development of catalysis by ion exchangers in the stage under consideration, which includes the period 1969–1975, has led to numerous confirmations of their advantages as catalysts for chemical reactions involving organic substances over soluble acids and bases, which have been used for a long time in acid–base catalysis.

The simplicity of separation of the ion exchangers from the reaction products opens new effective pathways to the solution of the global problem — the protection of nature from chemical pollution by eliminating or greatly reducing the amount of waste water and harmful gases produced in various branches of chemical industry manufacturing alkylphenols[12], phenols[13], epoxy-compounds[14], and other products. In many cases this advantage confers also additional benefits such as reduction of the risk of fire and explosion in the manufacturing process, the facilitation of continuous technological processes, the simplification of the use of heat-exchange apparatus, etc. Since cation and anion exchangers constitute different phases and are immiscible with the reaction mass, the methods of catalysis by ion-exchangers makes it possible to carry out in a single stage reactions proceeding via a cationic or anionic mechanism, for example the synthesis of aminoaldehyde resin and its esterification by butanol[15]. It is noteworthy, that, as a result of the application of ion exchangers, new advances have been made in the synthesis of aminoresins with a high purity and their practical properties have been thereby improved.

In very many cases ion exchangers surpass soluble acids and bases as regards the specificity of catalytic action and this leads to a decrease in the amount of reactants wasted on side processes and improves the yield of the desired product (for example in the esterification of propylene glycol by stearic acid[16] and in the decomposition of isopropylphenyl hydroperoxides[13,17]).

Naturally, the specificity of ion exchangers as catalysts of organic reactions must not be overestimated. As an illustration, we may quote a number of reactions of different types where at least one, and sometimes a whole series, of side products are formed together with the main product. Such reactions include the thiolysis of 1,3-dioxepan by ethanethiol[18], the alkylation of cresol by indene[19], as well as numerous condensation reactions catalysed by cation exchangers (those of bicyclopentadiene[20], 4-vinylcyclohexene[21], and $\alpha$-methylstyrene[22] with formaldehyde and of methylallyl alcohol with phenol[23]) or anion exchangers (the condensation of n-butylraldehyde with formaldehyde[24]). One of the main problems of catalysis by ion exchangers is the reduction to a minimum of side reactions and the possible acceleration of the main reaction, which is achieved by the selection of the optimum ion exchanger, solvent, molar reactant ratio, and experimental temperature.

Ion exchangers are milder catalysts than soluble acids and bases, which makes it possible to prevent undesirable reactions, for example the opening of the epoxide ring on epoxidation[14] and permits the extremely delicate synthesis of fructose-1,6-diphosphate by the condensation of triosephosphates[25], which was previously achieved only by enzymatic catalysis. This feature of the catalytic action of ion exchangers will undoubtedly find many further useful applications in biochemical and fine organic syntheses.

However, one should note that such reactions catalysed by the protons of soluble acids are either not accelerated by the so called standard or gel ion exchangers or give rise to the useful products in insignificant yields. Even a brief list of such reactions, including the interaction of

acetic acid with benzyl alcohol[26], the reaction of dodecyl alcohol with sorbic acid[27] (which hardly occurs in the presence of the usual KU-2 × 8 cation-exchange resin), the reaction of t-butyl hydroperoxide with aliphatic acids[28], and the reaction of benzene with propene[29], shows that the negative result is due to steric causes, namely the inability of the large molecules of the reactants or products to penetrate the resin micropores and enter or leave the gel phase.

In very many instances, these difficulties can be overcome by means of ion exchangers with an artificially created heterogeneity, usually synthesised from macroporous styrene–divinylbenzene copolymers. Such ion exchangers have been particularly effective as catalysts of reactions in non-solvating non-aqueous media: in the absence of swelling of high-molecular-weight polyelectrolytes, the access of the reactant molecules to the active groups is assured by the large internal surface area.

Table 1 lists the most important properties of typical porous sulphonated cation exchangers synthesised from the copolymers of styrene with different amounts of divinylbenzene.

**Table 1.** Certain properties of porous sulphonated cation-exchange resins[30] with different contents of divinylbenzene (DVB).

| DVB, % | 10 | 15 | 25 | 50 | 70 |
|---|---|---|---|---|---|
| Volume capacity, mequiv. $g^{-1}$ | 5.34 | 5.28 | 3.43 | 2.68 | 2.22 |
| Specific surface, $m^2 g^{-1}$ | 0.1 | 43.0 | 77.5 | 263.2 | 266.3 |
| True density, g $cm^{-3}$ | 1.44 | 1.43 | 1.40 | 1.33 | 1.31 |
| Apparent density, g $cm^{-3}$ | 1.38 | 0.96 | 0.86 | 0.49 | 0.48 |
| Total porosity, ml $ml^{-1}$ | 0.04 | 0.329 | 0.386 | 0.632 | 0.634 |
| Average pore radius, Å | — | 148 | 147 | 101 | 77 |
| Calculated pore wall thickness, Å | — | 110 | 89 | 26 | 19 |

The most striking feature noted when the data in Table 1 are inspected is the enormous specific surface of cation exchangers containing ≥ 15% of divinylbenzene and the considerable differences between the true and apparent densities, indicating the porous nature of the ion-exchange copolymers investigated. The average pore radius in the cation-exchange resin synthesised varies in the range 77–148 Å. Depending on the conditions of synthesis of the copolymers and ion exchangers, the pores can be larger or smaller (see pp. 54 and 55 in Polyanskii's monograph[11]), but in most instances their equivalent radius amounts to hundreds of angstroms. According to Dubinin's classification[31], such sorbents should be regarded as mesoporous, but the term "macroporous ion exchangers" has become firmly established in the literature on ion exchange; to avoid confusion, this term will be used henceforth in the present text. We may point out for comparison that gel ion exchangers contain cavities with molecular dimensions, varying in the range from 8 to 20 Å for the SBS cation-exchange resin and from 7 to 13 Å for the KU-2 cation-exchange resins with different degrees of cross linking (see p. 55 in Polyanskii's monograph[11]).

A study of the polymerisation of dimethylcyclosiloxanes has shown[32] that the catalytic activity of macroporous ion exchangers can be predicted on the basis of the overall porosity of the resins, which can be determined by simpler methods than the specific surface or pore radius. In the above reaction, the maximum catalytic activity was shown by sulphonic acid cation-exchange resins with an overall porosity of 0.8 $cm^3 g^{-1}$, a specific surface not less than 60–70 $m^2$, and a pore radius not greater than 300 Å. Naturally, these characteristics are not of general significance, but depend on the chemical structure of the reactants and products. It is also clear that the optimum ion exchanger should have a fairly high porosity and not unduly small pores; for macroporous ion-exchange polymers, these conditions are usually fulfilled in the presence of 20–30% of divinylbenzene (DVB). Ion exchangers with this degree of cross linking retain their porosity after many repeated swelling and drying operations and do not lose it as a result of conversion from one ionic form to another either. On the other hand, cation exchangers with 10% DVB lose their porosity entirely and become gel resins when they are kept in water or another solvating liquid[30]. Such changes can have a decisive influence on the catalytic properties of ion exchangers.

When macroporous ion exchangers began to be used, it was possible to achieve reactions which did not occur in the presence of gel resins[27,29], to accelerate other reactions with reduction or elimination of the induction period[33], and in certain cases to raise the yield of the desired product[13]. At the same time, reactions have also been described (alkylation of phenol by isobutyl alcohol) in which the macroporous cation exchanger employed did not have kinetic or other advantages over gel resins[34]. In aqueous or mixed media, the reactions can actually take place faster in the presence of gel cation exchangers (for example the inversion of sucrose[35] or the hydrolysis of esters[36]) if the molecules of the reacting substances do not penetrate into the pore walls of macroporous ion-exchange polymers, which have a dense three-dimensional network in the presence of a high DVB content, but do penetrate into the gel phase of cation exchangers with moderate degree of cross linking. Some authors[37] do not recommend at all the use of macroporous resins for the acceleration of the Prins reaction, since these ion exchangers sorb the reaction mass with cracking of the grains, which hinders both the repeated use of the catalyst and the filtration of the reaction mass through the latter. However, one should note that this conclusion cannot be regarded as general, since the authors[37] tested only one cation-exchanger specimen and did not determine its porosity. There is no doubt that the porometric characteristics of the ion exchangers influence not only their catalytic activity but also the effects due to the blocking of the active centres by the components of the reaction mixture (see pp. 505 and 506 in Polyanskii's review[2]) on which the stability of the operation of the catalyst depends.

Both macroporous and gel ion exchangers have been used not only in hydrogen- or hydroxide-forms, but also in salt-forms, functioning as Lewis acids or bases. These catalysts are as a rule more thermostable[38,39] and in some cases surpass cation exchangers in the H-forms and anion exchangers in the OH-forms as regards the specificity of their action. The use of carboxylic cation exchangers in the Zn-forms in the condensation of urea with formaldehyde[40] and of the Zn-forms of sulphonic acid cation exchangers in the alkylation of phenol[41] has been described. A gel sulphopolystyrene resin in the Fe-form has been used as the catalyst of the conversion of *para*-hydrogen[42] and the macroporous Amberlyst 15 cation exchanger, containing $Na^+$ counterions and those of *d* (or *f*) elements, proved to be an effective catalyst of the isomerisation of but-1-ene[43]. The activity and stereo-selectivity of the catalyst depend on the electronegativity of the counterions, i.e. on their strength as Lewis acids.

Metallised cation exchangers, obtained by the reduction of the corresponding ionic forms to the free metal, have been tested as substitutes for certain catalysts used in heterogeneous catalysis[44,45]. This interesting field undoubtedly requires further development. There are no data on the use of metallised anion exchangers, but the salt-forms of these polyelectrolytes have been used successfully in a few cases. In this connection mention should be made of the use of $Cu^{2+}$ or $Co^{2+}$ complexes with bifunctional anion exchangers as catalysts of the reaction of 2- or 4-vinylalkylpyridines with amines to form N-substituted aminoethylalkylpyridines[46,47] and also of the employment of a strongly basic anion exchanger in the chloroplatinate-form in a very interesting reaction involving the hydrosilylation of alkenes, alkynes, and unsaturated acid esters[48].

Together with the modification of ion exchangers with the aim of imparting catalytic functions to them, investigators have resorted to different procedures for the promotion or stabilisation of catalysts. It has been shown[49] that treatment of the AV-17 anion-exchange resins with aqueous suspensions of calcium and magnesium oxides, forming complexes with hydroxy-compounds, accelerates the reaction between formaldehyde and ethyl methyl ketone, increasing thereby the yield of the main reaction product—3-hydroxymethylbutan-2-one. Another modification procedure, based on the esterification of the sulphogroups by mercaptoethanol, increases the stability of the Dowex-50 W cation-exchange resin and the duration of its operation without a significant decrease of activity[50].

The problems of the stability of catalysts in the course of their operation and the causes and prevention of the changes in catalytic properties as well as regeneration procedures constitute a set of inter-related problems. It has been shown[51] that their solution is possible only by a joint consideration of the thermal stability of ion exchangers, in a broad sense of this term, and of their catalytic activity.

The first possible cause of the decrease of the catalytic activity of ion exchangers is the decrease of their exchange capacity owing to reactions involving the electrolytic or nucleophilic substitution of the active groups as a result of the interaction with the components of the reaction mixture, including the moisture present initially in the catalyst itself. This concerns the desulphonation of strongly acidic cation exchangers or the deamination of anion exchangers, which determine the position of the upper temperature limit of the prolonged use of ion-exchange resins: 150° and 300°C for sulphonated styrene–divinylbenzene copolymers in the hydrogen- and salt-forms respectively; 60–70° and 100–110° for highly basic anion exchangers in the OH- and salt-forms.

Under milder conditions, excluding desulphonation or deamination, the second cause of the decrease of catalytic activity operates—the blocking of the ion-exchange groups. This phenomenon is most typical in the presence of substances reacting with the active groups (for example, as a result of the esterification of the sulpho-group by alcohols[52]) and also on formation of polymeric or crystalline products of different types, shielding the counterions from interaction with the reactant molecules (for example, the blocking of cation exchangers in condensation[53,54], thiolysis[55], and alkylation[56] reactions and of anion exchangers in the hydrosilylation reaction[48]).

The third cause of the decrease of the activity and of the duration of the useful life of ion exchangers is the possible substitution of the $H^+$ and $OH^-$ counterions by other ions with formation of salt-forms which do not catalyse the reaction under the experimental conditions. The source of the substituting ions may be impurities in the reactants or the products of the corrosion of the reactor material. By passing the reactants through an ion-exchange column, the impurities are removed and the useful life of the catalyst is greatly increased[53].

The fourth cause of the decrease of the useful life of ion-exchanger catalysts is the limited osmotic stability of the latter, i.e. the disruption of their grains following changes in swellability in different media; the resulting fine particles offer a greater resistance to the flow of reactants and the process stops. For this reason, it was necessary to abandon the KU-2 cation-exchange resin as the catalyst of the condensation of mesityl oxide with methanol and preference had to be given to the less thermostable sulphophenolformaldehyde cation-exchange resin, the grains of which did not fragment; the mild reaction conditions (20–30°C) make this change feasible[57].

The changes in ion exchangers described above frequently influence the kinetics of the reactions which they catalyse (see Polyanskii[11], pp. 20 and 21 and Fig. 2, as well as the paper of Reikhsfel'd et al.[48]), are responsible for the decreased yield of the desired products and the enhanced formation of side products[58,59], and alter the selectivity of the catalytic action in reactions involving multicomponent mixtures of related substances and the composition of the reaction mass[60].

The intensity of the changes enumerated above, leading to a decrease of the useful life of the catalysts, depends on the nature of the ion exchanger, solvent, and reaction mixture, reaction temperature, the purity of the starting materials, and the corrosion resistance of the reactor material. In various syntheses, these parameters change over a wide range and it is therefore not surprising that investigators quote extremely different useful lives of resin catalysts. Without regeneration, catalysts of the KU-type in the H-form have been used in the synthesis of peracids (150 h),[14] in the dehydration of ethylene glycol to dioxan (200 h),[61] in the alkylation of *p*-cresol by isobutene (500 h),[62] and in the decomposition of isopropylphenyl hydroperoxide (1400 h).[17] The activity of the AV-17 anion-exchange resin in the chloroplatinate-form as the catalyst of the hydrosilylation of alkenes decreased sharply, owing to their partial polymerisation, after 20–30 h. However, when the polymers are periodically dissolved in hexane, the catalyst can be employed twenty times in the course of 180 h.[48]

The examples quoted show that an increase of the lifetime of the catalysts may be achieved only on the basis of a combined approach involving a comprehensive study of all the causes of the decrease of catalytic activity; the synthesis of new thermostable ion exchangers, on which investigators have been working persistently and not without success, constitutes only part of the general problem.

Despite the difficulties enumerated above, a considerable expansion of the fields of application of ion exchanger catalysis has occurred in the last few years. The synthesis of a wide variety of compounds is no longer its only field of application. The catalytic properties of ion exchangers are used to convert isomers with very similar properties into substances capable of subsequent separation by distillation[63], for the elimination of whole series of impurities from phenol[64], and for the selective extraction of isobutene from mixtures with n-butenes, which remain unchanged under the reaction conditions[12]. Ion exchanger catalysis is finding increasing applications in biochemical synthesis[65–67] and in analysis[68]. There is a continuous growth of interest in ion exchangers as catalysts in scientific disciplines related to chemistry.

## II. EXPERIMENTAL METHODS

Granulated ion exchangers are usually employed as catalysts, but in special cases, when the kinetic studies are performed to investigate the reaction mechanism and spectroscopic measurements have to be made, film or membranes are used[69,70]. The method of preparation of ion-exchange films has been described in a paper[70] and in a monograph[71].

Before use in catalysis, technical ion exchangers must be conditioned—the three-dimensional network has to be purified and conditioned in order to stabilise its structure. The best conditioning procedure is believed to involve the treatment of cation exchangers with 1–2 *N* NaCl or NaOH solutions, water, 1–2 *N* HCl solution, and again water, while anion exchangers are treated with 1–2 *N* NaCl or HCl solutions, 1–2 *N* NaOH solution, and again water. The treatment in the Na–H or Cl–OH exchange cycles lasts approximately 12 h in each case and is repeated three–four times. Cation and anion exchangers which are weak electrolytes are conditioned with NaOH or HCl respectively instead of NaCl, since otherwise the preparation of their salt-forms requires enormous volumes of reagents. There are almost no data concerning the influence of conditioning on the catalytic properties of ion exchangers, apart from a study[50] where it was noted that there is no change in sulphonated cation exchangers based on the styrene–divinylbenzene copolymer, used as catalysts of the condensation of phenol and acetone, after alternate treatment with NaOH and $HNO_3$ solutions. More extensive systematic studies are needed in order to reach final conclusions on this problem.

The elimination of low-molecular-weight organic impurities from ion exchangers is achieved by treatment with alcohols, benzene, an alcohol–benzene mixture, or acetone in Soxhlet apparatus. Methanol has been used successfully to regenerate the spent ion exchangers by removing polar blocking impurities[53] and a sulphonated cation exchanger of the polycondensation type, used as the catalyst of the hydration of isobutene, has been regenerated by treatment with concentrated sulphuric acid at 105°C for 2 h.[72]

Ion exchangers are converted into the required ionic form by passing through them a 1–2 M solution of the appropriate reagent (a strong acid, usually hydrochloric acid, in order to obtain cation exchangers in the H-form, alkali to produce anion exchangers in the OH-form, chlorides or other soluble salts in order to obtain salt-forms) until its concentration in the filtrate is constant, or preferably until the test for the displaced ion is negative. In the preparation of salt-forms of ion exchangers, one must bear in mind that hydrolysed ions may be absorbed from salt solutions. To avoid the displacement of the hydrolytic equilibrium in such cases and also in the preparation of any salt-forms of weakly acidic cation exchangers or weakly basic anion exchangers, they must be washed with 95% ethanol and not water. A high degree of substitution of counterions is sometimes achieved in the preparation of one salt-form from another and not from the H-form of the cation exchanger or the OH-form of the anion exchanger. Such a case has been described[73], the authors having used an anion exchanger in the tetrachloropalladate(II)-form as the catalyst of the hydrogenation of olefins and allyl alcohol[74]. A high degree of substitution of counterions can be achieved by displacing the equilibrium associated with the formation of a relatively undissociated compound. This principle has been used by Reikhsfel'd et al.,[48] who obtained the AV-17 anion-exchange resin with the $PtCl_6^{2-}$ counterion by passing an aqueous solution of $H_2PtCl_6$ through the resin in the OH-form. The mechanically sorbed acid was extracted with water by treating the hydrosilylation catalyst obtained in a Soxhlet apparatus.

Metallised cation exchangers have been obtained[75] from the macroporous Amberlyst 15 resin in the Na-form, through which aqueous solutions of $Pt(NH_3)_4Cl_2$, $Pd(NH_3)_4 \cdot Cl_2$, $NiCl_2$ in the presence of an excess of $NH_4OH$, or $AgNO_3$ in the presence of an excess of $NH_4OH$ were passed. The cation exchanger was then washed with water and alcohol, dried in air and then *in vacuo* at 107°C, and the ions reduced to the free metal in a stream of hydrogen or by treatment with an aqueous hydrazine solution which had been made alkaline; the resulting catalyst was used to accelerate the oxidation of ethanol under very mild conditions.

Ion exchangers designed to accelerate reactions in non-aqueous media are usually employed in the dehydrated state. In preparative studies, they normally are dried when the water in the ion exchanger can cause undesirable reactions of the components of the reaction mixture, for example the hydrolysis of esters in transesterification reactions[76]. In kinetic studies, it is necessary to bear in mind the influence of water on the rate of the catalysed reaction (see below) and one must therefore standardise rigorously the moisture content of the resin. In some cases, the nature of the reaction occurring depends on the resin moisture content (see p. 511 in Polyanskii's review[2]).

The behaviour of various cation and anion exchangers on drying by heat has been examined in detail[38,39]. The drying is carried out at atmospheric pressure in air, in a stream of hydrogen or helium, or *in vacuo*. Unfortunately, the recommended conditions are extremely varied even for ion exchangers of the same type and in most cases have been inadequately described and by no means always justified. In addition to the procedures described in the reviews quoted above, we shall list the most characteristic conditions used in the drying of sulphonated cation exchangers based on styrene–divinylbenzene copolymers and used as catalysts of various organic reactions: at 90°C and 14 mmHg;[77] at 90°C and $10^{-6}$ mmHg;[42] at 120°C[29,43] (residual pressure not indicated); at 120°C in a stream of helium dried at the temperature of liquid nitrogen[78] and having a partial water vapour pressure of $10^{-6}$ mmHg. Some workers use two-stage drying methods—initially at the usual pressure and then *in vacuo*. Thus the Zeocarb-225 cation-exchange resin is initially dried in a thermostat at 110°C for 48 h and then for 2 h at 150°C and a residual pressure of $10^{-2}$ mmHg. The additional weight loss in the second stage amounted to 10%.[79] The same cation exchanger has been dried[80] in a thermostat at 130°C (time not indicated) and in a vacuum of $10^{-2}$ mmHg at 120°C for 2 h. As in the previous case, the additional weight loss in the second stage amounted to 10%. Within the limits of the sensitivity of infrared spectroscopy, the cation exchanger dried under the above conditions in a stream of helium did not contain water. In the remaining cases, no data are quoted for the water content in the dried cation-exchange resins.

Some workers store the dried cation exchangers in a desiccator over $P_2O_5$ (sometimes in sealed tubes), while others proceed more correctly, drying the required amount of the cation exchanger directly before each experiment. It is noteworthy that, before introducing the sample into the reactor, it is desirable to test for soluble desulphonation products, which are formed during drying as a result of thermal hydrolysis or decomposition of the matrix[38]. For this purpose, it is sufficient to introduce approxi-

mately 200 mg of the resin into 5–10 ml of water, separate the liquid after stirring for 10 min, and titrate with 0.01 *N* hydrochloric acid using Methyl Orange; the amount of titrant used should not exceed 3–4 ml.

We believe that two-stage drying is the most effective and convenient method for routine work. Before drying *in vacuo*, it is desirable to separate the resin into fractions in order to isolate grains having a specified size and eliminate the fine particles, which increase the resistance of the resin to the flow of liquid.

It is desirable to fractionate the dehydrated resins by dry screening, which may be accelerated by means of a special apparatus[81] with an electric motor and an articulated transmission. A small amount of grains of similar size, suitable for accurate kinetic studies, can be obtained by using a Kapron [Russian nylon] brush to remove the grains caught in the mesh of each sieve. The authors of this review succeeded in obtaining by this procedure fairly homogeneous fractions of a carboxylic acid cation-exchange resin with grain sizes of 0.504 ± 0.021, 0.403 ± 0.016, and 0.262 ± 0.012 mm. In view of the possible inhomogeneity of the resins, the isolated fractions must be tested in terms of fundamental physicochemical properties.

Unfortunately, one should note that, even in modern studies on catalysis by ion exchangers, the catalysts employed are frequently not characterised in terms of their fundamental physicochemical parameters. Kinetic studies are thereby made almost completely valueless. The description of any ion exchanger used as the catalyst must include the characteristics of its thermal stability in the reaction mass, exchange capacity, and the coefficient of moisture absorption capacity. In kinetic studies on reactions occurring in the resin phase, it is also necessary to quote the partition coefficients of the reactant λ, to which the resin efficiency is related (see p. 505 in Polyanskii's review[2]). Methods for the determination of these parameters have been examined in Polyanskii's monograph[11] and in reviews[38,39]. In connection with recent studies, certain additional comments must be made concerning the partition coefficient.

According to Helfferich[82], this quantity is expressed in one of two ways:

$$\lambda' \equiv \bar{c}_i/c_i, \quad (1)$$

$$\lambda \equiv \bar{m}_i/m_i, \quad (2)$$

where $c$ and $m$ are respectively the molar and molal concentrations, $\bar{c}_i$ and $\bar{m}_i$ refer to the resin phase, $\bar{c}_i$ being expressed in terms of the number of moles of the given substance retained per unit volume of the swollen resin and $\bar{m}_i$ referring to the unit mass of the absorbed solvent. For reactions in aqueous solutions, $\bar{m}_i$ is found from the degree of sorption of the reacting substance by the resin and its water content. The concentrations of the substance in aqueous solution $c_i$ and $m_i$ have the corresponding significance.

It has been suggested[35] that the partition coefficient be defined as the ratio of the mass of the sorbate to the volume of the resin divided by the content of the same substance per unit volume of the solution. This definition is most convenient for the description of the partition of the reactants between resins and non-aqueous systems.

An approximate quantitative estimate of the partition coefficient is possible by means of the familiar relation

$$q = \lambda\bar{k}/k, \quad (3)$$

where $q$ is the relative efficiency (see p. 1046 in Polyanskii's review[1]) and $\bar{k}$ and $k$ are the rate constants for the reaction catalysed by ion exchangers and solutions of acids or bases respectively at the equivalent concentration of the catalyst ions. If $\bar{k} = k$, the efficiency of the resin may be inferred from the partition coefficient and conversely. Wolf[83], who suggested this principle, made the additional assumption that the active groups are present in the reaction volume (which was calculated from the exchange capacity and the weight of the resin sample) in the form of a 0.1 *N* solution. The efficiencies of three different Wofatits as catalysts of the hydrolysis of methyl acetate, ethyl acetate, and n-butyl acetate were calculated from the rate constants, measured in the presence of the resin and the equivalent amount of 0.1 *N* HCl, and are compared in Table 2 with the experimental partition coefficients of various substances which remain unchanged in the presence of Brønsted acids.

Table 2. The efficiencies of cation-exchange resins as catalysts of the hydrolysis of methyl acetate ($q$) and ethyl acetate ($q'$) at 20°C and their comparison with the partition coefficients λ between ion-exchange resins and 2% solutions of certain organic substances[83].

| System | $q$ | $q'$ | $\lambda$ ($C_6H_5OH$) | $\lambda$ ($CH_3COOH$) | $\lambda$ ($C_6H_6OH$) | $\lambda$ (n-$C_3H_7OH$) | $\lambda$ (n-$C_4H_9OH$) |
|---|---|---|---|---|---|---|---|
| Wofatit | 1.90 | 2.12 | 5.0 | 2.2 | 1.9 | 2.0 | 2.5 |
| Wofatit P | 2.44 | 3.17 | 19.6 | 4.3 | 2.2 | 2.2 | 3.0 |
| Wofatit KPS × 8 KPS×8 | 1.31 | 1.48 | 3.3 | 1.2 | 1.5 | 1.5 | 1.3 |

Table 2 shows that there is an approximate correspondence between the resin efficiency and the partition coefficient of an indifferent substance with the same number of carbon atoms as in the ester whose hydrolysis is investigated. Similar relations have been observed in the hydrolysis of esters catalysed by macroporous ion exchangers[84]. It has been shown[84] that the partition coefficients of alcohols and ketones are almost independent of the overall porosity, but decrease rapidly with increase of the divinylbenzene content in the cation exchanger. Data concerning the effect of the degree of cross linking on the partition coefficient of 1-butanol and benzoic acid between their mixtures and the Dowex-50 W gel cation-exchange resin have been published[85].

In studies of vapour-phase processes, it is necessary to measure the sorption of vapours by ion exchangers. This problem is solved by means of the classical sorption technique based on the use of the McBain balance[86] and its modifications[30]. With macroporous resins, these methods yield the overall sorption due to adsorption and capillary condensation in the mesopores, the macropores remaining unfilled under these conditions.

On the other hand, in contact with non-solvating organic liquids, open pores of any size are completely filled, which has been used by one of the present authors and Gorbunov to determine the overall porosities of macroporous ion exchangers[87]. For this purpose, 200–300 mg of the resin dried at 120°C for 8 h was placed in a dry test tube and covered with anhydrous solvents. After 2 h, the pores were completely filled, after which the samples were transferred quantitatively to dry weighed polyethylene test tubes with holes in the bottom, closed by lids, and centrifuged: for 1 min at 130*g* in the case of n-heptane and iso-octane, and for 5 min at 1200*g* in the presence of other more viscous and less volatile liquids, for example

n-decane. The test tubes were then reweighed and the weight increment was divided by the density of the corresponding liquid at the experimental temperature and by the weight of the initial sample of the dry resin, the overall porosity being calculated in $cm^3$ per gram of the sorbent. The method described provides a simple experimental solution of the problem of the determination of porosity and yields more accurate results than the densimetric methods usually employed for this purpose[88]. As stated above, the overall porosity is an important characteristic of the catalytic properties of macroporous ion exchangers and must therefore be determined in kinetic studies.

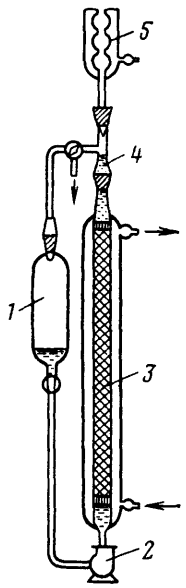

**Figure 1.** Apparatus for a catalytic process[32]: 1) collector; 2) metering micropump; 3) catalytic column; 4) packing; 5) reflux condenser.

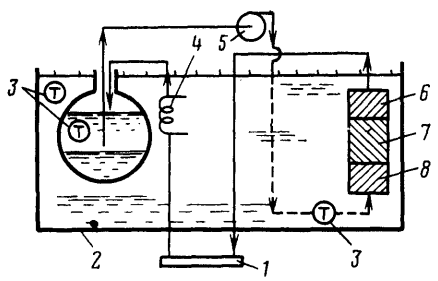

**Figure 2.** Reactor with circulation[35]: 1) polarimeter; 2) thermostat; 3) control devices; 4) heater; 5) pump; 6) glass beads or a weakly basic anion-exchange resin; 7) catalyst; 8) glass beads or a weakly acidic cation-exchange resin.

The reactions in the presence of ion exchanger catalysts are carried out in glass or metallic tubes (see pp. 81 and 82 in Polyanskii's monograph[11]), in reactors with mechanical[89] or pneumatic[90] stirring, and in various columns through which a stream of the test liquid is passed. In order to accelerate the reactions and the displacement of the equilibrium, one of the products, usually water, is removed, by separating its azeotrope with a suitable component of the reaction mixture[89] or a specially added indifferent solvent[91], for example toluene. The condensed reaction mixture is separated in a Dean–Stark trap, the organic layer being returned to the reactor. On the other hand, if the products must be separated by fractionation, the chemical reaction is carried out in an apparatus of the fractionating column type, which is filled above and below with glass packing and the resin is placed in the intervening gap. Chebotarev et al.[92] successfully carried out the hydrolysis of butyl butyrate on apparatus of this type using as the catalyst a sulphonated cation exchanger combined with a thermoplastic material and moulded in the shape of Raschig rings. Some investigators[93] recommend that a mixture of the resin and glass beads be introduced into the column in order to improve heat exchange.

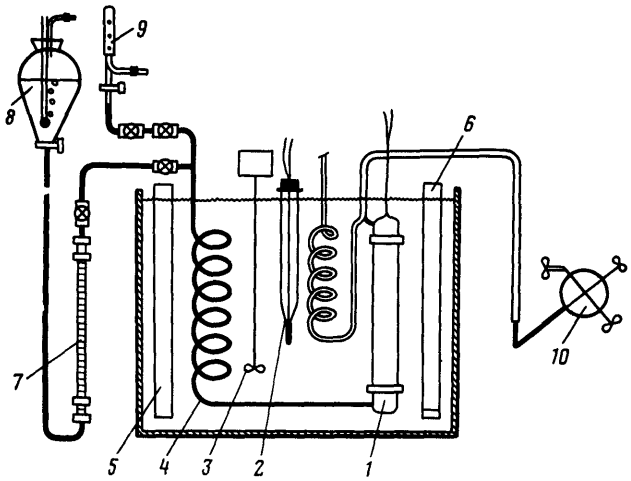

**Figure 3.** Apparatus with a tubular reactor[94]: 1) reactor; 2) thermoregulator; 3) stirrer; 4) evaporator; 5) and 6) heaters; 7) flow meter; 8) reservoir; 9) burette; 10) valve for the removal of gas.

All the above reactors are suitable for the investigation of kinetics, provided that conditions have been created in the system such that the reaction proceeds in the kinetic region, which is achieved by vigorous stirring or rapid circulation of the reactants in order to eliminate the effects of transport or film diffusion. Naturally such measurements are made with rigorous temperature control of the reaction volume and measurement of the temperature in the reactor itself.

Without going into details, Figs. 1–4 illustrate schematically several of the most interesting types of apparatus used to investigate the kinetics of liquid-phase[32,35] and vapour-phase[70,94] reactions. In the scheme shown in Fig. 2, provision is made for the continuous polarimetric monitoring of the reaction kinetics, while in the scheme illustrated in Fig. 3 the reaction kinetics are followed by a chromatographic method. Fig. 4 illustrates schematically a flow-type reactor with a membrane as the catalyst, which

combines the functions of a cell for the recording of infrared spectra. A reactor designed for the simultaneous investigation of reaction kinetics and the sorption of reactant vapour by the catalyst (from the increase in the length of a quartz coil) has been described[95].

The results of the study of the kinetics of different reactions will be examined in the next Section.

## III. KINETICS OF REACTIONS CATALYSED BY ION-EXCHANGE RESINS

During the period under consideration, the kinetics of reactions catalysed by ion exchangers have been studied at a rate higher than for research in other fields. The extensive experimental data obtained confirmed the validity of the general treatment of reactions in the presence of resins, in which Polyanskii[11] and Helfferich[82] saw the features of both homogeneous and heterogeneous catalysis.

Reactions occurring throughout the bulk of the swollen resin grain can be legitimately regarded as homophase processes, since there is no interface between the reaction mass and the catalyst itself. The kinetics of such reactions (and sometimes also the nature of the product formed) depend on the composition of the reaction mass in the catalyst pores, which is in its turn determined by the partition coefficient of each component between the resin and the external solution [see pp. 504 and 505 in Polyanskii's review[2] and Eqn. (3) in the present paper].

It is important to find the partition coefficients over a wide range of concentrations of the reactants if a different analytical expression describes the sorption isotherm of each. The isotherms can be described by the Langmuir equation for some substances and by the Freundlich equation for others, while a third group can give rise to complex saddle-shaped curves[96]. In such cases the enhancement of the absorption of one substance by the resin influences the degrees of sorption of the other components of the reaction mixture, which in its turn affects the reaction rate.

The fruitfulness of the combined study of the sorption of the reaction components by resins and of the kinetics of the catalysed reaction has been strikingly demonstrated[97,98]. According to the data of Reikhsfel'd et al.,[97] the effective rate constants for the transesterification of ethyl acrylate by butyl alcohol in the presence of different cation-exchange resins show an excellent correlation with the degrees of sorption of butanol from real reaction mixtures. The rate of this (and the reverse) reaction depends on the concentration of the intermediate complex $ROH_2^+$ formed as a result of the interaction of the alcohol molecules with the cation exchanger counterions. Naturally, there is no correlation of this kind if the intermediate complex, formed by the given reaction component (for example ethyl acetate in the study of Reikhsfel'd et al.[97]), is not reactive.

The true rate constants $k_{true}$ can be found from the sorbability by the resin of the component which forms a reactive complex and from the experimentally determined effective rate constants $k_{eff}$, using the relation

$$k_{eff} = k_{true}(\alpha_i^{rs} - \alpha_i^0), \qquad (4)$$

where $\alpha_i^{rs}$ is the sorbability of the above component calculated as the ratio of the number of moles of this substance in the catalyst phase to its overall amount in moles and $\alpha_i^0$ is the sorbability of the same component in the inactive form, determined by extrapolating the linear function $k_{eff} = f(\alpha_i^{rs})$ to the abscissa axis. In contrast to $k_{eff}$, which increases steadily and appreciably with the sorbability of the component forming the reactive complex, $k_{true}$ changes only slightly. The equilibrium constant depends on the sorbabilities of both components of the transesterification reaction; it can be easily calculated by means of the equation quoted by Reikhsfel'd et al.[98]

The difference between the compositions of the reaction mass in the resin phase and in solution is an important specific feature of catalysis by ion exchangers compared with homogeneous acid–base catalysis. A second characteristic of catalysis by ion exchangers, in terms of which it resembles heterogeneous catalysis, is that the reaction kinetics are frequently determined by adsorption processes. In such cases, the rate of reaction depends on the probability that the reactant molecules encounter fixed active centres. With increase in the concentration of the sorbed reactant, it rises initially, but reaches a limit as soon as all the active centres have been filled. This situation has been demonstrated, for example, in a study of the kinetics of the propylation of benzene in n-heptane on Amberlyst 15, the results being illustrated in Fig. 5 by a plot of the reaction rate against the concentration of the reactants. Evidently the behaviour of propene is described by the Langmuir–Hinshelwood model of an ideal adsorbed layer. The rate-limiting stage of the reaction is the electrophilic interaction of the chemisorbed propene with the benzene which has penetrated into the resin phase together with n-heptane. Since the concentrations of benzene in the inner and outer solutions vary in parallel, the rate of reaction increases continuously with increased concentration in the solution. The non-linearity of the curve describing the variation of the reaction rate with benzene concentration[29] indicates the inhibition of the reaction by n-heptane, which competes with the aromatic hydrocarbon in the swelling of the resin matrix.

The Langmuir–Hinshelwood model has been tested in studies of many other reactions catalysed by resins, for example esterification[99], transesterification[100], and

dehydration[101-104]. The authors of the above studies suggested that account be taken of the competition between the starting materials and reaction products for the active centres by introducing into the kinetic equations the adsorption equilibrium constant. For example, the kinetics of the vapour-phase dehydration of methanol and ethanol[101], in which two molecules sorbed on the active centres react, are described by the equation

$$r = \frac{k \cdot K_A^2 p_A^2}{(1 + K_A p_A + K_E p_E + K_W p_W)^2}, \qquad (5)$$

where $k$ is the reaction rate constant (mole $min^{-1}$ $mequiv.^{-1}$), $K$ the adsorption equilibrium constant ($atm^{-1}$), $p$ the partial pressure of the given component, and $r$ the rate of reaction (mole $min^{-1}$ $mequiv.^{-1}$) referred to the alcohol; the subscripts A, E, and W refer respectively to the alcohol, ester, and water. In solving equations of this type for liquid-phase reactions, it is recommended[103] that the concentrations of reactants be replaced by their activities in the condensed phase.

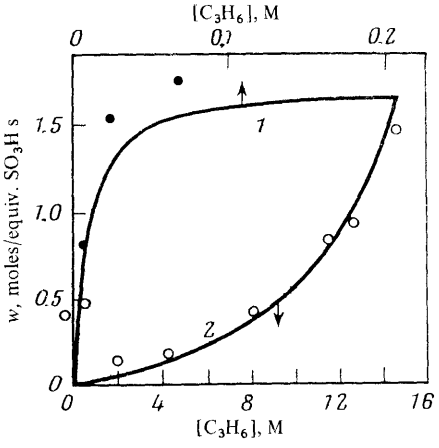

**Figure 5.** Variation of the rate of alkylation of benzene by propene with the concentrations of the components: 1) propene solution in benzene; 2) benzene–n-heptane mixture saturated with propene.

A possible cause of the inhomogeneity may also be the different states of hydration of the active groups within the bulk of each resin grain. This type of inhomogeneity, caused by the kinetics of the reaction under consideration, was taken into account by Heath and Gates[33] in terms of the "shrinking core" model which they proposed and used to account for the time variation of the efficiency of polystyrene cation exchangers with 8–12% DVB as catalysts of the dehydration of t-butyl alcohol. The anhydrous alcohol does not cause the swelling of the catalyst and the reaction, which begins only on the active surface centres, therefore proceeds very slowly (Fig. 6). Water, formed in the initial stage of the reaction, is partly transferred to the liquid phase and partly combines with the sulpho-groups via hydrogen bonds, causing swelling. This facilitates the transport of alcohol within the grain and accelerates the reaction. During the reaction, the boundary between the hydrated and non-hydrated zones in the grain is displaced inwards and, when each grain has been fully solvated, further absorption of water results in its binding to the active groups, which reduces the activity of the catalyst and hence the reaction rate. The duration of the induction period (see the left-hand branch of the curve in Fig. 6) increases appreciably with decrease of temperature and with increase of the resin grain size, owing to the influence of diffusional inhibition on the kinetics of the given reaction.

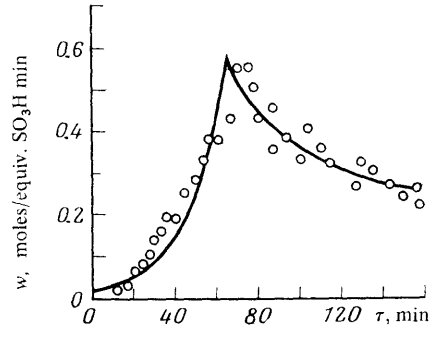

**Figure 6.** Kinetic curves for the dehydration of t-butyl alcohol.

The fact that the Langmuir–Hinshelwood model could be used to describe many reactions led to ion exchangers being considered as almost ideal catalysts with virtually equivalent active centres. Incidentally, other ideas have been frequently expressed in the literature, whose authors considered the inhomogeneity of the active groups in the steric[105], general chemical[106], and catalytic[43] sense of this term. We believe that this latter view corresponds more accurately to the present state of knowledge about the structure of ion-exchange resins[107], and the results of a direct experiment in which the non-equivalence of the active groups of Amberlyst 15 in the H-form was demonstrated by titrating it with a solution of n-butylamine in cyclohexane using Hammett indicators[108].

The third feature of catalysis by ion-exchange resins, in terms of which resins resemble non-ionogenic solid catalysts of gas- or liquid-phase processes, may be associated with the inhomogeneity of the active centres.

The role of diffusional inhibition, which constitutes a fourth feature of catalysis by ion-exchange resins, is manifested to a greater extent the larger the reactant molecules and the higher the degree of cross linking of the continuous-gel ion-exchange polymer[33,109-111]. Different workers have therefore used, in the kinetic description of catalytic reactions in the presence of ion-exchange resins, Boyd's theory of internal and external diffusion rate control (see pp. 27–30 in Polyanskii's review[11]) and the model of simultaneous diffusion and chemical reaction proposed by Wheeler and Thiele[33,35,112-114]. It is noteworthy that Boyd's theory was proposed for ion-exchange reactions and the Wheeler–Thiele model was designed for gas-phase reactions on the surfaces of solid catalysts. Nevertheless the mathematical apparatus associated with both concepts has been used successfully to investigate catalytic reactions on resins regardless of the phase state of the reactants.

One of the important features of the internal diffusion rate limitation is low activation energies, usually not exceeding 10 kcal mole$^{-1}$. Thus the activation energy for the hydrogenation of allyl alcohol is 3.4 kcal mole$^{-1}$ [74] and that for the alkylation of phenol by trimeric propene [115] amounts to 9.4 kcal mole$^{-1}$. Such low activation energies in the presence of diffusional inhibition in no way indicate a high activity of the catalyst: reactions of this kind proceed at a moderate rate. The product of the activation energy and the rate constant for the chemical reaction, which has been called [56] the "power of activation" ("aktivierungsleistung"), is of more general importance as a measure of the activity of the ion exchanger catalyst; for unimolecular reactions, this quantity is expressed in kcal litre mole$^{-1}$ s$^{-1}$. We believe that the product of the activation energy and the pre-exponential factor can serve as a criterion of catalyst activity.

Using the mathematical apparatus of the theory of absolute reaction rates, some workers [85,116] calculated the activation entropies from the activation energies and rate constants. It was shown that the entropy changes steadily, being a function of the degree of cross-linking of the resin and of the partition coefficients of the reactants between the solid and liquid phases.

The rate constants, expressed in the traditional way or their specific values referred to one milliequivalent of active groups of the ion-exchange resin, are usually employed as a direct characteristic of the reaction kinetics. In those cases where the rate constants do not remain invariant throughout the reaction owing to the influence of the blocking of the active groups or of a change in their solvation state, the kinetics are described by plots of the percentage conversion against time or by the usual kinetic curves.

The influence of various factors on the kinetics of reactions catalysed by ion exchangers has been examined in detail in Polyanskii's monograph [11] (pp. 37–62) and we shall therefore consider here only individual aspects of this problem.

The most important factors on which the reaction kinetics depend are usually thought to be the nature of the resin in a wide sense of this word, including the chemical structure of the matrix, the content of the cross-linking agent, the degree (or constant) of the electrolytic dissociation of the active groups, and the nature of the counterions. The catalytic activity of cation exchangers is correlated with their proton-donating capacity. For example, weakly acidic carboxylic acid cation exchangers hardly catalyse the Prins reaction between formaldehyde and styrene, while in the presence of sulphonated cation exchangers it does proceed [37]. Comparative data on the rates of dehydration of dimethylphenylmethanol and the transesterification of ethyl acetate by methanol in the presence of sulphonic and phosphonic acid cation-exchange resins have been published [102,117] and the considerable advantage of catalysts with strongly acidic active groups has been demonstrated. The activity of ion-exchange resins with active groups of the same type may differ markedly in the presence of matrices with different structures. For example, the KU-2 resin is less active in the dehydration of dimethylphenylmethanol than the sulphonated styrene–butadiene copolymer [117]. On the other hand, the condensation of phenol with acetone in aqueous alcoholic media [118] and the oxidation of ethylmethylphenylmethanol by hydrogen peroxide to a hydroperoxide [119] take place at a much higher rate in the presence of the KU-2 cation-exchange resin than in the presence of sulphophenol-formaldehyde resins with a dense structure of the three-dimensional network.

The problem of the effect of the degree of cross-linking on the reaction kinetics cannot be treated in isolation from the molecular size of the initial reactants and reaction products and sometimes also the degree of swelling of the catalyst on which the bulk-phase concentration of the active groups depends. If one of the components of the reaction mixture has large molecules, comparable to the diameter of the resin micropores, the rate of reaction usually decreases with increased content of the cross-linking agent in the matrix. Such relations have been established for the esterification of 1-butanol by benzoic acid [85], of pentyl alcohol by valeric acid, of isopentyl alcohol by isovaleric acid [52], and of propylene glycol by stearic acid [16], an increase in the degree of cross-linking having a particularly marked influence on the rate of formation of esters with the iso-structure [52]. In some cases even cation exchangers with a moderate DVB content (8%) do not catalyse the reaction, while in the presence of a lower degree of cross-linking it does proceed; such an example has been described in a study [50] devoted to the condensation of phenol with acetone.

If the molecular size of the reaction components is smaller than the size of the resin micropores, an increased degree of cross-linking does not enhance diffusional inhibition or steric hindrance to the formation of the active complex. The corresponding increase in the concentration of active groups or the decrease of the hydration number of the counterions [120], which become more accessible, as a result, to the reactant molecules, can then play the role of the factor accelerating the reaction with increase of the degree of cross linking. Such relations have been observed in studies on the kinetics of the decomposition of formic acid [78] and the dehydration of t-butyl alcohol [121]. However, one should note that Heath and Gates [33], who investigated a large assortment of catalysts in the same dehydration reaction, pointed out the non-monotonic variation of the rate with the degree of cross-linking: the cation exchanger containing 8% DVB proved to be the most active.

In the vapour-phase dehydration of isopropyl alcohol in the presence of homogeneous sulphonated cation-exchange membranes, the relative reaction rates depend on the partial vapour pressure of this substance diluted with nitrogen. At $p < 0.2$ atm, the membrane with 5% DVB was several times more efficient than the analogous catalyst with 2% of the cross-linking agent, but at $p \simeq 0.4$ atm the reaction rates were almost equalised. These differences have been accounted for [70] by a change in the reaction mechanism, but we believe it more likely that they are related to the state of solvation of the active groups.

Even in the presence of a high content of the cross-linking agent, macro-porous cation exchangers exhibit the same and sometimes even a higher catalytic activity [33,52,56] as weakly cross-linked ion-exchange polymers, but are much superior to the latter as regards chemical strength and osmotic stability. Fig. 7 presents the results of a comparative study of the efficiency of cation exchangers with 8% DVB and different porosities as catalysts of the dodecylation of phenol [56]. The porosity of the cation exchangers investigated is regulated by the introduction in the styrene–divinylbenzene copolymerisation stage of 20, 35, and 50% of petrol, which plays the role of an indifferent solvent. The alkylation kinetics in the presence of these catalysts are represented by curves *2*, *3*, and *4* in Fig. 7 respectively. The plots show that the activity of the macroporous ion exchangers falls with decrease in the amount of added indifferent solvent, since the porosity of the catalyst changes in the same direction. In conformity

with the general behaviour, the continuous-gel cation exchanger (curve *1* in Fig. 7) is the least efficient.

The rates of catalytic reactions are naturally influenced by the amount of ion exchanger, but the relations valid under these conditions are inconsistent with the general behaviour. For many reactions (apparently among those whose rate is limited by the chemical interaction step), for example, the esterification of ethyl acrylate[122], the hydrosilylation of unsaturated hydrocarbons[48], or the alkylation of phenols by benzyl alcohol[123], a linear relation has been established between the rate constant and the amount of catalyst. A linear relation between the logarithm of the rate constant and the amount of added catalyst has also been established for the esterification of benzoic acid by methanol[124], whose rate is limited by internal diffusion. An increase of the amount of anion exchanger from 15 to 30% in the aldol condensation of ketones with formaldehyde does not influence the rate of reaction[49]; this finding can be explained by the fact that the formation of hydroxyketones involves only a small proportion of the methylene component—its enolic form.

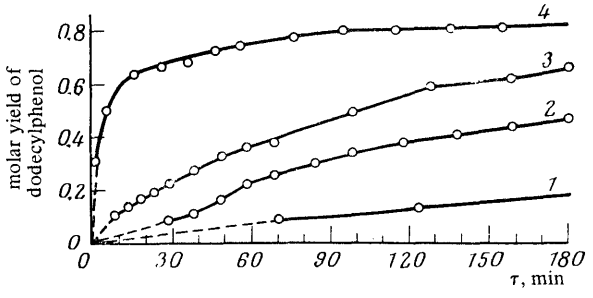

**Figure 7.** Kinetics of the dodecylation of phenol in the presence of gel (curve *1*) and macroporous (curves *2–4*) sulphonated cation-exchange resins; curves *2–4* correspond to macroporous resins obtained from a copolymer synthesised in the presence of 20, 35, and 50% of petrol respectively.

Since ion-exchange resins exhibit their catalytic functions via the counterions, the nature of the latter has a decisive influence on the reaction kinetics. It has been shown[121] that partial substitution of hydrogen atoms in sulpho-groups by alkali metal atoms leads to a decrease of not only general but also specific (i.e. referred to one milliequivalent of $H^+$ counterions) rate constants for the dehydration of t-butyl alcohol. The relative decrease of the reaction rate as a result of the substitution of $H^+$ by $Na^+$, $K^+$, or $Rb^+$ is the same, but in the mixed H–Li-form of the cation exchanger the effect is weaker. The above anomaly is explained by the fact that, in conformity with the laws of ion-exchange equilibrium, lithium substitutes a smaller number of protons in the most active groups than its electronic analogues, or by the involvement of the protons of the water molecules remaining in the cation exchanger after drying[93,121]. The study of the kinetics of the esterification of benzoic acid by 1-butanol led the authors[125] to the conclusion that, with increased degree of substitution of hydrogen ions in the sulphonated cation exchanger by alkali metal or alkaline earth metal cations, the ratio of the numerical partition coefficients changes appreciably and this affects the reaction kinetics, in conformity with Eqn. (3).

The substitution of hydrogen counterions can also lower the proton-donating activity of the sulpho-groups and can hinder the incorporation of the reactant in the three-dimensional polymer network; the change in the rate of propylation of benzene on Amberlyst 15 in accordance with a seventh-degree equation as a function of the fraction of hydrogen atoms converted into protons in relation to the overall content of counterions has been explained[29] by these effects. In reactions involving large molecules, the dependence of the rate constant on the degree of substitution of hydrogen counterions by other cations is influenced by the Thiele modulus, which is determined by the radius of the resin grain and the diffusion coefficient of the reacting substance[112]. Different kinetic relations correspond to different values of this modulus in the sucrose inversion reaction, the rate of which is controlled by internal diffusion.

The instances where the internal-diffusion limitation of the rates of reactions of large molecules and, in the case of a dense structure of the three-dimensional catalyst network, also of molecules of moderate size are fairly common in catalysis by ion exchangers. This cannot be said of external-diffusion rate limitation, since the reaction can be readily achieved in the kinetic region by increasing the rate of stirring of the reaction mixture under static conditions and the flow rates of the reactants under dynamic conditions.

The increase of the reaction rate with decrease of the catalyst grain size does not by itself demonstrate the presence of diffusional inhibition. For example, the rate of esterification of ethanol by propionic acid[126] increased with decrease of the catalyst grain size, but it was found that this was due to the inhomogeneity of the cation exchanger employed, the fine grains of which had a higher exchange capacity than the large grains. It is not therefore surprising that calculation of the specific rate constants referred to one milliequivalent of active catalyst groups yielded identical numerical values for three different fractions, showing that the reaction rate is limited by the chemical interaction step itself.

A reliable criterion of the presence of diffusional inhibition is the inverse proportionality between the reaction rate and the square of the grain radius for internal diffusion rate limitation and to the radius itself for external diffusion rate limitation. However, tests of these simple relations are frequently difficult because of the change in the size of the grains or in their physical state during the reaction itself. Thus a study of the kinetics of the esterification of stearic acid by propylene glycol[127] established for the first time the unexpected increase of the reaction rate with increase in the grain size of the KU-2 cation-exchange resin. It was found that the anomaly is due to the presence of a large number of accumulations of fine particles in the large-grain fraction, which become independent in the reaction mixture, where they act in accordance with their true size. On the other hand, if the aggregates of the cation exchanger grains are ground, screened, and redried, the normal relation is observed between the catalyst grain size and the reaction rate, corresponding to internal diffusion rate limitation.

The rate of formation of isobutene from t-butyl alcohol is higher the smaller the grain size up to the completion of the hydration of the Dowex-50W cation exchanger catalyst grains with the water produced, but, as dehydration proceeds, these differences are smoothed out, i.e. the diffusion-dependent rate limitation is replaced by chemical

rate limitation. All the foregoing considerations emphasise yet again the importance of taking into account and describing exactly the physical state of the ion-exchange resin catalysts employed.

The results of one correct series of experiments are presented in Table 3, which demonstrates the influence of the cation exchanger grain size, the method of drying the cation exchanger, and certain other factors on the kinetics of the esterification of salicylic acid by methanol[80]; analogous data for the inversion of sucrose have been published[79].

It follows from the data in Table 3 that the decrease in grain size, the elimination of water from the reaction mixture, and especially more thorough drying of the cation exchanger *in vacuo* lead to an increase of its catalytic activity. We shall consider in greater detail the last two factors. An increase of the activity of the cation exchanger catalyst with more thorough drying on raising the temperature has also been established in a study of the kinetics of the isomerisation of but-1-ene in the presence of the Na-Fe-form of Amberlyst 15.[43] The observed effects are very appreciable and are manifested by an almost twofold increase of the reaction rate constant with increase of the drying temperature of the resin from 75° to 150°C. In this reaction, they are caused by the more complete elimination of the water blocking the metal ions in the cation exchanger, which act as comparatively strong Lewis acids. The dehydration of the cation exchanger in the H-form in the above esterification reaction (Table 3) leads to the dissociation of the hydrogen bonds and increases the proton-donating activity of the sulpho-groups on formation of the intermediate complexes.

Table 3. The rate of esterification of salicylic acid ($w$ = g $h^{-1}$ per gram of cation-exchange resin) by methanol (M) in the presence of the Zeocarb-225 cation-exchange resin[80].

| Grain size, mm | −0,5+0,25 | | | | | −0,8+0,63 | |
|---|---|---|---|---|---|---|---|
| $H_2O$ in mixture with M, vol.% | 2[a] | 2 | 2[b] | 0 | 0[c] | 2 | 0 |
| $w$ | 13.39 | 13.31 | 13.36 | 16.81 | 34.09 | 10.66 | 12.66 |

Note. The amounts of cation exchanger in cases *a* and *b* were 10 and 40 g respectively and in the remaining cases 20 g; the salicylic acid : cation exchanger ratio was 6.90 and 1.73 in cases *a* and *b* and 3.45 in the remaining cases; the cation-exchange resin was usually weighed in the thermostat; it was weighed *in vacuo* only in experiment *c*.

However, cases are also known where thorough drying leads to the loss of the cation exchanger's ability to catalyse the reaction[128]. One should always remember the possible influence of water on the kinetics of the reaction, and one must therefore control rigorously the conditions in the drying of the ion exchangers and follow the changes in their grains (comminution and the formation of cracks); without this, it is impossible to expect reproducible data for the rate of the process investigated.

The purity of the reactants and solvents employed is also of great importance: it has been shown in a study of the kinetics of the dehydration of t-butyl alcohol[33,101], the condensation of phenol with acetone[50], and the esterification of n-butyl alcohol by acetic acids[129] that admixtures of proton-acceptors (water and alcohols) greatly reduce the catalytic activity of cation-exchange resins in the H-form. Admixtures of substances with proton-donating activity should influence in the same way the kinetics of reactions proceeding via intermediate anionic complexes; in both cases, the mechanism of the action of the ingredients reduces to the blocking of the active catalyst centres.

The influence of indifferent solvents on the kinetics of reactions catalysed by ion exchangers has been very little investigated despite the importance of this problem. It is clear, however, that, together with a simple change of the rate of the main process (as in the esterification of benzoic acid by 1-butanol[89]), the addition of solvents may influence the nature of the products formed (as has been noted for the Prins reaction[37]) or can retard parallel reactions (as in the hydration of isoprene[130]). In the esterification of benzoic acid by 1-butanol in n-heptane, benzene, and toluene[89], the logarithm of the reaction rate constant is a linear function of the reciprocal of the dielectric constant. However, one should note that the experimental points exhibit a marked statistical scatter, which may be caused by errors in the estimation of the partition coefficients used for kinetic calculations by Eqn. (3). The influence of the partition of the components of the reaction mixture on the kinetics of the transesterification of ethyl acrylate by 1-butanol in the presence of the KU-2 cation-exchange resin can be inferred from the data of Soviet investigators[131], who established the inverse dependence of the rate constants on the sorbability of solvents whose electronegative atoms are linked by hydrogen bonds to the sulpho-groups of the catalyst, which entails a decrease of the activity of the latter. At the same time there is a possibility of the solvation of the intermediate cationic complex, which also influences the kinetics of the reaction investigated.

The rates of catalytic reactions in the presence of ion exchangers also depend on the size of the solvent molecules and the reacting substances, which determines in many respects the swellability of the catalyst and the possibility of utilising all the reaction centres in the bulk of its grains[109]. The corresponding relations are manifested most clearly in studies on homologues, for which a decrease in the rate constant with increased size of the reactant molecules in the hydrolysis of esters[36] and the oxidation of aliphatic acids by hydrogen peroxide[14] in the presence of cation exchanger catalysts has been established. It has been shown for the last reaction and esterification in the presence of the KU-2 cation-exchange resins that straight-chain molecules react faster than their isomers, since they penetrate more readily into the catalyst grains. Naturally, apart from steric factors, the reactivity of substances is influenced also by inductive factors[132], the main role being attributed to the latter for straight-chain molecules containing not more than five carbon atoms (on the basis of the satisfactory agreement between the experimental data and the familiar correlation equation). For acids with the iso-structure, the correlation is weakened owing to the increasing importance of the role of the steric factor; the same tendency should be observed with increase of molecular size. For a differential assessment of the above factors, it is desirable not to restrict the treatment to the application of methods of correlation analysis and to supplement them by measurements of the efficiency of ion-exchange resins, using Hammett's procedure[1], and of the partition coefficients of the reactants between the solid phase and the external solution. There is no doubt about the usefulness of this combined approach.

The kinetics of reactions in a stream of reactants flowing through a layer of ion-exchange resin depends on the flow rate as well as the factors enumerated above. The fundamental equations derived for ideal plug flow reactors are usually employed in a kinetic description of such reactions[133]. In the integral form, the kinetic equations are

$$k_{\mathrm{I}}\tau = \ln(1-x), \tag{6}$$

$$k_{\mathrm{II}}\tau = \frac{2.3\gamma}{\rho n_0(\gamma-1)} \lg\frac{1-x}{1-\gamma x}, \tag{7}$$

where $x$ is the fractional conversion, $k_{\mathrm{I}}$ and $k_{\mathrm{II}}$ are the rate constants for first- and second-order reactions respectively, $\tau$ is the contact time, $\gamma$ the molar ratio of the reactants in the second-order reaction, $\rho$ the density of the reaction mass, and $n_0$ the initial number of moles of one reactant in the second-order reaction. Eqn. (6) describes very accurately the kinetics of the inversion of sucrose[112] and Eqn. (7) describes the kinetics of the alkylation of phenol by higher olefins[134] in the presence of sulphonated cation exchangers with a styrene–divinylbenzene matrix.

## IV. A BRIEF DESCRIPTION OF THE APPLICATION OF VARIOUS ION-EXCHANGE RESINS AS CATALYSTS OF REACTIONS OF ORGANIC COMPOUNDS

### 1. Hydrolytic Reactions

The hydrolysis of esters of aliphatic acids and alcohols[36,83,84,92], sucrose[83,112,135,136], acetals[136,137], $\epsilon$-caprolactone[138], and certain purine nucleosides[66] has been achieved in the presence of sulphonic acid and, in a few instances, phosphonic acid cation exchangers. Carboxylic acid cation exchangers have been shown to be highly specific catalysts of the hydrolysis of insulin[139]; a change in the length of the cross-linking agent molecule influenced the specificity of the action of these catalysts. Studies have been made on the kinetics of the hydrolysis of esters of aliphatic acids and aliphatic or aromatic alcohols[36,83,84] and of sucrose[136] in the presence of cation exchangers, the last report quoting the rate constants for inversion and the diffusion coefficients of the substrate in the sulphophenol-formaldehyde membrane used as the catalyst.

Highly basic anion-exchange resins proved to be effective catalysts of the hydrolysis of acrylonitrile[140] and nicotinonitrile[141]. Nicotinamide has been hydrolysed to nicotinic acid[141], which was sorbed by the catalyst, causing its deactivation. $\beta$-Cyanoethoxy-$\beta$-propylamide, formed via ethylene cyanohydrin, has been obtained from acrylonitrile instead of acrylamide, which is a product of the hydrolytic reaction in the presence of cation-exchange resins.

Catalytic hydrolysis of esters in the presence of sulphonic acid cation-exchange resins is of greatest promise for industrial applications; this reaction is virtually unaccompanied by side processes.

### 2. Hydration Reactions

Very few studies have been made on the use of ion exchangers as hydration catalysts. They were devoted to the hydration of 1,2-epoxybutane[142], olefins (propene[143] and isobutene[144]), and isoprene[130] in the presence of sulphonic acid cation-exchange resins and their aim was mainly preparative. In order to improve the conditions of contact of olefins with water and the KU-1 sulphonic acid cation-exchange resin catalysing the hydration reaction, Chaplits[145] and coworkers recommend that the reaction be carried out in the presence of an indifferent solvent. The hydration reactions of unsaturated hydrocarbons are accompanied by their polymerisation, which becomes more pronounced with increased concentration of the monomers in the mixture. In the presence of the carboxylic acid cation-exchange resin Amberlite IRC-84 acrolein and hydracrylaldehyde were hydrated[146]. The hydration of isobutene is used in industry as a method of selective extraction of this olefin[43] from butane–butene cracking fractions.

### 3. Dehydration Reactions

The dehydration of primary[77,93,94,101], secondary[69,70,147,148], tertiary[33,103,121,149], and dihydric alcohols[61] has been successfully achieved on sulphonic acid cation-exchange resins under comparatively mild conditions (as a rule at $t \leqslant 150^\circ$C), which rule out significant losses of capacity as a result of desulphonation. Under these conditions primary alcohols give rise to ethers only, while under more severe conditions olefins can be formed together with the ethers, tertiary alcohols yield only olefins, while secondary alcohols are dehydrated in both ways even at 100°C.[147] It has been shown for isopropyl alcohol that sulphuric acid does not catalyse its dehydration at 100°C. The dehydration of castor oil in the presence of the KU-2 cation-exchange resin has been achieved[150] at 180–230°C. Although the process conditions were much milder compared with earlier studies (see Polyanskii[11], p. 122), nevertheless one should note that a prolonged life of the cation-exchange resin cannot be expected under these conditions either, owing to its desulphonation. The more stable salt-forms with alkali metal counterions do not catalyse dehydration[93], but Amberlite-15 saturated with aluminium ions proved to be catalytically active[148].

In addition to the reactions involving the dehydration of alcohols to ethers and olefins, which frequently takes place simultaneously, there is a possibility of the polymerisation of unsaturated hydrocarbons to oligomers[69,117]. The dehydration itself can play the role of a side reaction in the esterification of dihydric alcohols. A cyclic acetal is formed from propylene glycol[151] and not the isomeric 2,4-dimethyldioxan, as suggested previously.

The dehydration of ethanol, which is of practical importance, can be carried out in the absence of parallel reactions and with a considerable displacement of the equilibrium (investigated by Hsu and Kabel[95]) to the right. The dehydration of dimethylphenylmethanol is believed to be irreversible[117]. The kinetics of these reactions have been described[33,70,93,95,121] and their mechanisms have been examined[69,93,121]. The dehydration of ethanol to diethyl ether and of t-butyl alcohol to isobutene is of interest for use on an industrial scale.

### 4. The Synthesis of Esters

Sulphonic acid cation-exchange resins are the most effective and most frequently used catalysts for the formation of esters from various compounds. The attempt to use phosphonic cation-exchange resins, even macroporous resins, has been unsuccessful[129]. The replacement of soluble acids by sulphonic acid cation exchangers as esterification catalysts sometimes reduces the reaction time[152]

or increases the yield of the desired product[153], apart from the usual advantages.

The main method for the synthesis of esters is esterification in the presence of sulphonic acid cation exchangers, which is achieved by interaction between (1) monohydric alcohols and aliphatic carboxylic[26,52,126,129,153-155], unsaturated[99,109,156], halogenocarboxylic[157], and aromatic acids[80,84,116,124] and (2) between dihydric alcohols and aliphatic monocarboxylic[16,127,158,159] and dicarboxylic acids[160]. In the latter case, the copolycondensation of diethylene glycol with various dibasic acids was carried out and, in order to accelerate the reaction and increase the molecular weight of the polyesters formed, it is recommended that it be performed in the presence of an excess of the alcohol in which the cation exchanger catalyst swells markedly. The favourable influence of the swelling of the cation exchanger in the alcohol on the rate of esterification of acetic acid by 1-butanol was demonstrated in another study[129]. The successful syntheses of esters with t-alkyl radicals and of phosphate esters in non-aqueous media[153,161] as well as the esterification of 20% aqueous solutions of acrylic and methacrylic acids[162] by methanol in the presence of hydroquinone as the polymerisation inhibitor merit particular mention.

In order to accelerate the esterification and displace the reaction equilibrium to the right, the reaction is frequently carried out in the presence of azeotrope-forming solvents, usually aliphatic or aromatic hydrocarbons[110,116]. This is unnecessary in transesterification[102], when anhydrides are made to react with alcohols[160], and when olefins[163] or the corresponding epoxy-derivatives[164] are made to react with acids.

In the presence of cation-exchange resins, there is a possibility of a wide variety of side reactions: dehydration of alcohols, polymerisation of the olefins formed, alkylation of solvents, and dehydration of esters. The kinetics of reactions uncomplicated by side processes have been examined in a number of investigations[89,100,102,124-126] and their mechanisms have been considered in two other studies[52,128].

The reactions between epichlorohydrins and carboxylic acids, leading to formation of monochlorohydrin esters[165] or polyepoxide ester [ether?] resins (see Polyanskii[11], p. 132), proceed via anionic intermediate complexes and are therefore accelerated by anion exchangers.

The synthesis of butyl acetate and other esters in the presence of cation exchangers and the esterification of aqueous solutions of acids are of interest for use on the industrial scale as a method for the utilisation and detoxication of industrial waste.

A continuous method for the manufacture of acrylate and methacrylate esters in the presence of the Dowex-50W cation-exchange resin has been described in a patent[166].

## 5. Alkylation Reactions

Only sulphonic acid cation-exchange resins are used as alkylation catalysts. Compared with aluminosilicates, they ensure an improved yield of the desired products[63]. In contrast to sulphuric acid, they do not cause the formation of sulphoesters and sulphones[167], are less complicated by side reactions involving the polymerisation of olefins and isomerisation[168] as well as transalkylation[167], and ensure the preferential formation of monoalkylphenols (see Polyanskii[2], p. 518). On kinetic grounds, some authors give preference to gel cation exchangers over macroporous cation-exchange resins[56,63,169], but one should bear in mind that pores absorb liquid having the same composition as tha in the external solution, which can increase the yield of dialkylphenols. Other conditions being equal, the nature of the alkylation products depends on the structure of the cation exchanger matrix[56,62,63,170] and reaction temperature[63].

The majority of studies have been devoted to the alkylation of phenols by alcohols[123,170-174], olefins[56,59,60,62,171,175-177], and cyclic dienes[168,175,178,179]. A few studies have been devoted to the alkylation of $\beta$-naphthol by olefins and other hydrocarbons[180], the alkylation of esters by olefins[169,181,182] and alkynes[183], the alkylation of aromatic amines by alcohols[184], and the alkylation of benzene by propene[29].

Apart from the side reactions enumerated above, the alkylation can be accompanied by dealkylation, the isomerisation of alkylphenols and alkyl phenyl ethers[171] as well as alkylating agents[172], and the cyclisation of alkenylphenols to coumarans[176]. In general, the consumption of reactants in side reactions is greater when the reactivity of the substance alkylated in the main reaction is lower. Certain side processes, for example polymerisation, can be reduced to a minimum by promoting the cation exchanger catalyst by sulphur-containing additives[171].

The results of the study of the kinetics of alkylation reactions have been published[29,123,134,185] and a mathematical description of the process has been given[186] whereby one can calculate the degree of conversion of the phenol and the temperature at any point in the reactor. The alkylation mechanism has also been examined[29,63,115,123,170,171].

The studies of Isagulyants and Belov ensured the wide scale industrial application of alkylation reactions in the presence of cation exchangers[167,171]. The alkylation is characterised by high heats of reaction[167,187] and the process is therefore carried out in a cascade of reactors, the heat released being removed in cooling units after each stage. The technological scheme of the alkylation process is described in Kharlambovich and Churkin's monograph[167].

## 6. Polymerisation and Isomerisation Reactions

Sulphonic acid cation exchangers and, in the case of substances with a high reactivity, phosphonic acid cation exchangers are used as catalysts for the polymerisation of aldehydes and unsaturated hydrocarbons to oligomeric products. This concerns the polymerisation of propene[108], $\alpha$-methylstyrene[117], the trimerisation of acetaldehyde[188,189], and formaldehyde[190], and the copolymerisation of $\alpha$-methylstyrene with $\alpha$-olefins[191]. The polymerisation of dimethylcyclosiloxanes has been achieved in the presence of the macroporous KU-23 sulphonated cation-exchange resin[32]. A carboxylic acid cation exchanger, converted into a peracid, has been used as an initiator of the polymerisation of methyl methacrylate and in the copolymerisation of the same ester with styrene[192]. In the presence of highly basic anion-exchange resins in the Cl-form, obtained by the amination of the chloromethylated styrene–divinylbenzene copolymer by various tertiary amines, acrylamide was polymerised and the polymerisation kinetics were investigated[193]. The kinetics of other polymerisation reactions have also been described[189,192].

Sulphonated cation exchangers have been used as catalysts of the isomerisation of hydrocarbons[43,108,194,195] and of the Beckmann rearrangement of cyclohexanone oxime to caprolactam, the desired rearrangement product being obtained in the highest yield in dimethyl sulphoxide[196]. The isomerisation kinetics have been considered in detail[43,108,194].

The polymerisation and isomerisation reactions are sometimes not accompanied by the formation of side products[189], but they frequently accompany one another or other processes. Such complications occasionally give rise to a whole spectrum of products[195], the nature of which depends on the structure of the catalyst employed. A number of workers have examined the mechanisms of the polymerisation reactions[189,193] and of the isomerisation reactions[43,194].

The trimerisation of acetaldehyde has been carried out on an industrial scale; the polymerisation reactions of dimethylcyclosiloxanes and olefins, forming part of industrial cracking fractions, are promising in this respect.

## 7. Condensation Reactions

The majority of studies involving the use of ion exchangers as catalysts of condensation reactions had as their aim the preparative synthesis of particular substances. The condensation of 2-mercaptoethanol with hydrogen sulphide[197], of alcohols with phenols[23,198], mesityl oxide[57,199], trioxan[200], and aldehydes[65], of aldehydes with olefins[53,201-203] (the Prins reaction), dioxan derivatives[204], and α-chloromethylstyrene[205], of phenol with acetone[50,206]†, of polycyclic phenols with boric acid[207], of diols with unsaturated aldehydes[208], of tris(hydroxymethyl)ethane with furfural[209], of higher primary aliphatic amines with sulphur-containing dicarboxylic acids[210], of *o*-phenylenediamine with naphthoic or heterocyclic acids[211], and of *o*-aminophenols with monocarboxylic acids[212] has been achieved in the presence of sulphonated cation exchangers. Anion exchangers have been used as catalysts of the aldol condensation of aldehydes[24,111] and ketones[213] and also for the acceleration of the condensation reactions of ketones with aldehydes[49,214], of aldehydes with nitroalkanes[215] and urea[40,216], and of alcohols with acrylonitrile[217]. In the condensation of aldehydes with urea, a strongly basic anion exchanger is much more effective as a catalyst than a moderately basic resin, but this cannot be regarded as a general rule.

The yield of condensation products is frequently reduced by side reactions[20,24,50,111], which hinders the study of the kinetics of the corresponding reactions and shows that it would be unjustified to overestimate the selectivity of ion-exchange resin catalysts. The results of kinetic studies have been described[24,49,50,57] and the reaction mechanisms have been considered[49,217].

The synthesis of cyclic acetals in the presence of ion-exchange resins and, as far as the authors are aware, a method for the synthesis of bis(hydroxyphenyl)propane have been used on an industrial scale. Various types of the Prins reaction and continuous methods for the synthesis of aminoresins are promising for industrial applications[15].

## 8. Various Reactions

Many reactions, which do not belong to the types considered, are also carried out in the presence of ion-exchange resins. These include various addition reactions, including hydrogenation[49,73,74,218-221], which are carried out in the presence of cation and anion exchangers (containing complex platinum group metal chlorides as the mobile ions), the oxidation of a number of compounds [carboxylic acids[14,222,223], cyclohexanone[224], derivatives of phthalic anhydride[225] (sulphonated cation exchangers are used as oxidation catalysts)], and the decomposition of various aromatic alkyl derivatives of mono- and di-hydroperoxides[13,17,226-228] (also in the presence of sulphonated cation exchangers). It is noteworthy that highly cross-linked gel cation-exchange resins either do not catalyse the disproportionation of hydroperoxides or lose their activity rapidly[17]. The kinetics of these reactions have been investigated[227,228] and two studies have been devoted to the mechanism and kinetics of the oxidation reactions[14,132].

Methods for the decomposition of hydroperoxides and the synthesis of peracids are of interest for incorporation in industrial processes. Recent studies on the thiolysis of 1,3-dioxans are of theoretical interest[229,230].

---o0o---

The new stage in the development of catalysis by ion-exchange resins considered in this review is characterised by a further improvement of the theoretical level of the relevant research as a result of the wide-scale employment of the kinetic approach. The extensive experimental data obtained reveal in the ion-exchange resin-catalysed reactions features of both homogeneous and heterogeneous catalysis.

Such a general treatment should stimulate the search for a new theoretical model of the catalytic reactions, which takes into account more fully all the aspects of the inter-relations between the ion exchangers and the reacting substances than the Langmuir–Hinshelwood and Wheeler–Thiele models employed at the present time. The necessary preparation for this advance should be ensured by a further development of kinetic studies on a wider basis: this concerns a systematic (and not sporadic, as hitherto) measurement of the partition coefficients and the refinement of their relation to the efficiency of ion-exchange resins using Hammett's method, the study of the influence of the type of solvent on the reaction kinetics, and the regular employment of methods of correlation analysis.

In connection with new theoretical tasks, it is necessary to give more attention to methods for the preparative treatment and investigation of ion-exchange resins as catalysts, in particular it is necessary to justify in greater detail the usefulness of conditioning and to make appropriate recommendations, to elucidate the causes of blocking and to develop regeneration methods, and to synthesise new types of ion exchangers with improved osmotic and thermal stabilities.

While noting the major achievements in catalysis by ion-exchange resins as a method of preparative organic chemistry, one should nevertheless mention the insufficiently wide-scale employment of macroporous, macronetwork, and oleophilic ion-exchange resins. The salt-forms of all resins and the hydroxide-forms of anion-exchange resins have been little used.

Certain advances have been made in the incorporation of ion-exchange resins in industrial processes, but they have still not reached the limit of the existing possibilities.

---o0o---

While the manuscript was with the Editors, a number of studies devoted to the kinetics of esterification and transesterification[231-234], hydrolysis[235], oxidation[236,237], condensation[238], and alcoholysis[239], catalysed by ion-exchange resins, were published.

† The catalyst is promoted by the addition of 2,2-dimethylthiazolidine.

A series of new studies were devoted to the use of ion exchangers as catalysts of esterification[240-242], hydrolysis[243,244], polymerisation[245,246], condensation[247-251], decomposition[252,253], and alkylation[254-262]. An interesting example of the employment of the catalytic properties of ion-exchange resins for the purification of bisphenols and hydroquinone has been described[263]. A few studies have been devoted to the application in catalysis of cation exchangers[264-266] and anion exchangers[266-269] metallised by Group VIII *d* elements or containing complex transition metal ions as counterions. The use of sulphonated polystyrene on a support consisting of aluminium sheets as a catalyst in a gas–liquid system has been described[270].

The mechanism of the blocking of the catalyst in the hydration of epoxyethane has been considered[271].

Rapid methods for the determination of the properties of ion-exchange resins, which are important for the understanding of their catalytic functions (exchange capacity, total porosity, and ionisation constants), have been described[272-274]. The paper by Polyanskii et al.[275] is devoted to the problem of the inhomogeneity of macroporous ion exchangers and its importance for catalysis, which has not so far been considered in the literature.

A monograph[276] deals with research techniques for ion-exchange resins.

# Tertiary Amines in Acyl Transfer Reactions

E.M.Cherkasova, S.V.Bogatkov, and Z.P.Golovina

The mechanism and kinetics of acyl transfer reactions in the presence of tertiary amines are examined and the quantitative relations between the rate of reaction and the structure of the acylating agent, the acylated substrate, the amine, and the solvent, temperature, and the ratio of the efficiencies of intramolecular and intermolecular catalysis are discussed. A number of examples of the application of tertiary amines as accelerators of acyl transfer reactions, which are of practical importance, are presented.
The bibliography includes 282 references.

CONTENTS

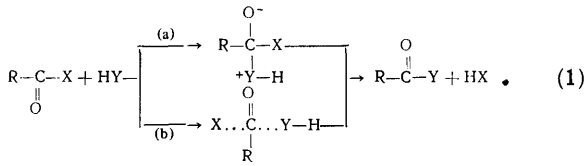
IV. Intramolecular catalysis 256
V. Examples of the practical applications of tertiary amines as accelerators of acylation reactions 258



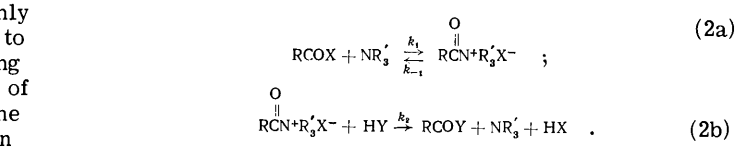
## I. INTRODUCTION

The accelerating influence of tertiary amines (TA) on acyl transfer reactions has been known since the end of the past century, but fundamental studies have been made only in the last decades. In this review, an attempt is made to give a systematic and critical account of these data (using studies published up to 1975) mainly from the standpoint of the reaction mechanism and quantitative allowance for the influence of the structure of the reactants on the reaction rate. The problems of the structure of the products and the synthetic aspects are only briefly discussed, since a relevant review has been published recently [1].

## II. THE REACTION MECHANISM. GENERAL KINETIC RELATIONS

### 1. General Consideration of the Mechanism. Type of Catalysis

Acyl transfer reactions can be described by mechanism (1), which has two main versions—the two-stage reaction (1a) with formation of a tetrahedral intermediate (TI) or the single-stage reaction (1b)†, the transition state of which resembles that of an $S_N2$ reaction:



(1)

The compounds RCOX in this reaction are usually acid halides (X = F, Cl, Br, or I), anhydrides (X = OCOR), esters (X = OR′), and more rarely acids (X = OH), amides (X = $NH_2$ or NHR′), etc.; the nucleophiles HY are water, alcohols, phenols, and amines.

†A unimolecular mechanism with formation of the cations $RCO^+$ is fairly rarely encountered and is not considered in this review.

The hypothesis of the nucleophilic catalysis‡ of acyl transfer reactions by tertiary amines [mechanisms (2a) and (2b)] was first put forward at the beginning of the 1950s [2-5]:

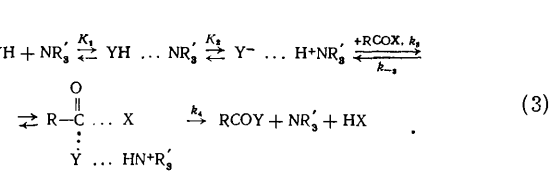
(2a)

(2b)

Koshland [2] used it to account for the acceleration of the hydrolysis of acetyl phosphate after the addition of pyridine; he regarded the isolation of solid acetyl-pyridinium chloride as evidence demonstrating the proposed mechanism. However, a direct comparison of the rates of formation and decomposition of the chloride with the overall reaction rate was not made and only the half-reaction times were compared. The same mechanism was proposed [3-5] for the hydrolysis of acetic anhydride (AA) on the basis of the significant influence of steric hindrance in the amine on the reaction rate. This influence was observed also in many other instances (see Section III) and the breakdown of the Brønsted and Hammett–Taft relations was observed when amines with variable steric characteristics were used, which was usually regarded by the authors as evidence for the nucleophilic nature of the catalysis. However, this conclusion cannot be regarded as fully rigorous, since the equilibrium in the formation of a hydrogen bond has been shown recently [6-8] to depend also on the steric structure of the amine, which can therefore influence the rate of reaction also in general base catalysis.

‡We employ the term "catalysis", although in certain cases tertiary amines are removed from the reaction as a result of their interaction with the products HX and this term does not therefore correspond to the strict definition of the concept of the "catalyst". However, the identity of the mechanism and characteristics of these reactions with those of others where tertiary amines are not removed from the reaction sphere justify the use of all cases of the single term "catalysis", the interaction of tertiary amines with HX being regarded as stoichiometric poisoning of the catalyst.

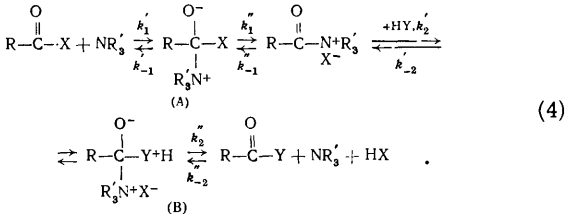
On the other hand, during the last 15 years new facts have been obtained, which can be regarded as evidence in support of nucleophilic catalysis.



1. The formation in the esterification of racemic alcohols RR'CHOH in the presence of optically active tertiary amines of esters having a single preferred configuration, *S* or *R*, depending on the alcohol and the amine[9]. This is apparently due to the preferential existence of the acylammonium salt (AAS) and the tetrahedral intermediate arising when it interacts with the alcohol in the least hindered conformation. Similar results were obtained for the reaction of phenylmethyl keten with alcohols in the presence of optically active tertiary amines[10].

2. Anomalies in the temperature variation involving either a very slight increase of $k_{cat}$ or even its decrease as the temperature rises, i.e. the apparent activation energy is $E_{act}^{app} \leqslant 0$.[11-13] This is satisfactorily consistent with the hypothesis of the reversible formation of an acylammonium salt, which is highly exothermic in the case of reactive amines. Since $E_{act}^{app} = \Delta H + E_2$ for mechanism (2a, b), where $E_2$ is the activation energy for the second stage (2b), it follows that, when $\Delta H \ll 0$, $E_{act}^{app}$ can also become less than zero. The increase of steric hindrance and decrease of the resonance stabilisation of the acylammonium salt hinder its formation, which leads to a general retardation of the reaction and to an increase of $E_{act}^{app}$. In general base catalysis, the reversible formation of a hydrogen bond is weakly exothermic and $E_{act}^{app} \leqslant 0$ is unlikely.

3. Kinetic relations: the hydrolysis of acetic anhydride is faster by several orders of magnitude in the presence of pyridine than in the presence of $CH_3COO^-$, despite their approximately equal basicities, which indicates different reaction mechanisms[3,4,14].



The most detailed and convincing evidence for a nucleophilic mechanism of catalysis by tertiary amines in aqueous solutions was obtained by Fersht and Jencks[14,15], who confirmed experimentally the possibility of the accumulation of analytically measurable concentrations of the acetylpyridinium ion (API), which had been predicted beforehand from an estimate of the free energy of its hydrolysis[16]. In water, which stabilises polar acylammonium salts, it was possible to detect the spectrum of the acetylpyridinium ion ($\lambda_{max}$ = 225 and 272 nm, $\epsilon \simeq$ 7000 and 4400) by the stopped flow method and also by employing the retardation of the hydrolysis of the acetylpyridinium ion by three orders of magnitude compared with its formaton in 9 M $NaClO_4$ solution; the two spectra proved to be identical[14]. It was also found that the rate of hydrolysis of the acetylpyridinium ion synthesised by the method of Sheinkman et al.[17] is equal to the rate measured by the stopped flow method in the direct interaction of acetic anhydride with pyridine in water. This implies that in this reaction (and probably in many analogous reactions) pyridine and other tertiary amines behave as nucleophilic catalysts.

On the other hand, a number of workers noted also the possibility of the operation of general base catalysis via the following mechanism:

(3)

This version will be examined in greater detail in Section III, but, as regards the problem as a whole, one must emphasise that the possibility of nucleophilic catalysi is determined primarily by the comparative basicity (in the general sense—nucleophilicity) of the leaving group and the attacking nucleophile. If the reaction is formulated in the general form (4), taking into account the intermediate tetrahedral intermediates (A) and (B), one may note that the dominant mode of their decomposition involves the elimination of the less basic ("easily removed") group[18]

(4)

Thus, when the leaving group X in RCOX is less basic than the tertiary amine, i.e. $pK_a^{HX} < pK_a^{HN^+R'_3}$, then (A) is converted preferentially into the acylammonium salt. As a result of this, nucleophilic catalysis is of decisive importance in the reactions of acyl derivatives with easily removed groups[19,20] and its efficiency decreases in the sequence of the following groups X: I > Br > Cl > F > RCOO. The specific situation depends on solvent; for example, the hydrolysis of acid fluorides and anhydrides in water is catalysed by tertiary amines[3,5,14,21,22] and the aminolysis of benzoyl fluoride[23] and of the majority of anhydrides in benzene is inhibited by tertiary amines[24,25]. In this medium, $F^-$ and $RCOO^-$ are probably stronger bases than $NR'_3$, which prevents the conversion of (A) into an acylammonium salt. However, for anhydrides of stronger acids, tertiary amines do exhibit catalytic properties[25,26]. Similarly, in the acylation of phenols in $CCl_4$ by acetyltrifluoroacetate in the presence of pyridine and its analogues, the rate of acetylation does not change, while the rate of trifluoroacetylation increases sharply and the latter process becomes of decisive importance[27,28].

On the other hand, the probability of general base catalysis increases in the reactions of substrates with groups which are difficult to remove[15,19,29] and which are more basic than the tertiary amine. For example $k_{cat}/k_0$ for aminolysis in the presence of carboxylic acids[30,31] or 2-hydroxypyridine[32] increases in the following sequence of groups X in ArCOX: Br < Cl < F < OAr.

On the other hand[33], the tetrahedral intermediates (B) will decompose preferentially with formation of the final products if the attacking nucleophile is a weaker acid than the ammonium ion, i.e. $pK_a^{HY} > pK_a^{HN^+R'_3}$. The validity of this condition also depends on the solvent in the general case. For example, in water carboxylic acids do not undergo acylation catalysed by tertiary amines (even in an undissociated form). However, in certain non-aqueous media we may have $pK_a^{RCOOH} > pK_a^{HN^+R'_3}$ and reaction (5),[34] leading to the formation of anhydrides and used for a long time as a method for their synthesis[35], becomes possible:

$$RCOOH + RCO^+NR'_3Cl^- \rightarrow (RCO)_2O + R'_3N \cdot HCl \quad . \qquad (5)$$

Anhydrides do not react further under these conditions. In the acylation of phenols, the situation where $pK_a^{ArOH} < pK_a^{HN^+R'_3}$ is also possible as a function of the solvent; here $k'_{-2} \gg k''_2$ and nucleophilic catalysis does not occur, although general base catalysis via mechanism (3) is possible[27,33,36-39].

When HY = $H_2O$, ROH, or $RNH_2$, the condition $pK_a^{HY} > pK_a^{HN^+R'_3}$ holds always and nucleophilic catalysis of the acylation of these compounds is possible and probably takes place in water and other polar solvents. On the other hand, one should note that, in aprotic solvents with low dielectric constants, the formation of products with a considerable separation of the charges and their intense localisation is energetically unfavourable and such products (to which acylammonium salts and tetrahedral intermediates belong) are characterised by a high energy level. This can lead to their approach to the corresponding transition states and, in the limit, to the occurrence of the reaction via a synchronous mechanism[40].

## 2. The Ratio of the Rates of Individual Stages. Kinetic Relations

In those cases where tertiary amines behave as nucleophilic catalysts of acyl migration, the reaction is usually irreversible under the experimental conditions ($k''_{-2} = 0$) and is described by mechanism (2) if the stage involving the formation of a tetrahedral intermediate is omitted. The problem arises of the ratio of the rates of the stages of this reaction. It has been found[2-5] that the process proceeds via a pseudostationary mechanism (the acylammonium salt does not accumulate)§ and, in the presence of an excess of the nucleophile, the kinetic equation is

$$v = (k_0 + k_{cat}[B]) \cdot [RCOX],$$

where [B] is the concentration of the base form of the amine and $k_0$ and $k_{cat}$ are the rate constants for the spontaneous reaction and the reaction catalysed by the tertiary amine respectively; here $k_0$ is negligibly small compared with $k_{cat}[B]$. The following equation then holds in a medium ensuring the complete dissociation of the acylammonium salt into ions:

$$k_{cat} = \frac{k_1 k_2 [HY]}{k_{-1}[X^-] + k_2 [HY]}$$

{the notation is the same as in mechanism (2), $k'_2 = k_2[H_2O]$ being used for hydrolysis in water}.

The ratio of the rates then depends on the concentrations of HY and the anion X and on their nucleophilic properties characterised by the constants $k_{-1}$ and $k_2$: in water the slowest stage is usually the formation of the acylammonium salt ($v_2 > v_{-1}$, $k_{cat} = k_1$).[2-5] By comparing the influence of pyridine on the hydrolysis of acetic anhydride in water and on the isotope exchange in its reaction with $CH_3^{14}COO^-$ (0.5–1 M), $k_{-1}/k'_2 \simeq 50$ litre mol$^{-1}$ was estimated[21]. A similar value (~80 litre mol$^{-1}$) was found for the hydrolysis of acetyl fluoride in water in the presence of pyridine[22]; here $k_1 = 15$ litre mol$^{-1}$ s$^{-1}$. It follows from these data that the acylammonium salt is in equilibrium with the initial substance[21,42]. The equilibrium is displaced to the left after the addition of dioxan[42,43], probably as a result of the decrease of polarity; when $[H_2O] < 4$ M, pyridine proved to be a weaker nucleophile than the acetate ion[42]. For the acetylpyridinium ion in water¶, $k_1 = 84$ litre mol$^{-1}$ s$^{-1}$, $k_{-1} = 910$ litre mol$^{-1}$ s$^{-1}$, and $k'_2 = 6.9$ s$^{-1}$, so that $k_{-1}/k'_2 = 130$ litre mol$^{-1}$.[14] Thus the reactivity of the acetylpyridinium ion in relation to the acetate ion is almost 4 orders of magnitude greater than in relation to water, assuming that $[H_2O] = 55$ M, $k_2 = k'_2/[H_2O] = 0.125$ litre mol$^{-1}$ s$^{-1}$, and $k_{-1}/k_2 = 7.3 \times 10^3$. Therefore, when the concentration of $CH_3COO^-$ (and in general of the ion $X^-$) is sufficiently high, we have $k_{-1}[X^-] > k_2[HY]$ and

$$k_{cat} = \frac{k_1 k_2}{k_{-1}[X^-]},$$

which has been observed, for example, in acetate buffers[5,42-44]. On the other hand, when the concentration of $X^-$ is extremely low, then, although $k_{-1} > k_2$, $v_{-1} = k_{-1}[X^-][AAS]$ may be smaller than $v_2 = k_2[HY][AAS]$ {in water $k'_2[AAS]$}. Indeed the rate of hydrolysis of acetic anhydride in water in the presence of pyridine is equal to the rate of acylation of anisidine and toluidine under these conditions ($k = 84 \pm 2$ litre mole$^{-1}$ s$^{-1}$) and is independent of the concentration of the acylated amines[14]. Consequently, under the given conditions, the lowest rate is observed for the stage involving the formation of the acetylpyridinium ion, for example we have $v_{-1}/v_2 \simeq 0.1$ and $k_{cat} = k_1$ when $[CH_3COO^-] \leq 10^{-3}$ M.

Since the lyonium ion $H_3O^+$ is the strongest acid in water, other species HY are stronger bases than water and are characterised by higher values of $k_2$. *p*-Toluidine and *p*-anisidine therefore react with the acetylpyridinium ion faster than $CH_3COO^-$ even at a concentration of 0.001 M.

On the other hand, in solvents of low polarity (benzene, dioxan, etc.) the reaction is usually of first order with respect to the acylated nucleophile over a wide range of its concentrations (see Section III, subsections 2 and 3). Within the framework of mechanism (2), this implies that the second stage determines the rate of reaction. This is probably associated with the absence of the dissociation of the AAs ion pair and hence the absence of the free $X^-$ ion in such solvents. The decomposition of the acylammonium salt into the initial components can then be regarded as a unimolecular process[33] and the expression for the rate of reaction becomes

$$v = \frac{k_1 k_2 [RCOX] \cdot [NR'_3] \cdot [HY]}{k_{-1} + k_2 [HY]}.$$

The transition to a unimolecular reaction leads to a considerable gain of activation entropy, as a result of which the process becomes faster and $k_{-1} \gg k_2[HY]$. Then

$$v = \frac{k_1 k_2}{k_{-1}} [RCOX] \cdot [NR'_3] \cdot [HY],$$

which has been observed experimentally. Under these conditions, $k_2$ may be greater than $k_{-1}$ but $v_2 < v_{-1}$ owing to the very low concentration of the acylammonium salt. In the limit, this version of the reaction can be converted into a synchronous process when the involvement of all the reactants in the transition state is responsible for the first order with respect to each.

An intermediate case has been described recently[41,45] involving a decrease of $k_{cat}$ during the acylation of *p*-anisidine and *p*-chloroaniline by sulphonyl bromides in nitrobenzene in the presence of pyridine (or its *N*-oxide), which the authors explained by the occurrence under these conditions of the equilibrium

$$[ArSO_2N^+C_5H_5Br^-] \rightleftarrows ArSO_2NC_5H_5^+ + Br^-.$$

The accumulation of the $Br^-$ ions displaced this equilibrium towards the less reactive ion pair, which decreases $k_{cat}$: the above relation disappears when the experiments

§ This conclusion has been confirmed[41] by the equality of the rates of consumption of the acylating and acylated components: the pre-stationary stage, involving the accumulation of the acylammonium salt, was observed only when the stopped flow method was used[14].

¶ The values for substituted pyridines are listed in Table 2.

are performed in tbe presence of an excess of added bromide[45]. Unfortunately, the authors were unable to calculate the equilibrium constant and the rate constants for the individual forms of the acylammonium salt.

On the other hand, for various stable acylammonium salts, such as acetylimidazolium halides, the relation $k_1 \gg k_2 \gg k_{-1}$ may hold even in non-polar solvents. The second stage is then slowest, but the acylammonium salt accumulates rapidly and irreversibly[46].

### 3. The Structure of the Intermediates

According to the data described above and also results obtained independently by conductimetric[47-49], potentiometric[50], infrared spectroscopic[17,51-66], NMR[57,58], and ultraviolet spectroscopic[14,59,60] measurements (see also Sheinkman et al.[1]), one can assume that acylammonium salts of the type $RCON^+R'_3X^-$ are the main intermediates in many acyl transfer reactions catalysed by tertiary amines†. On the other hand, by analogy with other acyl transfer reactions[65-71], one may assume that the reactions involving the formation and decomposition of acylammonium salts proceed via the tetrahedral intermediates (A) and (B) in Eqn.(4). However, these tetrahedral intermediates are probably fairly unstable, particularly in non-polar solvents, and a shallow minimum corresponds to them on the energy diagram, i.e. the transition states in the stages involving the formation and decomposition of the tetrahedral intermediate are similar to the intermediates themselves as regards energy and structure and in this sense the reaction is close to direct substitution of the $S_N2$ type[15,40]. One must emphasise that, according to some data[67,69-72], proton transfer in (B) is an important stage, since it is the only process which ensures the strengthening of the C–Y bond, i.e. the conversion of the readily removed group (a weak base) HY into a strongly basic group Y. This process is also particularly important in aprotic solvents, where it can occur spontaneously, and requires the cooperation of the base molecule[71]—in this sense one may speak of a combination of base and nucleophilic catalysis.

Table 1. Hydrolysis of the acid chlorides RCOCl in aqueous acetone (10.9 vol.% of water) in the presence of tertiary amines[87].

| R | Temp., °C | $10^4k_0$, $s^{-1}$ | $10^4k_{cat}$, $s^{-1}$ | | | |
|---|---|---|---|---|---|---|
| | | | $(CH_3)_3N$ | $(C_2H_5)_3N$ | pyridine | 2,4,6-trimethylpyridine |
| $CH_3$ | −40 | 0.975 | 35 000 | 7000 | $>10^5$ | 39 |
| $(CH_3)_3C$ | −40 | 0.027 | 770 | 1.2 | 6600 | 5.8 |
| $C_6H_5$ | −40 | 0.0047 | $>10^5$ | 35 000 | $>10^5$ | 30 |
| $2,4,6\text{-}(CH_3)_3C_6H_2$ | −40 | 1.22 | 1.2 | 1.2 | 1.79 | 1.1 |
| $2,4,6\text{-}(CH_3)_3\text{-}3,5\text{-}(NO_2)_2C_6$ | +20 | 0.056 | 2.5 | 7 | 93 | 0.17 |

Apart from tetrahedral intermediates, the formation of charge-transfer complexes has been demonstrated in a number of studies[53,73-82] in the first stage of the interaction of acylating agents with tertiary amines. It has come to be assumed that charge-transfer complexes can be converted into acylammonium salts (via a tetrahedral intermediate or via direct $S_N2$ substitution)[75-78], but one-electron transfer with formation of the acyl radical-ions $RCO^\cdot$ and amine radical-ions is more characteristic of these species. As a result of this, acid chloride–tertiary amine and acid anhydride—tertiary amine systems are capable (particularly for aromatic tertiary amines) of initiating effectively radical polymerisation[73,74,80-82].

On the whole, one should note that data for the structures and properties of acylammonium salts are still extremely incomplete, mainly because of their instability. However, stable polymeric acylammonium salts, obtained in the acylation of polyvinylpyridine partly alkylated by bulky groups, have been described recently[83]. The hydrophobic environment of the quaternary nitrogen atom probably prevents further reaction of these acylammonium salts. However, their properties were not investigated in detail.

## III. THE INFLUENCE OF REACTANT STRUCTURE ON THE REACTION RATE

### 1. The Hydrolysis of the Halides and Anhydrides of Carboxylic and Sulphonic Acids

The hydrolysis of acid halides and anhydrides has been one of the first acyl transfer reactions in the presence of tertiary amines which were investigated in detail as regards kinetics, mechanism, and structural relations. A study has been made of the accelerating influence of pyridine on the hydrolysis of acetic anhydride[3,4,84-86] and acetyl phosphate[2]. It has been found that 2-methyl- and 2,6-dimethylpyridines and also quinoline accelerate the process less effectively than 3- and 4-substituted pyridines and isoquinoline, probably owing to steric hindrance. The Bronsted equation holds separately for unhindered and hindered amines with the same proportionality coefficients $\beta$ (0.92) but different constant terms (10.36 and 9.42 respectively). According to Koskikallio[42], triethylamine is only 7 times more reactive in this reaction than pyridine despite a difference in $pK_a$ of almost 6 units (apparently also mainly owing to steric hindrance).

The role of the steric accessibility of the tertiary amine is clearly seen from the data in Table 1, particularly for the chlorides of hindered acids of the type of trimethylacetic acid[87]. Mesitoyl chloride is apparently hydrolysed via an $S_N1$ mechanism and catalysis by tertiary amines is not observed.

If the steric factor in the reaction investigated is constant, it is possible to observe the validity of the Brønsted and Hammett–Taft equations. The influence of the structure of the tertiary amines on the elementary stages of the hydrolysis of acetic anhydride has been examined[14]. It is seen from the results (see Table 2) that both the rate constants ($k_1$) and the equilibrium constants ($K_{eq}$) for the formation of the acetylpyridinium ion vary linearly with the basicity of the tertiary amine and $\beta = 0.87$ and 1.6 respectively. Thus the nucleophilic properties of substituted pyridines in relation to the carbonyl carbon atom vary in parallel with their basicity, the equilibrium nucleophilic properties being much more sensitive to the influence of the substituents than the basicity.

According to Fersht and Jencks[14], this indicates a greater "effective electronegativity" of the acyl group compared with the proton. On the curve relating the

†Other types of reactions of acylammonium salts have also been examined[1,61-64].

reactivity to structure for reactions of nucleophiles with the carbonyl group, pyridines are located close to a break-point[15,88,89]. As a result, while still retaining virtually the maximum dependence of their reactivity on basicity, they form highly reactive and selectively acylating agents (for example $k_{AcO^-}/k_{H_2O} = 7300$ for the acetylpyridinium ion, while the corresponding ratio for the acetylimidazolium ion is 29).[43]

Table 2. The interaction of acetic anhydride with tertiary amines in water (25°C, $I = 1$).[14]

| Amine | $pK_a$ | $k_1$, litre mole$^{-1}$ s$^{-1}$ | $k_{-1}$, litre mole$^{-1}$ s$^{-1}$ | $K_{eq}$ | $k_2$, s$^{-1}$ |
|---|---|---|---|---|---|
| $C_5H_5N$ | 5.51 | 84 | 910 | 0.092 | 6.9 |
| 4-$CH_3C_5H_4N$ | 6.33 | 490 | 262 | 1.86 | 2.3 |
| 3,4-$(CH_3)_2C_5H_3N$ | 6.79 | 1160 | 120 | 9.67 | 1.5 |
| 4-$CH_3OC_5H_4N$ | 6.82 | 935 | 30 | 31.2 | 0.4 |

The rate of reaction of the acetylpyridinium ion with water decreases with increase of the basicity of the initial tertiary amine and $\beta = -0.5$, i.e. water is relatively unselective in relation to these electrophiles. The possibility of direct polar coupling of the substituent with the reaction centre has been demonstrated for the acetyl-4-methoxypyridinium ion[14] and acetyl-4-dialkylamino-pyridinium ions[60]; this has also been confirmed by the correlation of lg $k_2$ and lg $k_1$ with $\sigma^+$. Here $\beta = -0.8$ and the sensitivity of the reaction to the basicity of the leaving group therefore increases with decrease of the reactivity of the electrophile[60]. On the other hand, in the hydrolysis of 3- and 2,3-substituted acetylimidazolium ions, which also exhibit an enhanced resistance to nucleophilic attack (the additional stabilisation corresponds to approximately 2.7 kcal mole$^{-1}$)[14], we have $\beta = 0.55$. Thus the relation between reactivity and sensitivity to the influence of the structure of the reactants on the rates of these reactions is on the whole fairly complex.

The only reaction for which the influence of the simultaneous changes in the structures of the catalyst and the acylating agent on the rate has been investigated is the hydrolysis of arenesulphonyl chlorides in the presence of substituted pyridines (RPy).[90,91] It was found that the correlation with $\sigma^0$ for R (sensitivity coefficient $\rho = -2.68$) and the Brønsted equation ($\beta = 0.45$) hold for the hydrolysis of $C_6H_5SO_2Cl$; the 4-acetyl and 4-cyano-derivatives deviate from this relation, possibly owing to the direct resonance interaction of the substituents with the reaction centre. Analogous correlations have been obtained for different R'$C_6H_4SO_2Cl$ (Table 3), where the coefficients $\beta$ vary linearly with $\sigma$ for R' (the slope is $0.122 \pm 0.002$). The values of $\rho$, characterising the influence of R' (they have been calculated for R' = H, *p*-$CH_3$, or *p*-$CH_3O$; the *para*- and *meta*-nitro-derivatives deviate towards reduced reactivities) increase linearly in their turn with increase of $pK_a$ for the amine (proportionality coefficient $0.114 \pm 0.004$). Thus, contrary to Hammond's postulate, in this series of reactions an increase of the reactivity of the reactants is accompanied by an increase of the coefficients $\beta$ and $\rho$.

Treating these quantities as characteristics of the degree of dissociation and formation of the bond in the transition state‡, the author suggested that, by virtue of its greater polarisability, sulphur forms bonds over greater distances than does carbon and that electron-accepting substituents in the acid chloride and electron-donating substituents in the amine catalyst promote the formation of bonds between them. The transition state thus becomes more "dense", i.e. the sum of the orders of the formed and ruptured bonds increases. On the other hand, electron-donating substituents in the acid chloride facilitate the preferential rupture of the bond, which is faster than the formation of the new bond.

Table 3. The influence of the structure of the sulphonyl chloride R'$C_6H_4SO_2Cl$ and the catalyst RPy on the rate of hydrolysis (water; 0.05 M NaCl solution; 25°C).[91]

| R | $pK_a$ | $\rho$ (with respect to R') | R' | $\sigma$ | $\beta$ (with respect to RPy) |
|---|---|---|---|---|---|
| 3,4-$(CH_3)_2$ | 6.46 | 0.89 | *p*-$NO_2$ | 0.78 | 0.557 |
| 4-$CH_3$ | 6.02 | 0.82 | *m*-$NO_2$ | 0.71 | 0.545 |
| 3-$CH_3$ | 5.68 | 0.78 | H | 0 | 0.457 |
| H | 5.21 | 0.69 | *p*-$CH_3$ | −0.17 | 0.441 |
| 3-$CH_3CO$ | 3.18 | 0.52 | *p*-$CH_3O$ | −0.45 | 0.406 |
| 4-CN | 1.90 | 0.34 | | | |
| 3-CN | 1.39 | 0.30 | | | |

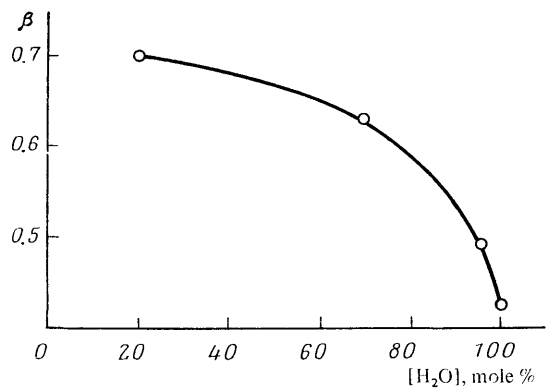


Figure 1. Variation of the Brønsted coefficient $\beta$ with the water content in acetonitrile in the hydrolysis of benzenesulphonyl chloride in the presence of pyridine[92].

However, we believe that the direct correlation of the coefficients $\beta$ with the orders of the formed and ruptured bonds is not always valid. For example, according to data[92] for the hydrolysis of benzenesulphonyl chloride in the presence of pyridine and 4-methylpyridine, $\beta$ increases from 0.43 to 0.70 when the mole fraction of water in the mixture with acetonitrile is reduced from 1 to 0.2, while in 45% aqueous dioxan solution $\beta = 0.79$. Fig. 1 shows that the greatest change in $\beta$ occurs in the presence of small amounts of added organic solvents, where significant changes in the structure of the transition state can hardly be expected.

‡Since the reaction was carried out in water, the acylammonium salt formation stage, regarded here as an elementary process, is probably rate-determining.

The difficulty of taking into account the steric accessibility of the nitrogen atom in the tertiary amine hindered for a long time a quantitative description of the dependence of the catalytic activities of aliphatic tertiary amines on their structure[13,93,94]. Such description has been based on a modified[95] Taft equation [Eqn.(6)], where the steric hindrance in the amines $R_1R_2R_3N$ was chaac: terised, on the basis of the isosteric principle, by the constants $E_N$ which are equal to the Taft steric constants $E_S$ for isosteric hydrocarbon substituents $R_1R_2R_3C$:

$$\lg k = \lg k_0 + \rho^* \sum \sigma^* + \delta E_N \quad . \qquad (6)$$

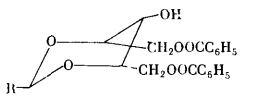
The applicability of this equation was tested in series where the amines (primary, secondary, and tertiary) behave as nucleophiles[95,96] and then in reactions where tertiary amines function as nucleophilic catalysts[97,98]. An equation relating quantitatively the catalytic activity of aliphatic tertiary amines to their inductive and steric characteristics was obtained for the first time for the hydrolysis of benzoyl chloride in 98% dioxan[97]:

$$\lg k = 2{,}80 - (2{,}0 \pm 0{,}2) \sum \sigma^* + (1{,}39 \pm 0{,}09) E_N .$$

Using this equation and also the analogous expressions for other reactions involving tertiary amines, the values of $E_N$ have been calculated for a fairly large number of tertiary amines[97,98]. These data give rise to the prospect of a quantitative description of many other acyl transfer reactions catalysed by tertiary amines, some of which will be examined in subsequent Sections.

## 2. Alcoholysis of Carboxylic and Sulphonic Acid Halides and Anhydrides

It is surprising that there are almost no literature data on the quantitative characteristics of the influence of tertiary amines on the acylation of phenols and particularly alcohols, which are important processes. For example, the mechanism of the catalysis of the acylation of phenols is still obscure. Thus the greater catalytic effect of tertiary amines in the acylation of phenols compared with alcohols and thiophenol[27,28,37,38] and the increase of this difference between the catalytic effects with increasing basicity of the amine[38] as well as the acidity of the phenol[37] support, according to the authors, a general base catalytic mechanism.



A detailed study of the reaction of $RC_6H_4OH$ with acetic anhydride in carbon tetrachloride in the presence of pyridine bases R'Py showed[99] that there is a satisfactory linear correlation between $\lg k$ and $\sigma^0$ for R with a slope $\rho = +1.52$. On the basis of the observed rate constants and $K_{ass}$ for the reactions of the same phenols with pyridine, the authors calculated the constants $k_B$, which were referred to the interaction of the complex ArOH...PyR' with acetic anhydride, and found that they too obey the Hammett equation with $\rho = +0.99$. The increase of the rate of reaction with enhancement of the electron-accepting properties of R confirms, according to the authors[99], the general base catalytic mechanism (for the non-catalytic reaction, $\rho = -0.82$).[27] $\rho = +0.6$ was also found for the reaction of phenols with benzoyl chloride in dioxan in the presence of triethylamine[39]. Later it was shown[100,101] that the introduction of strong electron-donating substituents R (for example, HO or $CH_3O$) likewise increases the reactivity of phenol, as a result of which the curve relating $\lg k$ to $\sigma$ shows an inflection in the range $\sigma = 0$–$0.1$; a similar inflection has been observed for the relation between $\lg k$ and the $pK_a$ for phenols (in dimethyl sulphoxide).[33] In catalysis by pyridine, the Hammett relation again had a descending branch with $\rho = -0.7$ and an ascending branch with $\rho = +0.4$.[39] According to the authors[33,39,100], these phenomena indicate a change in the mechanism of the catalytic reaction from nucleophilic for basic phenols ($\beta > 0$, $\rho < 0$) to the general base catalytic mechanism for acid phenols ($\beta < 0$, $\rho > 0$). The lower (by two orders of magnitude) catalytic activity of pyridine compared with that of triethylamine is also regarded as an argument in support of the above hypothesis[102]. However, one should note that the inflection in the Hammett or Brønsted plot can also be accounted for by the increased contribution of the direct polar coupling of electron-donating substituents of the type RO to the reaction centre[101]. We believe that one cannot fully rule out also the possibility of nucleophilic catalysis in the acylation of phenols—the inflection in the $\lg k$–$\sigma$ or $\lg k$–$pK_a$ curve can then be explained by a change in the relative rates of the stages [for example $k_2'$ and $k_2''$ in mechanism (4)]. The ready acylation of phenols by an equimolar amount of RCOOH in the presence of pyridine and chlorocyclophosphazene $(PNCl_2)_3$ has been explained[103] from the standpoint of nucleophilic catalysis. The reaction probably proceeds via the formation of a cyclophosphazenylpyridinium salt followed by interaction with RCOOH and the formation of an acylammonium salt.

The available information about the influence of the structure of the acylating agent in catalytic alcoholyses is limited to the above comparison of acetic anhydride, trifluoroacetic anhydride, and acetyl trifluoroacetate and also data[99] showing a decrease of the rate of acylation of *m*-nitrophenol in the presence of 3- and 4-quinolines by the anhydrides $(RCO)_2O$ in the sequence $CH_3 > C_2H_5 >$ iso-$C_3H_7 >$ t-$C_4H_9$. The proportionality between $\lg k$ in this series and the values of $E_S$ (or $E_S^0$) supports a steric type of effect although one cannot claim this with complete confidence in view of the relation between the values of $\sigma^*$ and $E_S$ for certain substituents R.[104]

Even less is known about the kinetics and structural characteristics of the acylation of alcohols. Since alcohols are weak acids and fairly strong nucleophiles, one may expect that tertiary amines will behave as nucleophilic catalysts in their acylation. This is confirmed by Bird's data[9], already mentioned, for the acylation of racemic alcohols RR'CHOH in the presence of optically active tertiary amines. It has been shown[105] that the methanolysis of a number of aliphatic acid halides in the presence of triethylamine proceeds via two competing mechanisms: via the formation of an acylammonium salt and via dehydrohalogenation with formation of a keten, which reacts further with methanol. Nucleophilic catalysis apparently also operates in the methanolysis of tetrachlorophthalic anhydride in the presence of pyridine[106]; by virtue of steric hindrance, dimethylaniline does not catalyse the process and actually gives rise to an inactive complex; because of this, the reaction is described by a kinetic equation of the Michaelis–Menten type.

The influence of the structure of tertiary amines and acylating agents has been investigated by Rogne[107] in the methanolysis of aromatic sulphonyl chlorides in the presence of pyridine and its methyl derivatives. As in hydrolysis (see Section III, subsection 1), electron-donating substituents in the tertiary amine and electron-accepting substituents in $RC_6H_4SO_2Cl$ increase the rate of reaction, the influence of R being more effectively described by the Hammett equation when $\sigma^+$ constants are used ($\rho^+ = 0.63$).

Similarly the rate of acylation of 5-hydroxy-1,3-dioxan derivatives of the type

where R = H or $C_6H_5$, by the chlorides of *para*-substituted benzoic acids and benzenesulphonic acid in pyridine is similarly correlated with the values of $\sigma^+$ ($\rho^+ = 0.83-0.95$ and 0.85 respectively)[108]. This indicates an appreciable contribution of the conjugation of the substituent with the reaction centre in the transition state. It was shown in the same study[108] that, in contrast to the majority of cyclic compounds where the equatorial hydroxy-group is more reactive than the axial group[108,109], in this case the axial epimers are more reactive; the authors explained this by the influence of the electronegative oxygen atoms in the ring.

Until very recently, there were no literature data for the influence of the structure of aliphatic alcohols on the rate of their catalytic acylation. We were able to show only recently[110,111] that this influence can be described by the extended Taft equation. The equation for the alcoholysis of benzoyl chloride in tetrachloroethylene is§

$$\lg (k/k_0) = (2.1 \pm 0.3)\,\sigma^* + (1.4 \pm 0.3)\,E_{S\,(RCH_2)}\ , \qquad (7)$$

the coefficients of sensitivity to inductive ($\rho^*$) and steric ($\delta$) influences being independent of the structure of the amine catalyst[111]. This shows that the electron density at the oxygen atom of the nucleophile increases during activation. Consequently the rate-determining stage of the process under the given conditions is attack by the alcohol on the carbonyl carbon accompanied by the transfer of a proton, the degree of dissociation of the O–H bond predominating over the degree of formation of the C–O bond[110]. The importance of the proton transfer xtage, which has been demonstrated theoretically[71] (see Section II, subsection 3), was also confirmed by studies of the isotope effect. In contrast to reactions in water, where the first stage is rate-determining and $k_H/k_D = 1.1 \pm 0.1$,[90,112] an isotope effect is observed in alcoholysis in a non-aqueous medium, indicating the involvement of proton transfer in the rate-determining stage[113]. One should note that similar considerations are applicable also to the acylation of phenols and the observed sign of $\rho^*$ in relation to the nucleophile cannot thus be regarded as a criterion of the type of catalysis.

The influence of the structure of tertiary amines on their catalytic effectiveness in the acylation of alcohols and phenols obeys the same relations as in the hydrolytic reactions. Thus the Brønsted equation holds for 3- and 4-substituted pyridines, high values of $\beta$ (between 0.85 and 0.93) being characteristic of the acylation of phenols, with the exception of the alcoholysis of trifluoroacetaldehyde ($\beta$ was not calculated[36] but an estimate based on the authors' data leads to $\beta \simeq 0.3$), probably owing to its higher reactivity.

The influence of pyridines in the methanolysis of sulphonyl chlorides can be described by the Brønsted ($\beta = 0.55$) and Hammett ($\rho = -3.0$) equations. The high negative value of $\rho$ shows, according to the author[107], that the first stage is rate-determining because of the high concentration of the nucleophile and the fairly high polarity of the medium. At the same time the lower solvating capacity of methanol compared with water leads to a more negative entropy of solvation (by approximately 15 e.u.) and decreases the overall rate of the process by two orders of magnitude.

As in other cases, sterically hindered 2- and 2,6-substituted pyridines (including 2-dimethylaminopyridine) exhibit a weak catalytic activity. The steric factor is particularly important when aliphatic tertiary amines are used. Thus a correlation between the rate of reaction and $\Sigma E_S$ for a number of tertiary amines of approximately equal basicity, $\delta = 0.84$ and 0.72 respectively, has been found in the benzoylation of phenol and *p*-nitrophenol in dioxan[102]. However, the approach based on the summation of the steric constants of substituents attached to nitrogen is inaccurate, since, in contrast to the polar characteristics, the steric characteristics are non-additive[114]. The application of equations of the type of Eqn.(6), using the steric characteristics of amines as a whole, is apparently more promising. Indeed, we were able to show[111] that the catalytic activity of tertiary amines in the benzoylation of alcohols in tetrachloroethylene is described by Eqn.(8) and that its parameters $\rho^*$ and $\delta$ are independent of the structure of the acylated alcohol:

$$\lg (k/k_0) = (-2.1 \pm 0.2) \sum \sigma^* + (0.91 \pm 0.09)\,E_N. \qquad (8)$$

Thus the influence of the structure of the alcohol and the amine on the rate of reaction is additive and the overall Eqn.(9) does not contain cross terms. This indicates a constant composition of the transition state for all the systems investigated in the coordinate space of the reaction, which is probably evidence for the occurrence of the reaction under these conditions by a nearly synchronous mechanism, owing to the weak solvating capacity of the solvent[40,110]. An increase of the latter increases the possibility of a shift of the transition state in the coordinate space, which leads to a relation between the rate of reaction and its sensitivity to changes in structure. This is manifested by the appearance of cross terms—in acylation in dioxan, for example, the correlation equation has the following form:

$$\lg k = 1.35 + 1.97\sigma^*_{(R)} + 1.34E_{S\,(RCH_2)} - 2.1 \sum \sigma^*_{(N)} + 0.92E_N\ , \qquad (9)$$

$$\lg k = 1.32 + 1.49E_{S\,(RCH_2)} - 1.71 \sum \sigma^*_{(N)} + 0.89E_N - 0.37\sigma^*_{(R)} \cdot E_N + \\ + 0.81 \sum \sigma^*_{(N)} \cdot E_{S\,(RCH_2)}. \qquad (10)$$

### 3. The Acylation of Amines by Carboxylic and Sulphonic Acid Halides and Anhydrides

The aminolysis of acid halides and anhydrides in the presence of tertiary amines is one of the most thoroughly investigated reactions owing to systematic studies by the Donets School of Chemistry¶. It has been shown for the reaction of benzoyl chloride with substituted anilines in benzene[24,117–119] that tertiary amines can be divided into

§ The steric effect of the group RO in Eqn.(7) is described by the constants $E_S$ for the $RCH_2$ groups, which are approximately isosteric with the RO groups.

¶ These investigations were continued by studies on the catalytic activities of amides, *N*-oxides, and other *O*-nucleophilic catalysts[115,116], the consideration of which is outside the scope of the present review.

several groups in terms of their catalytic activity, within which the Brønsted and Hammett–Taft equations hold†. On the other hand, it has been found that the catalytic activity of tertiary amines (with comparable basicities) falls on passing from unhindered heterocyclic amines to 2-substituted pyridines, quinoline, and dialkylanilines. Aliphatic cyclic tertiary amines are much weaker catalysts than would be expected from their basicity, because they are subject to an appreciable steric hindrance. For this reason, the linear Brønsted plot (Fig. 2) corresponding to these substances lies below the corresponding plot for the pyridines, although the slopes of the straight lines are virtually the same (0.81 ± 0.05 and 0.86 ± 0.01) [119]; the points corresponding to amines such as triethylamine lie lower still. Similar relations have been observed for the aminolysis of toluene-*p*-sulphonyl bromide in a 1 : 1 nitrobenzene–cyclohexane mixture [120,121].

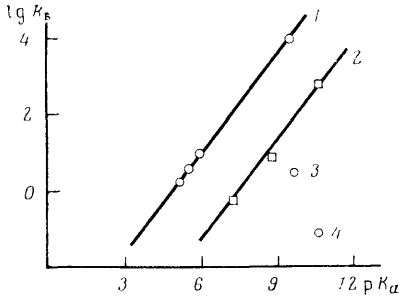


Figure 2. The Brønsted correlation for the reaction of benzoyl chloride with *m*-chloroaniline catalysed by tertiary amines [199]: 1) pyridine bases; 2) cyclic amines; 3) trimethylamine; 4) triethylamine.

The combination of a high capacity for resonance stabilisation, basicity, and steric accessibility is probably responsible for the extremely high catalytic efficiency of *N*-aryl- and *N*-alkyl-imidazoles [47,122–124]; the acylammonium salt is then unusually stable and can be fairly readily isolated and characterised [14,47]. Imidazole itself is relatively inactive as a catalyst, but its hydrochloride, which in some respects resembles acylammonium salts, is capable of transferring the acyl group to *m*-chloroaniline [125].

Further studies demonstrated the dependence of the efficiency of the catalyst on the properties of the acylating agent and the acylated substrate. Thus the catalytic activity diminishes in the aminolysis of ArCOHal with increase of the strength of the C–Hal bond, i.e. on passing from the bromide to the chloride, while the aminolysis of benzoyl fluoride is actually inhibited by pyridine [23,32]. Triethylamine catalyses the acylation of butylamine by benzoyl cyanide [126], while the aminolysis of the majority of carboxylic acid anhydrides is inhibited by pyridine [24,25,127].

† The catalytic activity of tertiary amine hydrochlorides has been noted in the aminolysis reaction [11,24,47,117–119], which is probably associated with the effect of the ion pair $C_5H_5N^+ \cdots Cl^-$ as a bifunctional catalyst.

However, catalysts may be observed on passing to the anhydrides of stronger acids: trichloroacetic [25], *p*-phenylthiobenzoic [128], and sulphonic acids [26]. On the other hand, the catalytic effect is observed following the enhancement of the nucleophilic properties of the tertiary amine, for example, in the case of 4-*NN*-dimethylaminopyridine [25], or when bifunctional catalysts of the type of 2-hydroxypyridine are used [32]. In the latter case, the change in the mechanism of catalysis is revealed by the change in its relative efficiency for different acylating agents: the $k_{cat}/k_0$ ratio for $C_6H_5COX$ diminishes in the following sequence of X: F ≫ Cl > Br.

The efficiency of the catalysis increases also on enhancement of the electron-accepting properties of the substituents in the acid halide, although the effect is not very great (see Table 4, Nos. 3–6). The polarisability of the reaction centre has a much greater influence on the catalytic activity of tertiary amines; Table 4 (Nos. 8 and 9) shows that, in the aminolysis of *p*-nitrobenzenesulphonyl bromide [129], pyridine is 30–40 times more effective than in the aminolysis of benzoyl chloride. An even greater catalytic effect has been observed in the reactions of sulphonic acid anhydrides [26], despite the opposite influence of the solvent, an increase of the polarity of which has been shown [46,130] to decrease $k_{cat}/k_0$.

Table 4. Efficiency of the catalytic effect of tertiary amines in the acylation of anilines $RC_6H_4NH_2$ (benzene, 25 °C).

| No. | Acylating agent | R | Catalyst | $k_0$, litre mole$^{-1}$ s$^{-1}$ | $k_{cat}$, litre$^2$ mole$^{-2}$ s$^{-1}$ | $k_{cat}/k_0$, litre mole$^{-1}$ | Reference |

*In nitrobenzene.

Analysis of the results based on Kirkwood's equation led the authors [46,130] to the conclusion that the polarity of the activated complexes in catalytic and non-catalytic reactions is approximately the same ($\mu_{\neq}$ = 19.8 and 19.6 D respectively), but in the catalytic process the activated complex is larger owing to the involvement of three molecules in its formation.

The efficiency of the tertiary amine depends significantly also on the properties of the acylated amine; thus it has been shown [118,120,129] that $k_{cat}/k_0$ increases with decrease of the basicity of the arylamine and the catalytic effect is shown most clearly for weakly basic amines. As a result of this, the values of $\rho$, characterising the sensitivity of the reaction to the influence of substituents in $ArNH_2$, decrease on passing from the non-catalytic to the

catalytic process, from −2.67 to −1.35 for the reaction with $C_6H_5COCl$ [118] and from −3.98 to −2.8 for the reaction with $p$-$NO_2C_6H_4SO_4Br$.[120,129] Finally, the influence of temperature on the above processes is expressed, in conformity with the relations discussed in Section II, by a decrease of the efficiency of the catalysis with increase of temperature.

### 4. Reactions of Esters

The influence of tertiary amines on the reactions of esters has been investigated for a long time and in great detail partly in connection with their similarity to many enzymatic processes. Greatest attention has been devoted in this connection to imidazole, which enters into the active centres of many hydrolases and is also probably an acyl transferring agent in the biosynthesis of acetylcholine[131,132]. Imidazole is involved in nucleophilic reactions via its tertiary nitrogen atom; on the other hand, the presence of the secondary nitrogen atom makes possible the elimination of the proton from the acylammonium salt, which leads to fairly stable acylimidazoles[133].

In conformity with what has been said in Section II, imidazole and other tertiary amines may catalyse via the nucleophilic mechanism only the hydrolysis of activated esters (phenol, thiol, etc. esters)[29,134-144] if $\Delta pK_a \leq 3$ for ArOH and the imidazolium ion. When $\Delta pK_a > 3$, the cooperation of general base catalysis with nucleophilic catalysis is necessary[137] and, for $\Delta pK_a \gg 3$, only general base catalysis is observed[137,140,145] or there is no catalysis at all[136,137]. The lactonisation of the amide and ester of $o$-hydroxymethylbenzoic acid is catalysed by imidazole and other bases[146,147], probably via the general base mechanism, as shown by the ratio $k_{H_2O}/k_{D_2O} = 3.46$ and the Brønsted coefficient (0.87).[147] The ability of imidazole to catalyse the hydrolysis of *NO*-diacetylserine amide has also been noted[148].

The solvent has a significant influence on the ratio of the basicities of the leaving group and the amine and hence on the type of catalysis. Thus the aminolysis of 2,4-dinitrophenyl acetate in benzene and chlorobenzene[149,150] is catalysed by pyridine, in contrast to aqueous solutions, probably via the general base mechanism. The fundamental argument used by the authors has been the observation of a correlation between $\lg k_{cat}$ for catalysts of different chemical types and their proton-accepting capacity, characterised by the constants for association with phenol[149] or $p$-fluorophenol[150], and also the fairly high values of $E_{cat}^{app}$ (7–10 kcal mole$^{-1}$).[151] On the other hand, the absence of correlation between the basicity of tertiary amines and their catalytic activity in the aminolysis of 2,4-dinitrophenyl acetate and other similar esters has been interpreted[152] as evidence for nucleophilic catalysis. Thus the problem cannot be regarded as solved.

Without going into the details of the mechanism of the reactions of esters, which have been considered in a number of monographs[18,29,89,153-155], we shall merely emphasise that the transition state in the rate-determining stage in such reactions is apparently extremely polar and close to a tetrahedral complex with separated charges[18,29,89]. This explains the decrease of the rate of reaction following the addition of alcohol to water[156]‡.

As in other instances, in the reactions of esters the catalytic activity of amines of the same type is described satisfactorily by the Hammett or Brønsted equation, but different correlation lines correspond to different classes. The Brønsted coefficient is usually approximately 0.7 to 0.8 [134,135] (the value of 1.62 obtained in one investigation[136] is probably erroneous due to the small number of compounds investigated). Substituted imidazoles are again the most active (for comparable basicities) and are followed in this respect by pyridines and the relatively less active aliphatic tertiary amines[135,136] as well as 2- and 2,6-substituted pyridines[159-162]. On the other hand, it has been found for the reaction of the esters $2,4\text{-}(NO_2)_2C_6H_3OOCR$ with aniline[152] and the hydrazides $p$-$R'C_6H_4CONHNH_2$ [163] that the catalytic activity of pyridine increases in the following sequence of R: $CH_3 < C_6H_5 < p\text{-}NO_2C_6H_4$ and in the following sequence of R′: $H < CH_3O < Br$. Thus the observed relations are typical for nucleophilic reactions, so that the authors' hypothesis of general base catalysis appears doubtful.

It has been shown for triazoles[164] as well as pyridine and phthalazine[165] that the catalytic activity of tertiary amines increases following the appearance of several neighbouring atoms in the heterocycle, which is associated, according to the authors, with the repulsion of the neighbouring lone electron pairs, resulting in an enhancement of the nucleophilic properties of the compound[165].

The efficiency of catalysis increases significantly when bifunctional derivatives are used in which the nucleophilic attack on the nitrogen is accompanied by proton transfer, the importance of which has already been mentioned. Thus, in the hydrolysis of $p$-nitrophenyl acetate (NPA), 2-hydroxy-, 2-hydroxyethyl-, and 4-($\gamma$-hydroxypropyl)-pyridines are much more active than the corresponding picolines[166]; serine and histidine are more active still. The mercaptoalkyl derivatives of imidazole and benzimidazole[167,168] and also 2-($o$-hydroxyphenyl)imidazole [169] are extremely efficient as catalysts. On the other hand, 4-($\beta$-diethylaminoethyl)- and 4-(diethylaminomethyl-imidazoles are less effective than imidazole itself[170]. It has been found[171] that the aminoalcohols $RR'NCH_2CH_2OH$ catalyse the decomposition of many phenyl esters, behaving at the same time as acyl transferring agents. According to the authors, *N*-nucleophilic catalysis does not occur in this case, the aminoalcohols undergoing *O*-acylation with subsequent rapid hydrolysis of the resulting esters.

Another interesting group of facts includes the effects observed in many instances in studies of the hydrolysis of esters, analogous to those noted in enzymatic catalysis. Thus the attainment of the maximum reaction velocity at a certain substrate concentration (Michaelis–Menten kinetics) and inhibition of the reaction by its products[172], which is characteristic of many enzymatic systems, have been observed in the hydrolysis of $p\text{-}NO_2C_6H_4OC(O)OCH_2CH_2\dot{N}^+.(CH_3)_2C_{12}H_{25}$ in the presence of *N*-stearoylhistidine; the rate of this reaction is 2000 times higher than in catalysis by *N*-acetylhistidine[173]. Similar phenomena have been observed in the hydrolysis of 4-carboxyphenyl acetate in

---

‡The decrease of the rate of acylation of neutral nucleophiles by nitrophenyl esters on passing to a micellar medium, characterised by a lower value of $\epsilon$ than water, has also been explained by the unfavourable influence of the non-polar environment[156-158].

the presence of 1-aminomethyl-4-(4'-imidazolyl)naphthalene[174]. Some of these effects (for example, kinetics simulating saturation) may be associated with the aggregation of the esters of higher aliphatic acids in water[175], but the fundamental cause is apparently the hydrophobic interaction of the catalyst with the substrate, which decreases the activation entropy. This probably accounts for the sharp increase of the rate of hydrolysis of the esters $p$-$NO_2C_6H_4OOCC_nH_{2n+1}$ in the presence of alkylimidazoles with increase of the number of carbon atoms in the substrate and the catalyst§ (see Table 5)[176-178].

Table 5. The influence of hydrophobic properties on the hydrolysis of the esters $C_nH_{2n+1}COOC_6H_4NO_2$ in the presence of the alkylimidazoles $C_mH_{2m+1}N{=}$ in water at 25°C.[177]

Polymeric catalysts of the hydrolysis of esters are of interest. In this respect, detailed studies have been made on partially alkylated polyvinylpyridines[65,180-184], polyaziridines[185], polyvinylimidazoles and the copolymers of vinylimidazole with other monomers[186-191,193], and the polyoxyethylene ester of $N$-benzoylhistidine[192]. In many instances these catalysts exhibited an efficiency several orders of magnitude higher than the corresponding monomers, the effect being particularly pronounced in the hydrolysis of esters with long hydrocarbon chains[185,190]. It is suggested that the active centres in these polymers are tertiary amino-groups, which behave as nucleophilic[65,181-183,186] or general base[185] catalysts (possibly in cooperation with other groups[186]); on the other hand, the efficiency of the catalysis is associated mainly with the concentration of the reactants in the active cavities formed by the hydrophobic parts of the polymer chain and the ammonium groups. However, one should bear in mind the fact that the effect of the concentration of the reactant may be extinguished owing to the decrease of the true reaction rate caused by the weak solvating capacity of the medium[156-158], which may be the reason for the insignificance of the effects in many instances[186,190].

(4-Imidazolyl)methoxy- or β-(4-imidazolyl)ethylaminocyclodextrins, in which the imidazole moiety and the OH group of the cyclodextrin act synchronously, combining with the acyl which is subsequently hydrolysed, constitute an unusual type of polymeric catalysts[194]. This mechanism, resembling the action of serine hydrolases, ensures the acceleration of the hydrolysis of NPA by a factor of 50 to 200.

§A similar phenomenon has been observed in the reaction of the same esters with the amines $C_nH_{2n+1}NH_2$ under the conditions of catalysis by a second amine molecule[179].

## 5. The Reactions of Isocyanates

It has been known for a long time that tertiary amines accelerate the reactions of nucleophiles with isocyanates[195-197]. The similarity of this process to the reactions of acid halides is clear from a review[93] and from the literature[98,198-206], namely the dependence of the catalytic activity of tertiary amines on their basicity and steric accessibility and the absence of correlation between $\lg k_{cat}$ and $pK_a$. On the other hand, there is satisfactory correlation based on Eqn.(6) and, as can be seen from Table 6, the reactions of isocyanates with alcohols are less sensitive to the structure of the tertiary amine than the analogous reactions of acid chlorides. When nucleophiles of the same type are varied (ROH, Table 6, Nos. 1 to 3), the values of $\rho$ and $\delta$ remain virtually constant, while, on passing to butanethiol (Table 6, No.4), the sensitivity of the reaction to both effects increases[98], probably by virtue of the greater bulk and greater polarisability of the sulphur atom compared with the oxygen atom. Bridged cyclic amines of the type of diazabicyclo-octane (DABCO) and quinuclidine are very effective catalysts in all cases, mainly because the degree of the steric hindrance is low (DABCO is close to trimethylamine as regards the value of $E_N$), while the basicity is high.

Table 6. The correlation parameters of the catalytic activity of tertiary amines in the reactions of phenyl isocyanate with nucleophiles in accordance with Eqn.(6).

The importance of the steric factor suggests a nucleophilic mechanism of the catalytic reaction with formation as an intermediate of the dipolar ion

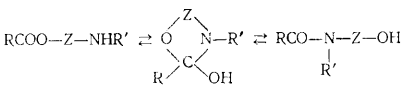
$$R{-}N{=}\overset{O}{\overset{|}{C}}{-}{}^{+}NR'_3 \leftrightarrow R{-}\overset{-}{N}{-}\overset{O}{\overset{\|}{C}}{-}{}^{+}NR'_3,$$

the stability of which increases owing to the resonance delocalisation of the negative charge. This leads to the possibility of observing this product by infrared spectroscopy[207] and also to the possibility of the separate determination of $k_1$ and $k_2/k_{-1}$; such data have been obtained for the reaction of phenyl isocyanate with alcohols in the presence of triethylamine and pyridine[93,196].

The efficiency of catalysis decreases in the following series of substances: butanol > water > diphenylurea[208] and increases with increase of solvent polarity[196,209] (non-specific solvation probably plays the main role[209]) and also after the addition of organotin compounds[209]. The latter themselves catalyse the reactions of isocyanates and their

role probably consists in activating the alcohol. Here the transition state is probably

### 6. Various Reactions



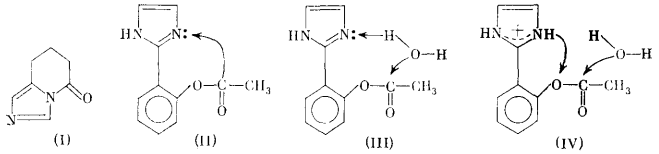
Among other reactions involving acyl transfer, the catalytic effect of tertiary amines has been observed in the aminolysis of carbamates[210] and the hydrolysis of a number of amides[211-215]. In most cases, the authors postulated the general base or general acid mechanism of catalysis[213,214] although Stauffer[212] adduced evidence supporting nucleophilic catalysis of the hydrolysis of trifluoroacetanilide by imidazole buffers.

In certain new studies, examples of unusually effective catalysis have been described. Thus the rate of hydrolysis of tetraethyl pyrophosphate catalysed by substituted benzimidazoles in the excited state has been found to be similar to the diffusional rate ($k \approx 10^{10}$–$10^{11}$ litre mole$^{-1}$ s$^{-1}$), which has been explained by the increase of the basicity of the catalyst on excitation to the singlet state and by the decrease of the energy barrier to the formation of the acylammonium salt[216].

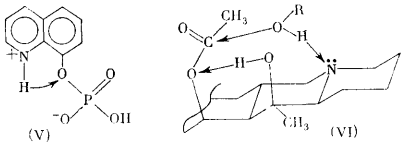
A study of the hydrloysis of 2-hydroxy-4-nitrophenyl sulphate[217] showed that polyaziridine, partly alkylated by dodecyl- and methylene-imidazole residues, accelerates the reaction by a factor of $10^{12}$, while imidazole itself exhibits only a weak catalytic activity. According to the authors, this effect is caused by the hydrophobic interaction of the substrate with the dodecyl groups and the subsequent nucleophilic catalysis by imidazole.

## IV. INTRAMOLECULAR CATALYSIS

The acyl transfer reactions with the intramolecular involvement of a tertiary amino-group are in many respects analogous to the N → O acyl migration with participation of a primary or secondary amino-group, which takes place, according to modern ideas[218-223], via the following mechanism (without taking into account the possible proton transfers):



However, since the acylammonium salts are unstable, they behave merely as reactive intermediates and the tertiary amino-group may be regarded as a nucleophilic catalyst. Among reactions of this type, studies have been made mainly on the reactions of amino-esters and to a less extent on the acylation of aminoalcohols.



### 1. Hydrolysis and Other Reactions of Aminoesters

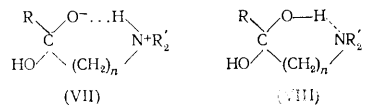
Intramolecular catalysis in the reactions of aminoesters is determined, like intermolecular catalysis, by the properties of the alkoxy-residue eliminated. If the amino-group in the anion $R'_2N-Z-O^-$ is more basic than $O^-$, the acyl residue in the ester $RCOO-Z-NR'_2$ may be transferred to the nitrogen atom with formation of the acylammonium salt $RCO(R')^+_2N-Z-O^-$, which undergoes further nucleophilic attack (nucleophilic catalysis)[29]. This mechanism is characteristic of activated esters, such as aryl (4-imidazolyl)butyrates[224,225]; in this case, the intermediate is the lactam (I). The amide and the methyl ester of the same acid are hydrolysed without the participation of neutral imidazole, although in the case of the amide the influence of the protonated form of imidazole was noted. Nucleophilic catalysis has been proposed also for the hydrolysis of *o*-(4-imidazolyl)phenyl esters[226,227], but, subsequently it was concluded on the basis of the ratio $k_{H_2O}/k_{D_2O} = 3.23$ and the activation parameters that general base catalysis operates in the reactions of these esters[228].

It has been shown[144] that the mechanism of the catalysis of the hydrolysis of substituted 2-imidazolylphenyl acetates depends on pH: in the alkaline region, nucleophilic catalysis (II) operates, in a neutral medium there is general base-catalysed cooperation with attack by imidazole on water (III), while in a weakly acidic medium general acid catalysis by the protonated form of imidazole (IV) operates:

The same possibilities occur also in other instances. Thus, according to some workers[228-232], general acid catalysis obtains in the hydrolysis of the zwitter-ion of 8-quinolinyl phosphate (V)[229] and substituted 4-benzimidazolylpeptides[230], while general base catalysis, confirmed by the ratio $k_{H_2O}/k_{D_2O} = 2.35$, operates in the hydrolysis and hydrazinolysis of 8-acetoxyquinoline[228,231] and also in the solvolysis of cevadine and other Ceveratrum alkaloids [for example, compound (VI)]; in the latter case, general acid catalysis by the OH group operates simultaneously[232]:

On the other hand, in the hydrolysis of 8-hydroxyquinoline monoesters with succinic or glutaric acid, a nucleophilic mechanism of catalysis, confirmed by the ratio $k_{H_2O}/k_{D_2O} = 1.05$, has been demonstrated[233].

In a few studies, where the efficiencies of the intermolecular and intramolecular catalysis were compared, the predominance of the latter has been demonstrated. Thus, it has been found[234] that the ratio of the rate constants for the hydrolysis of the esters $(CH_3)_2N(CH_2)_3.COOC_6H_4R$ ($k_I$) and the bimolecular hydrolysis of aryl acetates in the presence of trimethylamine ($k_{II}$) varies from 1260 (for R = H) to 5370 mole litre$^{-1}$ (for R = *p*-$NO_2$); here the entire gain is apparently achieved as a result of the effect associated with the mutual approach of the functional groups, resulting in a gain of translational entropy. The effect for δ-dimethylaminovalerate esters is smaller by a factor of 1.6–2.7 because the five-membered ring in the transition state is more favourable than



the six-membered ring. The values of $k_I/k_{II}$ for γ-(4-imidazolyl)butyrate esters are lower by two orders of magnitude—ranging from 94 (for R = *p*-$NO_2$) to 24 mole litre$^{-1}$ (for R = H).

In the hydrolysis of non-activated aminoesters, a significant catalytic effect by the tertiary amino-group has been found only in the case of 4-(β-acetoxyethyl)imidazole[224,227] and 5-acetoxymethyl-1-methylimidazole[235], which has been explained by the favourable nature of the cyclic transition state arising in this case in the O → N acyl transfer. In the remaining instances investigated, the introduction of a tertiary amino-group into the ester molecule accelerates its hydrolysis by not more than a factor of two (see Table 7) owing to the inductive effect of the amino-group[236-239]. The hydrolysis of esters of this kind is described by the general correlation equations for esters with a variable alcoholic component[238,240] and an appreciable catalytic effect (of the kind postulated, for example, by Schätzle et al.[241]) is therefore not observed.

Table 7. The influence of the amino-group on the alkaline hydrolysis of the aminoesters $RCOOCH_2CH_2X$.

| R | Conditions | $k$, litre mole$^{-1}$ s$^{-1}$ | | | | $\frac{k_{N(CH_3)_2}}{k_H}$ | $\frac{k_{+NH(CH_3)_2}}{k_{+N(CH_3)_3}}$ | References |
|---|---|---|---|---|---|---|---|---|
| | | X = H | X = $N(CH_3)_2$ | X = $+N(CH_3)_3$ | X = $+NH(CH_3)_2$ | | | |
| $CH_3$ | Water, 25° 0.07 M $KClO_4$ $I$ = 0.1 | 0.045 | 0.1 | 1.48 | 42.6 | 2.2 | 28.8 | 245 |
| | | — | — | 2.0 | 39.1 | — | 19.6 | 246 |
| $CH_2=C(CH_3)$ | Water, 25° $I$ = 0.5 | 0.035 | 0.042 | 0.60 | 16.5 | 1.2 | 27.5 | 238 |
| $C_6H_5$ | Water, 25° $I$ = 1 | 0.03 | 0.058 | 0.56 | 16 | 1.9 | 28.5 | 249 |
| $C_6H_5$ | 30 wt.% alcohol, 60° $I$ = 0.1 | 0.058 | 0.011 | 3.7 | 150 | 1.9 | 40.5 | 237 250 252 |

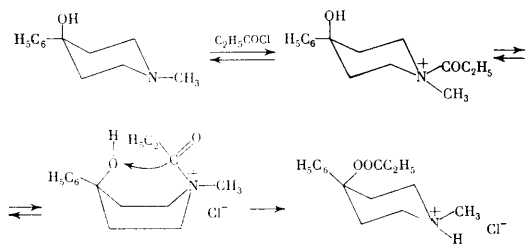


Table 7 shows that esters containing a charged ammonium group are hydrolysed much faster than their neutral analogues. For quaternary ammonium derivatives, this effect[242,243] is associated with the electrostatic interaction between the positively charged nitrogen atom and the negative charge arising in the transition state in alkaline hydrolysis and in this instance it is hardly useful to speak of catalysis, as was done by Smith and Williams[244]. On the other hand, the acceleration of the reaction by a factor of 20–40 for protonated aminoesters (see Table 7) is in all probability associated with the general acid catalysis by the N–H$^+$ group. This is confirmed by the decrease or disappearance of the above difference in compounds whose rigid structure prevents the approach of N$^+$–H to the ester group[252-256]. At the same time no evidence has been obtained for the N$^+$–H...O–C hydrogen bond in aminoesters by infrared spectroscopy[239,246-248] and PMR.[251] This suggests that the main effect in these instances is the stabilisation of a transition state close to the tetrahedral adduct (VII) as a result of proton transfer and the formation of the neutral compound (VIII) and not an increase of the charge δ$^+$ on the carbonyl carbon atom owing to the formation of a hydrogen bond, as suggested in a number of investigations[241,245,247,248]. The decrease of the degree of charge separation should lead to the "unfreezing" of the solvent and the corresponding gain of entropy of solvation. Indeed, it has been found[250] that the acceleration of the hydrolysis of the protonated forms of aminoesters is associated exclusively with the increase of the pre-exponential term (lg $A$). A similar conclusion was reached in a study of the hydrolysis of aminoacid esters[257]:

(VII) (VIII)

## 2. Acylation of Aminoalcohols

The hypothesis that nucleophilic catalysis by a tertiary amino-group is possible in the esterification reaction has been used for a long time to account for the large differences between the reactivities of the stereoisomers of heterocyclic aminoalcohols[258-263]. Thus it has been suggested[258] that 1-methyl-4-phenyl-4-piperidinols and *trans*-decahydro-4-quinolinols, having an axial OH group, react with propionyl chloride via the formation of an intermediate acylammonium salt and its intramolecular rearrangement via the mechanism

In epimers with an equatorial OH group, such rearrangement is difficult and acylation did not take place under the experimental conditions. It has been found[262,263] that only the 3-azabicyclo[3,3,1]nonan-9-ol isomer containing the OH and $CH_3N$ groups in the *syn*-positions is acylated.

This mechanism was confirmed quantitatively for the first time in a study[264] where it was shown that, on passing from cyclohexanol to 1,3-dimethyl-4-piperidinol, the rate of benzoylation in tetrachloroethylene (at 25°C) increases by more than four orders of magnitude. This demonstrated the occurrence of intramolecular catalysis, the efficiency of which was appreciably higher for compounds with an axial OH group, which agrees well with qualitative data[258]. Comparison of the rate constants for the bimolecular process and the trimolecular benzoylation of cyclohexanol in the presence of *N*-methylpiperidine led to the conclusion that the intramolecular catalysis in these systems is approximately 100 times more effective than the intermolecular catalysis.

Data concerning the involvement of a tertiary amino-group in the acylation of acyclic aminoalcohols have been fairly contradictory until recently. Thus the acceleration of the esterification of the alcohols $(C_6H_5)_2C(OH)(CH_2)_nNR_2$ relative to non-nitrogen-containing analogues was not observed[265]. Possibly this was due to steric factors hindering the intramolecular catalysis, since a high reactivity of the aminoalcohols has been demonstrated qualitatively in a number of other investigations[266-268]. This was confirmed quantitatively for the first time in a study[269] of the reaction of benzoyl chloride with the alcohols $Ar(R)C(OH)(CH_2)_nNR'_2$ in dioxan. It was shown

that the introduction of the $R'_2N$ group increases the reactivity of the alcohol by 6–8 orders of magnitude. The reaction was of first order with respect to the aminoalcohol in all cases, which demonstrates the occurrence of intramolecular catalysis, the efficiency of which decreases appreciably when $R' = CH_3$ is replaced by $R' = C_2H_5$ because of the steric hindrance to the formation of the aminoacyl salt. The ease of the subsequent $N \rightarrow O$ acyl migration was found to depend on the steric environment of the hydroxyl (Ar and R) and on the size of the ring formed.

The above correlation equations (9) and (10) for the benzoylation of alcohols in tetrachloroethylene and dioxan subjected to intermolecular catalysis by tertiary amines enabled us to calculate the rate of the hypothetical acylation of aminoalcohols under the conditions of catalysis by a second aminoalcohol molecule ($k_{III}$) and the ratio $k_{II}/k_{III}$, characterising the "effective" concentration of the catalyst. Table 8 shows that intramolecular catalysis is least effective in the esterification (in tetrachloroethylene) of diethylaminoethanol, which is most hindered among the alcohols investigated. The decrease of steric hindrance as a result of the increase in chain length of the replacement of the $(C_2H_5)_2N$ group by $(CH_3)_2N$ increases sharply the ratio $k_{II}/k_{III}$. An even more marked effect is attained when tetrachloroethylene is replaced by dioxan, which probably promotes proton transfer in the intermediate adduct.

Table 8. Acylation of aminoalcohols by benzoyl chloride at 25 °C.

| Aminoalcohol | Tetrachloroethylene | | | Dioxan | | |
|---|---|---|---|---|---|---|
| | $10^2 k_{III}$, litre$^2$ mole$^{-2}$ s$^{-1}$ [calc. from Eqn.(9)] | $10^2 k_{II}$, litre mole$^{-1}$ s$^{-1}$ (expt.) | $k_{II}/k_{III}$, mole litre$^{-1}$ | $10^2 k_{III}$, litre$^2$ mole$^{-2}$ s$^{-1}$ [calc. from Eqn.(10)] | $10^2 k_{II}$, litre mole$^{-1}$ s$^{-1}$ (expt.) | $k_{II}/k_{III}$, mole litre$^{-1}$ |
| $(C_2H_5)_2NCH_2CH_2OH$ | 0.24 | 0.092 | 0.4 | 0.23 | 4.7 | 20 |
| $(C_2H_5)_2NCH_2CH_2CH_2OH$ | 0.23 | 2.2 | 9.6 | 0.20 | 21 | 108 |
| $(CH_3)_2NCH_2CH_2CH_2OH$ | 5.0 | 35 | 7.0 | 4.5 | 1230 | 270 |
| $(CH_3)_2NCH_2CH_2OH$ | 3.4 | 34.6 | 10.1 | 2.7 | 6400 | 2370 |

The steric factor probably also plays an important role in the reactivity of the stereoisomeric 2-dimethylamino-1-phenyl-1-propanols, among which the *erythro*-isomer is esterified much faster by benzoyl chloride in methylene chloride[270] than the *threo*-isomer ($k = 1.0$ and 0.0039 litre mole$^{-1}$ s$^{-1}$ respectively). According to the authors, this is also associated with the stronger hydrogen bond in the latter isomer, which decreases the accessibility of the nitrogen atom to nucleophilic attack.

## V. EXAMPLES OF THE PRACTICAL APPLICATIONS OF TERTIARY AMINES AS ACCELERATORS OF ACYLATION REACTIONS

Since these problems have been described in detail[1,93], we shall consider only a few of comparatively new data. A series of studies by Korshak and coworkers on the polycondensation of aromatic acid dichlorides with bisphenols demonstrated the high catalytic efficiency of tertiary amines[7,271-272], the yield and the molecular weight of the polyarylate depending on the structure of the tertiary amine[7,99]. The polymers obtained are characterised by fairly narrow molecular weight distribution[271] and in many instances by a significant predominance of certain "frozen" rotational forms[272], which gives rise to the prospect of the synthesis of stereoregular polycondensation polymers. Thus it has been shown[273] that triethylamine gives rise to more complete interaction of diamines with tetracarboxylic acid dianhydrides accompanied by the formation of polyamides in the form of elastic films. Furthermore, tertiary amines are also effective catalysts of the synthesis of carborane-containing polyaminoamides; depending on the solvent and the structure of the tertiary amine employed, it is possible to obtain in this case soluble linear, soluble branched, or insoluble cross-linked polymers[274]. The use of tertiary amines as polycondensation catalysts leads in many instances to an improvement of the stability and mechanical and thermal properties of polyurethanes[275,276] and polyesters[277-279].

Examples of specific structural and stereospecific acylation in the presence of tertiary amines concern a different aspect of their application in acylation reactions. Thus, using triethylamine as the catalyst, Kurita achieved for the first time the direct selective *O*-tosylation of *o*-aminophenol[280]; it is of interest that, in the presence of pyridine, only *N*-acylation takes place. In the esterification of glycosides, it was also found that products involving the acylation of different hydroxyls are obtained on treatment with acetic anhydride and acetyl chloride in pyridine[281]. When sterically hindered alcohols, such as 1-methyl and 1-ethynylcyclohexanols, 2,4,6-trimethylphenol, etc., have to be acylated, 4-dialkylaminopyridine are effective catalysts[282]. The same substances have proved useful in the esterification of tertiary alcohols which are unstable in the presence of acids, namely linalool, 1,1-dimethoxy-4-methylpent-2-yn-4-ol, as well as methyl cholate and other steroid derivatives.

Generalisation and analysis of the accumulated data permit the conclusion that the possibilities of tertiary amines as acyl transfer catalysts have been by no means exhausted and further studies will undoubtedly expand the use of these compounds in industrial and laboratory practice.

# Latest Research on the Hydrosilylation Reaction

E.Lukevics

The latest (1964-1974) literature data on the hydrosilylation reaction are surveyed and the results of studies on hydrosilylation, the possibility of using new catalysts, new applications, and the commonest side reactions are considered. The bibliography includes 428 references.

CONTENTS

I. Introduction 264
II. New catalysts 264
III. The properties of hydrosilylation 266
IV. New applications of hydrosilylation 268
V. Anomalous and side reactions 269

## I. INTRODUCTION

During recent years, the hydrosilylation reaction has become the most popular method for obtaining a wide variety of carbofunctional organosilicon monomers. Thus, whereas during the first decade after its discovery (in 1947) approximately 150 publications with 500 examples of the reaction were devoted to hydrosilylation, during the last decade after the publication of the first monograph on hydrosilylation[1] (1964) the number of relevant publications already exceeded 1500. They describe approximately 10 000 instances of the application of the hydrosilylation reaction not only in the synthesis of monomers, but also in the formation of a new type of organosilicon polymers (the polyaddition reaction).

Attempts at a systematic arrangement of the enormous amount of experimental data on the hydrosilylation of unsaturated compounds (up to 1967) and on the employment of the hydrosilylation reaction for the synthesis of carbofunctional organosilanes (up to 1971) were undertaken in two major reviews[2,3]. Individual problems of hydrosilylation have been considered also in a number of other reviews[4-21].

This review surveys the results of research on hydrosilylation, gives a systematic account of data on the utilisation of new catalysts, and examines new possibilities for the application of the hydrosilylation reaction on the basis of data published up to 1975.

## II. NEW CATALYSTS

Chloroplatinic acid is the catalyst most frequently used for the hydrosilylation of the C=C double bond and the C≡C triple bond. It is usually employed in the form of a solution in isopropyl alcohol. However, in many instances, in order to avoid side reactions[22-32], shorten the induction period[33], and increase the yield of the isomer with a terminal silyl group[13,34], a solution of $H_2PtCl_6.6H_2O$ in tetrahydrofuran has been used. In some cases the catalyst was prepared in methanol[35], ethanol[36-39], butanol[40-46], 2-methyl-2-propanol[47,48], octanol[49-60], a 2-propanol–benzene mixture[61], cyclohexanone[62], dimethyl ether of ethylene glycol[63-67] or diethylene glycol[68-69], ethyl acetate[70], methyl benzoate[71,72], and dimethyl phthalate[73-77]. An active catalyst was obtained by treating $H_2PtCl_6.6H_2O$ with dichloromethylsilane at 20°C for 12 h.[78,79]. Chloroplatinic acid has also been used together with a buffer solution of a strong acid in water[80,81].

Since chloroplatinic acid may form a complex with the initial ethylenic or acetylenic compound, complexes of platinum derivatives with various unsaturated compounds, namely ethylene[82-91], cyclohexene[82,85,92-97], styrene and its derivatives[98-103], vinylsiloxanes[88,104-114], vinylpyridine[115,116], ethylene and pyridine[117-119], ethylene and phosphines[120,121], and alkylethylenes[21,122,123], as well as complexes with cyclopropane[124-128], ketones[62,129-131], nitriles[132-134], phosphines[132,135-142], phosphines on polymeric carriers[143,144], dialkyl sulphides[145-148], and sulphoxides[149] have been proposed as hydrosilylation catalysts.

The use of bivalent and quadrivalent platinum complexes of pyridine has also been described[132,150,151]. Sometimes amines (butylamine[152], tributylamine[153], and triethylenediamine[154,155]) were added to chloroplatinic acid in order to increase the yield of the reaction product, but in other instances the addition of amines inhibited hydrosilylation[21,22,33,156,157]. The addition of a small amount of amines can alter appreciably the mode of hydrosilylation (towards the formation of the β-isomer in the case of styrene[132]). Two-centre $Me_3PtI$ complexes[158] with pyridine[159,160] and hexamethyldiplatinum have also been used[158].

Platinum complexes on inorganic[144] and organic[143,161-164] polymeric carriers have begun to be employed on a wide scale recently. Polymeric platinum chelates with di-(8-hydroxy-5-quinolinyl)methane have also been proposed as hydrosilylation catalysts[165]. A solution of chloro-osmic acid in ethanol catalyses the addition of dichloromethylsilane to vinylsilanes, like chloroplatinic acid[166,167]. Palladium complexes, for example $(Ph_3P)_4Pd$,[140,168-176] $(Ph_3P)_2PdCl_2$,[144,168,177] $(PhCN)_2PdCl_2$,[177-180] $(Ph_3P)_2.(p\text{-quinone})Pd$,[140] $(Ph_3P)_2.$ .maleic anhydride.Pd,[140,181] and palladium complexes of diorganophosphinoalkylpolysiloxanes[144,182] proved to be effective catalysts of the hydrosilylation of alkenes and polyenes. The palladium(II) complexes of menthyldiphenylphosphine and neomenthyldiphenylphosphine have been used for the asymmetric hydrosilylation of styrene and cyclic conjugated dienes[178].

A wide variety of rhodium(I) complexes proved in many instances to be not inferior to platinum compounds as regards catalytic activity. Complexes of triphenylphosphine $[(Ph_3P)_3RhCl]$ [31,144,183-196] and diphenylphosphine $[(Ph_2PH)_3RhCl]$, [197] the triorganophosphinerhodium carbonyls $(Ph_3P)_2(CO)RhCl$, [187,188] $(Ph_3P)_3(CO)RhH$, [185,196] and $(Et_3P)_2(CO)RhCl$, [187] the rhodium carbonyl $[RhCl(CO)_2]_2$, [185,187] the olefin complex $[(C_2H_4)_2RhCl]_2$, [86,198] the bisdimethylglyoximato-complex $[(Ph_3P)(C_4H_7N_2O_2)Rh]_2$, [199-203] and certain others[204-206] have been proposed. The activity of the rhodium catalysts in the reaction of trichlorosilanes with hexene diminishes in the sequence[187]

$$[RhCl(CO)_2]_2 > (Ph_3P)_2(CO)RhCl > (Ph_3P)_3RhCl > (Et_3P)_2(CO)RhCl .$$

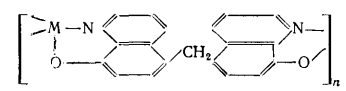
$(Ph_3P)_3RhCl$ in methylene chloride is less active in the reaction of dimethylphenylsilane with ethylene than $H_2PtCl_6.6H_2O$ in tetrahydrofuran[31]. The latter is also less sensitive to the effect of substituents in the benzene rings of aryldimethylsilanes. It has been shown that $[(C_2H_4)_2.RhCl]_2$ is a more active catalyst than $(Ph_3P)_3RhCl$. [198] Its use for the hydrosilylation of *cis*- and *trans*-hept-2-enes with trichlorosilane leads to trichloro-n-heptylsilane (as for $H_2PtCl_6$). [198]

The rhodium complexes of phosphines have been used successfully also for the hydrosilylation of C=O [195,207-219] and C=N [220-222] bonds. The asymmetric hydrosilylation of carbonyl compounds has been carried out in the presence of complexes with chiral ligands[142,208-210,213,215,218,219,223].

Rhodium complexes on polymeric carriers have been prepared recently[143,144,224-228] and it has been observed that these complexes catalyse effectively the addition of trialkyl- and trialkoxy-silanes to alkenes and of trialkoxysilanes to vinyl ethers and only slightly the addition of trichlorosilane to alkenes. On the other hand, the analogous platinum complexes catalyse the reactions with trichlorosilane more effectively than those with triethylsilane[143]. Ruthenium complexes have also been used for hydrosilylation[196,229,230], but iridium complexes of the type $(Ph_3P)_2(CO)IrCl$ have proved to be inactive[188].

New possibilities in the hydrosilylation reaction arose following the application of nickel complexes[132,169,170,231-243]. Thus, whereas the reaction of trichlorosilane with styrene in the presence of $H_2PtCl_6$ leads to the formation of a mixture of $\alpha$- and $\beta$-adducts with the $\beta$-isomer predominating (35 : 65), when $(Ph_3P)_2NiCl_2$ is used as the catalyst the main product is the $\alpha$-isomer (80 : 20), [231] while the use of $\pi$-$C_5H_5(CO)Ni$ [240] and $Ni(CO)_4 + Ph_3P$ (1 : 2) [132] yields exclusively the $\alpha$-isomer. The yield of hydrosilylation products, which usually does not exceed 20% in the presence of the phosphonickel catalyst, can be raised to 75% by employing CuCl as the cocatalyst. The mixture then contains up to 95% of the $\alpha$-isomer[213].

Acrylonitrile, methyl acrylate, vinyl acetate, cyclohexa-1,4-diene, and isoprene give rise to normal addition products only, even in the presence of dichloro[1,1-bis-(dimethylphosphino)ferrocene]nickel(II), which caused a marked disproportionation of the silane (83% of chloromethyloctylsilane) in the addition of dichloromethylsilane to oct-1-ene[234]. The $NiCl_2$ complex with 1,2-bis(dimethylphosphino)-*o*-carborane [(Dmpc).$NiCl_2$], containing an electron-accepting ligand, promotes the formation of $\alpha$- and $\beta$-isomers even in reactions with alk-1-enes[237]. For example, when propene interacted with trichlorosilane at 120°C for 20 h in the presence of (Dmpc).$NiCl_2$ ($10^{-3}$ mole per mole of the olefin), the addition product consisting of dichloroisopropylmethylsilane and dichloromethyl-n-propylsilane in proportions of 41 : 59 was formed in 40% yield[237]:



$$CH_3CH{=}CH_2 + MeSiHCl_2 \rightarrow \underset{\displaystyle CH_3}{CH_3CHSiCl_2Me} + CH_3CH_2CH_2SiCl_2Me .$$

The reactions involving pent-2-ene and hex-2-ene result in the formation, together with n-alkyl derivatives (20–50%), also of the products of the addition of the hydrosilane to the double bonds of the non-isomerised alk-2-enes[237].

Using *trans*-$[(+)$-$(R)$-$(PhCH_2)MePhP]_2NiCl_2$, it was possible to achieve the asymmetric hydrosilylation of $\alpha$-methylstyrene with dichloromethylsilane, which gave 31% of the $\beta$-adduct with a 17.6% enantiomeric excess of the *R*-isomer[238].

Ziegler systems of the type $M(acac)_n$–$AlEt_3$ (M = Ni, Co, or Fe) catalyse the addition of trialkyl- and trialkoxysilanes to 1,3-dienes, promoting the formation of 1,4-adducts. The nickel catalysts are the most active among them[239,244].

The catalytic activity of the polymeric chelates of Group VIII metals with di-(8-hydroxy-5-quinolinyl)methane

is determined by the nature of the metal M. For example, the platinum chelate is active in the reaction of trichlorosilane with hex-1-ene (2 h, 100°C, yield 70%). When M = Ni, the yield of trichlorohexylsilane was only 5%, while the rhodium and palladium chelates do not catalyse the reaction. In the reaction with triethoxysilane, the rhodium chelate (92%) proved to be more active than the platinum chelate (85%), while the palladium and nickel chelates showed virtually no catalytic activity[165]. The nature of the metal determines also the ratio of the $\alpha$- and $\beta$-isomers in the reaction of trichlorosilane with styrene: 95% $\beta$ for M = Rh, 92% $\beta$ for M = Pt, and 19% $\alpha$ for M = Pd. [165] The reaction of trichlorosilane with buta-1,3-diene in the presence of the palladium chelate results in the formation of 86% of *cis*-1-trichlorosilylbut-2-ene, while in the presence of the platinum chelate a mixture of four products is formed: *cis*-1-trichlorosilylbut-2-ene (16%), *trans*-1-trichlorosilylbut-2-ene (37%), 1-trichlorosilylbut-3-ene (14%), and 1,4-bis(trichlorosilyl)butane (4%). [165]

$Co_2(CO)_8$, [31,185,193,245-247] $HCo(CO)_4$, [248-250] $(Ph_3P)_3CoH_3$, [251] and other cobalt complexes [245,251,252] have been used for the hydrosilylation of alkenes. Dicobalt octacarbonyl also catalysed the $\alpha$-addition of chlorodimethylsilane to acrylonitrile[185].

The hydrosilylation of $\alpha$-alkenes[253-256] and acetylenes[256] is also catalysed by $Fe(CO)_5$. Here the initial alkene reacts in four ways: it interacts with the hydrosilane to form both the addition product and the dehydrocondensation product, isomerises, and is hydrogenated[254]:

$$PrCH{=}CH_2 + MeEt_2SiH \xrightarrow{Fe(CO)_5} MeEt_2SiCH_2CH_2Pr + MeEt_2SiCH{=}CHPr + C_5H_{12} + \text{isomeric pentenes.}$$

Dimanganese decacarbonyl[245] and cyclopentadienylmanganese tricarbonyl[257,258] have also been used as hydrosilylation catalysts.

Copper compounds [$Cu_2O$, $Cu_2Cl_2$, and $Cu(acac)_2$] in mixtures with organic cyanides are effective catalysts of

the hydrosilylation of acrylonitrile, promoting the formation of the $\beta$-adduct in the reaction with both trichlorosilane (70–78%) and dichloromethylsilane (80%).[259]

The addition of hydrosilanes of different olefins in high yields is initiated by $\gamma$-radiation[260-267] in view of the absence of side reactions, which are unavoidable in thermal addition[1,268].

Peroxides have been rarely used in recent years for the initiation of the hydrosilylation of the C=C bond[269-272], although a new catalyst has in fact been proposed, namely dicyclohexyl peroxycarbonate[273]. At the same time, the hydrosilylation of the N=N bond was actually achieved for the first time in the presence of a peroxide[274].

It has also been shown that the use of peroxy-catalysts in conjunction with ultraviolet irradiation permits the hydrosilylation of $\alpha$-alkenes[275-278] and cyclohexene[275] with trichlorosilane at a low temperature (0–20°C). The yields of the addition products reach 80–95%. Dichloromethylsilane also reacts fairly satisfactorily with alk-1-enes, while triethylsilane, triphenylsilane, triethoxysilane, and 3*H*-heptamethyltrisiloxane do not react under these conditions (30–40°C, 38 h).[277] The use of bis-(trimethylsilyl)mercury as the sensitiser accelerates the addition of trichlorosilane to oct-1-ene under the influence of ultraviolet irradiation by a factor greater than two relative to the reaction initiated by t-butyl peroxide[275]. The photochemical hydrosilylation of 1,3-dienes by trialkylsilanes takes place in the 1,4-positions and is catalysed by chromium hexacarbonyl[279].

## III. THE PROPERTIES OF HYDROSILYLATION

### 1. The Reactivity of Hydrosilanes

Kinetic studies on the hydrosilylation of hept-1-ene in the presence of $H_2PtCl_6.6H_2O$ showed that the rate of reaction decreases with increase of electron density at the hydrogen atom[31]:

$$\begin{array}{cccc} HSiCl_3 > EtSiHCl_2 > Et_2SiHCl > Et_3SiH \\ 3.00 \quad 2.64 \quad 1.94 \quad 1 \end{array} .$$

However, the changes are not additive and are not correlated with the inductive Taft constants $\sigma^*$, so that the differences between the reactivities in this series of hydrosilanes cannot be accounted for solely by the inductive effects of the substituents.

The rate of hydrosilylation of hex-1-ene increases on passing from tripropylsilane to diethoxypropylsilane[31]:

$$\begin{array}{ccc} Pr(EtO)_2SiH > Pr_2EtOSiH > Pr_3SiH \\ 15.26 \quad 4.33 \quad 1 \end{array} .$$

When the reaction is carried out in the presence of $H_2PtCl_6.6H_2O$, triethoxysilane proves to be less reactive than diethoxypropylsilane[31]; on the other hand, in the presence of $(Ph_3P)_3RhCl$ or $Co_2(CO)_8$ triethoxysilane proves to be more reactive[193]:

| | $(EtO)_3SiH$ | $>$ | $Pr(EtO)_2SiH$ | $>$ | $Pr_2EtOSiH$ | $>$ | $Pr_3SiH$ |
|---|---|---|---|---|---|---|---|
| $(Ph_3P)_3RhCl$ | 42.8 | | 28.4 | | 5.4 | | 1 |
| $Co_2(CO)_8$ | 119.0 | | 59.5 | | 27.5 | | 1 |

When rhodium complexes with phosphine ligands on a modified silica gel are used in the reactions with hexene, heptene, and ethyl vinyl ether, triethoxysilane also exhibits an enhanced reactivity:

$$(EtO)_3SiH > Et_3SiH > HSiCl_3 .$$

Trichlorosilane proved to be most reactive in the reaction of decene in the presence of the analogous platinum catalyst[144]:

$$HSiCl_3 > (EtO)_3SiH > Et_3SiH .$$

The increase of the rate of reaction with decrease of electron density in the Si–H bond has also been observed in the addition of aryldimethylsilanes $p$-$XC_6H_4(CH_3)_2SiH$ to ethylene. The rate of reaction in the presence of $(Ph_3P)_3RhCl$ increases on passing from dimethyl-$p$-methoxy-, to dimethyl-$p$-chloro-phenylsilane[31]:

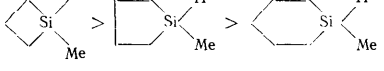
$$\begin{array}{ccc} Cl > H > MeO \\ 1.35 \quad 1 \quad 0.78 \end{array} .$$

It is noteworthy that, in hydrosilylation in the presence of platinum, rhodium, and ruthenium complexes, the rate of reaction depends also on the stability of the complex of the catalyst and the hydrosilane[280], which can lead to reactivity series inconsistent with the corresponding series based on the variation of reactivity established in the reactions involving $H_2PtCl_6$. For example, the yield of the product of the hydrosilylation of hexene in the presence of $(Ph_3P)_3RhCl$ decreases on passing from $Ph_3SiH$ (100%) to $Et_3SiH$ (60%) and $HSiCl_3$ (8%),[188]. The decrease of the yield of the hydrosilylation product with increase of the number of chlorine atoms has also been observed for chloroethylhydrosilanes[198], which is consistent with the series based on the increase of the stability of the complexes $(Ph_3P)_2RhH(SiCl_nR_{3-n})X$.[188] However, when a competition addition reaction was carried out, hydrosilanes with a greater number of chlorine atoms proved to be more reactive both in the presence of $(Ph_3P)_3RhCl$ [193] and $[(C_2H_4)_2RhCl]_2$.[198]

Hydrosilylation under the influence of dinuclear platinum complexes of styrene proceeds as a two-stage process owing to the conversion of the initial compounds into complexes with a much lower catalytic activity. The rates of cleavage of the olefinic complexes and of addition in the second stage of the reaction increase with decrease of the strength of the Si–H bond[98]:

$$MeSiHCl_2 > Me_2SiHCl > Me_3SiH .$$

Other reactivity series have also been obtained for hydrosilanes, namely for the hydrosilylation of $\alpha$-alkenes in the presence of $H_2PtCl_6$:[281]



$$\begin{array}{ccc} PrSiHCl_2 > EtSiHCl_2 > MeSiHCl_2 \\ 2.75 \quad 1.80 \quad 1 \end{array} .$$

and for the hydrosilylation of vinylsilanes in the presence of $H_2PtCl_6$:[282]

$$\begin{array}{ccccc} HSiCl_3 > MeSiHCl_2 > Me_2SiHCl > Et_3SiH \\ 6.75 \quad 2.88 \quad 1.62 \quad 1 \end{array} .$$

Analogous series were obtained for the hydrosilylation of octene in the presence of phosphinonickel complexes[234] and of allylmalonic acid esters in the presence of $H_2PtCl_6$.[283]

The reactivity of hydrosilacycloalkanes in the reaction with ethylene in the presence of 5% Pt/C decreases in the sequence[284]

Under these conditions, all the hydrosilacycloalkanes are much more reactive than their acyclic analogues[284]. In the competition reaction, the addition of the latter is inhibited until most of the hydrosilacycloalkane has reacted.

Furyl-[285], thienyl-[286], and ferrocenyl-hydrosilanes[287-290] are also very reactive.

In the reaction with $\alpha$-methylstyrene in the presence of $H_2PtCl_6$, cyclic hydrosilanes can be arranged in the following sequence in terms of decreasing reactivity:

$$(MeSiHO)_4 > (EtSiHO)_4 > (MeSiHNH)_4 > (EtSiHNH)_4 > (EtSiHS)_3 .$$

The series is consistent with the sequence based on the decrease of the electronegativity of the heteroatom[291,292].

Hydrosilazanes $(Me_2SiH)_2NR$ are also less reactive than the corresponding hydrosiloxanes[33,293]. The rate of their addition to allyldiethylamine decreases in the following sequence as a function of the group linked to the nitrogen atom[33,294]:

$$Ph > iso\text{-}Bu > H > Me, PhCH_2 .$$

The trisilylamines $(Me_3Si)_2NSiHMe_2$ and $(Me_2SiH)_3N$ react with olefins with difficulty in the presence of $H_2PtCl_6$.[269,295,296] This cannot be accounted for solely by the influence of steric factors, because under these conditions tris(dimethylsilyl)methane adds to octene with a satisfactory yield[269]. The increase of electron density at the silicon atom owing to the $p_\pi - d_\pi$ interaction in the N–Si bond plays a definite role in the decrease of the reactivity of compounds with an N–Si–H group. The sequence based on the decrease of reactivity

$$(Me_2SiH)_2NH > (Me_2SiH)_3N > Me_2SiHNR_2$$

shows that the reactivities of these compounds in the hydrosilylation reactions are determined by a set of different factors (conjugation, capacity for complex formation with the catalyst, and steric hindrance).

In contrast to trichlorosilane, in the reaction with alk-2-enes and alk-3-enes dichlorosilane forms in the presence of $H_2PtCl_6$ the corresponding 2- and 3-substituted derivatives instead of the n-alkyl derivatives[297].

Kinetic studies on the hydrosilylation of hexene, styrene, and its derivatives by organosilanes $RSiH_3$ in the presence of $H_2PtCl_6$ have led to the conclusion that hydrosilanes with aromatic groups are more reactive than alkylsilanes[24] and attack on the reaction centre by the olefin proceeds more readily the more marked are the electron-accepting properties of the substituent at the silicon atom[24,25,298]:

$$ClC_6H_4 > C_6H_5 > cyclo\text{-}C_6H_{11} > C_4H_9 > iso\text{-}C_5H_{11} .$$

The steric effects at the first stage of the reaction do not play a significant role. As the number of substituents on the hydrosilane increases, its reactivity falls[28]:

$$RSiH_3 > R_2SiH_2 > R_3SiH .$$

The hydrosilylation of *N*-propargylpiperidine, *N*-propargylperhydroazepine, and *N*-propargylmorpholine with triethylsilane in the presence of $H_2PtCl_6$ results in the formation of $\gamma$-adducts (relative to nitrogen) having the *trans*-configuration. On passing from triethylsilane to dibutylmethylsilane, 3*H*-heptamethyldisiloxane, and triethoxysilane, there is a gradual increase of the content of the $\beta$-adduct in the reaction products and for the last compound the yields of the $\gamma$- and $\beta$-adducts are almost equal[299].

The mode of hydrosilylation of styrene by halogenohydrosilanes in the presence of $H_2PtCl_6$ and the yield of products depend also on the nature of the halogen. The addition of alkylfluorosilanes leads to a mixture of $\alpha$- and $\beta$-isomers[300-302]. Under these conditions, the formation of the $\alpha$-isomer predominates in the presence of dialkylfluorosilanes[300]. Hydrofluorophenyl-, hydrofluorodiphenyl-, and hydrofluoro-$\alpha$-naphthyl-silanes are more reactive in competition addition reactions than the corresponding chlorohydrosilanes[303]. At the same time arylfluorohydrosilanes form a mixture of isomers with the $\alpha$-isomer predominating, while the arylchlorosilyl group adds only to the terminal carbon atom of the double bond[303,304].

The ratio of $\alpha$- and $\beta$-isomers formed in the hydrosilylation of acrylonitrile in the presence of the ternary catalyst $Bu_3N-(Me_2NCH_2)_2-CuCl$ decreases after the introduction of alkyl groups into the hydrosilane molecule[305]:

$$HSiCl_3 > PhSiHCl_2 > MeSiHCl_2 > Ph_2SiHCl > PhMeSiHCl > Me_2SiHCl .$$

The relative rate constants for the interaction of hexene with hydrosilanes under the influence of $\gamma$-radiation decrease in the following sequence[263]:

$$\begin{array}{ccccc} HSiCl_3 & > & Ph_3SiH & > & Et_3SiH \\ 100 & & 10 & & 1 \\ Ph_3SiH & > & Ph_2SiHCl & > & PhSiHCl_2 \\ 13.6 & & 2.4 & & 1 \end{array}$$

The first sequence can be accounted for by the activating influence of electronegative substituents on the reactivity of the intermediate radicals $X_3SiCh_3\dot{C}HR$, and the second by the possibility of the stabilisation of the chlorosilane radicals due to $p_\pi - d_\pi$ interaction.

## 2. The Influence of the Structure of the Unsaturated Compound on the Rate and Mode of Hydrosilylation

Certain regularities have also been established in the study of the influence of the structure of the unsaturated compound on the rate and mode of hydrosilylation. In the hydrosilylation of the C=C double bond in the presence of $H_2PtCl_6$, the reactivity of olefins is proportional to the electron density in the double bond[306]. Steric hindrance decreases the rate of reaction. The following reactivity series have been established for the addition of trichlorosilane to olefins at 120°C in the presence of $H_2PtCl_6$:[306]

$$\begin{array}{ccccccc} BuCH_2CH{=}CH_2 & > & Bu(CH_2)_4CH{=}CH_2 & > & cis\text{-}BuCH{=}CHMe & > & trans\text{-}BuCH{=}CHMe \\ 1.5 & & 1 & & 0.73 & & 0.5 \\ & & & > & cis\text{-}(trans\text{-})PrCH{=}CHEt & & \\ & & & & 0.35 & & \\ Me_3CCH_2CH{=}CH_2 & > & Me_3CCH{=}CH_2 & > & trans\text{-}Me_2CHCH{=}CHMe & & \\ 1.5 & & 1.06 & & 0.68 & & \\ & & PhCH_2CH{=}CH_2 & > & PhCH{=}CH_2 & & \\ & & 0.71 & & 0.54 & & \end{array} .$$

Another series was obtained in the hydrosilylation by alkyldichlorosilanes in the presence of $H_2PtCl_6$:[281]

$$\begin{array}{ccccc} PrCH{=}CH_2 & > & BuCH{=}CH_2 & > & AmCH{=}CH_2 \\ 1.39 & & 1.16 & & 1 \end{array} .$$

In the presence of $H_2PtCl_6$ [297] and $[(C_2H_4)_2RhCl]_2$, [198] alk-2-enes and alk-3-enes react with greater difficulty than alk-1-enes. Thus, whereas the yield of trichloro-n-heptylsilane in the reaction of trichlorosilane with hept-1-ene in the presence of $[(C_2H_4)_2RhCl]_2$ is 54% (85°C, 2 h), its yield in the reaction with *cis*-hept-2-ene does not exceed 10%, while in the reaction with *trans*-hept-2-ene it is only 1%.[198] On the other hand, in the presence of $(Ph_3P)_4Pt$ [137] and peroxides [271], the alkenes could not be hydrosilylated at all.

The hydrosilylation of compounds whose molecules contain several double bonds permits the comparative estimation of their reactivities. Thus the addition of dichloromethylsilane to hexa-1,5-diene (equivalent double

bonds) in the presence of $H_2PtCl_6$ involves both bonds[70,307], while in the addition to the natural terpene myrcene

$$(CH_3)_2\overset{(c)}{C}=CHCH_2CH_2C(\overset{(b)}{CH_2})-\overset{(a)}{CH}=CH_2,$$

which has three types of double bonds, the reactivity of the latter in the reaction with trichlorosilane in the presence of $H_2PtCl_6$ decreases in the sequence (a) > (b) > (c).[308,309]

The study of the hydrosilylation of unsaturated silanes containing two different unsaturated groups at the silicon atom by chlorodimethylsilane in the presence of $H_2PtCl_6$ made it possible to establish the following reactivity series[282]:

$$HC\equiv C>CH_2=CH>CH_2=CHCH_2>CH_2=C(CH_3)CH_2>CH_2=CH>CH_2=CHC_6H_4.$$

In the reaction with phenylsilane, the reactivity of unsaturated compounds decreases in the sequence[25,298,310]:

$$p\text{-}CH_3C_6H_4CH=CH_2>PhCH=CH_2>p\text{-}ClC_6H_4CH=CH_2.$$

A similar behaviour, involving an increase of the conversion and of the rate of reaction with increase of electron density in the double bond, was observed also in the hydrosilylation of substituted styrenes by dichloromethylsilane in the presence of the platinum–styrene complexes[98].

Certain other reactivity series of unsaturated compounds have also been obtained[291,311]; in reactions with hydrocyclosiloxanes:

$$PhCH=CH_2>PhCH(CH_3)=CH_2>CH_2=C(CH_3)COOMe>CH_2=CHCH_2CN;$$

in reactions with hydrocyclosilazanes:

$$PhCH=CH_2>CH_2=C(CH_3)COOMe>CH_2=CHCH_2CN>CH_2=CHCN;$$

in reactions with hydrocyclosilthianes:

$$PhCH(CH_3)=CH_2>CH_2=CHCH_2CN>CH_2=CHCN.$$

In the hydrosilylation of monosubstituted acetylenes $RC\equiv CH$ by triethylsilane in the presence of $H_2PtCl_6$, the amount of $\beta$-isomers increases with enhancement of the electron-donating properties of R.[21,312] The use of tetrahydrofuran as the reaction medium decreases the amount of the $\alpha$-isomer[21,313,314].

## IV. NEW APPLICATIONS OF HYDROSILYLATION

During recent years, it has been possible to achieve for the first time the hydrosilylation of the C=N, N=N, and N=O bonds.

Triethylsilane adds to *N*-substituted aldimines in the presence of $ZnCl_2$ at 150°C:[315]

$$PhCH=NR + HSiEt_3 \rightarrow PhCH_2N(R)SiEt_3.$$

Nickel and platinum halides behave similarly[316]. Rhodium complexes are much more active catalysts of the hydrosilylation of ketimines by trialkylsilanes and diorganosilanes, which makes it possible to carry out the addition at a lower temperature (30–50°C).[220,222] Their reactivity decreases in the sequence[221]

$$(Ph_3P)_3RhCl \gg (Ph_3P)_2Rh(CO)Cl > [(\text{hexa-1,5-diene})RhCl]_2 > [(\text{cyclo-octa-1,5-diene})RhCl]_2 > PdCl_2 > (Ph_3P)_2PdCl_2.$$

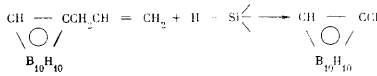
Palladium catalysts are less active but they can be used also for the addition of trialkylsilanes to the isocyanate group[317].

Trimethylsilane reacts with pyridine in the presence of palladium on charcoal (30°C, 25 h) with formation of *N*-trimethylsilyl-1,2-dihydropyridine (25%), *N*-trimethylsilyl-1,4-dihydropyridine (35%), *NN'*-bis(trimethylsilyl)-1,1'-dihydro-4,4'bipyridyl (25%), *N*-trimethylsilyl-1,2,3,6-tetrahydropyridine (12%), and many other trimethylsilylhydropyridines[318–321]. The Pd/C catalyst is more active than Rh/C, $PdCl_2$, Pt/C, and Ru/C. However, Rh/C acts more selectively, directing the process mainly towards the formation of *N*-trimethylsilyl-1,4-dihydropyridine[320,321]. In the reaction involving 3-methylpyridine in the presence of Pd/C, there is quantitative addition to the 1,4-positions. 4-Methylpyridine reacts four times as slowly as pyridine and the addition of trimethylsilane to 2-methylpyridine could not be achieved at all[321].

Triphenylsilane adds to the N=N bond of diethylazodicarboxylate in the presence of t-butyl peroxide in boiling benzene. The reaction proceeds slowly: the attainment of a 70% yield of the product requires eleven days. The addition was much faster under ultraviolet irradiation in the presence of t-butyl peroxide (3.5 h, yield 77%):[274,322]

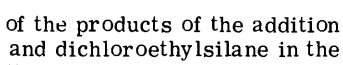
$$EtOOCN=NCOOEt + HSiPh_3 \rightarrow EtOOCN(SiPh_3)-NHCOOEt.$$

At a higher temperature (140°C), triphenylsilane adds to azobenzene (yield 30%):[322]



$$PhN=NPh + HSiPh_3 \rightarrow PhNHNPhSiPh_3.$$

Trimethylsilane adds to the N=O bond in trifluoronitrosomethane both under the influence of ultraviolet light and in the presence of $H_2PtCl_6$:[323]



$$CF_3N=O + HSiMe_3 \rightarrow CF_3NHOSiMe_3 + (CF_3)_2NOSiMe_3.$$

Together with the normal addition products (43 and 74% respectively), the *O*-trimethylsilyl derivative of bis(trifluoromethyl)hydroxylamine is also formed (28 and 16%).[323] Under the influence of ultraviolet light, trichlorosilane adds slowly to trifluoronitrosomethane (15 h, yield 17%). Trifluorosilane is much more reactive under these conditions (yield 80%).[324]

The addition of chlorohydrosilanes[325–330], alkoxyhydrosilanes[331–333], and hydrosiloxanes[326,334–338] to alkenylcarboranes in the presence of Pt/C, $H_2PtCl_6$, $FeCl_3$, or in the absence of catalysts (>200°C) leads to the corresponding alkylcarboranylsilanes and carboranylsiloxanes:

Trichlorosilane adds to 2-vinylfuran in the presence of $H_2PtCl_6$ on heating a tetrahydrofuran solution in a closed vessel to 80–85°C. After heating for 18 h, the yield of the hydrosilylation product is 60%:[339]

The yield of the products of the addition of dichloromethylsilane and dichloroethylsilane in the presence of $H_2PtCl_6$ is 70%, while the yield of the addition reactions involving ethoxy- and acetoxy-silanes is lower (approximately 50%) and that of the reactions with trialkylsilanes is lower still (approximately 30%).[339,340]

Unsaturated derivatives and other oxygen-containing heterocycles, namely oxetan[341–343] and tetrahydropyran[344–348], have been hydrosilylated.

It has been shown that alkenyl sulphides[349-353] combine with various hydrosilanes in the presence of platinum catalysts, like unsaturated ethers[1,3]:

$$RSCH_2CH{=}CH_2 + H{-}Si\langle \rightarrow RSCH_2CH_2CH_2Si\langle \ .$$

The hydrosilylation of unsaturated sulphones proceeds in the same way[354].

In the presence of several double bonds in the molecule whose positions relative to the sulphur atom are different, the bond most remote from the sulphur atom is the first to be hydrosilylated[355]:

$$CH_2{=}CH(CH_2)_nSCH{=}CH_2 + H{-}Si\langle \rightarrow \rangle SiCH_2CH_2(CH_2)_nSCH{=}CH_2 \ .$$

When the reaction was initiated by ultraviolet light, it was possible to achieve the quantitative addition of trichlorosilane, dichloromethylsilane, and trimethylsilane to bis(trifluoromethyl)aminoethylene[356,357]:

$$(CF_3)_2NCH{=}CH_2 + HSiCl_3 \rightarrow (CF_3)_2NCH_2CH_2SiCl_3 \ .$$

Azines derived from unsaturated ketones[358,359], 1-vinylsilatrane[369], and ketenes[361,362] have been hydrosilylated in the presence of $H_2PtCl_6$:

$$[CH_2{=}CHCH_2CH_2C(CH_3){=}N{-}]_2 + H{-}Si\langle \rightarrow \left[\rangle Si(CH_2)_4C(CH_3){=}N{-}\right]_2 \ ;$$

$$N(CH_2CH_2O)_3SiCH{=}CH_2 + H{-}Si\langle \rightarrow N(CH_2CH_2O)_3SiCH_2CH_2Si\langle \ ;$$

$$R_2C{=}C{=}O + H{-}Si\langle \rightarrow R_2C{=}CHOSi\langle \ .$$

It has been shown for the reaction with optically active hydrosilanes that the hydrosilylation of alkenes in the presence of $H_2PtCl_6$ and $[(C_2H_4).PtCl_2]_2$ proceeds with retention of configuration[90,363,364], which confirms to a certain extent the coordination reaction mechanism put forward[2,12,16,25,28,31,77,86,90,291,298,306,364-367].

## V. ANOMALOUS AND SIDE REACTIONS

In many cases the hydrosilylation of alkenes is accompanied by other processes associated with the reactions of the initial olefin, hydrosilane, or reaction intermediates. The commonest reactions of this kind are isomerisation[86,143,185,188,197,198,254,256,296,368,369] and hydrogenation[25,254,310] of the initial alkene and in some cases telomerisation[187,270].

The reaction of trichlorosilanes with 1-propylcyclohexene in the presence of $H_2PtCl_6$ proceeds with migration of the double bond and involves the formation of trichloro-3-cyclohexylpropylsilane, while the unreacted olefin consists of 1-propylcyclohexene (33%), 3-propylcyclohexene (3%), 4-propylcyclohexene (3%), and 1-propenylcyclohexane (2%):[85]

$$\bigcirc{-}C_3H_7 + HSiCl_3 \rightarrow \bigcirc{-}(CH_2)_3SiCl_3 \ .$$

Isomerisation is observed also in the hydrosilylation of $\beta$-pinene[370,371], and bicyclo[2,2,1]hepta-2,5-diene[372].

The hydrosilylation of arylalkenes $Ph(CH_2)_nCH{=}CH_2$ ($n$ = 1 or 2) and $PhCH{=}CH(CH_2)_mH$ ($m$ = 0-4) in the presence of $H_2PtCl_6$ is accompanied by isomerisation and leads to the formation of two products: with a terminal silyl group and with a silyl group located at the carbon atom adjoining the phenyl group[303]. For example:

$$PhCH_2CH{=}CH_2 + HSiCl_3 \rightarrow Ph(CH_2)_3SiCl_3 + PhCH(SiCl_3)CH_2CH_3 \ ;$$
$$PhCH{=}CHCH_3 + Me_2SiHCl \rightarrow Ph(CH_2)_3SiClMe_2 + PhCH(SiClMe_2)CH_2CH_3 \ .$$

With increase of $n$, the amount of the isomer with a terminal silyl group increases, falling as $m$ increases. The yield of this isomer rises in the following sequence of hydrosilanes[303]:

$$Me_2SiHCl > MeSiHCl_2 > HSiCl_3 \ .$$

The hydrosilylation of monosubstituted acetylenes in the presence of a mixture of nickel acetylacetonate and triethylaluminium is accompanied by dimerisation[239]:

$$2\,RC{\equiv}CH + HSiX_3 \rightarrow CH_2{=}CRCR{=}CHSiX_3 + RCH{=}CHCR{=}CHSiX_3 \ .$$

Dimerisation also occurs in the hydrosilylation of buta-1,3-diene in the presence of palladium catalysts[140,169,170]:

$$CH_2{=}CHCH{=}CH_2 + R_3SiH \rightarrow CH_3CH{=}CHCH_2CH_2CH{=}CHCH_2SiR_3 \ .$$

Various side reactions can occur in the hydrosilylation of unsaturated compounds containing functional groups capable of reacting with hydrosilanes. Thus, whereas trialkylsilanes add to perfluorocyclobutene on heating to 250°C, the reaction with 1,2-dichloro-3,3,4,4-tetrafluorocyclobutene under analogous conditions involves condensation and reduction instead of addition[373]:

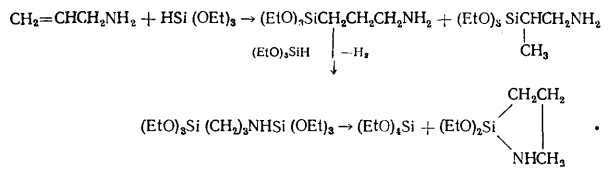
$$\begin{matrix} CF_2{-}CCl \\ | \quad \| \\ CF_2{-}CCl \end{matrix} \xrightarrow{R_3SiH} \begin{matrix} CF_2{-}CCl \\ | \quad \| \\ CF_2{-}CSiR_3 \end{matrix} + \begin{matrix} CF_2{-}CH \\ | \quad \| \\ CF_2{-}CCl \end{matrix} + R_3SiCl + HCl \ .$$

The hydrosilylation of allyl chloride[374,375] and methylallyl chloride[376] in the presence of $H_2PtCl_6$ is also accompanied by reduction. The ratio of the addition and reduction products depends on the structure of the hydrosilane, decreasing as chlorine atoms are replaced by methyl, phenyl, and ethoxy-groups[374,375]:

$$\underset{5.7}{HSiCl_3} > \underset{2.7}{MeSiHCl_2} > \underset{1.82}{PhSiHCl_2} > \underset{1.45}{Me_2SiHCl} > \underset{1.2}{MePhSiHCl} > \underset{0.38}{Ph_2SiHCl} > \underset{0.11}{MePh_2SiH}$$
$$EtSiH_2Cl > EtSiHCl_2 > Et_2SiHCl > (EtO)_3SiH > Et_3SiH$$

In the presence of $H_2PtCl_6$, triphenylsilane and methyldiphenylsilane reduce the nitro-group of $m$-nitrostyrene, while alkylchlorohydrosilanes add to the C=C double bond without affecting the nitro-group[377].

In the hydrosilylation of unsaturated esters by chlorohydrosilanes and alkoxyhydrosilanes, the cleavage of the C-O bond is also frequently observed[378-382]. For example, the hydrosilylation of allyl trifluoroacetate by dichloromethylsilane in the presence of $H_2PtCl_6$ involves the formation, together with dichloro-[3-(trifluoroacetoxy)-propyl]methylsilane (52%), of a number of other cleavage, reduction, and further reaction products[384]:



$$CF_3COOCH_2CH{=}CH_2 + MeSiHCl_2 \rightarrow \begin{cases} CF_3COO(CH_2)_3SiCl_2Me & (52.2\%) \\ CF_3COOCH_2CH_2CH_3 & (3.3\%) \\ CH_3SiHCl(OCOCF_3) & (\sim 13\%) \\ + \ MeSiCl_3 & (9.4\%) \\ + \ PrSiCl_2Me & (12.2\%) \\ + \ CF_3COO(CH_3)_3Si(OCOCF_3)ClMe & (7,3\%) \end{cases} .$$

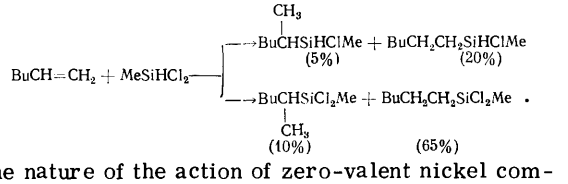
The addition of trichlorosilane to vinyl acetate under the influence of $\gamma$-radiation is accompanied by the reduction of the carbonyl group to the methylene group[265]:

$$CH_3COOCH{=}CH_2 + HSiCl_3 \rightarrow CH_3CH_2OCH_2CH_2SiCl_3 \ .$$

Belyakova et al.[385] was the first to show convincingly that the hydrosilylation of unsaturated compounds containing other functional groups[1,3] in the presence of $H_2PtCl_6$

may involve the silylation not only of the hydroxy- or carboxy-group, but also of the primary amino-group:

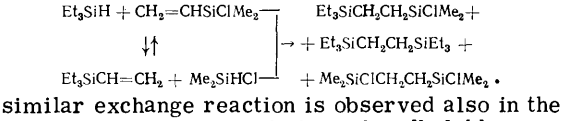
In hydrosilylation in the presence of platinum catalysts, the disproportionation of the initial hydrosilane is sometimes observed[296, 369, 375, 384, 386-390], for example:



$$2\,PhSiHCl_2 \rightarrow Ph_2SiHCl + HSiCl_3\ ;$$

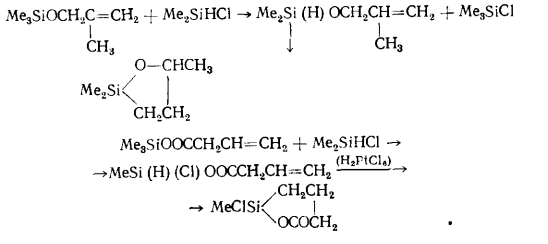
$$2\,Et_2SiHF \rightarrow Et_2SiH_2 + Et_2SiF_2\ .$$

In the presence of nickel catalysts this takes place to a more marked extent. The disproportionation of the hydrosilane in the hydrosilylation of alkenes, styrene, cyclohexene, and cyclo-octadiene in the presence of phosphinonickel complexes involves the formation of two different adducts[233, 234]:



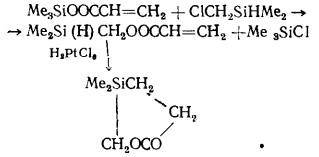
$$RCH{=}CH_2 + MeSiHCl_2 \rightarrow RCH_2CH_2SiCl_2Me + RCH_2CH_2SiHClMe + MeSiCl_3\ .$$

When the reaction of dichloromethylsilane with hex-1-ene is carried out in the presence of $[Me_3SiCH_2PBu_2]_2NiBr_2$ (120°C, 6 h), as many as four adducts are formed[232]:



The nature of the action of zero-valent nickel complexes, for example $(Ph_2PCH_2)_2(C_2H_4)Ni$, is comparable to that of the action of the corresponding nickel(II) complexes, but in the presence of the latter the induction period is longer[233]. The yield of the reaction product and the ratio of the anomalous and normal adducts increase with increase of the electron-donating capacity of the ligands and substituents in the olefin[234].

The reaction of triorganosilanes with chlorovinylsilanes is accompanied by the exchange of the hydrogen atom and the vinyl group of the initial silanes[391]:



A similar exchange reaction is observed also in the hydrosilylation of alkoxyvinylsilanes by alkylchlorohydrosilanes[392] and of pentamethylvinyldisilane by dichloromethylsilane[393].

The hydrosilylation of trimethylsilyl ethers of unsaturated alcohols[389, 394-396] and esters of unsaturated acids[397-399] by chlorodimethylsilane in the presence of $H_2PtCl_6$ is accompanied by the transilylation of the initial unsaturated silane with subsequent cyclisation owing to the intramolecular hydrosilylation of the intermediate allyloxy- and acyloxy-hydrosilanes, for example:

The interaction of acryloyloxytrimethylsilane with (chloromethyl)dimethylsilane proceeds with dissociation of the C–Cl bond and the formation of a six-membered lactone[400]:

During the recent 1½ years (from January 1975 to July 1976), 200 new studies on the hydrosilylation reaction were published, which indicates the growing popularity of this method of synthesis of organosilicon monomers and polymers.

A detailed study was made of the catalytic activity of nickel catalysts in reactions with carbonyl compounds[401-404] and of rhodium catalysts in reactions with olefins[405]. It has been shown[406] that $(Ph_3P)_3RhCl$ is an effective catalyst of the hydrosilylation of acrylonitrile not only by chlorohydrosilanes but also by trialkylsilanes (the $\alpha$-isomers are formed). The hydrosilylation of buta-1,3-diene has been investigated in detail in the presence of rhodium[407], palladium[408, 409], and nickel[410, 411] catalysts. New catalytic systems have been proposed for this reaction: nickel[412] or cobalt[413] salts mixed with sodium hydrodi-(2-methoxyethoxy)aluminate.

The study of hydrosilylation established that the reactivities of hydrosiloxanes[414] and vinylsiloxanes[415] $Me_{3-n}RSi(OSiMe_3)_n$ (R = H or vinyl) in this reaction decrease with increase of $n$. In the hydrosilylation of acetylenic compounds[416-420], the reaction rate increases with electron density in the triple bond and is to a large extent determined by the steric properties of the groups attached to the silicon atom.

It has been found that the hydrosilylation of divinyl sulphide by diethylsilane is accompanied by cyclisation with formation of a derivative of a new heterocyclic system—3,3-diethyl-2,4-dimethyl-1-thia-3-silacyclobutane[421].

Studies on the asymmetric hydrosilylation[422-428] of the C=C, C=N, and C=O bonds are developing to an increasing extent, which is of interest both for the synthesis of chiral amines and alcohols with a high optical purity and for the determination of the mechanism of the hydrosilylation reaction.

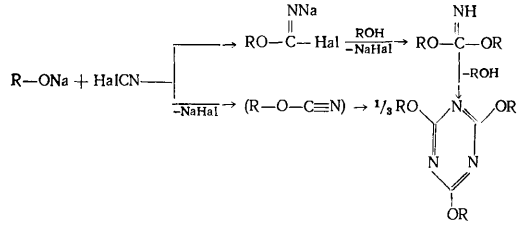
# The Synthesis of Polycyanates by the Polycyclotrimerisation of Aromatic and Organoelement Cyanate Esters

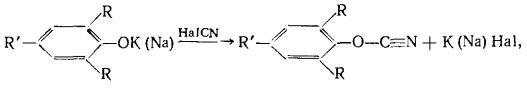
V.A.Pankratov, S.V.Vinogradova, and V.V.Korshak

Studies on the synthesis and properties of a new class of heat-resistant and thermostable polymers, obtained by the polycyclotrimerisation of aromatic and organoelement cyanate esters, are examined. Attention has been concentrated on studies devoted to the given reaction, the influence of the structure of polycyanates on their properties, and the specific features of these polymers due to the regularity of their structure. A number of general characteristics of polycyclotrimerisation, i.e. its usefulness as a method of synthesis of cross-linked thermostable polymers, are discussed. The bibliography includes 160 references.



CONTENTS

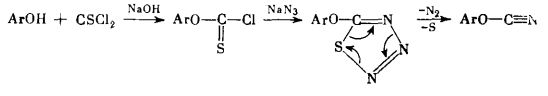
I. Introduction 278
II. The characteristics of the polycyclotrimerisation reaction of cyanate esters 279
III. Individual examples of polycyanates 281
IV. The specific features of the properties and structures of polycyanates 286



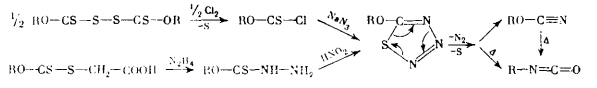
## I. INTRODUCTION

Cyanic acid HO–C≡N is involved in 1,3-prototropic tautomerism with isocyanic acid O=C=NH as a result of which esters of both cyanic acid (R–O–C≡N, cyanates) and the isomeric esters of isocyanic acid (R–N=C=O, isocyanates) are known. However, whereas isocyanates were discovered by Wurtz in the initial period of the development of organic chemistry in 1849,[1] the first examples of cyanates were synthesised by Stroh and Gerber as late as 1960.[2] Isocyanates assumed practical importance only 100 years after their discovery. Judging from the vigorous development of research on the chemistry of cyanates, one may predict with confidence that the corresponding period for these substances will be much shorter.

The attempts to synthesise cyanate esters were begun in 1857[3-13]. In the main, investigators tried to solve this problem by the reaction of phenoxides (or alkoxides) with halogenocyanogens[3-11], but cyanate esters were not isolated and the main reaction products were cyanuric acid esters. It was shown that an imino-ester of carbonic acid is formed as an intermediate under these conditions[9,13] and that the reaction mechanism can be represented as follows:



Nevertheless Stroh and Gerber[2] and later other investigators[14,15] succeeded in synthesising cyanate esters in this way from sterically hindered phenols:



where R = t-$C_4H_9$ and R′ = $C_6H_5$.

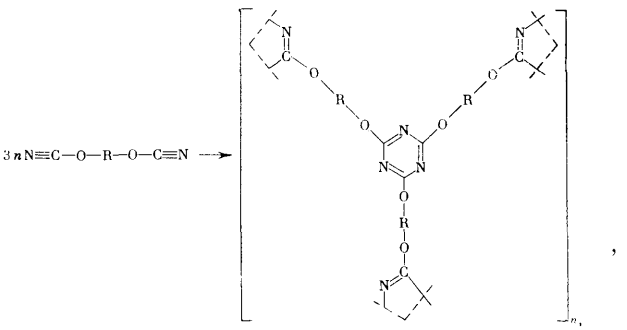
It was not until 1964 that several new methods of synthesis of compounds of this class were proposed[16-22]. Martin and coworkers[16-19] obtained aromatic and then aliphatic cyanates by the thermolysis of 1,2,3,4-thiatriazoles via the following mechanism:

Jensen and Holm[20,21] achieved the synthesis of aliphatic cyanates using a somewhat different scheme:

A method of synthesis of cyanate esters from phenols and acid alcohols involving their interaction with a halogenocyanogen in the presence of a hydrogen halide acceptor, which is promising from the standpoint of its application in industry, has been proposed by Grigat and Pütter[22]:

The reaction takes place at temperatures between −20° and +20° C in an organic solvent (for example acetone) and the yields of cyanates are nearly quantitative.

A number of other methods of synthesis of cyanates have been described in the literature[23-28], but they suffer from disadvantages such as a large number of stages and low yields, as a result of which they are less promising for practical purposes.



Bearing in mind that a number of reviews on the synthesis and properties of cyanate esters have already been published[29-34], we shall not concern ourselves in the present review with this field and attention will be concentrated on polymers based on cyanates and the processes leading to their formation.

The studies in the field of polymers based on cyanate esters developed only in the last decade. However, a sufficient number of data on these polymers, which are of interest from both theoretical and practical points of view, are already available and need to be surveyed. This applies particularly to research on the polycyclotrimerisation of cyanates, which has led to the discovery of many interesting general features of this new and promising method of synthesis of cross-linked thermostable polymers.

Studies on the polycyclotrimerisation of cyanate esters have been mainly designed to investigate the features of this reaction and the synthesis of new structures as well as various properties of polycyanates. The literature data have been reviewed in the same order in the present article. In addition, we shall consider also the few studies described in the literature on the synthesis of other less thoroughly investigated cyclopolymers based on cyanate esters.

## II. THE CHARACTERISTICS OF THE POLYCYCLOTRIMERISATION REACTION OF CYANATE ESTERS

The polycyclotrimerisation reaction of dicyanate esters with formation of cross-linked polymers (polycyanates) proceeds via the mechanism:

where R are different aromatic and organoelement groups.

Aryl cyanates are more reactive than nitriles because of the more electrophilic properties of the carbon in the N≡C group owing to the electron-accepting effect of the aryloxy-group[35,36]. Martin and Brause[36] established that the oxygen atom in the compounds HR–O–C≡N has an electron-donating effect on the aromatic group and at the same time enters into mesomeric interaction with the carbon of the nitrile group. However, the involvement of the unpaired electrons of oxygen in the mesomerism of the ring is greater than in the mesomerism of the nitrile group of aryl cyanates:

which promotes the enhancement of the electrophilic properties of the carbon of the N≡C group.

At the same time, like nitriles, aryl cyanates exhibit nucleophilic properties due to the presence in the N≡C group of the lone electron pair of the nitrogen atom and of electron-donating π-bonds. The cyclotrimerisation of cyanates is therefore accelerated by catalysts of both anionic and cationic type, depending on whether the nucleophilic nitrogen atom or the electrophilic carbon atom is attacked.

In recent years, Korshak and coworkers[37,38] put forward the concept of the heterogeneity of polymer linkages owing to the occurrence of a number of side reactions, apart from the main reaction involving the formation of the polymer system. Such "defectiveness" of the structure of a particular polymer leads in most cases to an impairment of properties such as heat resistance and thermal stability, physicomechanical parameters, etc.

It has been shown in many studies on the polymerisation of isocyanates, ethynyl derivatives, nitriles, and other compounds that the polycyclotrimerisation of these compounds involves, apart from the main process, numerous side reactions (chain polymerisation, dimerisation, etc.). Methods of synthesis excluding these side reactions have not so far been found[39-52] and the synthesis of polymers with a virtually defect-free structure is an urgent problem whose solution will permit a considerable improvement of many of their parameters and may lead to the formation of materials with qualitatively new properties.

A high selectivity in the cyclotrimerisation of the N≡C–O groups is characteristic of the polycyclotrimerisation of dicyanates with formation of cross-linked polymers. This is one of the fundamental features of the polycyclotrimerisation of these groups, which distinguishes them from other functional groups, such as the nitrile, isocyanate, ethynyl, etc. groups.

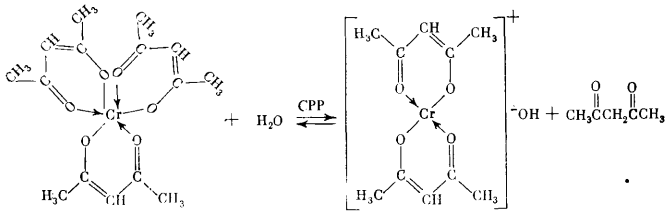
Furthermore, an exceptionally important feature is that, when the process is carried out under certain conditions, the cyclotrimerisation of the N≡C–O groups of tricyanates proceeds with virtually quantitative conversion. All these factors promote the achievement of "pure" polycyclotrimerisation with few defects and the formation of highly cross-linked polymers with a regular chemical structure[53-65].

Indeed the cyclotrimerisation of monofunctional cyanate esters led to the isolation of cyanurates in quantitative yields and no side products (dimers, linear polymers, etc.) could be detected chromatographically or by other methods[29,30,55,57,58]. Comparison of the spectroscopic and other characteristics of the polymers, obtained by polycyclotrimerisation and by specific synthesis from cyanuryl chloride and bisphenols, demonstrated their complete identity[54,55]. The absence of the signal characteristic of polyconjugated systems from the ESR spectra of polycyanates fails to confirm the possibility of the linear polymerisation of the N≡C groups of cyanates[55]. Furthermore, in the study of the polymerisation of dicyanates by infrared spectroscopy, it was not possible to detect either the dimerisation or isomerisation of the N≡C–O group; the infrared spectra did not contain absorption bands characteristic of linear acomethine structures either. In the discussion of the properties of polycyanates below, we shall consider also other direct and indirect evidence indicating the high selectivity of the cyclotrimerisation of NCO groups in the synthesis of these polymers.

One must nevertheless stipulate that the possibility of side reactions cannot of course be fully ruled out in the polycyclotrimerisation of aromatic cyanate esters. However, bearing in mind the entire set of the available literature data on this process, these reactions presumably take place to only a slight extent.

The comparative catalytic activities of various protic and aprotic acids and bases as well as their mixtures were investigated, using as an example 2,2-di-(4-cyanatophenyl)-propane, in the bulk polycyclotrimerisation of aryl dicyanates[56]. It was found that in the initial stages the polycyclotrimerisation of the N≡C–O groups of aryl dicyanates obeys the relations of the quasi-unimolecular reaction. The rate constants and activation energies for this process, carried out in the presence of various types of catalysts, were calculated and it was shown that the catalytic activities of tertiary amines and phenols are proportional to their $pK_a$ values and increase with the basicity of amines and the acidity of phenols. The corresponding correlations have been deduced.

The influence of the chemical structure of initial dicyanates of the type



$$NCOC_6H_4—A—C_6H_4OCN,$$

where A = $CH_2$, $C(CH_3)_2$, $C(CF_3)_2$, $CHC_6H_5$, or $C(CH_3)(C_6H_5)$, on their reactivity in polycyclotrimerisation in the presence of zinc chloride has been investigated and it has been shown that the rate of the process in the first stage is determined by the inductive effect of the substituents at the central carbon atom of the initial dicyanate, increasing as they become more electronegative. At more advanced stages of the reaction of the N≡C–O groups of the dicyanate, the rate depends also on the steric factors of the substituents at the central carbon atom of the dicyanate[56].

A series of studies by Bonetskaya and coworkers[57,59-62] were devoted to a detailed investigation of the kinetics and heats of the cyclotrimerisation and polycyclotrimerisation of aryl cyanates. Thus the kinetics of the cyclotrimerisation of phenyl isocyanate to triphenyl cyanurate have been investigated in solution in ditolylmethane in the presence of chromium(III) acetylacetonate with the aid of a double calorimeter[57] and it was shown that the reaction is autocatalytic. Its maximum rate is proportional to the catalyst concentration and the square of the monomer concentration. The heat of cyclotrimerisation of phenyl cyanate was determined as $\Delta H = -28.1 \pm 1.0$ kcal mole$^{-1}$. The stabilisation energy of the *s*-triazine ring has also been estimated and it has been noted that the ring is stabilised both as a result of the delocalisation of electrons with formation of a system resembling the π-electron system of the benzene ring and by the partial polarisation of the ring nitrogen–carbon bond. In order to estimate the stabilisation energy of the *s*-triazine ring, the experimental heat of the cyclotrimerisation of phenyl cyanate (PC) to triphenyl cyanurate (TPC) was compared with the heat of this reaction in the gaseous state ($\Delta H = -58.2$ kcal mole$^{-1}$). The latter quantity was calculated from the heats of formation of phenyl cyanate and triphenyl cyanurate evaluated additively from the increments for the corresponding groups[66] ($\Delta H_f = 29.7$ and 30.9 kcal mole$^{-1}$). The authors regard the difference $\Delta H = 26$ kcal mole$^{-1}$ between the experimental and theoretical heats as the stabilisation energy of the *s*-triazine ring (the stabilisation energy of the benzene molecule is approximately 36 kcal mole$^{-1}$).[57]

The kinetics of the polycyclotrimerisation of 2,2-di-(4-cyanatophenyl)propane (CPP) have been investigated and its heat measured by direct calorimetric determinations under conditions analogous to those of a model reaction[59-61]; it was established that the polycyclotrimerisation of CPP involves mainly the same kinetic features as the cyclotrimerisation of phenyl cyanate. The average heat of polycyclotrimerisation of CPP is[59,60] $\Delta H = -56.8$ kcal mole$^{-1}$, i.e. 28.4 kcal mole$^{-1}$ per N≡C–O group. The close agreement of this value with the heat of cyclotrimerisation of phenyl isocyanate ($\Delta H = -28.1$ kcal mole$^{-1}$) confirms, according to the author, the high selectivity of the polycyclotrimerisation of aryl dicyanates.

The cyclotrimerisation of aryl cyanates in the presence of chromium(III) acetylacetonate is autocatalytic (the variation of the rate with time passes through a maximum), although the reaction products [triphenyl cyanurate when phenyl cyanate is the starting material and oligomers in the polycyclotrimerisation of 3,2-di-(4-cyanatophenyl)propane] do not catalyse the process[57,59-62]. One of the causes of autocatalysis is probably the fact that chromium(III) acetylacetonate is catalytically inactive in the initial state. It was established[59] that the presence of traces of water in the reaction system has an appreciable influence on the rate of polycyclotrimerisation of CPP and traces of acetylacetone in the reaction mass after the latter had been thermostatted at 140°C were detected by gas–liquid chromatography. It was found that the addition of water to the reaction system increases and that of acetylacetone decreases the rate of reaction[62]. The results suggested that the active form of the catalyst is formed with participation of water and is in equilibrium with the normal form of the catalyst:

The autocatalytic nature of the cyclotrimerisation of aryl cyanates in the presence of chromium(III) acetylacetonate is associated with the accumulation of the active form of the catalyst as the reaction proceeds.

The enthalpy, entropy, and Gibbs free energy of the polycyclotrimerisation of crystalline and liquid CPP to a regularly cross-linked amorphous polymer have been calculated[63] (Table 1). The enthalpy of polymerisation found at 420 K (147°C), i.e. $-\Delta H_{pol} = 53.2$ kcal mole$^{-1}$, agrees within the limits of experimental error with the enthalpy of polymerisation determined by direct calorimetric measurements ($-\Delta H_{pol} = 56.8$ kcal mole$^{-1}$),[60] which confirms yet again that the polycyclotrimerisation of aryl dicyanates always proceeds in the same way. The decrease of entropy on polymerisation with formation of cross-linked systems, determined for the first time by Lebedev et al.,[63] proved to be −36 e.u., which is approximately 30% larger than for linear polymerisation.

Table 1. Thermodynamic parameters of the polycyclotrimerisation of 2,2-di-(4-cyanatophenyl)propane*.

| *T*, K | $-\Delta H^\circ_{pol}$, kcal mole$^{-1}$ | $-\Delta S^\circ_{pol}$, kcal mole$^{-1}$ K$^{-1}$ | $-\Delta G^\circ_{pol}$, kcal mole$^{-1}$ |
|---|---|---|---|

| 100.00 | 44.5 | 7.88 | 43.7 |
| 200.00 | 45.2 | 12.7 | 42.7 |
| 298.15 | 45.9 | 15.5 | 41.3 |
| 355.83 | 46.2 | 16.4 | 40.3 |
| | Monomer(l) ⇌ polymer(g) | | |
| 355.83 | 52.5 | 34.1 | 40.3 |
| 400.00 | 52.9 | 35.9 | 38.8 |
| 420.00 | 53.2 | 35.9 | 38.1 |

*The physical state of the monomer and polymer is indicated in brackets: c—crystalline; g–glass; l–liquid.

Table 1 shows that, in the temperature range 100–420 K, $\Delta H^\circ_{pol} < 0$ and $\Delta S^\circ_{pol} < 0$, which implies that CPP is a monomer with an upper limiting polymerisation temperature of 1480 K, i.e. much higher than the temperature of the onset of the thermal decomposition of the monomer and polymer. (Below 1480 K, there are no thermodynamic obstacles to the conversion of the monomer into a polymer, while above this temperature the polymer cannot be obtained.)

The absolute value of $\Delta G^{\circ}_{pol}$ shows that the equilibrium in the polymerisation reaction is almost completely displaced towards the formation of the polymer[63].

## III. INDIVIDUAL EXAMPLES OF POLYCYANATES

### 1. Homopolymers of Aromatic and Organoelement Dicyanate Esters

Table 2 presents the structures and melting points of di- and tri-functional aromatic and organoelement cyanate esters described in the literature as well as certain thermal characteristics of the polymers based on them. In most cases the monomers are crystalline substances with melting points much lower than those of the hydroxy-compounds from which they were obtained. Certain organoelement dicyanates (see Nos. 33 and 34, Table 2) are liquids at these temperatures. The temperatures of the onset of deformation (from thermomechanical curves) and the temperatures of the onset of decrease in weight (from thermogravimetric data obtained in air) are quoted in Table 2 as the thermal characteristics whereby a comparative assessment of the polymers is possible. Unfortunately there are no data on the behaviour of a number of polycyanates, which have been described largely in patents, at elevated temperatures.

Table 2. Di- and tri-functional aromatic and organoelement cyanates and the thermal characteristics of the polymers based on them.

* Here and henceforth the temperature of the onset of deformation ($T_{o.d.}$) was determined from the thermomechanical curve for a load 0.8 kgf $cm^{-2}$ and a heating rate of 80 k $h^{-1}$.

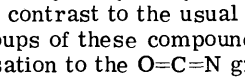
** The temperature of the onset of weight loss ($T_{w.l.}$), obtained from thermogravimetric analysis (heating rate 4.5 K $min^{-1}$), was assumed to be the temperature corresponding to the point of intersection of the tangents to the curve in the region where weight loss begins.

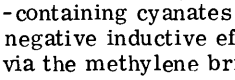
The polycyanates listed in Table 2 are highly cross-linked heterochain polymers the nodes of the networks of which consist of *s*-triazine rings, while the internodal fragments comprise the residues of aromatic bisphenols, polyphenols, and organoelement glycols and phenols. The data in Table 2 show that the presence of these thermally stable groups in the polycyanate structure promotes a high thermal stability of the latter. Furthermore, the results obtained in thermomechanical studies on polycyanates have demonstrated (see Table 2) that the temperatures of the onset of deformation are in most cases in the region close to the temperatures of the onset of weight loss, i.e. the

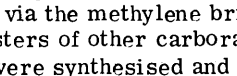
heat resistance of these highly structured rigid systems is limited by their thermal stability. The thermal, physicomechanical, and other properties of the most interesting polycyanates will be discussed below.

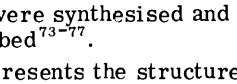
There are no literature data on polycyanates with unsubstituted aliphatic internodal fragments. Presumably the presence of flexible polymethylene chains in place of rigid aromatic rings in the polycyanate structure should have promoted an increase of the elasticity of these materials but, naturally, it would have been accompanied by some decrease of the thermal stability of the polymers. It is noteworthy that the initial monomers for such polymers, aliphatic cyanate esters, cannot be obtained from glycols and halogenocyanogens; on heating, they also readily isomerise to isocyanates[29].

It has been found that the hypothetical structures of polycyanates with aliphatic internodal fragments can be achieved by the introduction of perfluoro-groups in the $\alpha$-position relative to the cyanate group. Such fluorine-containing mono- and di-cyanates were obtained for the first time[81] by the reaction of the corresponding alcohols with chlorocyanogen in the presence of triethylamine. These cyanates are resistant to isomerisation and polymerise readily with formation of polymers whose thermal stability is not inferior to that of aromatic polycyanates[80]. Depending on the proportions of the mono- and di-cyanates taken for copolymerisation, polymers with glass points between $-40°$ and 350°C were obtained. They can be used as thermostable films, adhesives, and elastomers with improved fire resistance[80].









One of the most interesting examples of organoelement polycyanates comprises polymers containing carborane groups in the internodal fragments. A report on the synthesis of carborane-containing aliphatic cyanates based on 1,2- and 1,7-dihydroxymethylcarboranes was published in 1971.[78] In contrast to the usual aliphatic cyanates, the N≡C–O groups of these compounds proved to be resistant to isomerisation to the O=C=N groups. The resistance to isomerisation in such cases, as well as that of fluorine- and chlorine-containing cyanates[30,81], can be accounted for by the large negative inductive effect of the carborane ring, transmitted via the methylene bridges[78]. Subsequently dicyanate esters of other carborane-containing glycols and bisphenols were synthesised and polymers based on them were described[73-77].

Table 3 presents the structures of carborane-containing dicyanates and certain properties of their polymers. A characteristic feature of polymers based on dicyanatomethylcarboranes is lower heat resistance compared with aromatic polycyanates, but, as regards the temperature of the onset of weight loss, they are similar to their carbocyclic analogues[79]. The most interesting property of these polymers is the large amount of carbon-containing residue at elevated temperatures (between 500° and 1000°C), frequently with retention of a definite strength.

Like aromatic analogues, carborane-containing polymers are characterised by high physicomechanical parameters (specific impact strength up to 30 kgf cm $cm^{-2}$, bending strength up to 1700 kgf $cm^{-2}$, Brinell hardness up to 1500 kgf $cm^{-2}$, etc.); they can be readily converted into manufactured articles by the usual methods for working with thermoreactive polymers without the evolution of volatile materials[73-79]. Their conversion into manufactured articles is facilitated also by the fact that the initial monomers have relatively low melting points, ranging from 63°C (*m*-dicyanatomethylcarborane) to 158°C (1,2-dicyanatodiphenylcarborane).[73-79]

Owing to the strong adhesion of carborane-containing cyanates to various materials and other properties of practical value, which are indicated above, these polymers are used as heat resistant and thermostable films, coatings, binders for glass-fibre-reinforced plastics, adhesives, etc., particularly when a high resistance to ablation is necessary[73-79]. Large carbon-containing residues have been observed up to 1000°C for carborane-containing polycyanates not only when the latter were thermostatted in air but also in an inert atmosphere. Thus the polycyanate based on 1,2-di-(4-cyanatophenyl)carborane loses 2% of its weight in air at 900°C and 16% at the same temperature in an atmosphere of helium. In view of the low availability at the present time of carborane-containing monomers, it is of considerable interest that small amounts of added carborane-containing cyanates appreciably increase the thermal stability of polycyanates when they are copolymerised with the usual aromatic dicyanates[82]. Thus, whereas the polymer based on 2,2-di-(4-cyanatophenyl)propane without a carborane-containing additive loses 58% of its weight on heating in air for 1 h at 350°C, the weight loss by the polycyanates to which 0.25 mole % of 1,2-dicyanatodiphenylcarborane has been added amounts to 27%.[82]

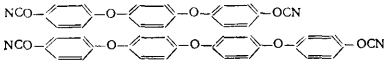
## 2. Polycyanates Based on Oligomers with Terminal Cyanate Groups

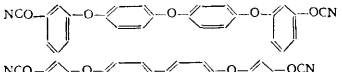
Apart from polymers based on low-molecular-weight monomeric dicyanates, polymers obtained by the polycyclotrimerisation of oligomeric dicyanate esters are of considerable interest because it is possible to regulate easily in this way both the length and the chemical structure of the internodal fragment, achieving thereby the specific synthesis of polymers with a particular set of properties.

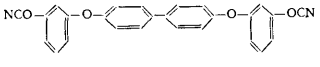
As for the polycyanates discussed above, the structure of the polymers obtained from oligomeric dicyanate esters consists of a trifunctional network with *s*-triazine rings at its nodes; the internodal distance is determined by the length of the initial oligodicyanate:

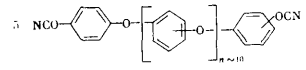
There are interesting data for polycyanates based on mono- and di-cyanates containing oligomeric fluoroalkylene and fluoroalkylene oxide linkages having the general formula[83]

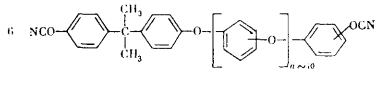
$$F_3C(CFX)_aA(CFX)_bCH_2OCN \text{ and } NCOCH_2(CFX)_aB(CFX)_bCH_2OCN,$$











where X = fluorine or perfluoroalkyl while A and B are a C–C bond or an $O(CFXCF_2O)_c$ group. These polymers are distinguished by resistance to the action of solvents and are used for impregnation and as adhesives, films, and binders for rocket fuel.

A number of polymers based on oligoarylene oxides with terminal cyanatophenyl groups have also been described in patents[84,85] (Table 4). The initial bisphenols were obtained by the Ullmann stepwise condensation of the corresponding aromatic dihalogeno-compounds with potassium methoxyphenoxide and subsequent hydrolysis of the methoxy-groups. The authors achieved the homopolymerisation of the dicyanates of oligoarylene oxides as well as their copolymerisation with aliphatic perfluorocyanates by heating the reactants at 50–200°C[84,85]. It was noted that the polymerisation temperature may be reduced to 25–100°C in the presence of catalysts, which were $AlCl_3$, $BF_3$, $FeCl_3$, $TiCl_4$, $ZnCl_2$, protic acids such as HCl, the salts of weak acids (NaOAc, NaCN, KSCN, and $NaHCO_3$), as well as basic compounds, for example NaOMe, KOH, pyridine, and triethylamine. The polymers obtained have a high thermal stability and rigidity and can be used as adhesives, coatings, and binders. The ultimate shear strength of the aluminium–aluminium adhesive seam, formed using the dicyanates[84] hardened for 1 h at 177°C and a pressure of 2 atm, are presented in Table 5.

Table 5. The ultimate strengths of the Al–Al adhesive seam formed using oligoarylene oxide dicyanates as the adhesives[84].

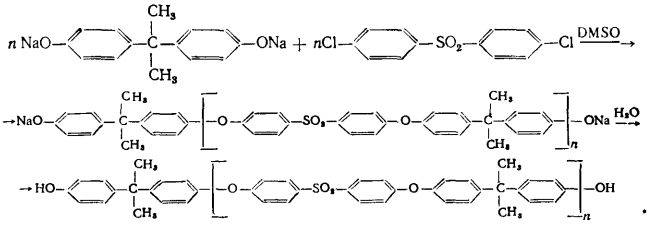
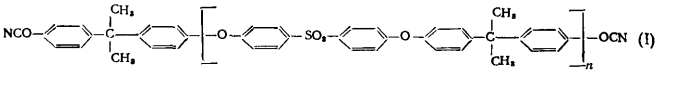
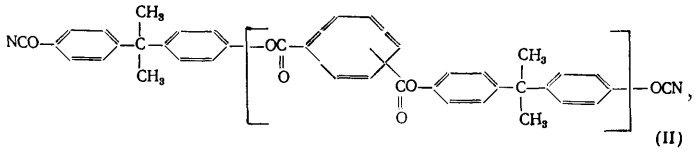
The synthesis of the dicyanates of oligoaryleneoligosulphones[86] and the oligoarylates[87] and polycyanates based on them[88] has been achieved recently. In contrast to earlier patents[84,85], in this case the initial oligoaryleneoligosulphones with terminal hydroxy-groups were obtained by the condensation of the dihalogeno-derivatives of diphenyl sulphone with alkoxides derived from 2,2-di-(4-hydroxyphenyl)propane in dimethyl sulphoxide[86]:







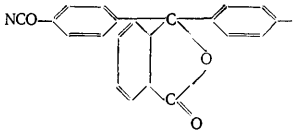


Table 6 presents certain thermal characteristics of a number of polycyanates based on the dicyanate esters of oligoaryleneoligosulphones:

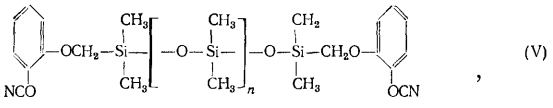
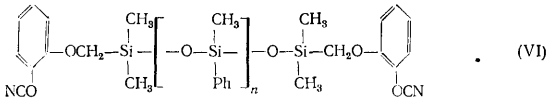
*Temperatures at which the polymer loses 5 and 10% of its weight respectively.



The study of the influence of the degree of cross-linking on the heat resistance of these polymers showed that, with increase of the degree of cross-linking, the glass temperatures of the polymers increase relative to linear high-molecular-weight polymers with a similar structure. Furthermore, in contrast to high-molecular-weight linear analogues, the thermomechanical curves for polycyanates show a viscoelastic plateau, the upper temperature limit of which is between 300° and 350°C, depending on the structure of the initial oligomer[88]. The region of the viscoelastic state of a carborane-containing oligoester was found to lie in the temperature range from 10° to 350°C, i.e. the polymer is an elastomer at room temperature.

Oligomeric dicyanates and oligodimethyl- and methylphenyl-siloxanes have also been used as the starting compounds for the synthesis of polycyanates[88-95]. The initial bisphenols for the synthesis of these dicyanates were obtained[88,89,93,94] by the cohydrolysis of $\alpha\omega$-dichlorosiloxanes with 2,2-dimethylbenzo-2-sila-1,4-dioxan via the following mechanism:



where $n$ = 1 - 150 for $R_1 = R_2 = CH_3$, $n$ = 1-20 for $R_1$ = $CH_2$ and $R_2 = C_6H_5$, and $n$ = 1-10 for $R_1 = R_2 = C_6H_5$.

Dicyanate esters based on these bisphenols were synthesised by acylating them with halogenocyanogens in the presence of tertiary amines[88,90]. Two types of oligomeric organosilicon dicyanates were obtained:

(V)

(VI)

Certain properties of the polymers based on these compounds are listed in Table 7.

Table 7. Properties of organosilicon polycyanates[88,89] based on the oligomeric dicyanates (V) and (VI).

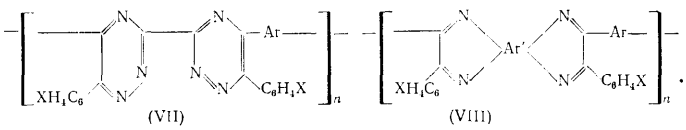
Depending on the length of the siloxane chain between the nodes of the network, these polymers have glass points between −120° and 180°C. It has been shown that organosilicon polycyanates have a high thermal stability and the region of their viscoelastic state lies within a wide temperature range: from −120° to 340°C, i.e. up to the temperatures of the onset of their degradation[88,91,95].

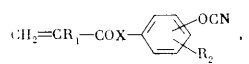


There are also patent data for cross-linked plastics obtained by the polycyclotrimerisation of the terminal N≡C−O groups of a prepolymer synthesised from the product of the reaction of $\epsilon$-caprolactone with various bisphenols[96]. These polymers have a high strength and hardness, exhibit strong adhesion, and can be used as coatings, binders, insulators, etc. The formation of

phenol-formaldehyde resins containing cyanate groups, by treating a novolak resin with chlorocyanogen in the presence of tertiary amines, has been described[97,98]. The polymers, hardened at elevated temperatures, are recommended as plastics, adhesives, and coatings.

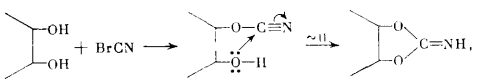
### 3. Polymers with Cyanate Side Groups

Studies devoted to the modification of known polymers by the introduction into their structure of reactive cyanate groups have been published[99-102]. Subsequent cyclotrimerisation of these groups or their interaction with various compounds yields cross-linked systems, which makes it possible to impart many new valuable properties to the initial polymers.



Thus Hergenrother[99] obtained high-molecular-weight polyphenylene-*asym*-triazines having the general formula (VII), where Ar = *m*- or *p*-$C_6H_4$ or *p*-$C_6H_4OC_6H_4$ and X = H, $C_2H_5$, $OCH_3$, $OC_6H_5$, $C_6H_5$, OH, Br, CN, OCN, $OC_6H_4CN$, and polyphenylenequinoxalines having the general formula (XIII), where Ar and X are the same as above (X can be in addition $CH_3$) and Ar′ = $C_6H_3C_6H_3$ or $C_6H_3COC_6H_3$.

(VII) (VIII)



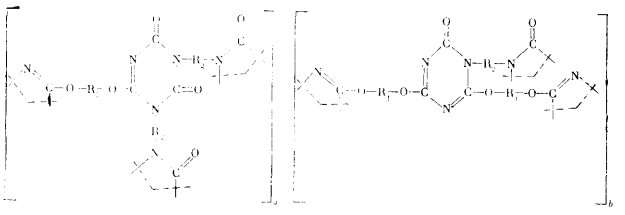
It has been shown that heat treatment of polymers with cyanate groups entails their cross-linking as a result of the cyclotrimerisation of the groups, which leads to a raising of the glass points of the resulting polymers compared with the initial polymers.

A method for the synthesis of cyanates from polymers containing vinyl groups and having the general formula

where $R_1$ = H, $CH_3$, or Cl, $R_2$ = H, Alk($C_{1-4}$), or Cl and X = O or H, has been described[100]. The above cyanates have been homopolymerised or copolymerised via the vinyl group with butadiene, isoprene, various acrylates, styrene, α-methylstyrene, and other compounds. Linear polymers were obtained with different contents of cyanate side groups. These polymers, which were subsequently heat-treated at 70–200°C, were converted into cross-linked systems as a result of the cyclotrimerisation of N≡C–O groups[100].

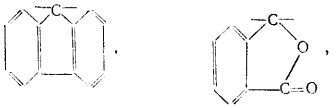
A method has been patented for the synthesis of polymers with cyanate groups, which were subsequently used to bind organic compounds containing a primary or secondary amino-group or an OH group[101]. For this purpose, a polymer containing primary or secondary OH groups (for example cellulose, agar, etc.) is treated with cyanate esters having the general formula $R(OCN)_X$ (R = halogenoalkyl and substituted or unsubstituted aromatic or heterocyclic groups and *x* = 1 or 2). Such a cyanate-activated polymer is capable of binding aminoacids and other compounds. The mechanism of the interaction of mercerised cellulose with bromocyanogen has been investigated[102] and it has been established that this results in the formation of cellulose iminocarbonate via the mechanism

the product being capable of interacting with protein. Such cellulose treated with BrCN has been used successfully as a matrix for the binding of biologically active proteins and their insolubilisation.



### 4. Copolymers of Cyanate Esters

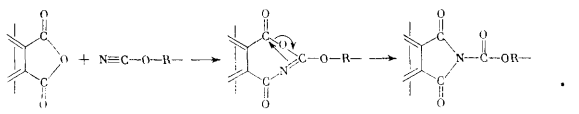
The modification of the properties of polycyanates in the desired manner can be achieved by the copolymerisation of dicyanates with one another, with monocyanates, and with various compounds to form network structures and also non-cross-linked soluble polymers.



An advantage of the copolymerisation of dicyanates with one another is that the mixtures of monomers are converted into a melt at lower temperatures than the initial dicyanates during their homopolymerisation and do not crystallise from the melt on cooling, which greatly simplifies the technology of the processing of such polymers[103]. Furthermore, by varying the structure and proportions of the initial dicyanates, it is possible to alter specifically properties of the polycyanates such as heat resistance, thermal stability, and physicomechanical parameters[82,103,104].

The copolymerisation of aryl dicyanates with monocyanate can yield, depending on the ratio of the initial monomers, polycyanates with different degrees of cross-linking as well as fusible and soluble polymers[82,104]. However, the physicomechanical properties of such copolymers are greatly inferior to those of the homopolymers of dicyanates and are sharply impaired with decrease of the degree of cross-linking. This is probably associated with the breakdown of the regularity of the cross-linking occurring in the homopolymerisation of dicyanates, so that cross-linked copolymers of aryl dicyanates with monocyanate become analogous to randomly cross-linked rigid-chain polymers (epoxide and phenol-formaldehyde polymers, polymers of the polyphenylene type, etc.) as regards physicomechanical properties[103]. Furthermore, the breakdown of the regularity of the cross-linking by the introduction of monocyanate into the polymers leads to a decrease of their heat resistance and thermal stability compared with homopolymers[103].

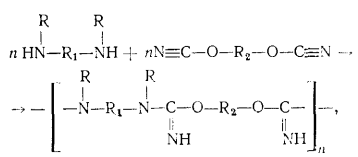
The synthesis of copolymers of isocyanates with cyanates having the general formula



has also been described[105]. Here $R_1$ and $R_2$ are aromatic mono-, bi-, or poly-cyclic groups containing the H, N≡C–O, $CH_3$, F, Cl, Br, N=C=O, $NH_2$, or OH ring substituents. Bicyclic groups can be separated by $-CH_2-$, $-C(CH_3)_2-$, $-C(CF_3)_2-$, $-O-$, $-SO_2-$,

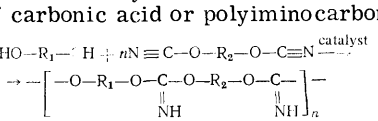
bridges, siloxane fragments, and aliphatic, cyclic aliphatic, arylalkyl, and fluorine- or boron-containing groups.

The resulting copolymers of isocyanates with cyanates have effective temperature characteristics and satisfactory physicomechanical parameters. They can be used as thermostable compositions, coatings, varnishes, binders for glass-fibre-reinforced plastics, etc.[105] Thus the copolymer of 9,9-di-(4-cyanatophenyl)fluorene and 9,9-di-(4-isocyanatophenyl)fluorene begins to decompose in air (according to thermogravimetric data) at 440°C and the temperature of the onset of deformation is 480°C.



The interaction of acid anhydrides with cyanate esters, leading to the formation of imidocarbonates, was described in 1970:[106]

This interesting reaction of cyanate esters was used to synthesise a new type of polymer—polyimidocarbonates[107-109]. These polymers were obtained by the migration copolymerisation of various dianhydrides of tetracarboxylic acids and aryl dicyanates in the melts or in solution in a high-boiling organic solvent. Depending on the structure of the initial compounds, the polymers had a softening temperature in the range 230–260°C, the temperature of the onset of their decomposition in air was in the range 300–350°C, and $\mu_{int}$ in DMF was up to 0.5 dl $g^{-1}$. In order to determine the structures of the polymers obtained, the authors[108,109] synthesised compounds simulating the main chain of polyimidocarbamates, namely *N*-(phenoxycarbonyl)phthalimide, di-*NN'*-(phenoxycarbonyl)pyromellitimide, and 4,4'-di-(*N*-phthalimidacarbamatophenyl)-2,2-propane.



Certain characteristics of the formation of polyimidocarbamates were investigated in relation to the interaction of 2,2-di-(4-cyanatophenyl)propane and the dianhydride of pyromellitic acid[109]. It was found that, for an equimolar reactant ratio, the product is a linear, fusible, and soluble polyimidocarbamate. With increase of the content of cyanate groups in the initial mixture and also when polyfunctional esters or acid anhydrides with a functionality > 2 are used, the products are cross-linked, infusible, and insoluble polymers[107]. The synthesis of a number of linear polymers based on bifunctional cyanates has been described[72,110,111].

It is also known that cyanate esters readily interact with primary and secondary amines, forming isourea ethers[25,29,30]. The migration copolymerisation of primary and secondary diamines with dicyanates yielded polymeric isourea ethers or polyisoureas[110,111] via the mechanism:

where $R_1$ is an aliphatic, alicyclic, arylalkyl, aryl, or heterocyclic group, R = H, alkyl, or aryl, and $R_2$ = aryl, alkyl, or a heterocycle. When cyanates or amines with a functionality > 2 are used, the products are cross-linked polymers[110,111].

The copolymerisation of cyanates with glycols and bisphenols proceeds similarly with formation of polymeric iminoesters of carbonic acid or polyiminocarbonates[72]:

However, in contrast to the synthesis of polyisoureas, the formation of polyiminocarbonates proceeds in the presence of bases such as alkali metal alkoxides, hydroxides, carbonates, metal hydrides, tertiary amines, etc.[72]

Departure from equimolar ratios in the case of bifunctional starting materials leads to the formation of polymers with terminal cyanato- or hydroxy-groups[72].

## IV. THE SPECIFIC FEATURES OF THE PROPERTIES AND STRUCTURES OF POLYCYANATES

Polycyanates are a new class of polymers with a regular network structure. Aromatic polymers having this type of structure with a high degree of cross linking were previously unknown. The change from the previously known randomly cross-linked structures to structures with a regularly constructed network, as in polycyanates, should have led to a quantitative change in many properties of the polymers. Indeed a number of unusual properties drew attention already in the first studies on polycyanates. Subsequently these polymers were investigated in greater detail and new properties, unusual for cross-linked polymeric systems, were found.

The results of studies devoted to a detailed investigation of thermal, physicomechanical, and other properties of polycyanates as well as the structural parameters of these polymers are discussed below. Particular attention has been devoted to the specific features of polycyanates due to their regularly cross-linked structure.

The majority of polytriazines, to the class of which polycyanates belong, are known to exhibit an enhanced thermal stability[45,47,55,112-115] due to the aromatic nature of the triazine ring whose thermal stability is close to that of the benzene ring[55,115-118]. A number of studies on the influence of the chemical structure of the initial monomers on the thermal stability of the polycyanates have been described in the literature[55,115,118,120]. Furthermore, in the majority of papers on the synthesis and properties of these polymers, certain characteristics of their thermal stability are also quoted. Investigations of the thermal stability of polymers having this type of structure but obtained by the polycondensation or polymerisation of monomers containing an existing *s*-triazine ring are also of definite interest[47,121,122].

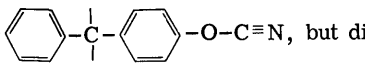
*The designations of the polycyanates here and in Tables 9 and 10 are the same as in the original papers[54,64,115,119,120].

**In contrast to other polymers, the carborane-containing polycyanate shows a 4.5% increase in weight at 600°C in air.



A comparative study has been made of the thermal and thermo-oxidative degradation under dynamic and isothermal conditions of polycyanates obtained by the polycyclotrimerisation of aryl dicyanates having the general structure  , but differing in the substituents at the central carbon atom [119]. The data obtained by the authors are presented in Tables 8–10.

*Number on the left—at 300°C, number on the right—at 350°C.

It was found that the decomposition reaction of polycyanates with different structures in air is of the same type; it proceeds in several stages and is accompanied by the evolution of heat. This is indicated by the exothermic effects observed in the temperature ranges 380–420° and 490–580°C. In the first decomposition stage, the decrease in weight is 20–40% and in the second stage up to 90%. An exception is the thermo-oxidative degradation of the polycyanate based on dicyanatodiphenylcarborane. The beginning of the decrease in the weight of this polymer is observed at 390°C and at 450°C the weight loss is 10%. On further increase of temperature, the weight of the polymer rises and at 650°C is 107% of the initial value. The weight then again gradually decreases, amounting to approximately 96% of the initial value at 850°C (Table 8). Other carborane-containing polycyanates behave similarly [72,75,77,79].

In an inert atmosphere, the decomposition of polycyanates also proceeds in two stages. Under these conditions the temperatures of the onset of decrease in weight and the temperature ranges corresponding to the vigorous decomposition of polycyanates are somewhat displaced towards higher temperatures compared with degradation in air [55,119]. Large residues of carbon are characteristic of the degradation of polycyanates in an inert atmosphere up to 900°C [55, 119].

In the series of polycyanates based on aryl dicyanates with different substituents at the central carbon atom, polymers with polycyclic groups (phthalide, fluorene, or anthrone types) at the central carbon atom in the initial dicyanate have a high thermal stability [55,119].

In order to investigate further the processes occurring following the exposure of polycyanates to elevated temperatures, a study was made of the kinetics of the decomposition of polycyanates based on 2,2-di-(4-cyanatophenyl)-propane (PTs-1), 4,4′-dicyanatobiphenyl (PTs-4), and 9,9-di-(4-cyanatophenyl)fluorene (PTs-9), as well as the degradation of the model compounds diphenyl cyanurate (IX), triphenyl isocyanurate (X), cyanuric acid (XI), and triphenyl-*s*-triazine (XII) [115,120]:

(IX) (XI) (XII)

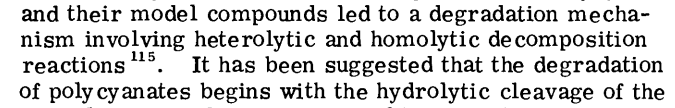
A study of the degradation process in air and *in vacuo* showed that the decomposition of polycyanates proceeds as a first-order reaction and obeys the Arrhenius equation. A comparative study of the kinetics of the decomposition of the polymers PTs-1, PTs-4, and PTs-9 *in vacuo* and in air showed that the polycyanate based on 9,9-di-(4-cyanatophenyl)fluorene, containing bulky subgroups, is more resistant to the action of high temperatures than the other two polymers. It was established that the presence of moisture in the polymers has a significant influence on the nature and degree of their decomposition.

The study of the degradation products of polycyanates showed that they consist mainly of $CO_2$, CO, $H_2$, compounds containing the triazine ring (cyanuric acid and its phenyl esters), phenol, and bisphenols. Furthermore, benzene, biphenyl (in the degradation of the polycyanate PTs-4) and fluorene (in the degradation of the polycyanate PTs-9) were detected in the degradation products.

Since the polycyanates investigated are highly structured complex systems, a detailed investigation of the degradation of which presents certain difficulties, a study was made of the degradation of triphenyl cyanurate, a compound which simulates the principal bonds in the three-dimensional structure of the polymer, to elucidate the mechanism of the decomposition process [55,115]. The results of the study of the degradation of this compound by chromatographic and mass-spectrometric methods showed that, as in the degradation of the polymers PTs-1, PTs-4, and PTs-9, the principal decomposition products are carbon oxide, phenol, and cyanuric acid. Comparison of the

thermal stabilities of the above model compounds derived from triazine permitted the conclusion that triphenyl-*s*-triazine exhibits the highest thermal stability (CO, $CO_2$, and $H_2$ were not detected in the volatile degradation products up to 500°C)[115]. The presence of water at high temperatures has virtually no influence on the temperature limits of the stability of triphenyl isocyanurate and triphenyl-*s*-triazine. At the same time, cyanuric acid proved to be extremely unstable in high-temperature hydrolytic reactions.

The study of the decomposition products of polycyanates and their model compounds led to a degradation mechanism involving heterolytic and homolytic decomposition reactions[115]. It has been suggested that the degradation of polycyanates begins with the hydrolytic cleavage of the ester linkage and is accompanied by the subsequent decomposition of the triazine ring via both heterolytic and homolytic mechanisms. It has been noted that the effect of the hydrolysis of the ester linkage in the early stages may be somewhat suppressed by the introduction of bulky side groups into the polycyanate chain[115].



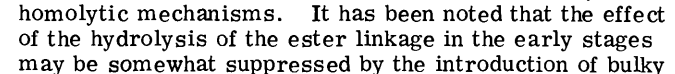
The influence of molecular weight ($M_C$) and of the chemical nature of the internodal fragments of polycyanates on their thermal and thermo-oxidative degradation has also been investigated[88]. In the polymers chosen for investigation, the internodal fragments were oligoarylene-oligosulphones:

$$-OC_6H_4C(CH_3)_2C_6H_4-[-OC_6H_4SO_2C_6H_4OC_6H_4C(CH_3)_2C_6H_4-]_n-O-,$$

$n = 1, 3, 5, 10$ ,

oligoarylates:

$-OC_6H_4C(CH_3)_2C_6H_4-[-OCOC_6H_4COOC_6H_4(CH_3)_2C_6H_4-]_n-O-$, $n=1,3,5$ and

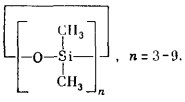


$-OC_6H_4-$ (C(O)O ring) $-C_6H_4-[-OCOC_6H_4COOC_6H_4-$ (C(O)O ring) $-C_6H_4-]_n-O-$, $n=5$,

a carborane-containing oligoester:

$$-OCH_2-C(B_{10}H_{10})-C-CH_2-[-OCO(CH_2)_8COOCH_2-C(B_{10}H_{10})-C-CH_2-]_n-O-,\ n=7,$$

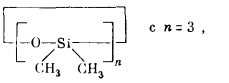
and oligosiloxanes:



where $n$ = 3, 5, or 10 for $R_1 = CH_3$ and $R_2 = C_6H_5$ and $n$ = 0, 1, 5, 10, 25, 50, 70, or 100 for $R_1 = R_2 = CH_3$.

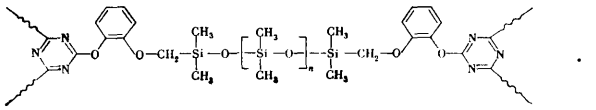
It was found that polycyanates based on oligoarylene-oligosulphones exhibit the highest thermal and thermo-oxidative stability (Table 6). An increase of $M_C$ of these polymers entails some increase in thermal stability. When oligoarylates are used as the internodal fragments, $M_C$ has hardly any influence on the temperature of the onset of decrease in their weight in air and in an inert atmosphere[88]. $CH_4$, $H_2$, and $CO_2$ were detected in the gaseous decomposition products of polycyanates with oligoarylene-oligosulphone internodal fragments, while in those with oligoarylate fragments CO was also detected.

The carborane-containing polymer has a lower temperature of the onset of decomposition in air compared with polycyanates containing oligoarylene-oligosulphone and oligoarylate internodal fragments, but, as for other carborane-containing polycyanates[73,75,77,79], it is characterised by a higher coke content at 900°C, while aromatic polymers are combusted almost entirely in air at 900°C.



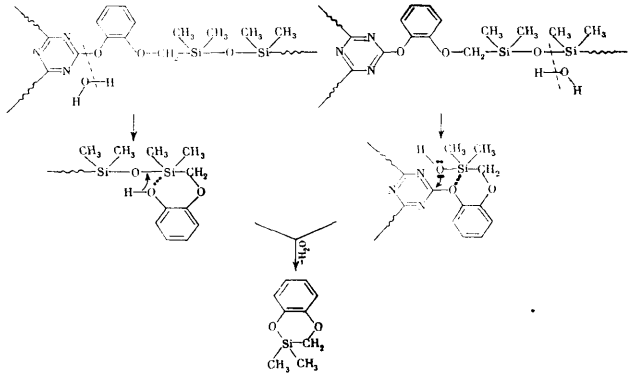
A study of the degradation of polycyanates containing oligosiloxane fragments of different lengths between the network nodes showed that an increase of $M_C$ entails an increase of the thermal and thermo-oxidative stabilities of the polymers, but, starting with a specific value of $M_C$, the thermal stability remains constant or actually diminishes somewhat.

The nature of the degradation of silicon-containing polycyanates, particularly at elevated temperatures, is the opposite of that of aromatic polycyanates, which are combusted almost in their entirety in air but leave appreciable carbon residues in an inert atmosphere at temperatures in the range 700–900°C. Appreciable coke residues, increasing with increase of $M_C$, are observed in the thermo-oxidative degradation of organosilicon polymers at high (up to 900°C) temperatures. On the other hand, siloxane-containing polycyanates decompose almost entirely on degradation in argon and for high values of $M_C$ the coke residues are insignificant. These findings have been explained[88] by the fact that, in the presence of oxygen, the siloxane chains form a structure via the organic groups attached to silicon, while in an inert atmosphere they are depolymerised with liberation of low-molecular-weight products having the structure



$n = 3$–$9$.

$H_2$, $CH_4$, and $CO_2$ were detected in the gaseous degradation products of silicon-containing polycyanates, while 2,2-dimethylbenzo-2-sila-1,4-dioxan (DMBD), catechol, the cyclic siloxane



с $n = 3$ ,

with $n$ = 3 ($D_3$) and $n$ = 4 ($D_4$), and other compounds were found among the low-molecular-weight substances[88]. Table 11 presents data obtained by pyrolytic gas chromatography for the composition of the low-molecular-weight products of the degradation of organosilicon polycyanates with the following structure of the internodal fragment:

A possible mechanism for the degradation of organosilicon polycyanates has been suggested on the basis of data obtained in the study of this process[88]. Thus the formation of 2,2-dimethylbenzo-2-sila-1,4-dioxan (Table 11), detected in considerable amounts in the degradation products, can proceed via the mechanism:

Interesting data have been obtained in a study[123] of the influence of the structure of the initial dicyanate esters, in particular the nature of the substituents at the central carbon atom of aryl dicyanates, on the physical characteristics of the polymers based on them. The results obtained in this and a number of other investigations[54,55,73-77,80,124-126] are presented in Table 12.

*The numbers of the polymers correspond to those in Table 2.

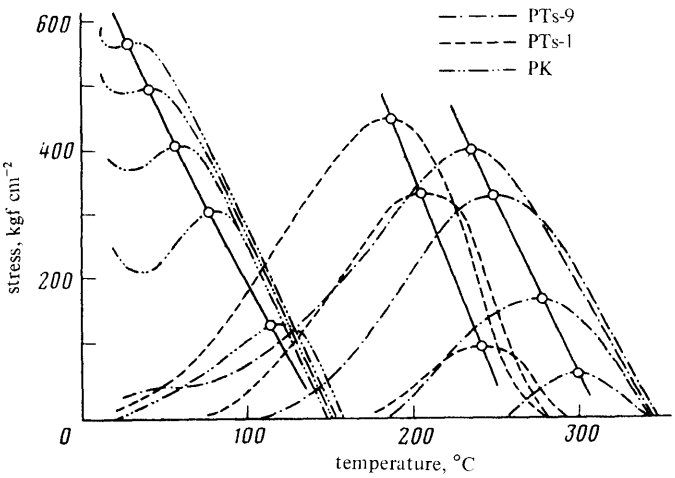
**a. amorphous, a.(cr.) amorphous with signs of crystallinity, cr.(1.ord.) crystalline with a low degree of order, and cr.(m.ord.) crystalline with a moderate degree of order.

The most striking feature of the study of a systematic series of polycyanates[54,55,123] based on bicyclic aromatic dicyanates (see Nos. 7–29, Table 12), differing in the nature of the bridge group between the phenyl groups, is that the polymers obtained from dicyanates having a flexible bridge group and small substituents at the central carbon atom (polymers Nos. 9–16, Table 12) have anomalously high specific impact strengths (up to 30 kgf cm cm$^{-2}$ in contrast to all known cross-linked aromatic polymers[127] On the other hand, the presence at the central carbon atom of identical and aromatic substituents (polymers Nos. 17–19) and also of polycyclic groups (polymers Nos. 20–28) leads to an appreciable decrease of this parameter in cast polycyanate specimens. However, in the latter instances the bending strength of the polycyanate is somewhat enhanced[54,55,103,123]. This type of influence of the structure of the substituents at the central carbon atom in bifunctional derivatives was also observed previously for a series of heterochain linear polymers[128-131].

The decrease of the distance between the network nodes to a single phenylene group (polycyanates derived from 1,3- and 1,4-dicyanatobenzenes) leads to an appreciable increase of the specific impact and bending strengths of the cast polymer specimens[123]. Furthermore, block specimens of aromatic and a number of organoelement polycyanates have high bending strengths, a Brinell hardness of approximately 1000–1700 kgf cm$^{-2}$, a tensile strength in excess of 1000 kgf cm$^{-2}$, a modulus of elasticity of approximately 30 000–50 000 kgf cm$^{-2}$, and a relative elongation on extension of 3–6%.[54,55,73-77,80,123,126] These polymers retain effective physicochemical properties also at elevated temperatures, as can be seen from Table 13 for the polycyanate based on 2,2-di-(4-cyanatophenyl)propane.

Table 13. Physicomechanical properties of the polycyanate based on 2,2-di-(4-cyanatophenyl)propane at different temperatures.

| Temp., °C | Tensile strength, kgf cm$^{-2}$ | Relative elongation, % | Modulus of elasticity, kgf cm$^{-2}$ |
|---|---|---|---|
| 20 | 1100 | 4.5 | 32 000 |
| 200 | 650 | 5.6 | 22 000 |
| 250 | 500 | 6.1 | 17 000 |



In order to elucidate the causes of the unusual mechanical properties of polycyanates, a study was made of the formation of the supermolecular structures of these polymers at different stages of their synthesis, starting from the initial monomer [2,2-di-(4-cyanatophenyl)propane] and continuing as far as the regular network system, with virtually quantitative conversion of the functional groups[64]. It was found that material with a globular structure is formed initially in polycycloprimerisation against the background of the characteristic cryptocrystalline structure of the monomer[64]. The size of the globules does not remain constant during polymerisation but gradually diminishes from approximately 500 to 100–200 Å. Subsequently the globules were found to aggregate in the final stage of polymerisation (for the conversion of the N≡C–O groups of approximately 98%) into fibrille-like formations.

Simultaneously with the study of the supermolecular structure of the polycyanates, the relaxation properties of the solid networks at different stages of the conversion of the N≡C–O groups of the initial monomer were also investigated[64]. With an increase of the degree of conversion, the relaxation curves are initially displaced towards highe

stresses and, after the attainment of approximately 90% conversion of the monomer, begin to shift to the region of lower stresses. The parameters of the Kohlrausch equation were calculated for various stages of the process. The results show that, as the polycyclotrimerisation of aryl dicyanates proceeds and with the consequent increase of the regularity of the network formed, the nature of the supermolecular structure of the polymer alters, which leads in its turn to a steady change of the mechanical properties of the network system–to an increase of elasticity[64].

It may be that, in the usual thermoreactive systems, the formation of a regular defect-free network can also lead to polymeric materials with an enhanced resistance to impact stresses and with an improved elasticity.

The study of the thermomechanical properties[53] of polycyanates showed that the temperatures of the onset of their deformation lie in a comparatively narrow range (360–410°C). However, the nature of the thermomechanical curves for polycyanates suggests that the deformation temperature is related to the degradative processes occurring in the polymers. This is confirmed by the fact that the temperatures of the onset of decomposition of polycyanates in air (from thermogravimetric data) lie in this region.

The regions corresponding to the effectiveness of the polycarbonate based on 2,2-di-(4-hydroxyphenyl)propane (PC) and the polycyanates based on 2,2-di-(4-cyanatophenyl)-propane (PTs-1) and 9,9-di-(4-cyanatophenyl)fluorene (PTs-9).

For a more detailed comparison of the heat resistances of highly cross-linked polycyanates synthesised from the dicyanate esters of bisphenols of different structures, the regions where the polymers can be used effectively were determined over a wide range of temperatures and mechanical stresses (see Figure).[123] The similarity of the non-isothermal stress relaxation curves and the curves bounding the region where the polymer is efficient, obtained for highly cross-linked systems (polycyanates) and for the linear heterochain polymers investigated in detail in previous studies[128–132], is striking; the Figure presents the polycarbonate curve as an example. The replacement of the isopropylene group by the fluorene group leads to an increase of the heat resistance of polycyanates over the entire range of temperatures and stresses investigated.

A study was also made of the influence of a number of other features of the structure of the initial dicyanate esters on the parameters of the region of the effective use of the polycyanates based on them[123]. It has been shown for polycyanates based on the oligomeric dimethylsiloxane dicyanates (V) that $M_C$ has a significant influence on many physicomechanical parameters of these polymers[88,91,95]. With decrease of $M_C$, an increase of tensile strength ($\sigma_t$) and the modulus of elasticity ($E_t$) as well as a decrease of the relative elongation on extension ($\epsilon_t$) are observed (Table 14).

Table 14. The influence of $M_C$ on the physicomechanical properties of organosilicon polycyanates based on the oligodicyanates (V).

| Number of dimethylsiloxane groups in internodal fragment | $\sigma_t$, kgf cm$^{-2}$ | $\epsilon_t$, % | $E_t$, kgf cm$^{-2}$ |
|---|---|---|---|
| 1 | 25 | 12 | 208 |
| 5 | 4 | 40 | 10 |
| 25 | 2 | 50 | 3 |
| 50 | 1 | 90 | 1 |
| 70 | 1 | 120 | 1 |

The packing coefficients for monolithic specimens of many amorphous and weakly crystalline linear polymers, having a large variety of structures and obtained by both polymerisation and polycondensation, vary within extremely narrow limits[133] and their packing densities are approximately the same ($k_{av}$ = 0.681). The packing coefficients have also been recently calculated for sterically structured systems[123]; these parameters for a number of polycyanates are listed in Table 12.

It has been found that the packing coefficients for closely cross-linked polymers with a wide variety of structures lie within a narrow range (0.673–0.697), the average value of the parameter for the polycyanates (0.686) being close to the average value for linear polymers (0.681). The virtual identity of the packing coefficients for linear and cross-linked polymers shows that the amorphous and weakly crystalline sterically structured, infusible, and insoluble polymers are just as closely packed as the linear, fusible, and soluble polymers.

The data for the packing of aromatic polycyanates led to the hypothesis that the mobility of the $C_{sp^3} - C_{sp^2}$ bond between the central carbon atom and the phenyl groups of the internodal fragments of the network exerts the main influence on the physical properties of many of these polymers, differing in the nature of the substituents at the central carbon atom[123].

The packing coefficients have also been calculated[88] for cross-linked polymers based on the dicyanates of oligoarylates, oligosulphones, and oligomeric methylphenyl- and dimethyl-siloxanes with different values of $M_C$ (see Tables 6 and 7). For the majority of polymers investigated as well as for polycyanates based on aryl dicyanates, the packing coefficients are found to be close to $k_{av}$ = 0.681. An exception are polymers containing dimethylsiloxane fragments of different lengths between the network

nodes. These polymers are characterised by anomalously low packing coefficients, decreasing with increase of $M_c$ from 0.651 (for $n = 0$) to 0.587 (for $n = 100$). The fact that the porosity of these systems is zero[88] makes it possible to attribute these anomalously low values to the loose packing of the macromolecules of the organosilicon polycyanates.

The principal parameters of the network structure of polycyanates have been investigated using as an example the polycyanates based on the oligomeric dicyanates (II) and (V) by the method derived from the statistical theory of viscoelasticity[88]. The investigation was performed by measuring the stress relaxation for a constant deformation and biaxial extension of film polycyanate specimens with oligosiloxane ($n = 5$, 25, 50, 70) and oligoarylate ($n = 1$ or 3) internodal fragments. The experimental and calculated parameters of the structures of these polymers are listed in Table 15. Evidently the experimental values of the average (numerical) molecular weight ($M_{ce}$) and the concentrations of the active chains $(V_c/V)_e$ per unit volume of the cross-linked polymers are close to the theoretical values $M_{ct}$ and $(V_c/V)_t$, which demonstrates the regularity of the networks of the polymers.

**Table 15.** Parameters of the network structures of polymers based on the oligomeric dicyanates (V) and (II).

| $n$ | $M_{ce}$, g mole$^{-1}$ | $M_{ct}$, g mole$^{-1}$ | $10^4(V_c/V)_e$, mole cm$^{-3}$ | $10^4(V_c/V)_t$, mole cm$^{-3}$ | $\frac{(V_c/V)_e}{(V_c/V)_t}$ |
|---|---|---|---|---|---|
| Polymers based on oligodicyanates (V) | | | | | |
| 5 | 500 | 800 | 21.00 | 13.86 | 1.50 |
| 25 | 3300 | 2280 | 3.00 | 4.39 | 0.70 |

| 70 | 7300 | 5614 | 1.30 | 1.23 | 0.74 |
| Polymers based on oligodicyanates (II) | | | | | |
| 1 | 700 | 686 | 16.34 | 17.35 | 0.94 |
| 3 | 1100 | 1352 | 11.09 | 8.87 | 1.25 |

A very interesting feature of many polycyanates is their capacity for crystallisation. Crystalline cross-linked polymers are known, but their internodal segments were flexible aliphatic and siloxane fragments with $M_c$ of at least 2100 and the crystalline structures of the cross-linked polymers were fully analogous to those of the initial crystalline oligomers and were in essence determined by them[134-139].

Korshak, Pankratov, and coworkers[140] were the first to obtain, using polycyanates, cross-linked, rigid-chain, fine-mesh network polymers with a completely different crystalline structure than that of the initial crystalline monomer: the formation of the crystalline structure of the network polymer takes place during its synthesis. In an X-ray diffraction study of the polycyanate based on 1,4-dicyanatobenzene, the authors[140] showed that, by altering the conditions of synthesis, it is possible to obtain polymers having the same chemical constitution but a different structure. Thus, whereas the specimen obtained in a solvent had a fully amorphous structure, the diffractometer trace for the specimen synthesised in bulk showed additional distinct reflections indicating the formation of a crystalline structure; $M_c = 108$ for this polymer. The authors suggested that, during polycyclotrimerisation in bulk, the polycyanate macromolecules are stacked in the form of parallel corrugated layers. However the tendency towards crystallisation[53-55,123] has also been observed for polycyanates based on a number of other dicyanates (Table 12)†. It appears that, when the initial monomer and the polycyclisation conditions are suitably chosen, structures of this kind can be obtained in a highly crystalline state.

The capacity of polycyanates for crystallisation as well as many other unusual properties of these polymers are a consequence of the regularity of their structure, produced as a result of the highly selective cyclotrimerisation of the N≡C–O groups of the initial monomers and the virtually quantitative completion of the polycyclotrimerisation reaction.

In conclusion, we may note the following fundamental advantages of both polycyclotrimerisation, as a new method for the synthesis of polymers, and of the polycyanates obtained by this method from aromatic and organoelement cyanate esters.

The initial monomers (cyanates) are obtained by a technologically simple procedure from a raw material which is produced industrially. In most cases, these monomers are relatively infusible substances, stable on storage even when catalysts are deposited on them.

Cyanates are polycyclotrimerised both in the presence and absence of catalysts and the process can be interrupted at the stage of oligomers having a consistency ranging from a viscous liquid to solid products readily soluble in many organic solvents (acetone, toluene, alcohol, chloroform, etc.). The manufacture of articles from cyanates in the form of monomers or oligomers is carried out by the traditional methods for the working of thermoreactive polymers without the evolution of volatile materials.

The high selectivity of the reaction and the occurrence of the latter with virtually quantitative conversion of the functional groups are characteristic of the polycyclotrimerisation of cyanates, which makes it possible to obtain regularly cross-linked polymers with strictly specified internodal distances made up of *s*-triazine rings. Polycyanates are therefore the first examples of a series of polymers obtained by polycyclotrimerisation for which it is possible to achieve in practice the hypothetical possibilities of this promising synthesis of polymers, particularly for the preparation of heat-resistant and thermostable materials.

It has been shown for aromatic polycyanates that, in contrast to the randomly cross-linked systems, these polymers possess, by virtue of the regularity of their chemical structure, anomalously high physicomechanical parameters for fine-mesh network rigid-chain polymers of this kind and in many cases are capable of crystallisation.

All these useful qualities of polycyanates as well as their effective adhesion to various materials permit their employment in many fields in modern engineering. Polycyanates are used as plastics[52-55,64,73-77,80,88,97,98,105,145], adhesives[73-77,80,84,85,88,96-99,105,146,147], and binders for glass-fibre-reinforced plastics[55,73-77,80,96,148-151], solid rocket fuel[152], and other materials[153,154] possessing in most cases enhanced heat resistance and thermal stability.

---o0o---

†It is noteworthy here that this interesting phenomenon has also been observed for rigid highly cross-linked polymers obtained by the polycyclotrimerisation of arylbis(cyanamides)[141-144].

During the preparation of the manuscript for the press, a number of studies devoted to the synthesis [155-158] and properties of polycyanates [159] and the investigation of the kinetics and heats of the polycyclotrimerisation of aryl cyanates were published [160].

# The Influence of the Magnetic Field on Processes Involving Radicals and Triplet Molecules in Solutions

R.Z.Sagdeev, K.M.Salikhov, and Yu.M.Molin

The results of studies of the influence of a constant magnetic field on reactions involving free radicals and triplet molecules in solutions are examined and the theoretical principles of the influence of the magnetic field on the recombination processes of free radicals (taking into account the spin effect) and the quenching of triplets are described. The theoretical models are compared with experimental data.
The bibliography includes 95 references

## I. INTRODUCTION

The research on the effects of the magnetic field in the kinetics of chemical reactions has been prosecuted since the end of the last century. Nevertheless, the range of systems in which reliable effects have been observed has been very limited until recently.

The influence of the magnetic field on the fluorescence of iodine vapour was observed in 1913.[1] This effect was interpreted by Franck and Grotrian[2] as a result of the changed rate in the magnetic field of a competing non-radiative process—magnetic predissociation. Since then, the magnetic predissociation of molecules has continued to attract the attention of investigators (see, for example,

Refs. 3–8). However, iodine molecules are apparently still the only example for which magnetic predissociation has been investigated experimentally.

The direct influence of magnetic predissociation on the rates of chemical reactions has been observed by Falconer and Wasserman[9], who noted that the photoisomerisation of but-2-ene catalysed by $I_2$ vapour is accelerated following the application of an 85 kG magnetic field.

The magnetic effect in heterogeneous catalytic reactions has attracted the attention of investigators, However, these studies did not lead to reproducible results (see, for example, Figueras Roca[10]), with the exception of the *ortho–para* conversion of hydrogen[11,12].

Yet another interesting example of the influence of the magnetic field on physicochemical processes is the acceleration of the destruction of positronium[13]. The Zeeman interaction of positronium with the magnetic field mixed the *ortho*- and *para*-levels and thereby reduces the lifetime of the long-lived triplet state.

Research into the influence of the magnetic field on reactions in solution has so far yielded negative results as a rule and the reported observation of the effect has frequently not been confirmed by subsequent experiments. In his review[14] of studies up to 1945, Selwood noted only one investigation[15] where the effect of the magnetic field on the rate of homogeneous reactions had been observed. Effects amounting to several per cent have been found in reactions during which the overall magnetic susceptibility of the system changed. This study was subsequently quoted in many communications, but even these results have been questioned. On repeating the experiments for two reactions which have been stated[15] to be most sensitive to the magnetic field, Kazakov[16] failed to confirm the effect. Selwood also reported[14] that he had attempted to reproduce certain results in the patent literature concerning the control of chemical reactions by the magnetic field. Negative results were obtained in all cases.

Reports concerning the observation of effects due to the magnetic field, which were not confirmed by other workers, were also published subsequently. Thus, Schmid et al.[17] reported the retardation by a factor of 8 of the polymerisation of styrene in a 16 000 G field at 80°C, but Collins and Bryce[18] were unable to reproduce this effect. Nor did the magnetic field affect the rate of decomposition of benzoyl peroxide[19]—the inhibitor of the polymerisation of styrene.

This situation led to scepticism concerning the problem as a whole. This was also promoted by the prolonged absence of any ideas concerning the possible physical mechanisms for an appreciable influence of the magnetic field on chemical reactions in solution. The possibility of the displacement of the chemical equilibrium owing to a change in magnetic susceptibility during the reaction has been considered theoretically[20]. Even under the most favourable conditions, the relative change in the equilibrium constant did not exceed $10^{-4}$ at room temperature according to these estimates.

The idea of the orienting effect of the magnetic field on the electron spins of free radicals or other paramagnetic species has been frequently discussed. However, under the usual experimental conditions (room temperature, magnetic field up to 10 000 G), the Boltzmann difference between the probabilities of different spin orientations is too small to result in appreciable effects.

The possibility of the orientation of molecules as a whole in the magnetic field, which might have influenced in some way their chemical reactivity, was considered finally. This effect has been shown[21] to be significant only for very large molecules (or conglomerates of molecules) with an anisotropic magnetic susceptibility (for example, the DNA molecules and for reactions in liquid crystals). The influence of the magnetic field on reactions in liquid crystals has been observed experimentally[22], but in the general case this effect cannot play an appreciable role.

In view of all the above considerations, ten years ago the majority of investigators believed that the magnetic field cannot have an appreciable influence on reactions in solutions, with the possible exception of biological systems. However, recently the attitude to this problem has changed radically. This was promoted by the observation of two phenomena. Firstly, magnetic effects were noted in processes involving triplet excitons in solids[23–25] (these problems are discussed in detail in the review by Sokolik and Frankevich[26]). The above studies stimulated research on analogous effects in solutions. Secondly, the phenomenon of chemically induced nuclear polarisation was discovered[27,29] and explained[29,30], which permitted the formulation of a clear-cut physical mechanism of the possible influence of the magnetic field on chemical radical reactions in solutions.

A number of experimental studies have been made in recent years on the influence of the magnetic field on the chemical reactions of free radicals and on processes involving triplet excited molecules in solutions. A fairly detailed theory of the effect of the magnetic field on the rates of these processes has been developed, an important feature of which involves allowance for cage effects characteristic of reactions in solutions. The results of these studies are summarised in the present review.

## II. THE MECHANISMS BY WHICH MAGNETIC FIELDS INFLUENCE CHEMICAL REACTIONS WITHIN THE FRAMEWORK OF THE MODEL OF THE "CAGE" RECOMBINATION OF RADICAL PAIRS

We shall consider initially radical reactions—the largest class of chemical reactions in which an effect of the magnetic field may be expected. It is now known that this influence can arise in the stage involving the recombination† of two radicals in a single "cage" and forming a radical pair (RP). The "cage" is understood in a fairly wide sense of the word—it is a region of effective recombination of the radicals of the given pair with one another[31]. As long as there are two radicals in this region, the probability of their reaction with other molecules is negligibly small compared with the probability of their recombination with one another. During their lifetime in the "cage", the radicals can undergo numerous repeated collisions. In the theory of radical reactions in solutions, two cases of cage recombination are distinguished. The first involves the recombination of correlated radical pairs, i.e. radical pairs in a definite spin state—singlet or triplet. Such radical pairs arise, for example, as a result of unimolecular decomposition under the influence of heat, light, or ionising radiation. The second case includes the reactions of non-correlated radical pairs (the so called F-pairs) where two randomly colliding radicals recombine. In such pairs, the statistical weight of the singlet state is 1/4 and that of the triplet state 3/4. The recombination reaction of radical pairs is selective with respect to the spin and as a rule takes place in the singlet

†The term "recombination" is used here in a wide sense and includes also disproportionation reactions.

state. The reaction probability therefore changes if the multiplicity of the radical pair is altered during its lifetime in the cage (see Fig. 1).

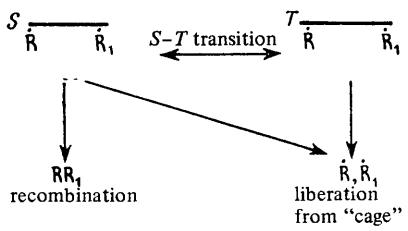

**Figure 1.** Schematic illustration of the processes occurring on recombination of radical pairs in the "cage". The efficiency of the recombination of a singlet radical pair decreases owing to the $S-T$ transition. A triplet radical pair can recombine solely after a $T \rightarrow S$ transition.

We shall consider in greater detail the mechanisms of singlet–triplet ($S-T$) transitions in radical pairs, since, according to the results of a theoretical study, the rates of these transitions can in fact be sensitive to the external magnetic field. Brocklehurst [32] put forward in 1969 the first idea, with a physical basis, concerning the possible mechanism of the influence of the magnetic field on singlet–triplet transitions in radical pairs. He examined the elementary process, typical for radiation chemistry, involving the recombination of an electron (or radical-anion) with its parent radical-cation. According to Brocklehurst [32], these two species form a singlet radical pair, since the initial ionisable molecule was in the singlet state. The transition of the pair to the triplet state can occur by the relaxation of electron spins. Since the electron paramagnetic relaxation times of radicals may depend on the magnetic field strength, the magnetic field may affect the ratio of the yields of the singlet and triplet excited molecules formed as a result of the recombinaton of these radical-ions. Although it is now clear that mechanisms leading to singlet–triplet transitions are more effective for free radicals or radical-ions, Brocklehurst's idea has not lost its importance for the prediction of field effects in systems with short paramagnetic relaxation times. It has been used in the development of a theory of the influence of the magnetic field on the quenching of excited triplet states in solutions [33].

A decisive step in the formulation of the most important mechanisms of $S-T$ transitions in radical pairs was made by Lawler and Evans in 1971, already on the basis of the advances in the field of chemically induced nuclear polarisation [34]. These investigators were the first to formulate the idea that the singlet–triplet transitions in radical pairs, invoked to account for chemically induced nuclear polarisation, must affect also the probability of the recombination of the radicals in the pair. They examined two mechanisms of the singlet–triplet transition in the pair: owing to the difference between the Zeeman frequencies of the radicals (the $\Delta g$ mechanism) and owing to the hyperfine interaction (the HFI mechanism) and showed that the efficiencies of the two mechanisms depend on the magnetic field strength. Subsequently these mechanisms were examined in detail in a number of studies. The manifestations of the $\Delta g$ mechanism [35–40] and the HFI mechanism [38,41–48] have been analysed.

Within the framework of the $\Delta g$ mechanism, the singlet state of the radical pair becomes mixed with only one of the triplet states $T_0$, having a zero projection of the overall spin of the unpaired electrons in the radical pair on the direction of the external magnetic field, i.e. only $S-T_0$ transitions are induced. This mechanism does not involve the two triplet states $T_{+1}$ and $T_{+1}$. The essential features of the $\Delta g$ mechanism for the evolution of the radical pair are illustrated in Fig. 2. The singlet spin state of the radical pair can be represented schematically by two magnetic moments processing about the direction of the field $H_0$ in such a way that their sum remains zero (Fig. 2*a*).

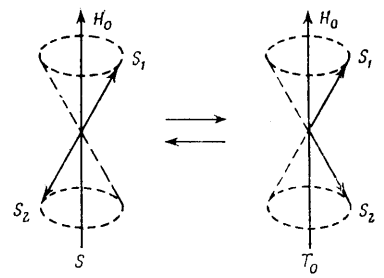

**Figure 2.** Schematic illustration of the $S-T_0$ transition via the $\Delta g$ mechanism. The difference between the Larmor precession frequencies of the $S_1$ and $S_2$ spins leads to transitions between the $S$ and $T_0$ states of the radical pair.

In the triplet state, the overall spin of the radical pair is unity and the $T_0$ state can therefore be represented in terms of the model illustrated in Fig. 2*b*). If the Larmor frequencies of the precession of the spin moments of the radical pair are different, then transitions between two reciprocal configurations of the vectors, shown in Fig. 2, will occur periodically during the precession, i.e. the difference between the Larmor frequencies of the radical pair spins leads to $S-T_0$ transitions. Their frequency is proportional to the difference between the Larmor frequencies of the radicals in the pair and increases linearly with the strength of the constant external magnetic field.

The manifestation of the HFI mechanism of the transitions of radical pairs in strong magnetic fields ($\gtrsim$1000 G) is similar to that of the $\Delta g$ mechanism: the local field induced by the HFI is combined with the external field and gives rise to a difference between the precession frequencies of the spin moments of the unpaired electrons of the radical pair, which leads to $S-T_0$ transitions. However, in weak external magnetic fields, comparable to the local field, a fundamental difference between the two mechanisms is observed: HFI begins to induce transitions from the singlet state to all three triplet states. The qualitative difference of the HFI mechanism is due to the fact that the magnetic spin moments of the unpaired electrons of the radical pair precess about the overall external and local (HFI) fields. In strong external fields, the direction of the overall field virtually coincides with that of the external magnetic field and the projection of the electron spin moments on to $H_0$ therefore remains the same. On the

other hand, in weak fields the overall field may not have the same direction as the external field, which results in the possibility of transitions not only to the $T_0$ state but also to the $T_{\pm 1}$ states.

Thus two fundamental mechanisms of the influence of the external magnetic field on the kinetics of chemical radical reactions have now been recognised: the $\Delta g$ and the HFI mechanisms. In the former case, the interaction, responsible for the singlet–triplet transitions in the radical pair in the cage, is itself intensified with increase of the magnetic field strength. In the second case, the field effect is associated with the dependence of the number of effectively operating channels for the singlet–triplet transitions in the radical pair in the "cage" on the magnetic field strength.

## III. DYNAMICS OF THE RADICAL PAIR SPINS

We shall now consider the singlet–triplet evolution of radical pairs. The following probability of the $S-T_0$ transition has been obtained for the $\Delta g$ mechanism [34-40]:

$$p_{ST_0} = \sin^2\left(\frac{1}{2}\Delta g \beta \hbar^{-1} H_0 t\right), \quad (1)$$

where $\Delta g$ is the difference between the $g$-factors of the radicals in the pair and $\beta$ is the Bohr magneton. Hence it is seen that the radical pair oscillates between the $S$ and $T_0$ states at a frequency

$$\omega_{ST_0} = |\Delta g| \beta \hbar^{-1} H_0. \quad (2)$$

For short times, when $\omega_{ST_0} t < 1$, the probability of the $S-T_0$ transition varies with the square of the magnetic field strength $H_0$:

$$p_{ST_0} \simeq \frac{1}{4}(g_1 - g_2)^2 \beta^2 \hbar^{-2} H_0^2 t^2. \quad (3)$$

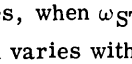
Over a long time interval, where $\omega_{ST_0} t > 1$, there are on average equal contributions of the $S$ and $T_0$ states of the radical pair.

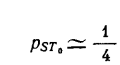
The singlet–triplet evolution of the radical pair in the case of the HFI mechanism is more complex, since under these conditions there is a possibility of transitions to all the triplet states and the transitions via different channels interfere with one another. Comparatively simple results are obtained only for short times, when $|A| t < 1$ ($A$ is the isotropic HFI constant) and the transitions via different channels are combined additively. In this case, the interaction of unpaired electrons with all the magnetic nuclei may be characterised by a single mean-square HFI constant [45]:

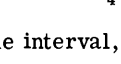
$$A_{\text{eff}} = \left\{\sum_k A_{1k}^2 + \sum_n A_{2n}^2\right\}^{1/2}, \quad (4)$$

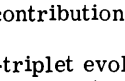
where $A_{1k}$ and $A_{2k}$ are the HFI constants of the radicals in the pair. In a zero external magnetic field, the probability of the transition of the radical pair from the singlet to the triplet state is

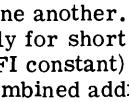
$$p_{ST}^0 \simeq \frac{3}{16} A_{\text{eff}}^2 t^2. \quad (5)$$











Correspondingly, the following expression has been obtained for strong fields when $g\beta\hbar^{-1}H_0 > A_{\text{eff}}$:

$$p_{ST_0}^{\infty} \simeq \frac{1}{16} A_{\text{eff}}^2 t^2. \quad (6)$$

Thus, for radical pairs with sufficiently short lifetimes, i.e. when the condition $A_{\text{eff}} t < 1$ holds, the ratio of the probabilities of the $S-T$ transitions in a zero field and in a strong field is 3, which corresponds exactly to the number of transition channels operating effectively in weak and strong fields.

For arbitrary lifetimes, the calculations of the probabilities of the $S-T$ transitions in radical pairs become more complex even in the two limiting cases of zero and strong fields. Calculations have therefore been made only for the simplest model radical pairs [41-47]. Table 1 presents the probabilities of the $S-T$ transitions for certain systems. As was to be expected, the calculations for short times yield $p_{ST}^0 = 3p_{ST_0}^{\infty}$. However, for comparatively long-lived radical pairs, a very remarkable feature of the HFI mechanism is observed: the probability of the $S-T$ transitions in weak fields, where three competing $S-T_0$, $T_{+1}$, $T_{-1}$ transition channels operate, is sometimes smaller than in strong fields where only one $S-T_0$ channel operates. Such anomalous properties are shown by radical pairs numbered V and VI in Table 1. This feature of the HFI mechanism is discussed in detail by Sarvarov and Salikhov [46].

Table 1. The probabilities of the $S-T$ transitions induced by the hyperfine interaction (nuclear spin $I = 1/2$).

| No. of pair | RP | $p_{ST}^0$ | $p_{ST}^{\infty}$ |
|---|---|---|---|
| I |  | $\frac{3}{16}\sin^2(At) + \frac{3}{4}\sin^2\left(\frac{A}{2}t\right)$ | $\frac{1}{2}\sin^2\left(\frac{1}{2}At\right)$ |
| II |  | $\frac{2}{3}\sin^2\left(\frac{3}{4}At\right)$ | $\frac{1}{2}\sin^2\left(\frac{1}{2}At\right)$ |
| III |  | $\frac{2}{3}\sin^2\left(\frac{\sqrt{3}}{4}At\right) + \frac{1}{3}\sin^2\left(\frac{\sqrt{3}}{2}At\right)$ | $\frac{1}{2}\sin^2\left(\frac{1}{2}At\right)$ |
| IV |  | $\frac{20}{27}\sin^2\left(\frac{3}{4}At\right) + \frac{4}{27}\sin^2\left(\frac{3}{2}At\right)$ | $\frac{1}{2}\sin^2\left(\frac{A}{2}t\right) + \frac{1}{8}\sin^2(At)$ |
| V |  | $\frac{3}{4}\sin^2\left(\frac{A}{2}t\right)$ | $\sin^2\left(\frac{A}{4}t\right)$ |
| VI |  | $\frac{15}{32}\sin^2(At) + \frac{3}{8}\sin^2\left(\frac{A}{2}t\right)$ | $\frac{1}{4}\sin^2\left(\frac{3}{4}At\right) + \frac{3}{4}\sin^2\left(\frac{A}{4}t\right)$ |

The above results were obtained on the hypothesis that the exchange interaction of the unpaired electrons of the radical pair is insignificant. This corresponds to the initial model where the $S-T$ transitions occur in the interval between two repeated collisions of the pair radicals, when the distances between the unpaired electrons are fairly large and the exchange integral $J$ is small, and not at the instant of direct contact between the radicals. However, in some cases the exchange interaction is presumably significant and this alters the process dynamics. In particular, such a situation can occur in biradical systems [49].

The nature of the influence of the exchange interaction on the $S-T$ transitions can be predicted fairly readily for the $\Delta g$ mechanism. Indeed, when no account is taken of the exchange interaction, the energy levels of the $S$ and $T_0$

states coincide, so that the transitions take place between two resonance levels. The exchange interaction splits the $S$ and $T_0$ levels, stops their resonance, and reduces the probability of the $S$ and $T$ transition [37].

In the HFI mechanism, the influence of the exchange interaction on the dependence of the $S-T$ mixing on the field is qualitatively different: the efficiency of the $S-T$ transitions passes through a maximum in the region of magnetic fields where the Zeeman splitting of the triplet levels is comparable to the singlet–triplet splitting and the singlet is in resonance with one of the triplet states, $T_{+1}$ or $T_{-1}$.

However, the exchange interaction ceases to play a role in singlet–triplet transitions if the lifetimes of the radical pairs in the "cage" are fairly short. Indeed, it can be shown that, for short-lived radical pairs, where $(\omega^2_{ST_0} + 4J^2)^{1/2}t < 1$, the probability of transition via the $\Delta g$ mechanism is independent of $J$ and coincides with the result defined by Eqn.(3) for $J = 0$. Similarly, in the case of the HFI mechanism of the singlet–triplet transition for short-lived radical pairs, where $(A^2_{\text{eff}} + J^2)^{1/2}t < 1$, the results defined by Eqns.(5) and (6) remain valid regardless of the exchange interactions.

Thus the dynamics of the radical pair spins are fully described in the case of the $\Delta g$ transition mechanism. For the HFI mechanism, calculations have been made of the dependence of the transitions of the radical pair on the magnetic field strength in the simplest systems, which made it possible to discover certain general characteristics over the singlet–triplet evolution of radical pairs. However, in the general case, a quantitative discussion of the effects due to the HFI mechanism, apparently requires calculations for each specific pair of radicals, since the transition probability depends significantly on the number of magnetic nuclei and the magnitude and signs of the HFI constants.

## IV. PHENOMENOLOGICAL MODELS OF THE RECOMBINATION OF RADICALS IN THE "CAGE"

Two models are considered for a phenomenological description of the recombination of radicals in the "cage": the diffusion [31] and exponential [25,29] models. According to the diffusion model, the "cage" for a radical pair consists of a region with a radius of approximately $10^{-7}$ cm and the lifetime of the radicals in the "cage" is determined by the time which they take to traverse this region. For solutions where the diffusion coefficient of radicals is $10^{-5}$ cm$^2$ s$^{-1}$, their lifetime in the "cage" is $10^{-9}-10^{-10}$ s.[31] This time can increase significantly, for example for highly viscous solutions. The recombination of radical pairs is treated phenomenologically. It is assumed that there is a reaction region, included between two concentric spheres with radii $r_0 - a$ and $r_0$, and that the recombination of singlet radical pairs in this region is characterised by a unimolecular constant $k(s^{-1})$.

Highly reactive radicals recombine on first contact with one another if the radical pair is in the singlet state. However, if the reactivity is not quite so high, repeated collisions of the radicals in the pair contribute to the overall recombination probability in addition to the first contact. Within the framework of the diffusion model, singlet–triplet transitions occur in the periods between collisions.

The statistics of repeated collisions in the "cage" have been examined in detail by Noyes [31]. On the basis of numerical calculations for repeated molecular collisions within the framework of "jumps" (the so-called random flight model), Noyes proposed the following approximation to the statistical weight $f(t)$ of the radicals in the "cage" involved in repeated encounters after a time $t$ when the initial distance between the pair radicals exceeds their collision radius by the distance of a single elementary jump [50]:

$$f(t)dt = \frac{0.24}{\tau}\frac{dt}{(t/\tau + 0.44)^{3/2}}, \quad (7)$$

with $\tau$ as the average time of a single elementary jump, a typical value of which is $\tau \simeq 10^{-11}$ s.

The exponential model of recombination differs significantly in its physical postulates from the diffusion model. In this model, repeated collisions of the radicals are not taken into account and it is assumed that a singlet–triplet transition occurs directly in the reaction zone. The liberation of radicals from the "cage" is described as unimolecular decomposition of the pair with a Poisson distribution of the radical pair lifetimes:

$$f(t)dt = \frac{dt}{\tau_c}\exp\left(-\frac{t}{\tau_c}\right), \quad (8)$$

where $\tau_C$ is the average lifetime of the radical pair in the "cage". The recombination of the radical pair in the singlet state competes with the process involving the liberation of the radicals from the "cage". The model described has been used in the theory of chemically induced nuclear polarisation [29] and in the theory of the triplet–triplet annihilation of electronically excited states in crystals [26].

The exponential model can describe adequately the kinetics of the recombination of radical pairs in the "cage" in a number of situations. When the solution contains a large number of radical traps, the probability of repeated contact between two given radicals becomes negligible and the "cage" recombination will correspond to the exponential model. The latter may be useful also when the radicals are held in the "cage" as a result of the formation of complexes or Coulombic attraction (in the recombination of radical-ions).

## V. APPROXIMATE CALCULATIONS OF THE EFFECT OF THE MAGNETIC FIELD IN RADICAL REACTIONS

For approximate estimates of the nature and scale of the field dependence of the probability of the recombination of radicals in the "cage" within the framework of the diffusion model, it is sufficient to restrict the treatment to a single repeated collision. It is then possible to calculate the probability of the $S-T$ transition averaged over the radical pair *ensemble*, using, for example, the distribution defined by Eqn.(7) with respect to the repeated collision times. Within the framework of the exponential model, one must find for such an estimate the probability of the $S-T$ transitions during the residence time of the radicals in the "cage", without taking into account recombination, averaged with the aid of the distribution defined by Eqn.(8). Presumably the efficiency of the recombination of the radical pair is proportional to the average population of the singlet state of the radical pair. The results of exact calculations confirm that this hypothesis is reasonable.

We shall now consider the results of estimates for an initial singlet pair. The following equations have been obtained for the probability of $S-T_0$ transitions induced by the $\Delta g$ mechanism: (a) within the framework of the exponential model [34]

$$\bar{p}_{ST_0}=\frac{1}{2}\frac{\omega^2_{ST_0}\tau_c^2}{1+\omega^2_{ST_0}\tau_c^2} \tag{9}$$

and (b) within the framework of the diffusion model[80]:

$$\bar{p}_{ST_0}=0.30\sqrt{\omega_{ST_0}\tau}. \tag{10}$$

We may note that the last result was obtained subject to the additional assumption that the quantity under the square root sign is small, which is true in most cases.

The typical differences between the $g$-factors of free radicals are $\Delta g \simeq 10^{-4}$–$10^{-3}$. Assuming that the lifetime of the radical pair in the "cage" is in the range $\tau_c \simeq 10^{-10}$–$10^{-9}$ s and that $\tau \simeq 10^{-11}$ s, we find that the $\Delta g$ mechanism should have a relatively weak influence on the probability of radical recombination in laboratory fields $H_0 \simeq 10^{-4}$ G. However, with increase of the viscosity by 1–2 orders of magnitude or for systems with a larger difference between the $g$-factors, the effects of the magnetic field may be considerable.

Table 2. The average probabilities of the $S-T$ transition in the radical pair for the diffusion model taking into account only one collision ($A\tau < 1$).

| No. of pair | $\overline{p^0_{ST}}$ | $\overline{p^\infty_{ST}}$ | No. of pair | $\overline{p^0_{ST}}$ | $\overline{p^\infty_{ST}}$ |
|---|---|---|---|---|---|
| I | $0.30\sqrt{A\tau}$ | $0.15\sqrt{A\tau}$ | IV | $0.34\sqrt{A\tau}$ | $0.20\sqrt{A\tau}$ |
| II | $0.24\sqrt{A\tau}$ | $0.15\sqrt{A\tau}$ | V | $0.22\sqrt{A\tau}$ | $0.21\sqrt{A\tau}$ |
| III | $0.30\sqrt{A\tau}$ | $0.15\sqrt{A\tau}$ | VI | $0.31\sqrt{A\tau}$ | $0.24\sqrt{A\tau}$ |

Note. The relation $\overline{p^0_{ST}} > \overline{p^\infty_{ST}}$ holds for all the radical pairs.

The results of calculations of the average probability of the $S-T$ transitions are summarised in Tables 2 and 3 for the HFI mechanism in the same systems for which Table 1 lists the solutions of the dynamic problems of the singlet–triplet evolution of the radical pair. The estimates which are based on the formulae quoted in Tables 2 and 3 for typical HFI parameters $A \simeq 10^8$–$10^9$ $s^{-1}$ and the parameters of the diffusion of radicals in solution $\tau_c \simeq 10^{-9}$ s and $\tau \simeq 10^{-11}$ s show that the probability of the $S-T$ transition changes by approximately 0.1 with increase of the magnetic field strength from zero to $H_0 \gg A$. There is a corresponding change in the probability of the recombination of radicals in the "cage". It follows from the data in Table 2 that the field effect depends on the specific structure of the radicals. The effect is small for radical pairs in which an anomalous time variation of the $S-T$ transitions is observed (for example, the radical pairs V and VI in Table 1). In this case, the contribution of the short- and long-lived radical pairs frequently cancel out on being averaged and the effect diminishes (Table 3).

For nuclei with a spin $I > \frac{1}{2}$, the probability of $S-T$ transitions has been calculated only in the case of radical pairs with a single magnetic nucleus [43,45]. Within the framework of the exponential model, the following results have been obtained for the initial singlet radical pair:

$$\bar{p}^0_{ST}=\frac{1}{2}\frac{I(I+1)A^2\tau_c^2}{1+\left(I+\frac{1}{2}\right)^2A^2\tau_c^2}, \tag{11}$$

$$\bar{p}^\infty_{ST_0}=\frac{1}{2(2I+1)}\sum_{m=-I}^{I}\frac{A^2m^2\tau_c^2}{1+A^2m^2\tau_c^2}.$$

Eqns. (11) make it possible to treat the changes in the radical recombination probability following isotopic substitution.

Table 3. The average probabilities of the $S-T$ transition in the radical pair for the exponential model.

| No. of pair | $\overline{p^0_{ST}}$ | $\overline{p^\infty_{ST}}$ |
|---|---|---|
| I | $\frac{3}{8}\left\{\frac{A^2\tau_c^2}{1+4A^2\tau_c^2}+\frac{A^2\tau_c^2}{1+A^2\tau_c^2}\right\}$ | $\frac{1}{4}\frac{A^2\tau_c^2}{1+A^2\tau_c^2}$ |
| II | $\frac{3}{4}\frac{A^2\tau_c^2}{1+{}^9/_4A^2\tau_c^2}$ | $\frac{1}{4}\frac{A^2\tau_c^2}{1+A^2\tau_c^2}$ |
| III | $\frac{1}{4}\frac{A^2\tau_c^2}{1+{}^9/_4A^2\tau_c^2}+\frac{1}{2}\frac{A^2\tau_c^2}{1+3A^2\tau_c^2}$ | $\frac{1}{4}\frac{A^2\tau_c^2}{1+A^2\tau_c^2}$ |
| IV | $\frac{5}{6}\frac{A^2\tau_c^2}{1+{}^9/_4A^2\tau_c^2}+\frac{2}{3}\frac{A^2\tau_c^2}{1+9A^2\tau_c^2}$ | $\frac{1}{4}\frac{A^2\tau_c^2}{1+A^2\tau_c^2}+\frac{1}{4}\frac{A^2\tau_c^2}{1+4A^2\tau_c^2}$ |
| V* | $\frac{3}{8}\frac{A^2\tau_c^2}{1+A^2\tau_c^2}$ | $\frac{1}{8}\frac{A^2\tau_c^2}{1+{}^1/_4A^2\tau_c^2}$ |
| VI* | $\frac{15}{16}\frac{A^2\tau_c^2}{1+4A^2\tau_c^2}+\frac{3}{16}\frac{A^2\tau_c^2}{1+A^2\tau_c^2}$ | $\frac{9}{32}\frac{A^2\tau_c^2}{1+{}^9/_4A^2\tau_c^2}+\frac{3}{32}\frac{A^2\tau_c^2}{1+A^2\tau_c^2/4}$ |

Note. The relation between $\overline{p^0_{ST}}$ and $\overline{p^\infty_{ST}}$ for radical pairs Nos. V and VI depends on $A\tau_c$: $\overline{p^0_{ST}} > \overline{p^\infty_{ST}}$ when $A\tau_c \leqslant 1$ and $\overline{p^0_{ST}} < \overline{p^\infty_{ST}}$ when $A\tau_c > 1$; for the remaining pairs, $\overline{p^0_{ST}} > \overline{p^\infty_{ST}}$.

## VI. GENERALISATION OF THE THEORY OF THE DIFFUSION RECOMBINATION OF RADICAL PAIRS AND RADICALS IN HOMOGENEOUS SOLUTIONS

A more detailed description of the influence of the magnetic field on radical reactions and also a description of the effect of the polarisation of nuclear and electron spins during chemical reactions required a revision of the traditional theory of the recombination of radicals in solution taking into account singlet–triplet transitions. Such generalisation of the theory for the recombination of correlated radical pairs has been achieved [37,45,47,51,52]. The theory of the recombination of radicals in random encounters in space, which takes into account logically the spin selection rules in the reaction and the role of interactions removing the spin prohibition, has been formulated [38,45]. In the generalised theory, it is necessary to

take into account simultaneously the changes in the spin and spatial coordinates of the radicals. This can be done using the formalism of the density matrix[53]. It has been shown [37,45,47] that the density matrix $\rho(\boldsymbol{r},t)$ of the *sub-ensemble* of radical pairs where the radius-vector between the radicals assumes a value $r$ at time $t$ satisfies the equation

$$\frac{\partial\rho(\mathbf{r},t)}{\partial t}=\hat{Q}_0\rho(\mathbf{r},t)-\frac{i}{\hbar}[\hat{V}(\mathbf{r}),\rho(\mathbf{r},t)]+D\Delta\rho(\mathbf{r},t), \tag{12}$$

where the first term on the right-hand side specifies the change in the pair spin density matrix without taking into account the interaction between the radicals, $\hat{V}$ represents the Hamiltonian for the interactoin between the unpaired electrons of the radical pair, and the last term describes the kinematic change in the pair density matrix owing to the mutual diffusion of the radicals.

In some studies[51,52], an additional term which takes into account the destruction of the radical pair as the result of recombination, was introduced into the right-hand side of Eqn.(12). Other workers [37,45,47] take into account the recombination reaction by introducing the appropriate conditions at the boundary of the reaction zone. The probability of the recombination of the radical pair is

$$p_{\text{rec}}=4\pi r_0^2 D\cdot Tr\int_0^\infty \mathrm{d}t\nabla\rho(\mathbf{r},t)|_{r=r_0}, \tag{13}$$

where $Tr$ indicates convolution with respect to the spin variables of the radical pair.

Specific calculations for radical pairs have been achieved hitherto only in terms of the $S-T_0$ approximation. If the initial distance between the radicals is $R_0$ for all radical pairs, then the field dependence of the recombination probability for the $\Delta g$ mechanism of the $S-T_0$ transition is described by the following relations[37]: (a) for a singlet precursor of the radical pair

$${}^{S}p_{\text{rec}}=\frac{r_0}{R_0}\frac{1}{1+q}\left[1+x+\cos\left(\frac{R_0-r_0}{r_0}x\right)\exp\left(-\frac{R_0-r_0}{r_0}x\right)\right]\Big/\left(2+\frac{1+2q}{1+q}x\right) \tag{14}$$

and (b) for a triplet precursor of the radical pair:

$${}^{T}p_{\text{rec}}=\frac{1}{3}\frac{r_0}{R_0}\frac{1}{1+q}\left[1+x-\cos\left(\frac{R_0-r_0}{r_0}x\right)\exp\left(-\frac{R_0-r_0}{r_0}x\right)\right]\Big/\left(2+\frac{1+2q}{1+q}x\right). \tag{15}$$

The following notation has been introduced in the above expressions:

$$q=D/kar_0,\quad x=(\omega_{ST_0}\tau_D)^{1/2},\quad \tau_D=r_0^2/2D. \tag{16}$$

The parameter $q$ defines the nature of the recombination: the rate of recombination is limited by the mutual diffusion of radicals for $q<1$ and by the reaction of radicals in the reaction zone (primary "cage") for $q>1$; $k$ is the rate constant for the recombination in a singlet pair ($s^{-1}$).

If the $S-T_0$ transitions are fairly rapid and there is sufficient time for their repeated occurrence during the lifetime of the radical pair in the "cage", then it follows from Eqns.(14) and (15) that the rate of recombination of the radical pair in the reaction zone is described by an average effective rate constant equal to $k/2$. The dependence of the recombination probability on field strength in moderate fields is described by equations which are qualitatively the same, as regards the nature of the dependence on $H_0$, as the approximate formulae obtained above taking into account only a single repeated encounter of the radicals. As an illustration, Fig. 3 presents the variation of the recombination probability of radical pairs with the magnetic field calculated from the formulae obtained by Salikhov et al.[37] The curves in Fig. 3 correspond to radical pairs which are initially located at the boundary of the reaction zone and correspond to different values of the parameter $\lambda$:

$$\lambda=\frac{k}{k+D/ar_0}. \tag{17}$$

Fig. 3 shows that the probability of the recombination of the initial singlet radical pair should fall with increase of the magnetic field and that of the triplet pair should increase.

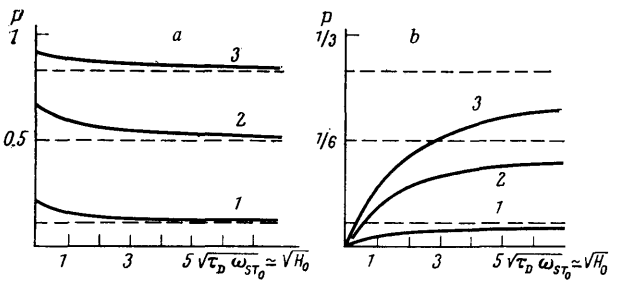


Figure 3. Variation with the magnetic field of the probability of the recombination of singlet (*a*) and triplet (*b*) radical pairs for the $\Delta g$ mechanisms of the $S-T$ transition corresponding to different values of $\lambda$: 1) 0.2; 2) 0.66; 3) 0.91.

The conditions for the observation of the field effect in the case of a triplet radical pair are particularly favourable, since in zero fields, where the $\Delta g$ mechanism is ineffective, the recombination product should be altogether absent.

In contrast to the recombination of correlated radical pairs, in the recombination of radicals in space one must consider the reaction of an *ensemble* of radicals randomly distributed in the system. The kinetic equations for the change in the spin density matrix for radicals A and B owing to their recombination reaction have been obtained[38,45] and are of the following form:

$$\left(\frac{\partial\rho^{\text{A}}}{\partial t}\right)_{\text{rec}}=-c_{\text{B}}(0)D\cdot Tr_{\text{B}}\int_{s(R)}\mathrm{d}s\Delta\rho^{\text{AB}}(r,t),$$
$$\left(\frac{\partial\rho^{\text{B}}}{\partial t}\right)_{\text{rec}}=-c_{\text{A}}(0)D\cdot Tr_{\text{A}}\int_{s(R)}\mathrm{d}s\Delta\rho^{\text{AB}}(r,t), \tag{18}$$

where $c_{\text{A}}(0)$ and $c_{\text{B}}(0)$ are the initial radical concentrations in solution. The right-hand sides of these equations describe the kinematic flux of the pair density matrix $\rho^{\text{AB}}$ from the "cage". Hence the solution of Eqns.(12) must be substituted as $\rho^{\text{AB}}$. However, in contrast to the recombination of radical pairs, for the reaction in a homogeneous solution with fairly long distances between the radicals, the following boundary condition must be adopted in conformity with the hypothesis that the correlation is weakened[54].

$$\rho^{\text{AB}}(r,t)\xrightarrow[r\to\infty]{}\rho^{\text{A}}(t)\times\rho^{\text{B}}(t). \tag{19}$$

Kinetic equations for the concentrations of radicals can be obtained from Eqn. (18) and (19) using the relations

$$c_{\text{A}}(t)=c_{\text{A}}(0)\cdot Tr\rho^{\text{A}}(t),\quad c_{\text{B}}(t)=c_{\text{B}}(0)\cdot Tr\rho^{\text{B}}(t). \tag{20}$$

The dependence of the recombination rate constant on the magnetic field has been analysed [38] with the aid of these equations in two cases: when the radicals have different $g$-factors and when one of the partners has a single magnetic nucleus with a spin of 1/2. For the $\Delta g$ mechanism, the recombination rate constant is

$$k_0 = 4\pi r_0 DF, \quad F = \frac{1}{2}\,\frac{1+x}{2(1+q)+(1+2q)x}. \tag{21}$$

Hence it follows that $k_0$ increases with the strength of the external magnetic field. This implies that the triplet radical pairs make the dominant contribution to the effect in random encounters. The influence of the magnetic field is particularly marked in diffusion-controlled reactions where $q < 1$. Fig. 4*a* presents the results of the calculation of the field dependence of the recombination efficiency in the encounter of two radicals for two values of $\lambda$.

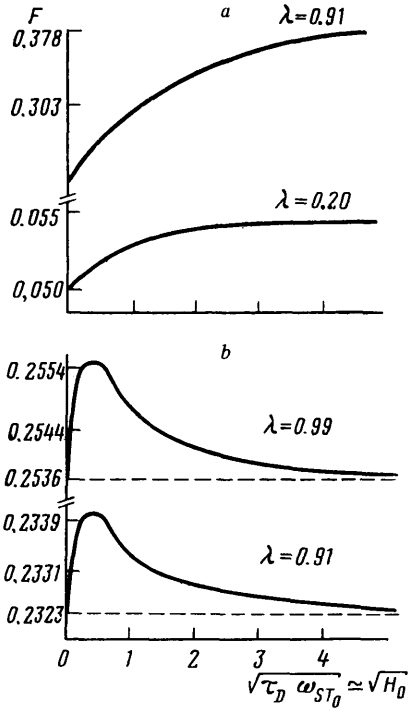

Figure 4. The efficiency of the recombination of radicals involved in random encounters in solution for the $\Delta g$ (*a*) and HFI ($A\tau = 0.01$) (*b*) mechanisms of the transitions in the radical pair in the "cage".

An interesting feature of the diffusion recombination of radicals in homogeneous solutions is that it reaches a steady state only for times of the order of the lifetime of the radical pair in the "cage" [55]. It has been shown [38] that singlet–triplet transitions increase the time taken by the reaction to attain kinetic conditions. For the $\Delta g$ mechanism, the rate of recombination tends to a steady-state value defined by Eqn. (21) in accordance with the law

$$k_0(t) = k_0\left(1 + \frac{r_0}{(\pi Dt)^{1/2}}\,2F\right). \tag{22}$$

Hence it follows that magnetic effects may be manifested also in the region where the recombination kinetics attain a steady state.

In $S$–$T$ transitions with a main HFI mechanism, exact relations for the field dependence of the rate constant have been so far obtained only when one of the radicals of the pair has a single magnetic nucleus with a spin of 1/2. [38] The results are illustrated in Fig. 4*b*, which demonstrates one of the unexpected but possible characteristics of the HFI mechanism: in fields $H_0$ comparable to the local field due to HFI there is a possibility of a maximum in the reaction efficiency. We may note that the changes in $F$ in regions of the maximum greatly exceed the difference between the values of $F$ in zero and strong magnetic fields. Presumably the appearance of the maximum is not obligatory for all radicals and should depend on their specific structure.

## VII. EQUATIONS DESCRIBING THE RECOMBINATION OF RADICALS WITHIN THE FRAMEWORK OF THE EXPONENTIAL MODEL

Bearing in mind that the exponential model of the recombination of radicals in solutions is widely used in the consideration of spin effects, we shall quote the corresponding kinetic equations. In the recombination of radical pairs, the pair density matrix satisfies the equation

$$\frac{\partial \rho^{AB}}{\partial t} = -\frac{i}{\hbar}[\hat{H}_{AB}, \rho^{AB}] - \frac{k}{2}(\hat{P}\rho^{AB} + \rho^{AB}\hat{P}) - \frac{1}{\tau_c}\rho^{AB}. \tag{23}$$

where the last term describes the liberation of the radicals from the "cage" and the penultimate term describes the destruction of the radical pair as a result of recombination; $\hat{P}$ is the projection operator onto the singlet state of the radical pair.

The kinetic equations describing the recombination of radicals in homogeneous solutions assume the following form [25,40,45]:

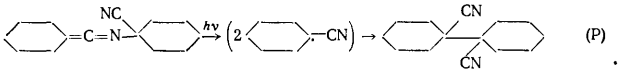
$$\left(\frac{\partial \rho^A}{\partial t}\right)_{rec} = -4\pi r_0 D \cdot c_B(0) \cdot T r_B(\rho^A \times \rho^B - \rho^{AB}),$$
$$\left(\frac{\partial \rho^B}{\partial t}\right)_{rec} = -4\pi r_0 D \cdot c_A(0)\, T r_A(\rho^A \times \rho^B - \rho^{AB}), \tag{24}$$

in which the pair matrix is found from the solution of the equation

$$\frac{\partial \rho^{AB}}{\partial t} = -\frac{i}{\hbar}[\hat{H}_{AB}, \rho^{AB}] - \frac{k}{2}(\hat{P}\rho^{AB} + \rho^{AB}\hat{P}) - \frac{1}{\tau_c}(\rho^{AB} - \rho^A \times \rho^B), \tag{25}$$

where, in contrast to Eqn. (23), account was taken also of the formation of the radical pair as a result of the random entry of two radicals into the "cage".

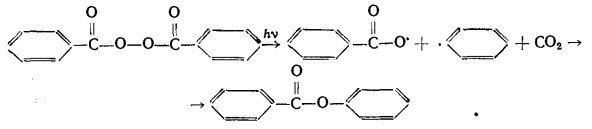
We may note that Eqns. (24) and (25) agree with the initial equations of the theory of the triplet–triplet annihilation of excitons in crystals [25] and of the quenching of excited triplet molecules in solutions [33]. We shall therefore return to these equations in the discussion of the quenching of the luminescence in solutions in the text below.



The solution of these equations show [40] that the exponential model yields qualitatively the same field dependence of the reaction efficiency as the diffusion model. Furthermore, exact calculations within the framework of the exponential model confirm the validity of the conclusions reached on the basis of approximate calculations.

## VIII. SPIN EFFECTS IN RADICAL REACTIONS

The models enumerated above for the description of the influence of the magnetic field on radical reactions are based on the hypothesis that spin effects play an important role in such reactions. We shall consider the experimental evidence for the manifestation of spin prohibitions in the recombination reactions of free radicals.



We shall consider in the first place the recombination of correlated radical pairs in the "cage", where the recombination efficiency may be expected to depend on the spin multiplicity of the radical pair (in the absence of mechanisms of rapid transitions between different spin states).

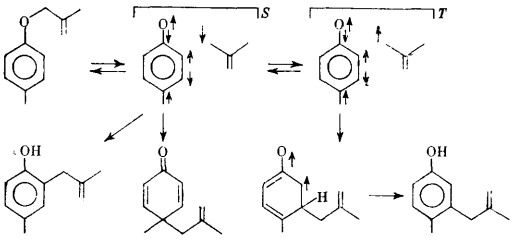
The influence of the spin multiplicity of radical pairs has been taken into account in a number of studies where direct and sensitised photolytic reactions were compared. Thus Fox and Hammond[56] observed an appreciable difference between the yields of the products of the recombination of two cyanocyclohexyl radicals in the photolysis of *N*-(1-cyanocyclohexyl)pentamethylene ketenimine:

(P)

In direct photolysis (via an excited singlet state) in carbon tetrachloride, approximately 24% of succinonitrile (P) is formed. The triplet-sensitised decomposition under the same conditions gives only 8% of compound (P). Thus the probability of the recombination of singlet radical pairs is in this case three times greater than that of the triplet pairs. Similar effects have been observed in the direct and sensitised photolysis of benzoyl peroxide[57]:

The yield of phenyl benzoate was approximately 3% for the triplet radical pairs and approximately 8% for the singlet pairs.

The effects of the spin multiplicity of the sensitiser on the formation of phenyl benzoate have been investigated recently for the same system[58]. Benzoyl peroxide solutions in toluene or benzene were irradiated by light from a high-pressure mercury lamp in the presence of aromatic hydrocarbons (naphthalene, fluorene, phenanthrene, etc.), which are singlet sensitisers, and also of aromatic ketones—acetophenone, benzophenone, and 2-methylbenzophenone. The latter are typical triplet sensitisers. It has been shown that the yield of phenyl benzoate is $\leqslant 3.0\%$ in the presence of triplet sensitisers and $\geqslant 10\%$ in the presence of singlet sensitisers.



Another class of reactions in which spin prohibition may be manifested includes the recombination of radicals in space. When two radicals react in each collision, the rate of their recombination will be determined solely by the rate of diffusion. The rate constant for such a diffusion-controlled reaction is defined by the expression

$$k_D = \left(\frac{4\pi N}{1000}\right)(\sigma_A + \sigma_B)(D_A + D_B), \qquad (26)$$

where $N$ is the Avogadro number, $D_A$ and $D_B$ are the diffusion coefficients of the radicals A and B in the reaction medium, and $\sigma_A$ and $\sigma_B$ are their reaction radii.

However, one should bear in mind that two radicals recombine in the collision only when the radical pair formed as a result of their encounter is in the singlet state. Since the probability of singlet encounters is 1/4, presumably the measured values of $k_D$ should be smaller by a factor of 4 than those predicted by Eqn.(26). Analysis of the experimental results for the kinetics of the recombination of organic radicals does indeed show this relation. The values of $k_D$ calculated by Eqn.(26) for the most typical experimental conditions are approximately $8 \times 10^9$ litre mole$^{-1}$ s$^{-1}$.[59] On the other hand, the measured constants for bimolecular radical reactions do not as a rule exceed $2 \times 10^9$ litre mole$^{-1}$ s$^{-1}$.[59]

The above behaviour does not apparently obtain in reactions involving hydrogen atoms, H, OH and $HO_2$ radicals, and solvated electrons [60]. They are of interest for the process under consideration, because they are not sterically hindered and have zero activation energy. However, it has been found that the experimental values of $k_D$ for these reactions are close to those calculated by Eqn.(26). The causes of the apparent absence of spin prohibition in reactions of this class have been examined[60]. The very interesting possibility of the influence of the electron spin on the orientation effect in radical reactions is discussed in another investigation[61]. In the Claisen photochemical rearrangement (the photolysis of allyl *p*-methylphenyl ether), the authors observed the formation of the product of the substitution of the allyl group not only in the *ortho*- and *para*-positions but also in the *meta*-position in the aromatic ring. In the analogous thermal rearrangement, *meta*-products are not formed. The possibility of the formation of *meta*-products in the photochemical rearrangement can be understood by examining the following mechanism proposed on the basis of the analysis of the effects of chemically induced nuclear polarisation in this reaction:

The radical pairs formed in the singlet state yield mainly *ortho*- and *para*-substitution products. For triplet pairs, *ortho*- and *para*-substitution is spin-prohibited. However, the spin density is negative in the *meta*-position, so that addition of the allyl radical in this position can occur in the triplet radical. According to the authors, this in fact explains the formation of the *meta*-product.

The above examples show that the electron spin effects have in many instances a very marked influence on the kinetics of the recombination of free radicals. Consequently, when the rates of radical reactions are considered, account must be taken of electron spin prohibitions.

We shall now consider the effects of nuclear spin in radical recombination reactions. It follows from the above theoretical analysis that the hyperfine interaction of nuclei with electrons in the radical pair can lead to a singlet–triplet transition, i.e. to a change of the multiplicity of the radical pair. Since the HFI energies are different for different nuclear isotopes, one may expect differences between the recombination efficiencies of the radical pairs containing these isotopes. We shall call this phenomenon the magnetic isotope effect, in contrast to the usual kinetic isotope effect [34,37].

Experimental studies on isotope effects in radical reactions have been comparatively few and are practically all concerned with the rate of decomposition of organic peroxides and azo-compounds (see, for example, Seltzer and Hamilton [62] and Rummel et al. [63]). In many cases, anomalously large secondary isotope effects were observed in the thermal analysis of hydrogen- and deuterium-containing compounds ($k_H/k_D \simeq 1.3-1.4$) [63] which it would be tempting to interpret in terms of the difference between the magnetic properties of hydrogen and deuterium. The HFI constants for H and D are indeed known to differ by a factor of approximately 7. Consequently there is a greater probability of a change in the spin state (from $S$ to $T$) in hydrogen-containing radical pairs and thus one may expect that the efficiency of the reverse recombination of the primary pair, with reformation of the initial compound, will be smaller than for the deuterium analogue.

Unfortunately, in all these cases one cannot rule out the possibility that the isotope effect arises in the primary decomposition of the molecule and not in the reactions of the radical pair. There is then a possibility of an alternative explanation of the nature of the observed isotope effects, associated with the differences between the zero-point vibrational energies [64]. We shall only mention that a quantitative interpretation of the secondary isotope effects within the framework of these ideas involves considerable difficulties. We are familiar with only one study where a direct isotope effect on the rate of recombination of the radical pair was observed [65]. We shall consider it in greater detail. A study was made of the thermal decomposition of azobisisobutyronitrile (AIBN) and [12-D]AIBN in chlorobenzene at 65 °C. The decomposition mechanism can be represented in the following form:

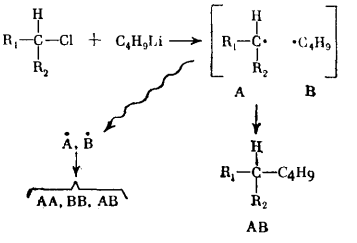
$$R{-}N_2{-}R \xrightarrow{k_I} (2R^{\cdot}) + N_2 \quad ,$$

$$(2R^{\cdot}) \xrightarrow{k_{II}} \text{recombination},$$

$$(2R^{\cdot}) \xrightarrow{k_{III}} 2R^{\cdot}\ \text{(diffusion)},$$

$$\dot{R}{=}N{\equiv}C{-}\overset{CH_3}{\underset{CH_3}{\overset{|}{\underset{|}{C^{\cdot}}}}} \quad ,$$

where round brackets represent the cage. The cage effect in this system has been studied in a large number of investigations and is well known. The authors were able to measure the quantity $a = k_{III}/(k_{II} + k_{III})$ which is inversely proportional to the efficiency of the recombination within the cage. It was found that $a_H = 0.56 \pm 0.015$ and $a_D = 0.51 \pm 0.015$. Since the radical recombination reaction ($k_{II}$) has virtually zero activation energy, the usual kinetic isotope effect is impossible. The observed difference between $a_H$ and $a_D$ has been attributed [65] to the influence of the mass of the radicals on their diffusion from the "cage". According to the authors, the probability of the diffusion of heavy radicals (with D) is lower, so that $a_D < a_H$. However, this explanation conflicts with the accepted theory of radical recombination in the "cage" [66]. According to Koenig and Fischer [66], the opposite effect should be observed—heavier radicals should give rise to a smaller yield of the recombination product (i.e. $a_D > a_H$).



The observed effect can be simply explained on the basis of the different magnetic properties of the isotopes. In this case, it is possible to estimate quantitatively the expected magnitude of the isotope effect.

According to Eqn. (4), the effective HFI constants for radical pairs are $4 \times 10^8$ and $10^9$ rad $s^{-1}$ for [12-D]AIBN and [12-H]AIBN respectively. On substituting these values in the theoretical expression for the radical pair recombination probability (see Table 2, RP I), we find that the calculated isotope effect on the radical recombination efficiency (approximately 10%) agrees well with the observed value.

The above discussion shows that the possibility of the manifestation of "magnetic" effects must be borne in mind in the analysis of the nature of the experimental kinetic isotope effects in radical recombination reactions.

## IX. EXPERIMENTAL DATA FOR THE INFLUENCE OF THE MAGNETIC FIELD ON RADICAL REACTIONS

A number of studies, where the influence of the magnetic field on the rate of radical reactions was considered, have now been made. Some [41,42,47,48,67-69] were devoted to the reactions of alkyl-lithium with arylchloromethanes in solutions. The observation and analysis of the effects of the chemically induced polarisation of $^1H$, $^{19}F$, and $^{13}C$ nuclei showed that these reactions proceed via the following radical mechanism:

Thus the initial pair of two alkyl radicals in the singlet state is the direct precursor of the final product.

It has been observed [42] that, following an increase of the magnetic field from the terrestrial field (approximately 0.5 G) to $H = 20\,000$ G, the ratio of the main products AB and AA changes appreciably in the reaction of pentafluorobenzyl chloride ($R_1 = C_6F_5$ and $R_2 = H$) with butyl-lithium in boiling hexane. In a high magnetic field, [AB]/[AA] increases by 30%. It is readily seen that the observed effect is in good qualitative agreement with the HFI mechanism of the influence of the magnetic field discussed above. Indeed, in a strong field the probability of the $S-T$ transition in the pair of pentafluorobenzyl and butyl radicals diminishes, which entails an increase in the probability of the radical recombination within the cage. The latter leads in its turn to an increase of [AB]/[AA] with increasing magnetic field strength.

The study of the overall variation of [AB]/[AA] with field strength for this reaction [48] confirmed that the observed effect is due to the HFI mechanism. Fig. 5 illustrates the experimental variation of the ratio of the products AB and AA with the magnetic field strength for the reaction of pentafluorobenzyl chloride with butyl-lithium. The curve is S-shaped with a transitional region corresponding to $H \simeq 50-200$ G. Approximate calculations for the HFI model predict precisely this type of dependence of the population of the singlet state $p_S$ and the corresponding probability of the recombination of the singlet radical pairs on the magnetic field [48]. Fig. 6 illustrates the variation of $p_S$ with the magnetic field strength for several values of the HFI constant for a model radical pair with a single proton, calculated within the framework of the exponential model. Fig. 6 (curve *1*) shows that $p_S$ for radical pairs with $At < 1$ increases with increasing magnetic field and that the transitional region corresponds to

$H \simeq A/\gamma$. In the system investigated, the radical pair contains several magnetic nuclei and an appreciable change in $p_S$ should be observed in fields $H \simeq A_{eff}/\gamma = \frac{1}{\gamma}(\sum_i A_i^2)^{1/2} \simeq$ 60 G. Thus theoretical estimates within the framework of the HFI model agree satisfactorily with experiment.

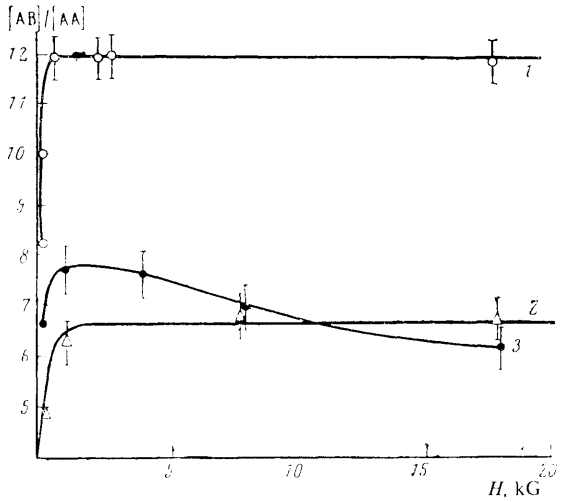


Figure 5. Experimental variation of the ratio of the reaction products AB and AA with the magnetic field strength in the reaction of $C_4H_9Li$ with pentafluorobenzyl chloride (curve *1*), *p*-fluorobenzyl chloride (curve *2*), and chlorodi-(pentafluorophenyl)methane (curve *3*).

It has been shown [69] that the influence of the magnetic field can also be observed in reactions of butyl-lithium with a series of other arylchloromethanes $\begin{matrix} R_1 \\ \\ R_2 \end{matrix}\!\!\diagdown\!\!\diagup\!\!\text{CHCl}$, where $R_1 = C_6H_5$ and $R_2 = H$ (1), $R_1 = C_6H_4F$ and $R_2 = H$ (2), and $R_1 = R_2 = C_6F_5$ (3). The field dependence of [AB]/[AA] for compound (2) is of the same form as for the reaction of pentafluorobenzyl chloride with butyl-lithium (Fig. 5). Consequently, the magnetic field effects in this system are described by the HFI mechanism. On the other hand, in the reaction of chlorodi(pentafluorophenyl)methane in strong fields, an appreciable decrease of [AB]/[AA] is observed instead of a plateau (Fig. 5). The increase of [AB]/[AA] in fields ranging from 0.5 to 1000 G for chlorodi(pentafluorophenyl)methane is described satisfactorily by the HFI mechanism. The decrease of this ratio on further increase of $H$ has been explained [68,69] by the difference between the Zeeman energies of the electrons in the radical pair ($g_1\beta H - g_2\beta H$), which provides an additional mechanism of the singlet–triplet transition (the $\Delta g$ mechanism) and leads to a decrease in the probability of the radical recombination within the cage. A study of the effects of the chemically induced polarisation of the $^1H$ and $^{19}F$ nuclei did indeed demonstrate an appreciable difference between the *g*-factors of the di(pentafluorophenyl)methyl and butyl radicals [70]. The field dependence of the population of the singlet states of the radical pair has been calculated [68] within the framework of the exponential model with a simultaneous examination of the HFI and $\Delta g$ mechanisms of the $S$–$T$ transition in a radical pair with the same magnetic nucleus With a suitable choice of parameters, the calculated curve agrees satisfactorily with experimental curve (cf. Figs. 5 and 6).

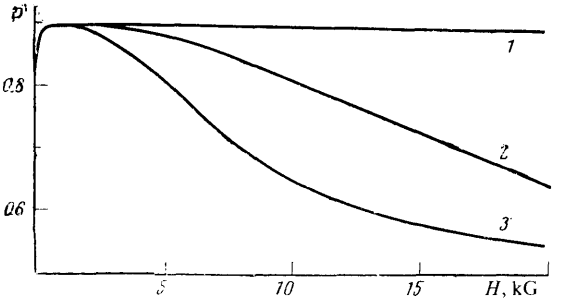

Figure 6. Calculated variation of the population of the singlet state of the radical pair having a single magnetic nucleus with the external magnetic field: *S* precursor; $\tau_c = 10^{-9}$ s; $A = 10^9$ rad $s^{-1}$; $\Delta g$: 1) 0; 2) 0.005; 3) 0.01.

The parameters specified in theoretical models to which the observed influence of the magnetic field corresponds have been discussed [48]. Using the experimental values $\{[AB]/[AA]\}_\infty = 12.2$ and $\{[AB]/[AA]\}_0 = 8.5$ for the reaction of pentafluorobenzyl chloride with $C_4H_9Li$ within the framework of the diffusion model of the radical pair for $A_{eff} = 10^9$ rad $s^{-1}$, $\tau = 6 \times 10^{-10}$ s was obtained as the time of the diffusion jump. This value exceeds appreciably the typical diffusion jump times ($10^{-11}$ s) for solvents with the usual viscosities. In order to account for this discrepancy, the authors [48] used the hypothesis [71] according to which the radicals in the system investigated are not involved in the reactions in a free state but in the form of a complex with an associated species of the organolithium compound. It is reasonable to expect that the characteristic diffusion time of such a conglomerate will be much longer than for a typical radical pair (approximately $10^{-11}$ s).

Thus one may conclude that, in order to obtain appreciable effects of the magnetic field on radical reactions (tens per cent), it is necessary to investigate reactions where the intermediate free radicals exhibit an anomalously low mobility ($10^{-9}$–$10^{-10}$ s). One of the ways of reducing diffusional mobility is to carry out the reactions in viscous solvents. It has been shown [42] for the above reaction of pentafluorobenzyl chloride with $C_4H_9Li$ that an increase of the viscosity of the solvent on passing from hexane to cyclohexane does indeed increase the magnetic effect. In the usual instances of radical reactions in solvents with normal viscosities ($\tau \simeq 10^{-11}$ s), insignificant magnetic effects are to be expected ($\lesssim 10\%$), these may not be susceptible to detection by the existing analytical methods. Analysis of the literature shows that all the published examples where the absence of an effect of the magnetic field on radical reactions in solvents has been demonstrated [18,19,72] can be included in precisely this class.

An interesting observation of the effects of the magnetic field has been made in a study [73] of the recombination of a pair of negative and positive radical ions. The idea of

the experiment was as follows. The solvent (squalane) molecule was ionised by pulse irradiation with fast electrons. Fluorene molecules, present in solution at a low concentration, capture both the electron and the parent positive ion. This results in the formation of a singlet pair of radical-ions linked by Coulombic forces and inevitably recombining. Before recombination, the radical pair may undergo the $S-T$ transition. The formation and recombination of the radical-ions can be represented schematically as follows:

$$S \rightsquigarrow S^+ + e^- , \quad (27)$$

$$S^+ + M \longrightarrow S + M^+ , \quad (28)$$

$$e^- + M \longrightarrow M^- , \quad (29)$$

$$M^+ + M^- \longrightarrow M^* + M . \quad (30)$$

Here S is the solvent (squalane), M the fluorene molecule, and M* the excited singlet and triplet states of fluorene. Presumably, as in the recombination of neutral free radicals, the magnetic field can influence the rate of the $S-T$ transition and hence the ratio of the excited singlet and triplet molecules.

An important experimental advantage in the study of this process has been the fact that the product of the recombination of the radical-ions is a molecule in an electronically excited state. The existing optical methods make it possible to determine with a high accuracy the concentrations of both singlet (from the fluorescence) and triplet (from the absorption) states. It is noteworthy that, in contrast to the radical reactions discussed above, the radical-ions formed in the pair cannot emerge from the "cage" and recombine with a probability of unity, since the initial distance between the charges (50–150 Å) is smaller than the Onsager radius for the solvent investigated (300 Å).

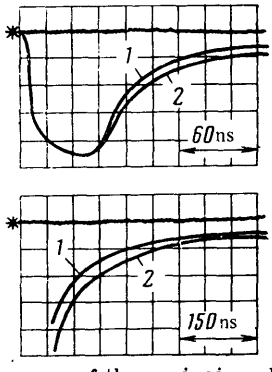

Figure 7. Oscillogram of the emission observed in the pulse radiolysis of a 0.01 M solution of fluorene in squalane in a 3 M eV electron accelerator[73]: 1) without a magnetic field; 2) in a 1000 G magnetic field.

Fig. 7 presents the oscillogram of the emission spectrum observed in the pulse radiolysis of a 0.01 M solution of fluorene in squalane using an electron accelerator with an energy of 3 M eV. Evidently, in a magnetic field ($H$ = 1000 G) the emission intensity after the pulse (approximately 50 ns) is appreciably higher. The observed effect implies that the population of the precursor singlet radical-ion pairs increases in the magnetic field, which can be explained qualitatively within the framework of the HFI model. A study[73] of the field dependence of the fluorescence intensity confirmed this conclusion. Fig. 8 shows that the overall form of the experimental curve is analogous to that calculated for the HFI mechanism (cf. Fig. 6). Since the yield of the singlet states increases in the magnetic field, one may expect a simultaneous decrease in the yield of the excited triplet states. Although in the latter case the situation is greatly complicated owing to the longer lifetime of the triplet states, the authors[73] nevertheless succeeded in observing experimentally a slight decrease of the concentration of triplets in the magnetic field (Fig. 8). It is noteworthy that, in control experiments with an anion, where the mechanisms of the magnetic effects discussed above do not operate, the magnetic field has almost no influence on the yield.

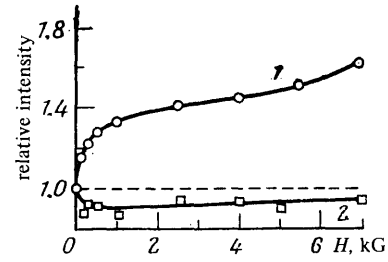

Figure 8. The influence of the constant magnetic field on the intensity of fluorescence (curve *1*) and absorption (curve *2*) in the pulse radiolysis of fluorene solutions in squalane[73]. The fluorescence and absorption were observed at 100 ns intervals after the pulse.

Analogous experiments designed to investigate the magnetic effects on the recombination of fluorene radical-ions in solutions have been carried out using a source of $\gamma$-radiation. The results of the measurements of the fluorescence intensity on radiolysis in different magnetic fields are illustrated in Fig. 9. It is noteworthy that, in contrast to the earlier investigation[73], here a study was made of the recombination of radical-ions in solvents of different viscosities. For the most viscous solvent (squalane), the effect of the magnetic field on the fluorescence yield and hence on the population of the singlet radical pairs is a maximum. In benzene, which had the lowest viscosity, the field effect could not be observed at all, while an intermediate situation was noted for cyclohexane. These results as well as those discussed above[42] confirm the theoretical conclusion that an increase of solvent viscosity can increase significantly the effect of the magnetic field in the recombination of the radical pair.

In conclusion, we shall consider the possibility of an effect by the magnetic field on radical reactions in solids. In this case, the decrease of diffusional mobility should in general favour the magnetic effects within the framework

of the mechanisms considered, with participation of radical pairs. So far there have been no reports in the literature of experimental observations of such effects.

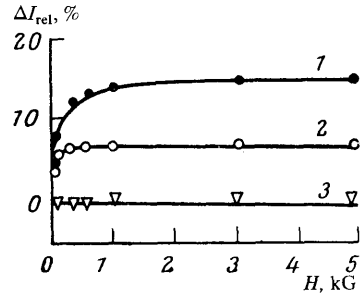

Figure 9. The influence of the magnetic field on the fluorescence intensity ($\Delta I_{rel}$ is the increase of the intensity) in the $\gamma$-radiolysis of fluorene solutions in different solvents: 1) squalane; 2) cyclohexane; 3) benzene[74].

The influence of the magnetic field on the concentration of free radicals in the low-temperature photolysis of formaldehyde has been investigated[75] by ESR. The system is of interest because the pair formed as a result of the photolysis

$$H_2CO \xrightarrow{h\nu} H\dot{C}O + \dot{H}$$

contain radicals with very high HFI constants: atomic hydrogen with $A$ = 500 g and the formyl radical with $A$ = 132 G. Only the formyl radical is detected in the ESR spectrum at 77 K, while the H atom is insufficiently stable under these conditions. The kinetics of the accumulation of HĊO radicals were studied in magnetic fields of 75 and 6200 G directly in the cavity of the ESR spectrometer (the residual magnetic field was 75 G). The experiments showed that the steady-state concentration of formyl radicals is higher in the photolysis in a high field (Fig. 10). The most important mechanisms of the destruction of HĊO radicals, leading to the establishment of a steady-state concentration, are associated with the following reactions:

$$H\dot{C}O \rightarrow \dot{H} + CO, \quad (31)$$

$$\dot{H} + H\dot{C}O \rightarrow H_2CO, \quad (32)$$

$$\dot{H} + H\dot{C}O \rightarrow H_2 + CO. \quad (33)$$

It has been suggested[75] that the magnetic field influences the recombination of a formyl radical and a hydrogen atom in a random encounter within the matrix [reactions (32) and (33)]. Indeed the sign of the effect corresponds qualitatively to the HFI mechanism of the influence of the magnetic field on $F$ pairs.

Analogous experiments, carried out with deuteroformaldehyde[75], failed to show an appreciable effect of the magnetic field on the steady-state light-induced concentration of DĊO radicals. According to the authors, this may be associated both with the lower HFI constants for the D atoms and DĊO radicals compared with Ḣ and HĊO and with the reduced mobility of atomic deuterium.

The effects of the magnetic field on the radiation-induced polymerisation of methyl methacrylate and acetaldehyde have been investigated at low temperatures[76,77] and it was found that the magnetic field influences both the rate of polymerisation and the molecular weight of the polymers formed. Since these processes can proceed via a free-radical mechanism, presumably the mechanisms of the influence of the magnetic field on the radical pair reactions examined above operate in these cases too. Both chain initiation and quadratic chain termination are magnetically sensitive stages of radical polymerisation.

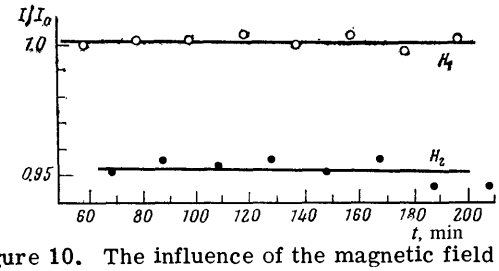

Figure 10. The influence of the magnetic field on the steady-state photochemically induced concentration of formyl radicals in the low-temperature photolysis of formaldehyde at 77 K ($H_1 > H_2$).[75]

In conclusion of this section, we may quote that the influence of the magnetic field on radical reactions is now fairly well understood. At the same time, it is clear that the regions where the expected effects should be maximum are so far not susceptible to experiment. This involves in the first place carrying out the reactions under conditions where the diffusional mobility of the radicals is lower by 1–2 orders of magnitude than the usual mobility and, in the second place, the study of the products of the triplet radical pairs within the "cage", where the effect of the relative change in the rate of reactions should be particularly pronounced.

## X. PROCESSES INVOLVING TRIPLET MOLECULES

Like free radical reactions, processes involving triplet molecules can be selective with respect to spin and can depend for this reason on the external magnetic field. As already mentioned in the introduction, such dependence was observed for the first time in solid organic crystals[23–26]. These studies stimulated analogous research on liquids. Spin-selective processes, which have been investigated experimentally in liquids and for which an effect of the magnetic field has been observed, are listed below.

1. The quenching of the excited triplet state by a free radical[78,79]. This process has a doublet final state and the quenching step can therefore occur only in collisions where the triplet molecule and the radical are in a collective doublet state.

2. Triplet–triplet annihilation[80]. In a random encounter in solution, a pair of triplet molecules can form singlet, triplet, and quintet states with respect to the total spin. Quenching takes place in the singlet state, since it leads to the formation of molecules in ground and excited singlet states.

3. The quenching of excited triplet states by oxygen [81]. Since oxygen has a triplet ground state, this process is analogous to the triplet–triplet annihilation and is also spin-selective.

4. The photochemical oxidation of aromatic hydrocarbons [82]. The primary stage in this reaction is the formation of an excited singlet oxygen molecule as a result of the collision of an excited triplet hydrocarbon molecule with oxygen in the ground state. The influence of the magnetic field on this process has so far been established only for the reaction in the solid phase.

The influence of the magnetic field on the above processes is interpreted in terms of a mechanism formally identical with that examined for the recombination reactions of free radicals. According to the dominant view, the magnetic field influences the dynamics of the spins of two paramagnetic species, i.e. the rate of change of the multiplicity of the pair of paramagnetic species which have collided in solution. The change in multiplicity can occur both on direct contact of the species and during their lifetime in the "cage", during the intervals between repeated collisions of a given pair of paramagnetic species.

As in the recombination of radicals, the change in spin multiplicity can again be induced by the $\Delta g$ and HFI mechanism. However, the transitions due to the dipole–dipole interaction of the unpaired electrons of each of the triplet molecules are more effective for the latter. In solutions, the thermal motion of triplet molecules modulates this dipole–dipole interaction in a random fashion, which leads to an effective paramagnetic relaxation of the triplet molecules. These relaxation transitions mix the states of two paramagnetic species with different multiplicities. Thus the influence of the magnetic field on elementary processes involving triplet molecules in solutions is interpreted as the result of the field dependence of the relaxation transitions caused by the fluctuating dipole–dipole interaction in the triplet molecules. We point out yet again that this interpretation is quite equivalent to the mechanism proposed by Brocklehurst [32] to account for the effect of the magnetic field in radiation-chemical reactions.

The influence of the magnetic field on processes involving triplet molecules in solutions has been examined theoretically by Atkins and Evans [33], who investigated comparatively non-viscous solutions where the molecular rotation is fairly rapid so that stochastic perturbation theory and the Redfield equation can be used to calculate the kinetic coefficients describing the relaxation transitions [33]. A theory of the processes under consideration may be developed on the basis of the fundamental equations which were quoted above in the discussion of the radical recombination reaction [Eqns. (12)–(25)]. The specific features of a real system are reflected in the formulation of the equations for the pair density matrix $\rho AB$.

Atkins and Evans calculated the probability of the triplet–triplet annihilation in arbitrary magnetic fields. The following expression has been obtained for the ratio of the intensities of the fluorescence accompanying this annihilation in strong (approximately 10 000 G) and zero magnetic fields:

$$I_H/I_0 = 1 - 0.61\Phi_{TT}(k(0)\tau_a)^{1/2}, \quad (34)$$

where $\tau_a$ is the duration of the elementary step in translational diffusion, $\Phi_{TT}$ is related to the probability $\lambda_T$, that the triplets which have collided will be annihilated subject to the condition that the pair was in the singlet state during the encounter, by the expression

$$\Phi_{TT} = \lambda_T/(1-\lambda_T); \quad (35)$$

and $k(0)$ is the spectral density of the dipole–dipole interaction at zero frequency:

$$k(0) = (D^2 + 3E^2)\tau_r. \quad (36)$$

Here $D$ and $E$ are the principal values of the dipole–dipole interaction tensor and $\tau_r$ is the characteristic rotational relaxation time.

Analogous reasoning for the quenching of triplet molecules by radicals leads to the following results [33]:

$$I_H/I_0 = 1 + 0.95\Phi_{DT}(k(0)\tau_a)^{1/2}, \quad (37)$$

where $\Phi_{DT}$ is related to the probability of the quenching of the triplet $\lambda_D$ in such a collision, where the pair was in the doublet state, by the expression

$$\Phi_{DT} = \lambda_D^2/\left(1 - \frac{4}{3}\lambda_D + \lambda_D^2\right). \quad (38)$$

Theoretical analysis shows that the probabilities of the triplet–triplet annihilation and of the quenching of the triplet biradicals in solutions should decrease with increasing magnetic field strength. The opposite variation with the field should be observed for the fluorescence intensity in such a case. The theory predicts in addition that the transitional region is located in fields corresponding to the equality of the Zeeman and rotational frequencies.

The theoretical results [33] are in good qualitative and quantitative agreement with numerous experiments [80–90]. Tables 4–6 list systems in which the magnetic field has an effect on the elementary processes involving triplet molecules.

Table 4. Experimental results for the influence of the magnetic field on the rate of triplet–triplet annihilation in solutions (for delayed fluorescence).

| Reaction | Change in luminescence intensity, % (for H = 8 kG)** | References |

*E = excimer.

**In the magnetic field, the luminescence intensity diminishes, indicating a decrease in reaction rate.

The first successful observation of the influence of the magnetic field was made in 1969 by Faulkner and Bard in a study of the delayed fluorescence of anthracene in solution on photoexcitation [80]. Delayed fluorescence (DF) is known to arise as a result of the formation of an excited singlet state on annihilation of two triplet states: $T + T \rightarrow$

$S + S_0$ ($T$ and $S$ are the excited triplet and singlet states and $S_0$ is the ground state of the molecule). The DF intensity is then defined by the expression

$$I_{DF} = \frac{1}{2}\Phi_f k_a (I_a \Phi_T \tau)^2, \quad (39)$$

where $\Phi_f$ is the probability of fluorescence, $k_a$ the rate constant for the triplet–triplet annihilation, $I_a$ the rate of absorption of light, $\Phi_T$ the probability of the formation of the triplet state, and $\tau$ the lifetime of the triplet state.

It has been observed[80] that the DF intensity decreases with increase of the magnetic field strength (see Fig. 11 and Table 4). In principle, both $\Phi_T$ and $k_a$ are magnetically sensitive quantities. Experiments on sensitised photolysis permitted a more unambiguous solution of this problem. Whereas in direct photolysis the triplet states of anthracene arise as a result of an intercombination transition from excited singlet states, on sensitisation they are populated in a triplet–triplet energy transfer process. Consequently, in such cases the efficiency of the formation of triplet states $\Phi_T$ is determined by different processes. It has been shown[80] that the variation of the DF intensity with the magnetic field is the same for both direct and sensitised photolysis. This enabled the authors[80] to conclude that the observed variation of the DF intensity in the magnetic field is due to the influence of the latter on the triplet–triplet annihilation rate constant. The decrease of the rate of the triplet–triplet annihilation in the magnetic field (to 7%), manifested in the DF spectra, was subsequently observed also for a number of other systems (see Table 4). It is noteworthy that the effect of the magnetic field depends strongly on the solvent, which apparently indicates a significant role of the medium in the annihilation processes. In a study of DF in pyrene and 1,2-benzanthracene solutions[84], it was possible to observe the influence of the magnetic field not only on the fluorescence of the monomeric molecules but also on that of dimers (exciplexes).

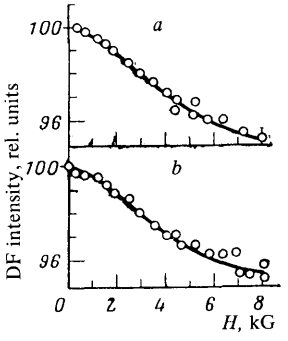

Figure 11. The effect of the magnetic field on the intensity of delayed fluorescence observed in the photolysis of anthracene in solution in chloroform (*a*) and dimethoxyethane (*b*) [80].

Numerous experimental studies have been devoted to the quenching of triplet states by free radicals (Table 5). In the presence of radicals, the DF lifetime is appreciably shortened and the effect of the magnetic field on the fluorescence intensity is of the opposite sign (the intensity increases with increase of the field strength). The usual mechanism for the process is

$$T + T \xrightarrow{k_a} S + S_0, \quad (40)$$

$$T + R \xrightarrow{k_R} S_0 + R, \quad (41)$$

$$T \xrightarrow{k_0} S, \quad (42)$$

where R is a quenching agent in a doublet state (free radical).

Table 5. Experimental results for the influence of the magnetic field on the quenching of triplet states by radical-ions.

| Reaction $R + T \rightarrow R + S_0$ | Concentration of radicals (molecules), M | Change in luminescence intensity, % (H = 8 kG)* | Method of recording | Refs. |

*The DF and ECL intensity increases in the magnetic field, indicating a decrease of the rate of reaction.
**H = 6 kG.
***For the ECL experiments, the "radical concentration" column lists the concentrations of the initial compounds from which the radical-ions are formed.

The magnetic field affects reactions (40) and (41) in the same way, decreasing the constants $k_a$ and $k_R$. However, it is readily seen that, when reaction (41) predominates over reaction (40), the DF intensity, determined by the overall concentration of triplets, will decrease in the magnetic field. The change in the nature of the influence of the magnetic field on DF can be readily traced when the relative concentration of radicals is varied (see Table 5): the effect increases with increasing concentration of the radical-ions.

Together with the DF method, electrogenerated chemiluminescence (ECL) has been widely used to investigate the effect of the magnetic field on elementary processes involving triplet states. The idea of such experiments is as follows. In an electrochemical cell containing an electrolyte (as a rule tetrabutylammonium perchlorate) and the test compound (for example, anthracene), the radical-ions $R^+$ and $R^-$ are produced. The subsequent processes are listed below:

$$R^+ + R^- \rightarrow R + T \quad \text{(electron transfer)},$$
$$R^+ + T \rightarrow R^+ + S_0 \quad \text{(quenching of triplets by radical-ions)},$$
$$T + T \rightarrow S + S_0 \quad \text{(triplet-triplet annihilation)},$$
$$R^+ + S \rightarrow R^+ + S_0 \quad \text{(quenching of singlet by radical-ions)},$$
$$T \rightarrow S \quad \text{(non-radiative processes), etc.}$$

The luminescence intensity due to the excited singlet states is recorded in the experiments.

Virtually all the systems in which the influence of the magnetic field on ECL was observed belong to the class of reactions with an "energy deficit", since the energy evolved on electron transfer is insufficient for the direct formation of the excited singlet state. It has been shown in a number of studies that in such systems the luminescence intensity increases with increasing magnetic field strength (up to 30%). This effect is usually explained by the fact that radical-ions play an important role in the reactions as triplet quenching agents. Since the excited states generated in ECL processes are formed together with radical-ions, the rate of quenching by the latter species undoubtedly constitutes the main factor influencing the luminescence intensity. The excited singlet states are quenched less effectively owing to their short lifetime. Table 5 presents the effects of the magnetic field for a single field strength $H \simeq 8$ kG in the systems investigated. Fig. 12 illustrates as an example the typical variation of the ECL intensity with the magnetic field. We may note that this type of variation is in full agreement with the theory of Atkins and Evans [33].

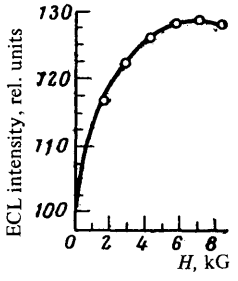

Figure 12. The influence of the magnetic field on the intensity of the electrogenerated chemiluminescence in a system containing rubrene and the radical-cation of Würster's Blue. [86]

The influence of the magnetic field on the quenching of the delayed fluorescence of anthracene and pyrene by molecular oxygen has been observed [81] (see Table 6). As for quenching by radicals, the magnetic field increased the DF intensity. The observed effect has been explained [81] by the following mechanism:

$$T + T \rightarrow S + S_0, \quad (43)$$

$$T + {}^3O_2 \rightarrow S + {}^1O_2. \quad (44)$$

Table 6. Experimental results for the influence of the magnetic field on the quenching of triplet states by oxygen [81].

| Reaction | Oxygen pressure, atm | Change in DF intensity, % ($H$ = 8 kG) |
|---|---|---|
| (Anthracene)$^T$ + (Anthracene)$^T$ in dimethylformamide* | 0 | -3 |
| | $3.0 \times 10^{-3}$ | +3 |
| | $6.0 \times 10^{-3}$ | +5 |
| (Pyrene)$^T$ + (Pyrene)$^T$ in dimethylformamide** | 0 | -2 |
| | $6.0 \times 10^{-3}$ | +1 |

*Anthracene concentration $2.1 \times 10^{-4}$ M.
**Pyrene concentration $2.6 \times 10^{-4}$ M.

At high oxygen concentrations, reaction (44) predominates and the DF intensity should therefore increase. The formation of singlet oxygen as a result of the reaction with an excited triplet hydrocarbon molecule [a reaction of type (44)] is probably the primary stage of the photochemical oxidation reaction. Since this reaction depends on the magnetic field, presumably the rate of photochemical oxidation of aromatic hydrocarbons is also sensitive to the magnitude of the magnetic field. The effect of the magnetic field in the photochemical oxidation reaction has so far been observed only in the solid phase [82]. The influence of the magnetic field on the surface conductivity of solid tetracene has been noted in the presence of oxygen [82]. The observed effect has been explained by the influence of the field on the photochemical oxidation reaction, leading to an increase of photoconductivity.

## XI. OTHER SYSTEMS

The two classes of processes examined do not exhaust all the systems in which effects of the magnetic field have been observed. The mechanisms of these effects in such instances can be regarded as fairly well understood, but, together with these, there have been reports of magnetic effects whose mechanism remains obscure.

There have been fairly numerous studies on the influence of the magnetic field on biochemical processes, including the effects of preliminary magnetisation. Polish workers [91-93] have published several reports about the influence of the magnetic field on reactions involving hydrogen peroxide. The effect of the preliminary magnetisation has also been observed in a number of instances. On the other hand, we may note that magnetic effects in the decomposition of hydrogen peroxide itself have not been observed [18]. Interesting data have been obtained by Hammond [94] in a study of the photochemical *cis–trans* isomerisation of stilbene and piperylene. The magnetic field (up to 9 kG) affects both the rate of reaction and the

steady-state photochemically generated isomer ratio when the reaction is sensitised by aromatic ketones. The magnitude of the effect is approximately 10%. On the other hand, the magnetic field has no influence when the process is carried out without a sensitiser.

The only available explanation of this effect, described in the literature, is similar to that of the explanation of the $\Delta g$ effect in radical pairs [95].

## XII. CONCLUSION

The influence of a constant magnetic field on processes involving free radicals and excited triplet states in solutions (radical recombination, triplet–triplet annihilation, quenching of triplet states by free radicals, the interaction of triplets with molecular oxygen, etc.), has now been reliably established and physically justified models of these phenomena have been proposed. The theoretical models are based on the postulate that the magnetic field alters the probability of the intercombination transition in pairs of reacting species. It is remarkable that even energetically weak influences (smaller than $kT$), such as hyperfine interactions and the difference between the Zeeman frequencies, can lead to appreciable effects of the magnetic field. The role of these interactions does not consist in overcoming energy barriers, but depends on the fact that they constitute a kind of "key", which may alter the multiplicity of the pair of reactants and result in their conversion from a multiplet, where the reaction is spin-forbidden, into a reactive state and conversely. Thus the effects of the magnetic field under consideration involve the manifestation of the spin prohibition rules in reactions of free radicals and triplet molecules. The magnetic isotope effect may be regarded as yet another important manifestation of spin prohibitions in radical recombination reactions. It is due to the fact that different nuclear isotopes differ in the magnitude of the hyperfine interaction responsible for the singlet–triplet transitions in the radical pairs.

Summarising the development of this research, one should note that the existing theoretical models describe satisfactorily the available experimental literature data not only qualitatively but also quantitatively. The range of processes in which magnetic effects may be observed, the scale of these effects, and the conditions most favourable for their observation have been clearly outlined.

# Weak Hydrogen Bonds

V.K.Pogorelyi

The literature data on the properties of hydrogen bonds involving the elements in the Third, Fourth, and Fifth Periods are surveyed and an attempt is made to determine the factors which have a decisive effect on the proton- and electron-donating capacities in series of compounds of the same type formed by elements in different Periods and Groups.
The bibliography includes 222 references.

IV. Certain general problems of the hydrogen bond 331

## I. INTRODUCTION

Hydrogen bonds play an important role in various chemical, physical, and biological reactions[1], which is the reason for the increasing interest in the study of various systems with hydrogen bonds. However, the majority of investigations have been concerned with hydrogen bonds in compounds formed by the elements in the Second Period, such as nitrogen, oxygen, fluorine, and (to a lesser extent) carbon. Extensive experimental[1-7] and theoretical[8-11] data have accumulated in this field and have been to a large extent reviewed. Hydrogen bonds involving elements in the Third and subsequent Periods have been investigated much less. The available information about this problem is sporadic and frequently contradictory. Until recently, it used to be assumed[1] that these elements either do not tend to form hydrogen bonds or give rise to relatively weak bonds.

In recent years, there has been a significant growth of interest in the so called weak† hydrogen bonds for two reasons. Firstly, the course of chemical processes is determined not only by strong interactions associated with large changes in the energy of the reactants but also by weak interactions, which influence the process probability but hardly alter the energy spectrum of the reaction. Such interactions play an especially important role not only in chemical but also in biological systems. Secondly, studies of this kind extend significantly our ideas about the nature of the hydrogen bond.

This review deals with studies on weak hydrogen bonds involving the atoms of Group V–VII elements. A separate section is devoted to the properties of hydrogen bonds involving sulphur compounds, since after the publication of the review of Zuika and Bankovskii[12], the literature was supplemented by numerous quantitative data. This section includes also studies which showed that the properties of hydrogen bonds between interacting molecules determine not only the kinetics but also the mechanism of the fast proton exchange reaction. Particular attention has been devoted to the identification of the factors which determine the nature of the changes in the proton- and electron-donating capacities in the hydrogen bond as a function of the electronic structure of the relevant atoms, i.e. as a function of their position in the Periodic System.

In this paper, an attempt is made to survey and analyse the available literature data (up to 1974 inclusive) for the properties of weak hydrogen bonds and about the influence of these bonds on protolytic reactions, such as tautomerism and rapid proton exchange.

## II. THE HYDROGEN BOND INVOLVING SULPHUR COMPOUNDS

### 1. MERCAPTANS AND THIOPHENOLS

#### (a) Self Association

There is no doubt about the self association which occurs in liquid mercaptans RSH and their solutions in inert solvents as a result of the SH...S hydrogen bonds. The spectroscopic and physicochemical studies on this problem have been considered in detail in a review[12]. However, the vast majority of the relevant data are qualitative. Quantitative results on the self association of mercaptans have been obtained by Miller and coworkers[13-16] using NMR. Hu and Miller[16] studied the self association of mercaptans in terms of the variation of the chemical shift of the SH protons ($\tau_{SH}$) with concentration in carbon tetrachloride or cyclohexane solution. The measured dimerisation constants $K$ showed that the tendency towards self association increases in the sequence $C_6H_5SH \ll C_2H_5SH < n\text{-}C_3H_7SH < i\text{-}C_3H_7SH < n\text{-}C_4H_9SH$.

The hydrogen bond strengths $\Delta H$ in the self-associated species of mercaptans, aminomercaptans, and mercaptoethers have been obtained[16-24]. According to Yablonskii et al.,[21] $-\Delta H = 0.1-0.4$ kcal mole$^{-1}$ for the SH...S hydrogen bonds and $-\Delta H = 0.5-0.8$ kcal mole$^{-1}$ for the SH...O bonds in mercaptoethers. Hu and Miller[16] determined the SH...S bond strength in the self-associated mercaptan species from the temperature variation of $\tau_{SH}$. As in the study of Marcus and Miller[15], relatively low values of $K$ were obtained. It was found that the bond strength ($-\Delta H \simeq 1$ kcal mole$^{-1}$) is likewise low and depends little on the nature of the substituents. A low SH...S bond strength is indicated by the results of quantum-chemical calculations

†We employ the term weak for hydrogen bonds whose formation involves the elements in the Third, Fourth, and subsequent Periods.

for the hydrogen bond in $H_2S$ solutions[25-27] ($-\Delta H \simeq 1.7$ kcal mole$^{-1}$). The infrared spectroscopic studies on certain mercaptans at reduced temperatures by Alencastro and Sandorfy[28] agree with these data. The tendency towards self association increases on passing to aminomercaptans.

Table 1 shows that mercaptans form weak hydrogen bonds, whose strength is much lower than that of the analogous alcohol complexes. This can be explained by the fact that, on passing from oxygen to sulphur, there is an appreciable decrease of the proton- and electron-donating capacities of the hydrogen bond (see below).

When the mercaptan molecule contains electronegative atoms such as oxygen and nitrogen (mercaptoethers and aminomercaptans), the tendency towards self association should increase, since there is an increase in the proton-donating capacity of the SH group and the possibility of the formation of the SH...O and SH...N hydrogen bonds with stronger electron donors appears.

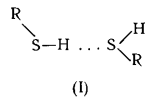

**Table 1.** The thermodynamic characteristics of the hydrogen bond in the dimers of certain mercaptans.

*The SH...N bond, in the remaining cases the SH...S bond.
**The infrared spectroscopic method, in the remaining cases the NMR method.

A study has been made[29] of the self association of *p*-substituted thiophenols and the interaction of the SH groups with the heteroatoms of the substituents has been observed. *p*-Amino- and *p*-fluoro-thiophenols are self-associated to a greater extent than thiophenol itself owing to the formation of the SH...N and SH...F bonds.

The structure of the self-associated thiol species constitutes at the present time the most controversial problem. With the exception of rigid systems, such as those in crystals, or systems with fixed configurations, such as those in biopolymers, it is difficult to characterise the geometry of the hydrogen bond. Since a linear hydrogen bond is usually stronger, presumably open-chain dimers (I) should be formed preferentially in solution. Indeed quantum-chemical calculations for $NH_3$, $H_2O$, $H_2S$, and HF have shown that type (I) dimers are energetically preferable[30-34]. However, the relatively low entropies of the hydrogen bond (Table 1) can be explained by the formation of cyclic dimers (II)[16]:

(I)

(II)

Structures (I) and (II) probably exist in solution. According to data[16,28] for aromatic thiols, apart from dimers (I) and (II) there is a possibility of complexes with the hydrogen bonds SH...$\pi$, the formation of which should lead to an additional increase in the complexity of the structure of the solution. However, the conclusion[15] that the thiophenol self-associated species have a tetrameric structure in carbon tetrachloride solution at a normal temperature is doubtful, since the infrared spectra show bands corresponding to self-associated species of a higher order than dimers only at low temperatures[28].

On the basis of the available data[16,17,35,36], one can formulate a series in terms of the decrease of the hydrogen bond strength ($-\Delta H$, kcal mole$^{-1}$) in the self-associated species of the alkyl compounds or hydrides of various elements:

$$ROH(\sim 4) > RNH_2(\sim 3.5) > RSH(\sim 1) \gg R_3CH$$

or

$$HF > H_2O > H_3N > H_2S \gg H_4C.$$

Evidently this series agrees with the electronegativity series for the corresponding elements.

(b) Association

The results of the study of physicochemical properties and spectroscopic investigations have shown that mercaptans and thiophenols form associated species in proton-donating solvents via the SH...O, SH...N, SH...Cl, etc. hydrogen bonds. However, there are relatively few quantitative data for the properties of these bonds and a systematic treatment of the latter is not available. The first quantitative characteristics of association involving thiophenol as the proton donor were obtained by NMR[37-39]. A detailed study of the hydrogen bonds in the 1 : 1 associated species of certain mercaptans with various electron donors has been made by Hu et al.,[40] who investigated hydrogen bonds of the type SH...S, SH...O, SH...O=C, SH...O=S, SH...O=P, and SH...N. It was found that the strengths of these bonds are low (Table 2) and change little when the electron donor is altered. For the same electron donor, the strengths of hydrogen bonds with various alkanethiols are virtually constant.

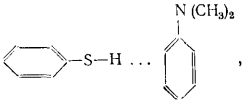

**Table 2.** The thermodynamic characteristics of the hydrogen bonds between certain mercaptans and different electron donors[40].

| Donor | $t$, °C | $\Delta\tau_C$, p.p.m. | $10^2K$, litre mole$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |

Table 2 and literature data[37,38] show that there is no correlation for the association of thiols with various electron donors between the chemical shift on complex formation $\Delta\tau_C$ and the bond strength‡. The equilibrium constant $K$ is likewise unrelated to the bond strength[40]. Its changes for different electron donors are determined mainly by the change in entropy.

Hydrogen bonds involving thiophenol have been investigated to a somewhat greater extent. The thermodynamic characteristics of the hydrogen bonds between thiophenol and electron donors of different types have been obtained[43,44]. The association of thiophenol, thiocresol, and *p*-bromothiophenol with ethylene trithiocarbonate has been studied by ultraviolet spectroscopy[45]. The dimerisation constants obtained ($K_2$, litre mole$^{-1}$) were used to establish a series based on the variation of the proton-donating capacity of the thiophenols investigated: *p*-bromothiophenol (0.87) > *p*-thiocresol (0.75) > thiophenol (0.64). This series is inconsistent with the expected acidities of the thiophenols[46,47] (which was also noted by Mukherjee et al.[45]) and with the conclusions reached by the present author and Gragerov[39]. Possibly the discrepancies are due to the inaccuracies in the determination of $K_2$.

The present author and Kukhtenko[48] studied by NMR the association of thiophenol and its derivatives with electron donors of the *n*- and $\pi$-types: anisole, dimethyl-aniline, and thioanisole. The concentration and temperature variation of $\tau_{SH}$ showed that thiophenol forms mainly complexes of the $\pi$-type with dimethylaniline:

while n-complexes are mainly formed with thioanisole:

for which $-\Delta H = 1.6$ kcal mole$^{-1}$ and $-\Delta S = 9.0$ e.u. were obtained. It was found that the probabilities of the formation of *n*- and $\pi$-complexes with anisole are almost identical. The hydrogen bond formed by thiophenol with butyl methyl ether is characterised by the following parameters: $-\Delta H = 2.7$ kcal mole$^{-1}$ and $-\Delta S = 9.6$ e.u. Comparison of the heats of association of thiophenol with this ether and acetone showed that the ketone forms a stronger bond ($-\Delta H = 3.2$ kcal mole$^{-1}$).[39] This result conflicts with the view[49] that ethers should form stronger hydrogen bonds than ketones, since the lone electron pair of the oxygen atom in ketones has a greater amount of *s* character ($sp^2$ hybridisation). This treatment is based solely on the donor–acceptor model of the hydrogen bond and does not take into account the contribution of the electrostatic interaction, which is probably significant for ketones owing to the strong polarisation of the bond in the carbonyl group.

The data obtained[37,48] make it possible to arrange the bases investigated in a series in terms of decreasing $\pi$-electron-donating capacity in relation to the formation of hydrogen bonds with thiophenol: *NN*-dimethylaniline > anisole > benzene > thioanisole. Thioanisole is a less effective $\pi$-electron donor, since the $\pi$-electron density in its ring may be reduced owing to $\pi$–$d$ conjugation. Furthermore, the $p$–$\pi$ conjugation in thioanisole is less effective than, for example, in anisole itself, since the difference between the energy levels of the $p$ and $\pi$ electrons ($\Delta n = 1$) hinders the interaction of these orbitals[50]. The above hypotheses agree with the type of change in the Hammett $\sigma$ constants on passing from alkoxy- to alkylthio-substituents[51].

The influence of the electronic nature of the substituents in both proton donor and electron donor molecules on the spectroscopic and thermodynamic characteristics of the SH...O=C hydrogen bond in the thiophenols–acetophenones system has been investigated[52] by NMR. As was to be expected, the stability of the associated species increases with increase of the electron-accepting capacity of the substituents in the thiophenol ring. The dependence of $\Delta H$ on the Hammett $\sigma$ constants is described by the equation

$$\Delta H_A = 2.2 + 1.9\sigma. \quad (1)$$

The energy of the hydrogen bond increases with increasing electron-donating capacity of the substituent in the acetophenone molecule:

$$-\Delta H_B = 2.4 - 1.2\sigma. \quad (2)$$

Comparison of the reaction constants for the two series investigated ($\rho_A/\rho_B = -1.6$) shows that the changes in the properties of the proton donor and electron donor under the influence of substituents affect to an equal extent the strengths of the hydrogen bonds between thiophenols and acetophenones. The change in $\Delta H$ for the S–H...O=C hydrogen bond in this system is more sensitive to the change in the properties of the proton donor than in those of the electron donor.

In a study of the OH...O hydrogen bonds between *p*-substituted 2,6-di-t-butylphenols and anisoles or acetophenones[53], the opposite relation was obtained—the change in the OH...O bond strength was found to be more sensitive to changes in the properties of the electron donor. Comparison of the properties of the SH...O=C and OH...O=C hydrogen bonds reveals not only quantitative differences (the SH...O=C bond is weaker) but also qualitative differences—the changes in the properties of the proton acceptor and proton donor respectively play the main role in the variation of the OH...O=C and SH...O=C hydrogen bond strengths.

The hydrogen bond between thiophenol and acetic acid has been investigated[54] and the quantities $K^{45°} = 0.38$ (mole fraction)$^{-1}$, $-\Delta H = 1.2$ kcal mole$^{-1}$, and $-\Delta S = 5.9$ e.u. have been determined. Despite the much lower acidity of thiophenol than that of acetic acid ($pK_a = 6.52$ and 4.76 respectively[47]), thiophenol in fact functions as the proton donor and the acid as the electron donor. The reason for this is probably that OH...S hydrogen bonds, which the acid might form as the proton donor, cannot compete in strength with the OH...O=C bonds in the acid dimers, since electron-donating functions are appreciably weakened on passing from oxygen to sulphur[55-58].

The thermodynamics of the hydrogen bond being substituted thiophenols and thiobenzoic acids has been studied[59]. The latter differ sharply from acetic acid in the proton- and electron-donating properties. In this system too, it was also found that thiophenol behaves as the proton donor on formation of hydrogen bonds, while the thiolo-form of thiobenzoic acid is the electron donor despite the fact that thiophenol is the weaker acid. Of the two possible dimer structures

‡ The weak temperature variation of $\Delta\tau_C$ may be neglected[41,42].

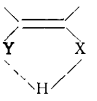
structure (III) is apparently preferable, since hydrogen bonds of the type SH...S cannot compete with bonds of the type SH...O as regards strength. We may note that the effects of substituents (Table 3) are consistent with the proposed structure of the associated species.

Thus the available data[54,59] show that, when thiophenol is involved in association with acetic and thiobenzoic acids, and probably with other carboxylic acids, there is preferential formation of dimers in which thiophenol plays the role of the proton donor and the carbonyl group of the acid is the electron donor (SH...O=C). These bonds are probably stronger than the OH...S and even more so the SH...S hydrogen bonds, which might be formed if the acid and thiophenol changed roles, since the increase of electron-donating capacity when S is replaced by O has a greater effect on the energy of the hydrogen bond than the weakening of the proton-donating capacity on passing from OH to SH.[55]

Table 3. The spectroscopic and thermodynamic characteristics of the hydrogen bond in the association complexes of thiophenols with thiobenzoic acids.

| R | $\Delta\tau_C$, p.p.m. | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|
| | $R_A-C_6H_4SH+C_6H_5COSH$ | | |
| 2,5-$(CH_3)_2$ | 1.85 | 1.9 | 8.1 |
| 4-$OCH_3$ | 1.58 | 2.0 | 8.1 |
| 4-$CH_3$ | 2.08 | 2.1 | 9.6 |
| H | 1.52 | 2.1 | 8.3 |
| 4-Cl | 1.70 | 2.2 | 9.3 |
| 2,5-$Cl_2$ | 1.75 | 2.5 | 11.4 |
| | $C_6H_5SH+R_n-C_6H_4COSH+CCl_4$ | | |
| 4-$OCH_3$ | 1.58 | 2.0 | 6.6 |
| H | 1.52 | 1.7 | 6.2 |
| 4-Cl | 1.41 | 1.6 | 6.9 |

Thus the structure of the complexes and the properties of the hydrogen bonds are determined by the proton- and electron-donating capacities of the interacting components and not by their acidity or basicity, and in many cases the acidity and proton-donating capacity vary in opposition (for example, on passing from thiophenol to phenol the acidity decreases, while the proton-donating capacity increases sharply[60-62]).

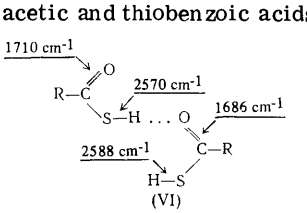


(c) The Intramolecular Hydrogen Bond

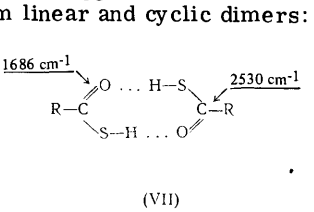
The presence of the intramolecular SH...B (B = O, N, or Cl) intramolecular hydrogen bonds in *o*-substituted thiophenols has been noted in a number of studies[63-69]. The NMR and infrared spectra as well as measurements of the dipole moments of a series of substituted thiophenols confirmed[70] the presence of an intramolecular hydrogen bond in *o*-halogeno-, *o*-methoxy-, *o*-nitro-, and *o*-methoxycarbonyl derivatives. The SH...B intramolecular hydrogen bond causes an appreciable increase in the intensity of the absorption band due to the vibrations of the SH group without a significant shift of the wavenumber. A much stronger hydrogen bond has been observed in *o*-methoxycarbonylthiophenol, in the molecule of which a six-membered chelate ring may be formed as a result of the intramolecular hydrogen bond.

It has been shown[71] that the SH group does not form an intramolecular hydrogen bond in $\alpha$-mercaptocarboxylic acid esters, while a bond of this kind persists in thiosalicylic acid and its esters even in solution in acetonitrile. According to Ginzburg and Loginova[66], $-\Delta H = 0.9$ kcal mole$^{-1}$ for the S–H...O=C hydrogen bond in thiosalicylic acid.

In contrast to $\omega$-*NN*-dialkylaminomercaptans[72], in aminothiophenols chelation is found to occur owing to the SH...N or NH...S hydrogen bonds[73]. It follows from the infrared spectra that such bonds are not formed in *o*-aminophenols or are significantly weaker. Consequently the proton- and electron-donating functions of sulphur are more effective than those of oxygen in the formation of intramolecular hydrogen bonds, while in association processes the opposite behaviour is observed. These findings are consistent with the calculations on intermolecular and intramolecular hydrogen bonds involving sulphur and oxygen atoms[74,75].



In rigid systems, such as five-membered chelates with intramolecular hydrogen bonds, the large size of the sulphur atom and diffuseness of its 3*p* orbitals ensure more satisfactory conditions than in oxygen for the overlapping of the interacting orbitals on formation of the bonds. Consequently the properties of the intramolecular hydrogen bonds



are determined by the nature of the proton donor and acceptor, the linearity of the XH...Y bond, and the distance between the donor and acceptor atoms[76].

2. THIOCARBOXYLIC AND PHOSPHOROTHIOIC ACIDS

Thiocarboxylic acids RC(O)SH should form more stable self-associated species than thiophenols and mercaptans via the SH...O=C hydrogen bonds. However, the literature data on this problem are contradictory. Thus it has been suggested[77] that the degree of self-association of thioacetic acid is low in view of the observed decrease of the wavenumber and increase of the intensity of the $\nu$(SH) infrared band on passing from the gas to the liquid. In the gas phase[78] and in carbon tetrachloride solutions[79], no signs of the self-association of thioacetic acid were observed, which conflicts with the results of another study[80], where the intensities of the $\nu$(C=O) and $\nu$(SH) bands of thioacetic and thiobenzoic acid were found to vary with concentration, indicating unambiguously the formation of SH...O=C hydrogen bonds. The chemical shift of the SH protons was also found to depend on the concentration of thiobenzoic acid in benzene[81] and of thioacetic acid in carbon tetrachloride[82]. It has been suggested[83] that thioacetic and thiobenzoic acids form linear and cyclic dimers:

(VI)

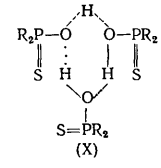
(VII)

With decrease of temperature, the probability of the formation of the cyclic structure (VII) increases.

All the foregoing considerations suggest that the occurrence of the self-association of thiocarboxylic acids has been established. The present author[84,85] obtained by NMR data for the structures and thermodynamic characteristics of the hydrogen bonds in the self-associated species of *p*-substituted thiobenzoic acids. It was found that $-\Delta H = 6.2$ kcal mole$^{-1}$ and $-\Delta S = 21$ e.u. for the unsubstituted acid. Comparison with data for benzoic acid[86] ($-\Delta H = 10.6$ kcal mole$^{-1}$ and $-\Delta S = 18.8$ e.u.) showed that the S–H...O=C bonds are much weaker than the O–H...O=C bonds. On the other hand, thiobenzoic acids are much more self-associated than thiophenols and mercaptans. It has been shown[84] that the values of $\Delta H$ and $\Delta S$ for thiobenzoic acid represent the overall effect of the formation of two hydrogen bonds. Consequently the acid dimers have the cyclic structure (VII). These results apply solely to the thiolo-form of the acid (VIII), since in inert solvents the presence of the thiono-form (IX) was not observed[87,88].

In electron-donating solvents, the complex-formation process is accompanied by the formation of a new molecular structure with mobile protons, which are involved in rapid exchange with the protons of the OH groups of the solvent (methanol, acetic acid). This is probably associated with the formation of appreciable amounts of the thiono-tautomer owing to the displacement to the right of the equilibrium

$$\underset{\text{(VIII)}}{C_6H_5C(O)SH} \rightleftarrows \underset{\text{(IX)}}{C_6H_5C(S)OH}$$



compared with the solution in carbon tetrachloride. The present author believes that this influence of electron-donating solvents on the state of the thiol–thione equilibrium should be sought by comparing the properties of the self-associated species and complexes formed with the solvent by the tautomeric species (VIII) and (IX).

As a result of complex formation with the electron donor (B), the self-associated species of the acid (VII) decompose. The associated species of the thiono-form $C_6H_5C(S)O–H..B$ produced under these conditions are more stable than those of the thiolo-form $C_6H_5C(O)S–H...B$, since the hydroxy-group is a more effective proton donor in the hydrogen bond than the mercapto-group. This in fact leads to the appearance in solution of an appreciable amount of the thione tautomer (IX).

The present author also investigated[85] the influence of substituents on the self-association of thiobenzoic acids (Table 4). The relation obtained between $\Delta H$ and the Hammett $\sigma$ constants suggests that the change in the proton-donating capacity of the mercapto-group plays a decisive role in the alteration of the stability of the self-associated species of thiobenzoic acids. The change in the electron-donating capacity of carbonyl oxygen is of secondary importance and can affect only the magnitude but not the sign of the reaction constant $\rho$ in the Hammett equation. For thiobenzoic acids, this quantity ($\rho = 1.8$) is significantly smaller than the value found[39] for the association of thiophenols with acetone ($\rho = 2.4$).

On passing from mono- to di-thiobenzoic acid, the tendency towards self-association decreases sharply. According to infrared spectroscopic data, all the signs of the self-association of dithiobenzoic acid vanish already in a 20% solution in carbon tetrachloride[89]. This can be explained by the fact that the SH...S=C hydrogen bond formed in dithiobenzoic acid dimers is much weaker than the S–H...O=C bond in monothiobenzoic acid dimers.

In contrast to thiocarboxylic acids, the monothio-derivatives of phosphorus-containing acids exist in inert solvents in the form of the thione tautomers[90]. The self-association of diethylphosphinothioic, *o*-ethyl methylphosphonothioate, and diethyl phosphorothioate has been investigated by NMR[91] in carbon tetrachloride solution on the basis of the temperature and concentration variation of the chemical shift of the hydroxyl protons. Analysis of these data by Lippert's method[92] showed that the main type of equilibrium in solutions of the above acids is monomer ⇌ trimer. It was established that the values $-\Delta H \simeq 18$ established for the monothio-derivatives of phosphorus-containing acids correspond to the overall effect of the formation of three hydrogen bonds of the type OH...O and that the trimers have the cyclic structure

(X)

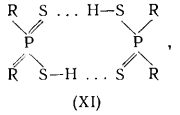
Consequently the thiophosphoryl sulphur cannot compete with the hydroxyl oxygen as the electron donor in the hydrogen bond.

Table 4. The spectroscopic and thermodynamic characteristics of the self-association of the acids *p*-$RC_6H_4C(O)SH$ in $CCl_4$ solution ($\Delta S = -21$ e.u.).

| R | $\Delta\tau_c$, p.p.m. | $K^{27°}$, (mole fraction)$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $\sigma$ |
|---|---|---|---|---|
| $OCH_3$ | 1.33 | 0.40 | 5.7 | —0.268 |
| H | 1.33 | 0.95 | 6.2 | 0.000 |
| F | 1.34 | 0.95 | 6.2 | 0.062 |
| Cl | 1.32 | 1.83 | 6.6 | 0.227 |

Table 5. The spectroscopic and thermodynamic characteristics of the hydrogen bond in the self-associated species of organophosphorus monothio-acids $R_1R_2P(S)OH$.

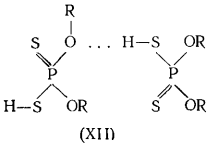
| $R_1$ | $R_2$ | $\tau_0$, p.p.m. | $\Delta\tau_c$, p.p.m. | $10^{-3}K^{40°}$, (mole fraction)$^{-2}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|---|---|---|
| $C_2H_5$ | $C_2H_5$ | 3.80 | 1.47 | 4.0 | 18.0 | 41.8 |
| $C_2H_5O$ | $CH_3$ | 4.39 | 2.00 | 5.7 | 17.8 | 40.5 |
| $C_2H_5O$ | $C_2H_5O$ | 4.47 | 2.19 | 10.0 | 18.0 | 39.4 |



The data in Tables 4 and 5 show that, on passing from thiobenzoic acids to thio-derivatives of phosphorus-containing acids, there is a sharp increase of the ability to form self-associated species. This is due to the increase of the strength of the hydrogen bond when the mercapto-group is replaced by the hydroxyl as the proton donor, although this involves a significant gain in entropy, caused by the increased complexity of the structure of the self-associated species.

Thus the structures and properties of the self-associated species of monothio-acids depend on the position of the thiol–thione equilibrium. As stated above, in thiobenzoic acids the equilibrium is displaced towards the thiolo-tautomer, which results in the formation of the cyclic dimers (VII) with oxygen as the electron donor, similar to the carboxylic acid dimers[93]. For thio-derivatives of phosphorus-containing acids, the equilibrium is displaced towards the thiono-form, dimers of type (VII) becoming less stable owing to the reduced electron-donating capacity of sulphur and cyclic trimers (X), with oxygen as the donor, whose structure resembles that of the self-associated species of alcohols, are formed[94].

The self-association of dithio-derivatives of phosphorus-containing acids has been investigated in greater detail. Thus the infrared spectra of solutions of diethyl and dimethyl phosphorodithioates[95] and of phenyl phenylphosphonodithioate and ethyl ethylphosphonodithioate[89] in carbon tetrachloride showed a splitting of the $\nu$(SH) band. The doublet structure of this band and the dependence of the relative intensities of its components on concentration and temperature were explained by the self-association of the acids with formation of SH...S bonds. Self-association of this type is assumed for both phosphorodithioic[96] and diphenylphosphinodithioic[97] acids. On the other hand, cryoscopic measurements have shown[98] that phosphorodithioic acids exist in benzene solutions as monomers. Presumably the decomposition of the self-associated species in this system is caused by the formation of complexes by the acid with the solvent (benzene). There is at present no doubt about the possibility of the formation of hydrogen bonds of the type SH...$\pi$.

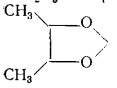


Many workers[99,100] believe that the doublet structure of the $\nu$(SH) band is due to the presence of two rotational isomers with intramolecular hydrogen bonds between the SH groups and the oxygen atoms of the substituent or the sulphur atom in the P=S group.

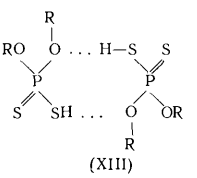
Quantitative studies on the hydrogen bonds in the self-associated species of phosphorodithioic acids have been carried out by NMR and infrared spectroscopy. Thus a study has been made[101,102] of the hydrogen bond strengths in the self-associated species of a number of phosphorodithioic acids and in their complexes with dioxan. The authors[101,102] suggested the cyclic structure

(XI)

for phosphinodithioic acids and the linear dimeric structure



(XII)



for the self-associated species of phosphonodithioic and phosphorodithioic acids. We may note, however, that the conclusion concerning the preferential formation of structure (XII), reached[101] on the basis of a comparison of the values of $\nu$(SH) for self-associated species and complexes with dioxan as well as the hypothesis that the proton-accepting capacity of the oxygen in the RO substituent is greater than that of the thiono-sulphur in the P=S group appear to have little justification. One should also note that the same workers[102] believe that the thiophosphoryl group in phosphinic acids gives rise to more stable associated species than those produced by the oxygen of the substituent in phosphonic and phosphoric acids.

An NMR study has been made[103] of the self-association of dithio-derivatives of phosphorus-containing acids. In agreement with previous results[101,102], it was shown that the main type of equilibrium in solutions of these acids in carbon tetrachloride or cyclohexane is monomer $\rightleftharpoons$ dimer. The value of $\Delta H$ for self-association obtained by infrared spectroscopic (Table 6) and NMR methods (Table 7) agree satisfactorily when account is taken of the experimental error.

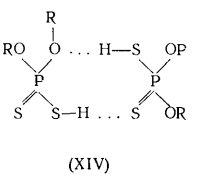


Table 6. The spectroscopic characteristics and strength of the hydrogen bonds formed by organophosphorus dithio-acids $R_1R_2PSSH$ in their self-associated species and in their complexes with dioxan.

| $R_1$ | $R_2$ | Self association | | Complex with dioxan | |
|---|---|---|---|---|---|
| | | $\nu_{SH...S(O)}$, cm$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $\nu_{SH...O}$, cm$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ |
| n-$C_3H_7$ | n-$C_3H_7$ | 2405 | 3.2 | 2445 | 2.0 |
| $CH_3$ | $C_6H_5$ | 2405 | 3.4 | 2440 | — |
| $CH_3$ | $CH_3O$ | 2460 | 2.1 | 2470 | — |
| $CH_3$ | $C_2H_5O$ | 2460 | 2.1 | 2470 | — |
| $CH_3$ | n-$C_3H_7O$ | 2460 | 2.4 | 2470 | — |
| $CH_3$ | iso-$C_3H_7O$ | 2460 | 2.0 | 2470 | — |
| $C_2H_5$ | $C_2H_5O$ | 2460 | 2.3 | 2460 | 1.8 |
| $C_2H_5O$ | $C_2H_5O$ | 2460 | 2.1 | 2460 | 1.5 |
|  | | 2460 | 2.4 | 2450 | 1.8 |

The stability of the complexes (XI) of phosphinodithioic acids varies in the range 2.6–3.4 kcal mole$^{-1}$. Consequently the energy of the SH...S=P hydrogen bond is close to 1.5 kcal mole$^{-1}$. As already mentioned, in phosphonodithioic and phosphorodithioic acids, both thiono-sulphur and oxygen atoms in the substituent can behave as electron donors. For this reason, these acids can give rise to the following structures apart from complexes of types (XI) and (XII):

(XIII)

(XIV)

The conclusion[101,102] that the open-chain dimers (XII) are formed preferentially by phosphonic and phosphoric acids is inconsistent with thermodynamic data[101–103]. Thus the energy of the SH...O hydrogen bond between dithio-derivatives of phosphorus-containing acids and dioxan is 1.5–1.8 kcal mole$^{-1}$.[101] On the other hand, the strength of the bond of the same type but with the oxygen atom of the substituent at the phosphorus atom should be smaller, since in this case the electron-donating capacity of the oxygen atom is reduced owing to the effect of the $p\pi - d\pi$ conjugation[106,107]. Table 7 shows that the bond energy in the self-associated phosphonic and phosphoric acid species varies from 2.7 to 4.3 kcal mole$^{-1}$. Clearly

a structure of type (XII) with a single SH...O hydrogen bond cannot alone account for the observed heats of complex formation. On the other hand, cyclic structures of types (XI), (XIII), and (XIV) are consistent with experimental data. We therefore suggest that phosphonodithioic as well as phosphinodithioic acids form mainly cyclic dimeric self-associated species in solution in inert solvents. This conclusion is further confirmed by the similarity of the values of $\Delta S$ for self-association obtained for complexes of all three types of acids (Table 7).

When data for the self-association of mono- and di-thio-derivatives of phosphorus-containing acids are compared, sharp differences are discovered[108]. The self-associated species of the monothio-derivatives have a trimeric cyclic structure formed by OH...O hydrogen bonds, while the dithio-acids give rise to cyclic dimers with SH...S and SH...O bonds. It was noted that, when oxygen is replaced by sulphur, both the electron-donating and the proton-donating capacity of the hydrogen bond are reduced. The sharp differences between the values of $K$, $\Delta H$, and $\Delta S$ for the self-associated species investigated are therefore based not only on the differences in the numbers of the hydrogen bonds forming the complexes but also in their properties.

## 3. HYDROGEN BONDS AND RAPID PROTON EXCHANGE REACTIONS INVOLVING SH GROUPS

It was shown previously[55,109-111] that the initial stage of the proton transfer reaction between molecules or ions is the formation of an intermediate reaction complex in which the reactions centres of the interacting species are brought closer together by hydrogen bonds, which ensures the most favourable mutual orientation of the centres for the reaction. The increase of the strength of the hydrogen bond in the intermediate complex leads to a decrease of the height and width of the potential barrier to the reaction, which facilitates proton transfer via both the classical mechanism and as a result of the tunnel effect. These are also the causes underlying the observed correlations between the kinetic and activation parameters of rapid proton exchange reactions and the thermodynamic characteristics of the hydrogen bond between the exchanging reactants[55].

However, the dependence of the mechanism of the rapid proton exchange reactions on the structure of the complexes and the properties of the hydrogen bond between the exchanging components has still been inadequately investigated. This problem has been solved in a number of studies[54,59,120-122] for reactions involving SH, COOH, and COSH groups. Reactions of this type occupy an important place in various biochemical processes[123].

The kinetics and mechanism of the rapid proton exchange between the SH groups in a series of substituted thiophenols and the COOH group of acetic acid, catalysed by sodium acetate, have been investigated[54,120] by NMR. It was established that the rate-limiting stage of the reaction involves proton transfer from the thiophenol to the acetate ion in the bimolecular complex formed by hydrogen bonds:

$$PhSH \ldots {}^-OAc \rightleftarrows PhS^- \ldots HOAc. \qquad (3)$$

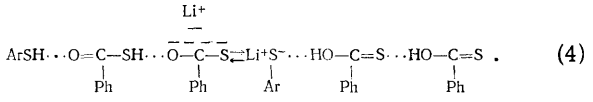
The increase of the rate constant and the decrease of the activation energy with enhancement of the electron-accepting capacity of the substituents in the thiophenol ring (Table 8) are consistent with the proposed exchange mechanism (3).

**Table 8.** The kinetic and activation parameters of the fast proton exchange reaction between ArSH and AcOH catalysed by sodium acetate.

| Substituent | $10^{-2}\,k^{40°}$, litre mole$^{-1}$ s$^{-1}$ | $E$, kcal mole$^{-1}$ | lg $A$ |
|---|---|---|---|
| 2,5-$(CH_3)_2$ | 4.3 | 10.1 | 9.7 |
| 4-$OCH_3$ | 10.5 | 9.5 | 9.7 |
| H | 16.2 | 9.3 | 9.7 |
| 4-Cl | 49.0 | 8.9 | 9.9 |
| 2,5-$Cl_2$ | 169.8 | 8.8 | 10.4 |

It is of interest to compare these data with the results of studies on the proton exchange between thiophenols and methanol in an alkaline medium[124] which proceeds in the trimolecular complex

$$ArSH \ldots \underset{|}{\overset{CH_3}{O}}H \ldots {}^-SAr \qquad (XV)$$

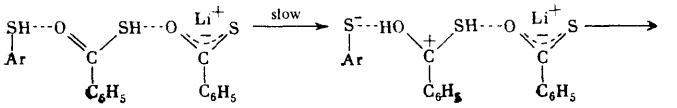


and its rate is limited by proton transfer from the thiophenol to the alcohol. The activation energy is in this case much more sensitive to the influence of the substituents in the thiophenol ring than in reaction (3). This can be explained by the levelling of the strengths of the AH...B hydrogen bonds involving a strong electron donor (for example $B = OH^-$ or $AcO^-$) and differing in the strengths of the proton donors, like the differences between the acid strengths in highly basic solvents. The activation energies for the exchange reaction involving such hydrogen bonds, which depend on the strength of the latter, are therefore also levelled.

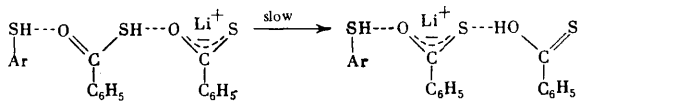
The proton exchange between the SH and COOH groups in thiolactic acid $CH_3CH(SH)COOH$, between 1-methylethanethiol and acetic acid[121], and in mercaptoacetic acid $HSCH_2COOH$[122] takes place in a binary complex of type (3)

when the process is catalysed by sodium acetate. The values of $k$, $E$, and $\lg A$ are listed below:

| Compound | $10^{-2}k$, litre mole$^{-1}$ s$^{-1}$ | $E$, kcal mole$^{-1}$ | $\lg A$ |
|---|---|---|---|
| Thiolactic acid | 3.6 (42° C) | 11.8 | 10.7 |
| 1-Methylethanethiol | 0.1 (46° C) | 14.2 | 10.8 |
| Mercaptoacetic acid | 7.1 | 12.4 | 8.5 |



The proton exchange between a series of thiophenols and thiobenzoic acid, differing sharply from acetic acid in its proton- and electron-donating properties, has been investigated[59] and it has been established that, when the process is catalysed by lithium thiobenzoate, its rate-limiting stage involves proton transfer in the trimolecular complex formed by hydrogen bonds:



(4)

This complex arises as a result of the association of the dimers $C_6H_5SH\cdots O{=}C(SH)C_6H_5$ (III) present in the system with lithium thiobenzoate, since trimolecular collisions of thiophenol, acid, and catalyst molecules are unlikely. The formation of the complex or its decomposition cannot limit the rate of exchange, since they are rapid reactions involving the formation or dissociation of hydrogen bonds.

The data obtained for the influence of substituents on the kinetics of reaction (4) provided evidence in support of a detailed exchange mechanism. Three schemes are possible: single-stage synchronous transfer of two protons [reaction (4)] and two-stage ionisation schemes [reactions (5) and (6)], in the slow stage of which the thiobenzoic acid or catalyst molecule is protonated:

(5)

(6)

Scheme (6) is inconsistent with the influence of substituents on the rate of reaction, since the rate of the slow stage in this scheme should not depend on the substituents in the thiophenol ring. On the other hand, mechanisms (4) and (5) are consistent with experimental data. Furthermore, a quantitative relation has been observed between the kinetic parameters of the exchange reaction and the thermodynamic characteristics of the hydrogen bond in the dimeric species formed by thiophenols with thiobenzoic acid (Tables 3 and 9). This relation presupposes proton transfer in the slow stage via the S–H...O=C hydrogen bond [see scheme (5)].

We may note that a considerable similarity between the kinetics and mechanisms of the rapid proton exchange reactions of thiophenols with thiobenzoic acid[59] and methanol[124,125] has been observed. In both cases, the rate of reaction is described by a third-order kinetic equation, the substituents in the thiophenol ring have the same type of influence, and even the corresponding catalytic rate constants and activation energies are similar. Presumably, such analogy is due to the similarity of the slow stages in the above processes—proton transfer via the SH...O hydrogen bond in accordance with a type (5) mechanism.

Table 9. The kinetic and activation parameters of the fast proton exchange reaction between substituted thiophenols and thiobenzoic acid catalysed by lithium thiobenzoate.

| Substituent | $10^{-3}\,k^{40°}$ litre mole$^{-1}$ s$^{-1}$ | $E$, kcal mole$^{-1}$ | $\lg A$ |
|---|---|---|---|
| 2,5-$(CH_3)_2$ | 4.6 | 8.7 | 9.8 |
| 4-$OCH_3$ | 13.6 | 8.0 | 9.7 |
| 4-$CH_3$ | 13.1 | 7.8 | 9.6 |
| H | 20.9 | 7.8 | 9.8 |
| 2,5-$Cl_2$ | 140.0 | 4.8 | 8.5 |

In contrast to the above similarity, the exchange of thiophenols with thiobenzoic acid differs as regards kinetics and mechanism from the seemingly analogous proton exchange reaction between thiophenols and acetic acid. The weak hydrogen bond between thiophenol and acetic acid and the marked tendency of the latter to undergo self-association cause the alkali-catalysed rapid proton exchange involving the SH and COOH groups to proceed via the bimolecular mechanism (3), the acetic acid molecule not being involved in the slow stage. On the other hand, the stronger hydrogen bond between thiophenol and thiobenzoic acid and the much smaller (compared with acetic acid) tendency of the latter towards self-association explains why the proton exchange between the SH and COSH groups take place in a trimolecular hydrogen-bonded complex.

Thus the data examined in this section constitute undoubted proof that the properties of the hydrogen bond between the exchanging components determine not only the kinetics but also the characteristics of the mechanism of rapid proton exchange.

## 4. THE ELECTRON-DONATING CAPACITY OF SULPHUR COMPOUNDS

The proton- and electron-donating properties of the hydrogen bond formed by the SH groups of mercaptans, thiophenols, and thiocarboxylic acids, as well as the thio-derivatives of phosphorus-containing acids were examined above. Other types of sulphur compounds, for example sulphides $R_2S$, thioketones $R_2C{=}S$, phosphine sulphides $R_3P{=}S$, etc. do not have a mobile proton but can nevertheless form hydrogen bonds as electron donors by virtue of the lone electron pairs of the bivalent sulphur atom.

Convincing evidence for the association of sulphur compounds of this type with various proton donors has been compiled in the literature[12]. For example, the OH...S,[126-128] OH...S=P,[129] OH...S=C,[130,131] NH...S,[132] and CH...S[133]

bonds have been discovered. The electron-donating properties of the hydrogen bonds formed by amines, ethers, and sulphides (thioethers) with phenols and alcohols have been compared[134-140].

The values of $\Delta H$ quoted in Table 10 show that the electron-donating capacity of the hydrogen bonds formed by amines is twice as great and that of the bonds formed by ethers approximately 1.5 times as great as that of the bonds involving sulphides.

**Table 10.** Hydrogen bond strengths in the complexes of amines, ethers, and sulphides with alcohols and phenols.

The data obtained have been analysed[136] with the aid of the Drago relation[141]

$$-\Delta H = E_A\ E_B + C_A\ C_B, \qquad (7)$$

where the empirical parameters $E_A$ and $C_A$ refer to the proton donor and $E_B$ and $C_B$ refer to the electron donor. The values of $E_A$ and $E_B$ characterise the ability of the donor and acceptor to enter into an electrostatic interaction, while $C_A$ and $C_B$ determine the contribution to the overall bond energy by the donor–acceptor (covalent) forces. Calculation of the contributions of the electrostatic ($-\Delta H_E = E_A E_B$) and donor–acceptor ($-\Delta H_C = C_A C_B$) interactions to the overall energy of the hydrogen bond showed that, when dioctyl ether, methyldioctylamine and dioctyl sulphide are involved in association with aliphatic alcohols, the contributions of the electrostatic forces to the overall energy of the hydrogen bond are 83, 56, and 34% respectively. Consequently, according to Pearson's classification[142], ethers are "hard" bases, sulphides are "soft" bases, while amines are "hard-soft" bases.

The electron-donating capacities of ethers and sulphides in relation to alkyl halides have been compared[143]. The data obtained by gas–liquid chromatography (GLC) are difficult to interpret in terms of the hypothesis that complexes are formed in this system only via the C–H...O and C–H...S hydrogen bonds. Thus the stabilities of the complexes formed by chloroform with di-n-octyl ether and di-n-octyl sulphide are 2.38 and 1.93 kcal mole$^{-1}$ respectively. These values agree with the usual hypothesis that the electron-donating capacity in the hydrogen bond decreases on passing from oxygen to sulphur[12,55]. On the other hand, the complex of bromoform with the ether ($-\Delta H$ = 2.17 kcal mole$^{-1}$) proved to be less stable than that with the sulphide ($-\Delta H$ = 2.28 kcal mole$^{-1}$). Furthermore, the replacement of chloroform by bromoform leads to a decrease of the stability of the ether complex in accordance with the reduced proton-donating capacity of bromoform relative to chloroform[144-147], while the opposite behaviour applies to the sulphide—the bromoform complex is more stable than the chloroform complex. In order to account for the above findings, the authors[143] assume that in the association of halogenoalkanes with ethers and particularly with sulphides complexes with charge transfer of the $n \rightarrow \sigma^*$ type[148] between the oxygen or sulphur atoms (n-electron donor) and halogen atoms (electron acceptor) are formed in addition to the hydrogen bond. The contribution of the charge-transfer interaction increases and the tendency towards the formation of hydrogen bonds diminishes on passing from the ether to the sulphide and from chloroform to bromoform. Possibly the classic electrostatic interaction, which may be enhanced with increase of atomic polarisability on passing from O to S and from Cl to Br, plays an important stabilising role for such relatively weak "contact" complexes[149,150].

The hydrogen bonds between phenylacetylene and ethers and sulphides have been investigated[133] by NMR and infrared spectroscopy. The formation constants of the 1 : 1 complexes formed by sulphides are approximately five times smaller than those of the complexes formed by ethers.

**Table 11.** The thermodynamic characteristics of the hydrogen bonds formed by chloroform, phenol, and ethanol with certain sulphides and disulphides.

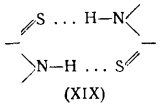
The electron-donating capacities in the hydrogen bonds of sulphides and disulphides may be compared on the basis of the available data[151-153] (Table 11). It is striking that the strength of the hydrogen bond diminishes approximately by a factor of two on passing from sulphides to disulphides. The chemical bond between two sulphur atoms weakens their electron-donating properties. This observation was made for the first time by Epshtein and Zhdanova[153], but has not been explained. The present author believes that the cause of the weakening of the electron-donating capacity of disulphides may be as follows. The multiplicity of the chemical bonds between two sulphur atoms may increase, because, apart from a single $\sigma$ bond, there is a possibility of interaction of the $\pi$-type between the $3p$ orbital of the lone electron pair of one atom and the vacant $3d$ orbital of another, which is suitable as

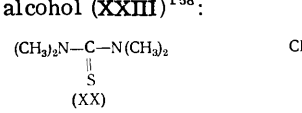
regards symmetry. Such interaction must lead to an increase of the degree of delocalisation of the 3*p* electrons and hence to a decrease of the orbital electron density. This entails a decrease of the capacity of the 3*p* orbital of the lone electron pair of the sulphur atom for overlapping with the 1*s* orbital of the hydrogen atom of the proton donor, which leads in its turn to the weakening of the hydrogen bond noted above. An increase of the amount of double bond character in S–S in disulphides is indicated by the data quoted in Foss's paper[154].



Hydrogen bonds involving the electron-donating C=S, P=S, and As=S groups have been investigated[155-161]. The abilities of certain enaminothiones to form hydrogen bonds has been compared in an infrared spectroscopic and NMR study[155] with those of the corresponding oxo-analogues. It was observed that the efficiency of the thiono-group as an electron donor may be less effectively reflected in an intermolecular hydrogen bond than in the case of the carbonyl group. The opposite is true of intramolecular conjugated chelate systems, which has been attributed to the 6π-electron stabilisation of the chelate, including the expansion of the orbital of the sulphur atom.

Hydrogen bonds of type N–H...S=C have been discovered[157] in the self-associated species of the heterocyclic thioamides (XVI)–(XVII):

(XVI) (XVII) (XVIII)

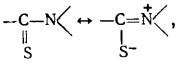


According to X-ray diffraction data[162], 2-mercaptobenzothiazole (XVII) forms centrosymmetric cyclic dimers with a short hydrogen bond. The infrared spectra of the thioamides (XVI)–(XVIII) hardly change on passing from crystals to a dilute solution in carbon tetrachloride. The cyclic dimeric structure of the associated species

(XIX)

probably persists also in carbon tetrachloride solution. The intensity of the ν(NH...S) bands and the values of $\Delta\nu = \nu(HN) - \nu(NH...S)$ show that the strength of the hydrogen bond in complexes of type (XIX) increases in the sequence (XVI) < (XVII) < (XVIII). This conclusion is consistent with the observed dimerisation constants, which are 88, 570, and 5540 litre mole$^{-1}$ for complexes (XVI), (XVII), and (XVIII) respectively, and the results of a study[163] of the influence of hydrogen bonds on the ultraviolet spectra of the same compounds.

The OH...S=C hydrogen bond has been investigated calorimetrically in relation to the association of tetramethylthiourea (XX) and *NN*-dimethylthioacetamide (XXI) with alcohols—hexafluoroisopropyl alcohol (XXII) and trifluoroethyl alcohol (XXIII)[158]:



(XX) (XXI)

The energies of the OH...S=C hydrogen bond in the associated species formed by compound (XX) with compounds (XXII) and (XXIII) are 6.5 kcal mole$^{-1}$ ($\Delta\nu$ = 445 cm$^{-1}$) and 4.6 kcal mole$^{-1}$ ($\Delta\nu$ = 290 cm$^{-1}$), while the energies of the bond of the same type in the complexes formed by compound (XXI) with compounds (XXII) and (XXIII) are 6.0 kcal mole$^{-1}$ ($\Delta\nu$ = 430 cm$^{-1}$) and 4.3 kcal mole$^{-1}$ ($\Delta\nu$ = 280 cm$^{-1}$). According to the literature[164], the bond energies in the complexes formed by phenol with alkylthioureas are 4–4.8 kcal mole$^{-1}$. Comparison of Sherry and Purcell's data[158] with those of Singh et al.[44] showed that the electron-donating capacity of sulphur increases in the sequence

This is probably associated with the increasing contribution of the electrostatic interaction to the energy of the OH...S=C hydrogen bond in the above series owing to the greater contribution of the dipolar structure in thioamides

than in thioketones.

The electron-donating capacity of sulphur in the P=S and As=S groups has been investigated by infrared spectroscopy and calorimetry in a number of studies[158-160] (Table 12). The enthalpies of formation of the hydrogen bond with phenol have shown that the electron-donating capacity of the As=S group is only slightly greater than that of the P=S group and much smaller than that of the As=O group with similar substituents.

**Table 12.** The hydrogen bond strengths and the ν(OH) band shifts in the complexes formed by phenol and fluorinated alcohols with thio-derivatives of phosphorus-containing acids, phosphine sulphides, and arsine sulphides and oxides.

| | | | $C_6H_5(C_2H_5)_2As=O$ | 711 | 8.6 |

The empirical parameters $E_B$ and $C_B$ [see Eqn. (7)] for the sulphur-containing bases investigated have been calculated[158]. As was to be expected, the parameters found for S donors differ significantly from the corresponding characteristics of "hard" oxygen- and nitrogen-containing donors, namely in the case of sulphur the parameters $C_B$ are greater and the $E_B$ are smaller. This implies that the covalent contribution to the strength of the hydrogen bond involving an S donor plays a decisive role. This conclusion is consistent with results[136] according to which S donors are classified as "soft" bases.

## III. VARIATION OF THE PROTON- AND ELECTRON-DONATING CAPACITIES IN SERIES OF COMPOUNDS OF THE SAME TYPE FORMED BY GROUP V–VII ELEMENTS

### 1. GROUP V ELEMENTS

The electron-donating properties in the hydrogen bonds formed by compounds of Group V elements, with the exception of nitrogen, have been very little investigated. Nevertheless, the available literature data[165,166] make it possible to trace certain regularities in the variation of the electron-donating capacities of analogous nitrogen, phosphorus, arsenic and antimony compounds. In the studies quoted, the association of pyrrole, phenol, and methanol with the electron donors $(C_2H_5)_3Y$ (Y = N, P, As, or Sb) was investigated and it was found that all the compounds form hydrogen bonds with the proton donors. Antimony and even arsenic exhibit semimetallic properties, but form hydrogen bonds nevertheless. There is probably a significant contribution of the *p* or *d* orbitals to that of the free electron pair of antimony, imparting to the latter directional properties, which are required in the formation of the hydrogen bond.

According to the data in Table 13, the electron-donating capacity in the N–H...Y (Y = N, P, As, or Sb) hydrogen bond decreases in the sequence $(C_2H_5)_3N > (C_2H_5)_3P > (C_2H_5)_3As > (C_2H_5)_3Sb$. This might have been expected, since the fundamental properties change in the same direction[167] and the formation of the hydrogen bond is the first stage in the acid-base interaction with proton transfer[168].

**Table 13.** Characteristics of the hydrogen bonds formed by pyrrole and phenol with $R_3Y$.

| Y | $\Delta\nu$, cm$^{-1}$ | $K^{30°}$, litre mole$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|---|
| | | Pyrrole, N–H...Y | | |
| N | 310 | — | — | — |
| P* | 216 | 1.53 | — | — |
| P | 166 | 0.89 | 3.0 | 10.0 |
| As | 101 | 0.37 | 2.5 | 10.0 |
| Sb | 65 | 0.23 | — | — |
| | | Phenol, O–H...Y | | |
| N | 556 | 90.00 | 9.1 | — |
| P | 333 | 4.50 | 4.3 | 11.0 |
| As | 219 | 1.01 | 3.4 | 11.0 |
| Sb | 155 | 0.43 | 2.9 | 11.0 |

*R = n-$C_4H_9$, in the remaining cases R = $C_2H_5$.

The significant discrepancy between the very large change in basicity and the relatively small change in electron-donating capacity in the $R_3Y$ series has been discussed[165]. For example, the difference between the basicities of $(C_2H_5)_3P$ and $(C_2H_5)_3As$ amounts to 5 p$K$ units, while the association constant changes only by a factor of 2.5. There exist two alternative explanations of the variation of the basicity in the series of analogous compounds of the elements belonging to the same Group: either in terms of the Gibbs rehybridisation theory[169] or in terms of the theory of electron correlation repulsion[167]. Both theories are based on allowance for the electronic configuration of the central atom (the reaction centre of the base) in the proton transfer. According to Gurka and Taft's results[170], the formation of the hydrogen bond can be regarded as only partial proton transfer, since the electronic configuration of the central atom changes in this process to a much lesser extent than on protonation. Hence follows the small change in electron-donating capacity on formation of the hydrogen bond.

As will be seen below, there are other explanations in the literature of the insignificant change in electron-donating capacity on transition from, say, phosphorus to arsenic or from sulphur to selenium, based, in particular, on the examination of the contributions of various mechanisms to the redistribution of electron density between the proton donor and electron donor on complex formation.

The nature of the changes in electron-donating capacity in the O–H...Y[166] and N–H...Y[165] (Y = N, P, As, or Sb) bonds is the same. The values of $\Delta\nu$, $K$, and $\Delta H$ (Table 13) show that the electron-donating capacity of Y in the O–H...Y bond diminishes in the sequence N > P > As > Sb. The greatest changes in the above quantities occur in the transition from nitrogen to phosphorus. Arsenic and antimony are characterised by similar electron-donating capacities. This may be associated with the increase of the polarisability of the orbital of the free electron pair on passing to heavier elements in Group V, which leads to an increase of the contribution of dispersion forces to the energy of the hydrogen bond. At the same time the charge-transfer interaction may be intensified, since the ionisation potential of Y diminishes.

It is noteworthy that the Badger–Bauer rule[171] holds for the A–H...Y hydrogen bonds (Y is a Group V element), since there is a linear correlation between $\Delta\nu$ and $\Delta H$.

The proton-donating capacities of compounds with X–H (X = N, P, or As) groups have been investigated only for X = N. There have been no direct experimental studies on the properties of the X–H...B hydrogen bond with X = P or As. There are only indirect data which suggest that, on passing from amines to phosphines or from ammonium to phosphonium compounds, the proton-donating capacity of X–H falls. Such studies include those of the rapid proton exchange between trimethylphosphonium ions and water[172] or between dimethylphenylphosphonium ions and methanol[173]. The results of these studies have been examined in detail in a review[55] and compared with those for the analogous reactions involving N–H bonds.

A sharp decrease of proton-donating capacity on passing from N–H to P–H is indicated by the *ab initio* calculations[27] of the energy of the hydrogen bond in the ammonia and phosphine complexes with the hydrides of the electronegative elements in the Second and Third Periods. For example, $-\Delta H$ = 4.07 kcal mole$^{-1}$ for the complex $H_2N$–H...$OH_2$, while for the complex $H_2P$–H...$OH_2$, $-\Delta H$ is only 1.06 kcal mole$^{-1}$.

The problem of the type of change in proton-donating capacity on passing from P–H to As–H still remains unresolved.

### 2. GROUP VI ELEMENTS

The first quantitative studies on the relative electron-donating capacities in the hydrogen bonds formed by analogous compounds of Group VI elements include those of West and coworkers[174,175], where the thermodynamic characteristics of the hydrogen bonds between phenol and the electron donors $(n\text{-}C_4H_9)_2Y$ or $(t\text{-}C_4H_9)_2Y$ (Y = O, S, Se or Te) were determined by infrared spectroscopy. It

was shown for the first time that the atoms of heavy Group VI elements behave as electron donors in the formation of the OH...Se and OH...Te hydrogen bonds.

The replacement of oxygen by sulphur or selenium lowers significantly the strength of the hydrogen bond with phenol (Table 14). The maximum difference between the values of $\Delta H$ is observed on passing from oxygen to sulphur.

Table 14. Characteristics of the hydrogen bonds between phenol and dibutyl chalcogenides $R_2Y$[175] (the results of West et al.[174] are given in brackets).

| Y | $\Delta\nu$, cm$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|
| O | 278 | 5.71 (5.98) | 15.5 (11.8) |
| S | 254 | 4.19 (4.26) | 13.5 (9.0) |
| Se | 240 | 3.69 (3.72) | 14.9 (7.6) |
| Te | 220 | — | — |
| O* | — | 7.31 | 22.0 |
| S* | — | 4.87 | 12.2 |

*R = t-$C_4H_9$, in the remaining cases R = n-$C_4H_9$.

It is striking that the values of $\Delta H$ found by West and coworkers[174,175] are virtually the same, while the values of $\Delta S$ diverge significantly. According to Pimentel and McClellan[1], values of $-\Delta S$ in the range 8–12 e.u. are the most probable for hydrogen bonds having average energies between 4 and 6 kcal mole$^{-1}$. The values of $\Delta S$ quoted in the second study by West et al.[175] are apparently too low (i.e. their absolute values are too high), while the earlier results[174] are more correct. The measured values of $\Delta\nu$ agree with the results of later investigations[176].

Table 15. The spectroscopic and thermodynamic characteristics of the hydrogen bonds formed by phenol and indole with diethyl chalcogenides $(C_2H_5)_2Y$.

| Y | $\Delta\nu$, cm$^{-1}$ | $\Delta k/k$ | $K^{40°}$, litre mole$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|---|---|
| | | Phenol, O-H...Y | | | |
| O | 274 | 0.146 | 4.50 | 5.63 | 14.9 |
| S | 251 | 0.134 | 0.80 | 3.35 | 11.1 |
| Se | 236 | 0.126 | 0.62 | 3.15 | 11.1 |
| Te | 213 | 0.114 | 0.50 | — | — |
| | | Indole, N-H...Y | | | |
| O | 155 | 0.860 | 1.72 | — | — |
| S | 136 | 0.760 | 0.72 | — | — |
| Se | 132 | 0.740 | 0.69 | — | — |
| Te | 130 | 0.730 | 0.48 | — | — |

Note. $\Delta k/k \simeq 2\Delta\nu/\nu_0$ is the relative change in the force constant of the O–H or N–H bond on formation of the hydrogen bond[178].

The hydrogen bonds formed by phenol and indole with diethyl ether and its sulphur, selenium and tellurium analogues have been investigated by NMR and infrared spectroscopy[177]. It was found that the N–H group in indole and the O–H group in phenol form hydrogen bonds not only with oxygen and sulphur but also with selenium and tellurium. Chojnowski and Brandt[177] attempted to analyse the results (Table 15) in order to determine which type of interaction—electrostatic or charge-transfer—makes the main contribution to the energy of the hydrogen bond. It was suggested that the contribution of the electrostatic interaction to the A–H...$Y(C_2H_5)_2$ hydrogen bonds (A–H is a constant moiety and Y = O, S, Se or Te) should decrease on passing from oxygen to tellurium, since the negative charge on the electron-donating atom diminishes in the same sequence, but the contribution of charge transfer to the overall bond energy should then increase, since the ionisation potential of Y diminishes.

Table 15 shows that all the characteristics of the complex-formation reactions ($\Delta\nu$, $\Delta k/k$, $K$, and $\Delta H$) decreases from oxygen to tellurium. Consequently the electron-donating capacity of Y in the hydrogen bond diminishes in the sequence O > S > Se > Te.

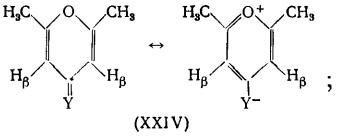
Since $\Delta k/k \simeq b^2$, where $b$ is the coefficient defining the contribution of the state with electron transfer to the overall wave function of the complex[179,180], i.e.

$$\psi = a\varphi(AB) + b\varphi(A^-B^+), \qquad (8)$$

the observed decrease of $\Delta k/k$ and hence of the coefficient $b$ [Eqn. (8)] from oxygen to tellurium implies a decrease of the contribution to the overall energy of the hydrogen bond due to the charge-transfer interaction. It is believed[177] that the interaction of this type is not of decisive importance in the formation of hydrogen bonds, since the increase of the H...Y bond length from oxygen to tellurium causes a greater decrease of its strength than the postulated increased influence of charge transfer on $\Delta H$ as the ionisation potential of Y diminishes[181].

According to Pogorelyi et al.,[182] butyl chalcogenides form hydrogen bonds not only with the proton-donating OH and NH groups but also with the mercapto-group of thiophenol. As was to be expected, the strength of the SH...Se and SH...Te bonds is lower than that of the OH...Se and OH...Te bonds. The values of $\Delta H$ for the complexes investigated (Table 16) diminish in the sequence O > S > Se > Te.

Table 16. The thermodynamic parameters of the hydrogen bonds formed by 2,6-di-t-butylphenyl (ArOH) and thiophenol with di-n-butyl chalcogenides $(n\text{-}C_4H_9)_2Y$.



| Y | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|---|
| | $C_6H_5SH$ | | ArOH | |
| O | 2.7 | 10.3 | 3.8 | 13.2 |
| S | 2.4 | 8.1 | 3.3 | 11.7 |
| Se | 2.3 | 8.1 | 3.3 | 12.0 |
| Te | 2.1 | 7.9 | 3.1 | 12.2 |

The observed[175-177,182] decrease of the electron-donating capacity of Group VI elements with increase of $n$ (the principal quantum number of the orbital of the free electron pair of Y) is probably an indication that the main contribution to the energy of the A–H...Y hydrogen bond (Y = O, S, Se, or Te) comes from the redistribution of the charge owing to the overlapping of the 1$s$ orbital of the bridging hydrogen atom with the $np\sigma$ orbital of Y.[181] With

increase of $n$, the $p$ electrons become more diffuse, and their orbital density decreases, with a consequent decrease of the capacity of the corresponding orbitals for overlapping and there is an appreciable intensification of the repulsion forces between A and Y due to the inner electrons of Y.

However, the above treatment does not rule out another explanation—the decrease of $\Delta H$ in the sequence O > S > Se > Te may be caused by the weakening of the electrostatic interaction, since the negative charge diminishes from oxygen to tellurium.

In this connection, the results of a study of hydrogen bonds involving 2,6-dimethyl-4-pyrone and its thio- and seleno-analogues are of interest[183-185]:

(XXIV)

Y=O, S, or Se .

Compounds of the type of the pyrone (**XXIV**) differ from dialkyl chalcogenides by the presence of an appreciable negative charge, localised on the electron-donating centre—the exocyclic oxygen, sulphur, or selenium atom[184], which may affect the relative contributions of different types of interactions to the hydrogen bond energy.

Table 17 shows that the results obtained by the NMR[185] and infrared spectroscopic[184] methods agree satisfactorily. For both phenol and methanol, the strength of the hydrogen bond decreases in the sequence pyrone > thiopyrone > selenopyrone. In conformity with its greater proton-donating capacity, phenol forms more stable complexes than methanol.

Table 17. The spectroscopic and thermodynamic characteristics of the hydrogen bonds in the association complexes of 2,6-dimethyl-4-pyrone and its thio- and seleno-analogues with methanol and phenol.

| Proton donor | $\tau_0$, p.p.m. | $\tau_C$, p.p.m. | $K^{40°}$, litre mole$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |

Note. $\tau_0$ and $\tau_C$ are the chemical shifts of the $-H\beta$ protons of the pyrone derivatives investigated in the monomer and complex respectively.
*Infrared spectroscopy; NMR was used in the remaining cases.

The dependence on $n$ of $\Delta H$ for the hydrogen bonds between different proton donors and bases where the electron-donating centres are Group VI elements is similar for the pyrones (**XXIV**) and dialkyl chalcogenides. The strength of the hydrogen bond and hence the electron-donating capacity decrease with increase of $n$. The present author believes that these data demonstrate that the mechanism of the redistribution of electron density owing to charge transfer from the highest occupied orbital of the electron donor to the antibonding $\sigma$ orbital of the A–H bond does not play a decisive role in the formation of the hydrogen bond between the atoms of Group VI elements, regardless of the structure of the electron donor molecule.

Thus the electron-donating properties of Group VI elements are determined mainly by the overlapping between the 1$s$ (H) and $np$ (Y) orbitals. This conclusion is confirmed by the correlation between the strength of the hydrogen bonds formed by ethers and sulphides with the integral for the overlap of the orbital of the $np$ electrons of the oxygen and sulphur atoms with the 1$s$ orbital of the bridging hydrogen atom[186].

Together with the redistribution of the charge via the orbital overlapping mechanism, there is also a change in the contribution to $\Delta H$ by the electrostatic interaction. The negative charge on the heteroatom decreases approximately by a factor of two on passing from oxygen to tellurium in dialkyl chalcogenides[177]. On the other hand, in pyrones the negative charge increases somewhat when oxygen is replaced by sulphur[187] and possibly by selenium. This does not, however, lead to an increase of $\Delta H$ in the above series as a result of the increasing contribution of the electrostatic interaction, probably because of the increase of the atomic radius of Y.

Egorochkin et al.[188] inferred a change in the electron-donating capacity of chalcogens in the compounds $[(C_2H_5)_3M]_2Y$ (M = Si, Ge or Sn) from the value of $\Delta\nu$(C–D) i.e. from the shift of the C–D band of deuterochloroform on complex formation. According to $\Delta\nu$ measurements, the electron-donating capacity of Y in the $[(C_2H_5)_3Si]_2Y$ series diminishes in the sequence Te > Se > S > O, which is the exact reverse of the series quoted above for chalcogen–carbon compounds. In the series with M = Ge or Sn, the general sequence in terms of decreasing electron-donating capacity, i.e. O > Te > Se > S, also differs from the series for carbon compounds. According to the authors[188], the complete or partial inversion of the electron-donating capacity series for chalcogens on passing from carbon compounds to compounds of its electronic analogues can be accounted for by the effects of the $p\pi - d\pi$ conjugation between M and Y, which leads to a decrease of the electron-donating capacity of Y. The capacity of chalcogens for $p\pi - d\pi$ conjugation with the elements of the carbon subgroup diminishes in the sequence O > S > Se > Te and the capacity of Group IV elements for such conjugation varies in the sequence Si > Ge > Sn. If this is the case, then the electron-donating capacity of oxygen linked to silicon should diminish to the greatest extent owing to the $p\pi - d\pi$ conjugation.

Table 18. The spectroscopic and thermodynamic characteristics of the hydrogen bonds formed by 2,6-di-t-butylphenol (ArOH), thiophenol, and selenophenol with pyridine[195].

| Proton donor | Bond | $\tau_0$, p.p.m. | $\Delta\tau$, p.p.m. | $K^{40°}$, (mole fraction)$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|---|---|---|
| ArOH | O—H ... N | 5.17 | 3.20 | 3.0 | 5.0 | 14 |
| PhSH | S—H ... N | 6.85 | 3.12 | 1.2 | 3.2 | 10 |
| PhSeH | Se—H ... N | 8.62 | 4.42 | 2.5 | 3.4 | 9 |

The present author believes that the decrease of the electron-donating capacity of $(R_3M)_2Y$ on replacement of, say, M = C by M = Si with Y constant can be accounted for with the aid of the concept of the $p_\pi - d_\pi$ conjugation. On the other hand, the series based on the variation of the electron-donating capacity of Y for different M proposed by Egorochkin et al.[188] and their treatment appear to be doubtful. Firstly, these series have been established only on the basis of the $\Delta\nu$(C–D), which reflect only the change in the strength of the C–D bond on complex formation and may not be correlated with the energy of the hydrogen bond (for a more detailed treatment, see below). For this reason, the basicity series can be established reliably only by measuring the thermodynamic characteristics of the hydrogen bond. Furthermore, the series proposed by Egorochkin et al.[188] conflict with other data[189,190] for hydrogen bonds involving the compounds $R_3P{=}Y$ (Y = O, S, Se or Te). The latter studies established on the basis of determinations of $\Delta H$ that the sequence based on the variation of the electron-donating capacity of chalcogens linked to phosphorus agrees fully with the corresponding series for carbon compounds, i.e. O > S > Se > Te. We may note that the effect of the $p_\pi - d_\pi$ conjugation in the P=Y bond should be greater than in the Si–Y bond, since the increase of nuclear charge from silicon to phosphorus causes a contraction of the atomic *d* orbitals of phosphorus and this leads in its turn to an improvement of the conditions for $d-p$ overlapping[191]. Thus, there are at present no adequate grounds for the assumption that the sequence based on the variation of the electron-donating capacity in the hydrogen bonds of chalcogens in their compounds with silicon is different from that in compounds with carbon or phosphorus.

The situation is different in rigid systems, such as, for example, the intramolecular hydrogen bond. We examined above studies from which it follows that, on formation of hydrogen-bonded chelates, sulphur can behave as a more effective electron donor than oxygen. However, there are insufficient data to extend this series to selenium compounds let alone tellurium compounds.

The intramolecular hydrogen bond in 3-methyl-1-phenyl-4-phenylaminomethylene-5-pyrazolone and in its thio- and seleno-analogues has been investigated by NMR[192]. The measured values of $\tau_{NH...Y}$ and $J_{NH-CH}$ (the spin–spin interaction constants) suggest[192] that the strength of the N–H...Y (Y = O, S, or Se) intramolecular hydrogen bond, giving rise to six-membered conjugated chelate rings, increases in the sequence O < S < Se. The construction of planar models enabled the authors of the above study to conclude that the geometry of the selenium derivative is more favourable from the standpoint of the formation of a hydrogen bond than that of the oxygen and sulphur analogues. The model for selenopyrazolone demonstrates an almost linear disposition of atoms in the N–H...Se fragment and hence the most effective overlapping of the 1*s* orbital of the hydrogen atom with the pure *p* orbital of the lone electron pair of selenium. Possibly the increase of the strength of the intramolecular hydrogen bond in the sequence O < S < Se is also due to the molecular geometry, which is more favourable for the formation of the bond.

The strength of the intermolecular hydrogen bond in the cyclic dimers of 2-pyridone and its thio- and seleno-analogues increases, as expected, in the opposite sequence: O > S > Se.[193] Planar models of these complexes show that the ring strain in the dimer increases on replacement of oxygen by sulphur and even more so on its replacement by selenium.

The proton-donating capacity in the X–H...B (X = O, S, Se, or Te) hydrogen bond in chalcogen compounds has been very little studied. It has only been firmly established (see, for example, Zuika and Bankovskii[12]) that, on passing from oxygen compounds to the analogous sulphur compounds the proton-donating capacity of X–H is sharply reduced. This is associated with the increase of the overlap integral $\int_{X-H} = \psi_{1s(H)}.\psi_{np(X)}.d\tau$ and of electron density at the bridging hydrogen atom when X = O is replaced by X = S, which entails a decrease of the residual capacity for overlapping of the 1*s*(H) orbital[61,194]. Furthermore, the replacement of O by S leads to a decrease of the dipole moment of the X–H bond and hence to a decrease of the contribution of the electrostatic interaction to the overall energy of the hydrogen bond. When these explanations are extended to selenium and tellurium compounds, one may expect that the proton-donating capacity will decrease in the sequence OH > SH > SeH > TeH. However, no experimental confirmation of this hypothesis has so far been obtained. There has been only one relevant study[195] where the hydrogen bonds formed by 2,6-di-t-butylphenol, thiophenol, and selenophenol with pyridine were investigated. It was found, contrary to expectation, that selenophenol forms with pyridine an even stronger hydrogen bond than does thiophenol, although, judging from the values of $\tau_0$, the electron density at the hydrogen atom in the X–H bond increases monotonically in the sequence OH < SH < SeH (Table 18).

The present author suggests that the observed sequence based on the variation of the proton-donating capacity, namely OH > SH < SeH, can be accounted for on the basis of the following postulates. According to Lippincot and Schroeder[196], the heat of formation of the X–H...B hydrogen bond can be represented by the sum

$$\Delta H = Q_{X-H} + Q_{X\ldots B} + Q_{H\ldots B},$$

where $Q_{H...B}$ is the exothermic heat of formation of the new bond, $Q_{X-H}$ the endothermic heat of extension of the X–H bond, and $Q_{X...B}$ the endothermic heat of interelectron repulsion arising when the atoms X and B approach one another. On passing from oxygen to sulphur and to selenium, $Q_{H...B}$ falls, while $Q_{X...B}$ increases for the reasons described above. These changes reduce $\Delta H$ in the above sequence. Since the strength of the X–H chemical bond diminishes on passing from oxygen to selenium, $Q_{X-H}$ decreases in the same direction, which may result, depending on the magnitude of the effect, in an increase of $\Delta H$. The influence of the weakening of the X–H bond formed by the proton donor on $\Delta H$ is probably particularly important for strong ionising electron donors, such as, for example, nitrogen-containing bases, since partial or complete proton transfer

$$X{-}H\ldots N \rightleftarrows X\ldots H\ldots N \rightleftarrows X^-\ldots H{-}N^+,$$

accompanied by a significant change in the length of the X–H bond, is most probable in such systems. Whereas the change in $\Delta H$ on passing from phenol to thiophenol is probably determined mainly by the changes in $Q_{H...B}$ and $Q_{X...B}$, the influence of the low strength of the Se–H bond on $\Delta H$ becomes appreciable for selenophenol. Such joint influences of all three effects on $\Delta H$ can in fact explain why thiophenol and selenophenol form hydrogen bonds of similar strength with the same electron donor.

### 3. GROUP VII ELEMENTS

In early studies[197-200], the changes in electron-donating capacity in the hydrogen bonds of halogen compounds were inferred from the values of $\Delta\nu$(OH) for phenol or methanol. It was assumed that the Badger–Bauer rule[171] is valid for the O–H...Y system for any Y. Measurements of $\Delta\nu$(OH) showed that the electron-donating properties are enhanced in the sequence F < Cl < Br < I. However, analysis of the thermodynamic characteristics of hydrogen bonds of different types showed[1,201] that the Badger–Bauer rule is applicable only to a limited range of related compounds.

The data in Table 19 are completely inconsistent with the earlier conclusion concerning the sequence of the changes in the proton-accepting capacity of the covalently bound halogen. Quantities such as $-\Delta H$ and $-\Delta F$ (the free energy change) decrease in the sequence F > Cl > Br > I, while the values of $\Delta\nu$ vary in the opposite sequence. According to the literature[201,202], $\Delta F$ for the intramolecular hydrogen bond in 2,6-dihalogenophenols decreases in the sequence Cl > Br > F > I. However, the results of Baker and Kaeding[201] and Richards and Walker[202], on the one hand, and West et al.,[174] on the other, are not inconsistent, since mainly steric factors influence the changes in $\Delta F$ in systems with intramolecular hydrogen bonds.

Table 19. The thermodynamic and spectroscopic characteristics of the hydrogen bonds formed by phenol with cyclohexyl halides[174].

| Electron donor | $\Delta\nu$, cm$^{-1}$ | $-\Delta H$, kcal mole$^{-1}$ | $-\Delta F^{25°}$, kcal mole$^{-1}$ | $-\Delta S$, e.u. |
|---|---|---|---|---|
| Cyclohexyl fluoride | 53 | 3.13 | 1.31 | 6.1 |
| Cyclohexyl chloride | 66 | 2.21 | 0.87 | 4.5 |
| Cyclohexyl bromide | 82 | 2.05 | 0.85 | 4.0 |
| Cyclohexyl iodide | 86 | 1.72 | 0.82 | 3.0 |

West et al.[174] put forward a qualitative explanation of the absence of correlation between $\Delta H$ and $\Delta\nu$ in many instances. $\Delta H$ is known to reflect the total energy of the A–H...Y–R interaction, i.e. the H...Y bond strength; $\Delta\nu$ represents a measure of the weakening of the A–H bond only. Consequently, for a constant proton donor A–H, $\Delta\nu$ may be correlated with $\Delta H$ for small changes in the electron donor molecule, i.e. in R, but such correlation need not necessarily persist when Y is altered or even when the degree of hybridisation of the electrons in Y is changed.

The results of West et al.[174] were confirmed by NMR and infrared spectroscopic measurements[203] of the association constants of phenol with n-hexyl fluoride, n-butyl chloride, n-butyl bromide, and n-butyl iodide. Although there are certain quantitative discrepancies between the values of $K$ determined by different methods, nevertheless the sequence based on the variation of the proton-accepting capacity of alkyl halides (F > Cl > Br > I) remains unchanged. The values of $\Delta H$ for the association of phenol with $C_6H_{11}F$ (0.9 kcal mole$^{-1}$) and $C_6H_{11}Cl$ (0.5 kcal mole$^{-1}$), which were determined calorimetrically[204], proved to be smaller by a factor of 3–4 than the $\Delta H$ for the same systems calculated from infrared spectroscopic data[174]. For the O–H...X (X = F or Cl) bonds, the absolute value of $\Delta H < 1$ kcal mole$^{-1}$ should probably be regarded as too low, since a weaker proton donor (chloroform) forms with carbon tetrachloride C–H...Cl bonds having $-\Delta H \simeq 1.5$ kcal mole$^{-1}$.[205]

The intramolecular O–H...X (X = halogen) bonds in *o*-substituted halogenophenols and the influence of these bonds on the position of the *cis–trans* equilibrium have been studied in a number of investigations[206-210]. The values of $\Delta H$ obtained[210] show that the strength of the intramolecular hydrogen bond decreases in the sequence F (1.63) = Cl (1.63) > Br (1.53) > I (1.32) for the gas phase, and in the sequence Cl (1.62) > Br(1.57) > I (1.45) ≥ F (1.44) for cyclohexane solutions. According to Tiensung Lin and Fishman[209], the values of $\Delta H$ for the gas phase are approximately twice as large, although a similar sequence persists: Cl (3.41) > Br (3.13) > I (2.75). The behaviour of fluorine[210], which forms virtually the strongest hydrogen bond in the gas phase and the weakest in solution, is the most remarkable. According to Carlson and Fateley[210], the sequence of halogens based on the variation of their electron-donating capacity in the gas phase is consistent with the sequence which would be expected from the size and electronegativities of the halogens. On the basis of its electronegativity alone, fluorine should form a stronger bond than chlorine, but the smaller size of the fluorine atom causes some decrease in bond strength, since the OH group is unable to approach sufficiently closely for optimum overlapping of the 1*s*(H) and 2*p*(F) orbitals. In inert solvents, *o*-fluorophenol forms the least stable intramolecular hydrogen bond, which indicates the highest *trans* : *cis* ratio. The *trans*-isomer is probably stabilised in this case by the preferential formation of intermolecular hydrogen bonds, since the electron-donating capacity of fluorine is a maximum in the series of halogens.

The relative proton-donating capacities of hydrogen halides have been investigated[211-214]. It was found for solutions in aromatic hydrocarbons that the relative shift $\Delta\nu/\nu$ of the X–H bond on formation of a hydrogen bond with a standard electron donor diminishes from HF to HI.[211] The ratio of the band intensities of the bound and free H–X molecules increases in the same sequence. On this basis, it was concluded that the stability of the hydrogen-bonded complexes is determined by the acidity of HHal and that the relative band shift does not characterise the stability of this complex. A similar claim was made by workers[212] who measured the frequencies of the complexes formed by HF, HCl and HBr with dioxan. However, other results[213,214], obtained from measurements of $\Delta H$ for the hydrogen bonds between HX and benzene, carbon tetrachloride, ketones, and ethers in carbon tetrachloride solutions and in the gas phase, cast doubt on these conclusions[211,212]. It was found that the energy of the hydrogen bond formed by HX with all the electron donors enumerated above is a maximum for HF, decreasing on passing to HCl and still more on passing to HBr. For example, in the case of acetone $-\Delta H$ for HF, HCl, and HBr is 8.4, 6.1, and 5.7 kcal mole$^{-1}$ respectively. The energy of the X–H... B hydrogen bond and the relative frequency shift were found to vary in parallel.

Thus the strength of the hydrogen bond formed by the proton donors X–H (X = F, Cl, Br, or I) with a specified acceptor decreases with increasing acidity of the hydrogen halide, which is probably due to the decrease of the residual capacity for overlapping of the 1*s*(H) orbital as the electronegativity of the halogen diminishes. It is noteworthy that, according to Shchepkin[214], the maximum change in the energy of the X–H... B bond occurs on passing from HF to HCl. When HCl is replaced by HBr, the change is much smaller. In the series of proton

donors PhXH (X = O, S, or Se) the small differences between the $\Delta H$ for the heavy atoms can probably be explained by the weakening of the X–H bond, which is said[196] to compensate to some extent the decrease in $\Delta H$ owing to the reduction of the residual capacity for overlapping of the 1*s*(H) orbital in the same direction.

Thus the electron-donating capacity of R–X and the proton-donating capacity of X–H decrease in the sequence F > Cl > Br > I, the maximum difference between these properties being observed on passing from fluorine to chlorine.

## IV. CERTAIN GENERAL PROBLEMS OF THE HYDROGEN BOND

The sum total of the data discussed in previous sections makes it possible to establish certain general regularities in the variation of the proton- and electron-donating capacities in the hydrogen bonds formed by analogous compounds of Group V–VII elements. An attempt will also be made to determine wherever possible the factors which play a decisive role in the variation of the properties of the A–H...Y, X–H...B, and X–H...Y hydrogen bonds (where A–H and B are standard proton and electron donors and X and Y are a series of elements belonging to a single Group or Period).

For the A–H...Y hydrogen bonds, the electron-donating capacity of Y, belonging to the given Group, diminishes on passing to heavier elements: N > P > As > Sb; O > S > Se > Te; F > Cl > Br > I. The greatest differences between the electron-donating capacities are observed on passing from the elements in the Second Period to those in the Third Period, i.e. between nitrogen and phosphorus, between oxygen and sulphur, and between fluorine and chlorine, while for heavier elements the differences are much less pronounced. We may note that even elements such as antimony, tellurium, and iodine, which are of the metallic or semimetallic type, are capable of forming hydrogen bonds as electron donors. Proton-accepting capacity can probably be regarded as virtually the exclusive property of the free electron pair and there is at present no reason to deny the possession of this property by still heavier atoms such as those of bismuth, polonium, and astatine.

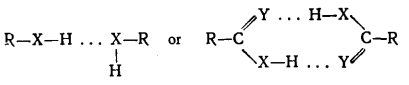
According to modern ideas[10,181], the main contribution to the formation of the hydrogen bond comes from the electrostatic interaction, the repulsion of electron clouds, and the redistribution of electron density. The latter involves the overlapping of the 1*s*(H) and *np*(Y) orbitals and charge transfer from the highest occupied orbital of the proton acceptor Y to the antibonding $\sigma$ orbital of the proton donor A–H. The data obtained for the decrease of the electron-donating capacity in Groups V–VII on passing to heavier elements suggest that the main contribution to the hydrogen bond energy is made by the overlapping of the 1*s*(H) and *np*(Y) orbitals. With increase of $n$, $p$ electrons become more diffuse and their orbital density diminishes; together with the interelectron repulsion, which increases in the same direction, this causes a decrease of the capacity for overlapping of the *np*(Y) orbital. From the standpoint of the model of charge-transfer complexes, the opposite behaviour would be observed—the electron-donating capacity of Y should increase with increase of $n$, since this entails a diminution of the ionisation potential.

We may note that the role of charge transfer in the hydrogen bond is the most controversial problem. This model is attractive, because it involves the inclusion of hydrogen-bonded complexes in the general class of donor–acceptor complexes. However, the correlation between the ionisation potentials of Y and the thermodynamic characteristics of association by hydrogen bonding is limited[1]. The most important experimental argument against the charge-transfer model of the hydrogen bond is the absence of the charge-transfer band from the spectra of hydrogen-bonded complexes[215]. Analysis of the infrared spectra with the aid of the vibronic theory[178,216], based on Mulliken's ideas[180], also showed[166] that charge transfer does not play a decisive role in the formation of the hydrogen bond by the elements of the same Group as electron donors.

As already stated, the effect of charge transfer may reduce merely to a decrease of the difference between the heats of association of neighbouring members of the Group as the ionisation potential is reduced. The increase of the polarisability of the electrons in Y with increase of $n$, resulting in an increase of the contribution of dispersion interaction, may play the same role.

The fastest decrease of proton-accepting capacity with increasing atomic number has been observed in a series of electron donors belonging to Group V. Chojnowski[166] explains this by the fact that the greatest differences between the hybridisations of the free electron pair orbital are characteristic of Group V elements. This follows from a comparison of the valence angles in the corresponding alkyl derivatives: 109° for $(CH_3)_3N$, 100° for $(CH_3)_3P$, and 96°C for $(CH_3)_3As$ in Group V and 111° for $(CH_3)_2O$ and 105°C for $(CH_3)_2S$ in Group VI. These data show that the increase of the amount of $s$ character of the free electron pair orbital, resulting in a decrease of its capacity for overlapping[217,218], is faster in Group V than in Group VI. If one assumes by analogy that the amount of $s$ character increases at the lowest rate in Group VII, one can understand the small change in electron-donating capacity on passing from chlorine to bromine and iodine.

We shall now consider how the electron-donating capacity changes in the A–H...Y hydrogen bonds for Y belonging to different Groups in the same Period. It was established previously[1] that the electron-donating capacity of the elements in the Second Period decreases in the sequence N > O > F, i.e. with increase of the electronegativity of Y. The data in Tables 13–15 and 19 suggest that this tendency in the variation of the electron-donating capacity is maintained in the Third, Fourth, and possibly Fifth Periods (P > S > Cl; As > Se > Br; Sb > Te > I), although the differences for neighbouring numbers of the series gradually diminish with increasing number of the Period. Calculations of the hydrogen bond energy[27] and the H...Y bond populations[219] showed, in agreement with experimental data, that the electron-donating capacity of Y decreases in the sequences P > S > Cl and Se > Br.



Thus the available data suggest that the electron-donating capacity of Group V–VII elements in the same Period decreases with increasing electronegativity, in contrast to the series of electron donors in a single Group. Consequently the electrostatic interaction is not of decisive importance in the formation of hydrogen bonds even with "hard" bases such as oxygen and fluorine compounds. The proton-accepting capacity of the elements in a single Period is probably determined by the redistribution of charge between the molecular fragments of the complex AH...Y owing to the overlapping of the 1*s*(H) and *np*(Y) orbitals and as a result of charge transfer from the *np*(Y) orbital of the proton acceptor to the antibonding $\sigma$ orbital of the A–H bond of the proton donor. On passing from nitrogen to fluorine, from phosphorus to chlorine, etc., the number of free electron pairs of the atom Y increases,

which leads to an intensification of the interelectron repulsion [176] in A...Y and impairment of the conditions for the overlapping of the 1*s*(H) and *np*(Y) orbitals. Furthermore, the increase of the ionisation potential in the same direction hinders charge transfer to the antibonding $\sigma$ orbital of the A–H bond. The joint operation of the above factors can account for the observed decrease of the electron-donating capacity within the limits of the same Period on passing to heavier elements.

We shall now consider how the proton-donating capacity changes in the X–H...B hydrogen bond, although, as we have seen, there are very few literature data for the elements in the Third, Fourth, and Fifth Periods. Nevertheless, one can assume that, for elements of the same Group or Period, the following series based on decreasing proton-donating capacity are valid: NH > PH, OH > SH ≃ SeH, FH > ClH > BrH > IH, FH > OH > NH, and ClH > SH > PH. [27]

The proton-donating capacity of the XH group is known [2] to be determined mainly by the tendency of the H atom in this group to accept electrons from the B atom, using the residual capacity for overlapping of the 1*s*(H) orbital. This capacity should increase with decrease of the overlap integral of the X–H bond [60], i.e. with increase of the degree of dissociation of the hydrogen atom as a proton. With increase of the electronegativity of the X atom, the overlap integral for the X–H bond diminishes, which entails an increase of the proton-donating capacity of the X–H group. Furthermore, the dipole moment of the X–H bond and hence also the contribution of the electrostatic interaction to the hydrogen bond energy increase with increasing electronegativity of X. These factors are in fact responsible for the increase of the proton-donating capacity of X–H on passing to heavier elements in the Period and to lighter elements in the Group. It is noteworthy that, within the limits of the same Period, the acidity and proton-donating capacity of X–H are the same, since the X–H bond energy and the degree of dissociation of the hydrogen atom as a proton vary in opposition. On the other hand, within the limits of a single Group, the bond energy and the degree of dissociation vary in parallel, which gives rise to the inverse relation between acidity and proton-donating capacity.

We shall now consider how the properties of the hydrogen bond are affected by the simultaneous variation of the proton- and electron-donating capacities of the interacting molecules. Such a situation arises in self-association processes:

when the substituent is altered. Electron-accepting substituents, for example, increase the proton-donating capacity of the X–H group but reduce the electron-donating capacity of X or Y. The overall effect of the substituent will depend on the relative contributions of the electron donor and proton donor to the hydrogen bond energy. Three cases are possible: (a) the contribution of the electron donor is greater than that of the proton donor and the introduction of electron-donating substituents strengthens the bond; (b) the contribution of the proton donor plays a decisive role and electron-accepting substituents strengthen the hydrogen bond; (c) the increase (decrease) of the proton-donating capacity of the X–H group is compensated by the decrease (increase) of the electron-donating capacity of X or Y and the strength of the hydrogen bond should not then depend on the nature of the substituent.

Analysis of the experimental data enabled the author of this review to put forward certain hypotheses of a general type [85]. Thus it has been established that the strength of hydrogen bonds in self-associated species of substituted anilines increases following the introduction of electron-donating substituents [220]: the tendency of mercaptans towards self-association is more pronounced than that of thiophenol [15]; the degree of self-association of phenols increases in the sequence *p*-chlorophenol < *p*-fluorophenol < *p*-cresol [221] and the stability of the self-associated species increases on passing from ethyl alcohol to t-butyl alcohol [94]. All these data lead to the conclusion that, in series of compounds forming hydrogen bonds of the type NH...N, SH...S, OH...O, and probably in general "homoquantum" bonds of the type X–H...X′ (where X and X′ are atoms of elements belonging to the same Period), the variation of the hydrogen bond strength is determined mainly by the variation of the properties of the electron donor.

On the other hand, in series of compounds associated via "heteroquantum" bonds of the type X–H...Y (where X and Y are elements belonging to different Periods), the variation of the stability of the associated species is presumably determined by the variation of the properties of the atom whose electrons, involved in the formation of the hydrogen bond, are characterised by a larger principal quantum number. Thus the variation of $\Delta H$ for the S–H...O bond should be determined by the variation of the proton-donating capacity of the SH group and for the NH...P bond by the variation of the electron-donating properties of the phosphorus atom under the influence of substituents. The latter hypothesis explains the type of influence of substituents on the stability of self-associated species of thiobenzoic acids [85], the ratio of the quantities $\rho$ [Eqns. (1) and (2)] for the association of thiophenols with acetophenones [52], and the shift of the thiol–thione equilibrium [88] under the influence of substituents.

Since the influence of substituents reduces the electronic polarisation of the reaction centre of the molecule, an explanation of the essential physical features of the empirical rule which has been formulated [85] is provided by calculations, involving complete neglect of differential overlapping (CNDO/2), of the charge shifts [222] in the molecular fragments of the HSH...$OH_2$ and HOH...$SH_2$ complexes [195]. These complexes provide one of the simplest examples of "heteroquantum" hydrogen bonds. It was found that the charge shift in the $H_2O$ molecule functioning as either an electron or proton donor is zero or many times smaller than the charge shift in the $H_2S$ molecule. This can be accounted for by the fact that, on passing from oxygen to sulphur, the deformability and polarisability of the electron clouds increase. The above results show that, on formation of the "heteroquantum" hydrogen bonds SH...O and OH...S, the maximum charge shift occurs precisely in the fragments of the complex where a change in properties is stated [85] to have a decisive influence on the change in bond energy. Consequently the greater sensitivity of the energy of a "heteroquantum" hydrogen bond to changes in the properties of the atom with the higher principal quantum number of the valence electrons can be explained by the fact that the maximum charge shift on formation of the hydrogen-bonded complex occurs in the molecular fragment with this atom.

# Vibrational Spectra of Free Radicals

L.A.Kotorlenko and S.A.Samoilenko

A survey of results obtained on the vibrational spectra of simple free radicals, polyatomic neutral radicals, and polyatomic radical-ions is accompanied by 141 references.

CONTENTS

I. Introduction 337

III. Vibrational spectra of polyatomic free radicals 339
IV. Vibrational spectra of radical-ions 341

## I. INTRODUCTION

The vigorous development of the chemistry and physics of free radicals during recent years is due to their important role as intermediate species in many chemical reactions and biological processes. Simple free radicals have been detected in the spectra of planets, comets, and stellar objects. Many problems of structural and theoretical chemistry, as well as chemical kinetics, are solved by means of free radicals. Such questions as the structure of electron shells and their modification under the influence of perturbations, the mechanisms of chemical reactions and physical processes causing magnetic relaxation of nuclei, etc. can be settled. Interest in free radicals arises also from their widespread application in many fields of science and technology. They are used as paramagnetic probes and spin labels in the physical chemistry of polymers, biophysics, and molecular biology. Stable free radicals act as inhibitors of the degradation of polymeric materials in technology. Many of them are employed in magnetometers and radio-frequency lasers.

Detailed studies have been made of the chemical properties, electron spin resonance spectra, and electronic spectra of free radicals, and their electronic structure has been calculated by quantum-chemical methods. The Nobel Prize was awarded in 1971 for a long series of investigations on the electronic spectra of simple radicals (Herzberg's monograph[1]). However, little work has been done on the vibrational spectra, which give valuable information both for identifying free radicals and for determining their electronic structure. The vibrational spectra of simple radicals have been more fully studied. Two reviews[2,3] have covered the literature on their infrared spectra up to 1971. The data given in most papers on the vibrational spectra of polyatomic radicals are fragmentary and non-systematic. Only quite recently have the first publications appeared in which the problem of interpreting vibrational spectra for several neutral and charged polyatomic radicals has been posed and more or less solved, and their force field has been estimated.

The present Review examines the literature on the vibrational spectra of neutral and charged polyatomic free radicals, as well as recent publications on the spectra of simple radicals not covered in the 1971 reviews by Andrews and by Milligan on the infrared spectra of simple radicals stabilised in neutral rigid matrices. Papers on the spectra of polyatomic radical-ions have been divided into three groups. The first comprises those with qualitative descriptions of spectra and an approximate assignment of one of two bands. The second group combines investigations on the variation of several characteristic frequencies in series of radical-ions of similar structure. The third group consists of recent papers giving an interpretation of the vibrational spectra of several stable radical-ions based on the calculation of normal vibrations, as well as an estimate of their force field and a comparison of the force constants with parameters of their electronic structure.

## II. VIBRATIONAL SPECTRA OF SIMPLE FREE RADICALS

Simple free radicals comprising a few atoms are very unstable owing to their very great chemical activity, so that the recording of their vibrational spectra presents considerable difficulties. Since their lifetime is very short ($10^{-3}$–$10^{-5}$ s), two approaches have been made to determining the vibrational spectra of such radicals: (1) the free radicals were fixed in rigid, inert matrices, which lowered their reactivity and lengthened their lifetime to such an extent that the usual instruments could be used; or (2) an infrared spectrometer having a scanning time $< 1$ ms was used. Since the production of such an instrument is a complex technical task, accomplished not long ago[4,5], the matrix isolation of free radicals has become widely used. The possibility of thereby obtaining infrared spectra of free radicals, as well as unstable molecules and ions, was demonstrated by Pimentel and his coworkers, and this method was developed and perfected in his own laboratory. Details of the method of matrix isolation have been given in the reviews[2,3], together with a discussion of procedures for obtaining simple radicals and identifying them from their spectra. In almost all the above studies the reliability of the assignment was improved by investigating every possible isotopic variety of the radicals and comparing the spectra of radicals prepared in different ways.

The reviews give results on the infrared spectra of methyl and halogenomethyl radicals, as well as radicals obtained by adding a third atom to a diatomic molecule (e.g. HCO, HalCO, HalOO, HOO), halogenated radicals (e.g. OF, OCl, CF, CCl, $NF_2$), radicals obtained by the photolysis of silane and halogenated silanes, and several others. Much of the work covered in the reviews was in a stage of further development, as is indicated by the appearance of communications on continued investigations of the infrared spectra of the radicals mentioned[2,3]. Thus a higher concentration of the $HO_2$ radical has been obtained[6] than in previous work. The spectra of four compounds of

formula $DO_2$ differing in isotopic composition with respect to oxygen have been reported for the first time. Calculation of the vibrations of $HO_2$ having various isotopic compositions confirmed the previous assignment of the 1389-$cm^{-1}$ band to the deformation vibration of OOH, but the 1101-$cm^{-1}$ band to the O–O stretching vibration. A bond angle of 105 ± 5° gave good agreement with experiment for $DO_2$. The relatively low force constant of the O–H bond in $HO_2$ and the near equality of the force constants of the O–O bonds in $HO_2$ and $O_2$ are compatible with the close similarity of their electronic structures, evident in the location of the corresponding electron transitions in the same spectral range. A recent analysis[7] of the vibrational spectra of peroxyl and deuteroperoxyl obtained in various ways reveals a positive isotopic shift of the $\nu_3$ vibration (1101 and 1123 $cm^{-1}$ for $HO_2$ and $DO_2$ respectively) and a negative shift for $\nu_2$ (1389 and 1020 $cm^{-1}$). Analysis of the spectral data for isotopically substituted derivatives of the $HO_2$ radical led to the conclusion that the oxygen atoms were not equivalent, which showed that the radical has an unsymmetrical structure.

The frequency of the out-of-plane deformation vibration of the methyl radical (611 $cm^{-1}$) differs significantly from the harmonic approximation. Riveros showed[9] that this discrepancy is consistent with the planar structure of the radical established from electron spin resonance data if the anharmonicity of the out-of-plane motion is taken into account. This success led Smith and Andrews[10] to use perturbation theory to calculate the anharmonic potential function of the ground state for out-of-plane deformations in the series of radicals $CH_2X$ (where X = Cl, Br, I). The calculated potentials were compared with the harmonic functions, and employed to confirm the observed isotope shifts. With $CH_3$ and $CH_2X$ the quartic anharmonic constants make a significant contribution to the potential energy, so that the harmonic force constants are considerably too low. Subsequently these workers extended the range of halogenomethyl radicals studied by infrared spectroscopy, by investigating the tri-,[11] di-,[11] and mono-iodomethyl[12] radicals. The 1106-$cm^{-1}$ band in the spectrum of $CHI_2$ was assigned to oscillation of the HCI angle, and the 716-$cm^{-1}$ band to an antisymmetric stretching vibration of the C–I bonds. With $CDI_2$ these vibrations give bands at 850 and 653 $cm^{-1}$ respectively. The 693-$cm^{-1}$ band of the $CI_3$ radical is attributed to stretching of the C–I bonds. The spectrum and the force field of $CH_2I$ were compared with the corresponding characteristics of the other monohalogenomethyl radicals. All three iodomethyl radicals show an unusually large force constant of the C–I bond in comparison with the value for $sp^3$-hybridised carbon atoms. It was considered that the change in hybridisation from $sp^3$ to $sp^2$ was insufficient to explain this observation, and $\pi$-bonding of the $\pi(p-p)$ and $\pi(p-d)$ type was assumed.

Milligan and his coworkers[13] examined the infrared spectra of the two halogenated methyl radicals $CClF_2$ and $CCl_2F$, and established that, as in $CHCl_2$ and $CCl_3$, the carbon–chlorine bond in $CCl_2F$ is considerably stronger than in stable molecules. Considering the possibility that the bond is strengthened by the presence of $\pi(p-d)$ interaction, these workers point out that such interaction will be considerable with a planar or almost planar structure, but a non-planar structure has been established for trichloromethyl.

One of the few studies demonstrating the possibility of applying yet another method of vibrational spectroscopy to unstable free radicals is an investigation of the Raman spectrum of the OF radical obtained photolytically on exposure in an argon matrix to a laser source[14]. The results support the assignment based on the infrared spectrum.

Investigation of the Raman spectra of the $NF_2$ radical in the gaseous state at high temperatures (up to 250°C)[15] is equally interesting from the point of view of technique. The frequencies of the completely symmetrical vibrations $\nu_1 = 1074$ $cm^{-1}$ and $\nu_2 = 572$ $cm^{-1}$ agree well with the corresponding frequencies in the infrared spectrum of the gaseous state.

The frequencies of the free radical NCN observed in the infrared spectrum in different matrices have been given[16–18] as $\nu_2 = 423$ $cm^{-1}$ and $\nu_3 = 1475$ $cm^{-1}$. The 2672-$cm^{-1}$ band detected at high concentrations of the radical was interpreted[19] as $\nu_1 + \nu_3$, which yielded $\nu_1 = 1197$ $cm^{-1}$.

The spectrum of the CNN radical in a matrix contains the bands[20] $\nu_2 = 393$ $cm^{-1}$, $\nu_1 = 1241$ $cm^{-1}$, and $\nu_3 = 2847$ $cm^{-1}$. From the estimated force constants it was concluded that the CN bond was almost triple, and the NN bond almost double. Vibration frequencies of the diazomethyl radical HCNN and its deuterated analogue were given[21] without interpretation. The bands at 1756, 1158, and 392 $cm^{-1}$ were attributed[22] to the dicyanomethylene free radical $C_3N_2$. These wave-numbers are close to those calculated for a linear molecule having the force constants of molecules of similar structure.

Use of a multiple-pass gas cell to give an optical path of 80 m yielded an infrared band at 1360 $cm^{-1}$, assigned[23] to an antisymmetric vibration of the symmetrical nitrate free radical $NO_3$ in the gas phase. The corresponding band of the planar nitrate ion lies at 1315 $cm^{-1}$.

Milligan and Jacox[24] observed the infrared bands $\nu_2 =$ 1499 $cm^{-1}$ and $\nu_3 = 3220$ $cm^{-1}$ for the $NH_2$ radical, displaced to 1496 and 3215 $cm^{-1}$ respectively for $^{15}NH_2$. A band at 1321 $cm^{-1}$ was detected in the spectrum of NDH, and $ND_2$ was characterised by a band at 1110 $cm^{-1}$. Investigating the infrared spectrum of NHF and its isotopic analogues, these workers[25] interpreted the observed two fundamental frequencies as $\nu_2 = 1432$ $cm^{-1}$ and $\nu_3 = 1000$ $cm^{-1}$.

Ogilvie[26] has recently revised the earlier interpretation[27] of the infrared spectrum of the HNO radical, and has suggested a new assignment of bands after comparing the geometrical parameters of the radical with the frequencies: he attributes the band at 2719 $cm^{-1}$ to N–H vibration, and that at 2043 $cm^{-1}$ to N–D, corresponding to the greater lengths of these bonds.

The infrared emission spectrum of the OH free radical has been determined by Murphy[28] for the fundamental and overtone regions. The fundamental band proved to be weaker than had been expected. The relative probabilities of the transitions were determined from the intensity ratio of fundamental and overtone bands, and hence the dipole moment function $\mu(R)$OH was calculated.

All three fundamental frequencies—$\nu_1 = 985$ $cm^{-1}$, $\nu_2 =$ 496 $cm^{-1}$, and $\nu_3 = 1042$ $cm^{-1}$—were observed with the $SO_2^-$ radical-anion stabilised as a charge-transfer complex with caesium and other alkali metals in an argon matrix[29]. The isotopic data indicate that interaction between $SO_2^-$ and $Cs^+$ is slight, so that all vibrational frequencies of normal and isotopic $SO_2^-$ can be calculated in good agreement with experiment without regard to the influence of the caesium ion. The slight splitting of the principal frequencies suggested that the oxygen atoms were not equivalent. Estimates by these workers indicate an $SO_2^-$ bond angle of ~ 160°, while the SO bond was considerably weaker than in $SO_2$, owing to the addition of the nineteenth valency electron to an orbital that was bonding for the terminal oxygen atoms and antibonding for the SO bonds.

The infrared spectra of the halogen dihalides have been investigated in a matrix[30-32]. The 696-$cm^{-1}$ band in the spectrum of the free radical $HCl_2$ has been assigned[30] to the $\nu_3$ vibration; the corresponding band in $DCl_2$ is at 464 $cm^{-1}$. Examination of the infrared absorption spectrum of the $HBr_2$ radical gives[31] $\nu_3 = 727$ $cm^{-1}$ and $\nu_1 = 165$ $cm^{-1}$, and indicates a linear structure ($D_{\infty h}$ symmetry) as for $HCl_2$. The spectrum of the radical $HI_2$, also interpreted[32] on the hypothesis of $D_{\infty h}$ symmetry, gave $\nu_3 = 682$ $cm^{-1}$ and $\nu_1 = 121$ $cm^{-1}$. The potential functions of all three radicals contain a large quartic term, which governs the anharmonicity of the H–Hal vibrations. Inspection of the force constants indicates that the hydrogen bonds are as strong in the $HHal_2$ radicals as in the $HHal_2^-$ ions. Comparison of the force constants in the series of hydrogen dihalides and the corresponding ion leads to the conclusion that the contribution of the quartic term to the potential function is larger for the radicals than for the ions. In the case of the ions the contribution of the anharmonic term diminishes with increase in size of the halogen atom, a tendency that is even more marked in the neutral radicals. Thus removal of an electron from a non-bonding orbital in $HHal_2^-$ has little effect on the hydrogen bond, but a marked effect in increasing the anharmonicity of the potential function. From the results for the above three radicals it was suggested[31] that $HF_2$ should be stable.

The spectra of the free radicals $CO_2^-$, $CCl_3$, and $CH_3CO$ have been recorded[33] in a rotating cryostat enabling infrared and e.s.r. spectra to be determined on the same specimen. Those of the first two radicals were obtained to check the technique; the spectrum of the acetyl radical, obtained for the first time, was investigated in greater detail. The 1796-$cm^{-1}$ band was assigned to a vibration of the carbonyl group; the 958-$cm^{-1}$ band was interpreted as due to a carbon–carbon stretching vibration.

Flash photolysis in the vacuum ultraviolet has recently been used[34] to obtain the radicals $C_3$, $C_3H$, $C_3H_2$, and $C_3H_3$ isolated in a matrix, as well as the allyl radical, and a preliminary assignment of the infrared bands has been made.

Pimentel et al.[35] obtained the infrared spectrum of the methyl radical in the gaseous state for the range of out-of-plane vibrations (450–740 $cm^{-1}$), using their method of rapid scanning spectroscopy. The observed frequencies (607 and 603 $cm^{-1}$ for $CH_3$, 561 and 558 $cm^{-1}$ for $CH_2D$, and 461 $cm^{-1}$ for $CD_3$) are close to those of the matrix-isolated radical and its deuterated derivatives, and were assigned to out-of-plane deformation vibrations of umbrella type. The lower frequency was due not to inversion of a pyramidal molecule but to a vibrationally excited methyl radical. The potential function of the out-of-plane vibration was calculated on the hypothesis that the radical had a planar structure. The anharmonicity was described by a quartic term, and could not be neglected in the case of $CD_3$.

In concluding this Section we may note the procedure suggested by Johnston et al.[36] for observing the infrared spectra of free radicals, based on the method of molecular modulation. Intense flash photolysis gives a fairly high concentration of radicals, with which, owing to fast reactions, it is often possible to observe not the species formed initially but their reaction products. The proposed method enables spectra of free radicals to be obtained at the very low concentrations obtainable with moderate light intensities. The photolysing light is switched on and off periodically, which slightly modulates the concentration of the radicals formed and of other intermediate products. The periodic variation in the concentration of unstable compounds, by slightly varying the absorption, modulates the intensity of the transmitted infrared beam. When the spectrum is scanned, the modulated intensity is obtained only within regions characteristic of the radicals or other short-lived products. Measurements of the phase shift during molecular modulation can be used to estimate the lifetime of the radical. Compounds are in general identified from the position and the form of the infrared bands. But when the spectrum is unknown or the bands overlap, the method permits identification of the absorbing substance as initial reactant, intermediate compound, or secondary product from the magnitude of the phase shift.

The radical ClO, formed photolytically from gaseous chlorine and oxygen, was detected in the gas phase from the absorption spectra and the phase shifts found in this work; the frequency 942 $cm^{-1}$ is consistent with the value for the matrix-isolated radical. Analysis of the phase shifts of the infrared absorption led to assignment of the 1127-$cm^{-1}$ band to the $HO_2$ radical obtained by photolysis of ozone in the presence of hydrogen peroxide (1101 $cm^{-1}$ in the case of matrix isolation). This method, though technically complicated, may give valuable information on short-lived radicals, especially at very low concentrations.

## III. VIBRATIONAL SPECTRA OF POLYATOMIC FREE RADICALS
