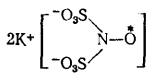
Little use of vibrational spectroscopy has been made in studying neutral radicals obtained by the homolytic cleavage of bonds. Karagonis[37] was one of the first to employ the infrared spectrum to determine the structure of the triphenylmethyl radical. From the number of infrared-active vibrations it was concluded that a planar structure was the most probable. No features of a radical character have been detected[38] in the infrared spectra of several perchlorodi(and tri)phenylmethyl radicals, merely a slight bathochromic shift in the frequency of the benzene ring ~ 1500 $cm^{-1}$. An analysis of the vibrational structure of the luminescence spectra of three arylmethyl radicals has been given[39] without assignment of the vibrational frequencies.

A series of papers contain data on the infrared spectra of phenoxy-radicals[40-50]. With 2,4,6-tri-t-butylphenoxyl[40,41] the hydroxyl band of the phenol at ~ 2.7 μm disappears, and the band appearing at 6.4 μm is assigned to the $\nu$(C–O*) vibration (where the asterisk denotes the unpaired electron). From the position and number of carbon–oxygen stretching bands[41-45,48] it was concluded whether the phenoxy-radicals were present in monomeric or dimeric form. The same bands were examined in elucidating structure of the 2,2-bis-(3,5-di-t-butyl-4-hydroxyphenyl)propane diradical[47].



A systematic investigation of the infrared spectra of stable phenoxy-radicals and related molecules has been made[51-53] in order to reveal the influence of the unpaired electron on the force field of the molecule. The infrared spectra of three phenoxy-radicals—2,4,6-tri-t-butylphenoxyl[52], 2,6-di-t-butyl-4-(2,6-di-t-butylquinobenzyl)phenoxyl (galvinoxyl), and 3,3′,5,5′-tetra-t-butylindophenoxyl[53]—have been interpreted. The most significant difference between the spectra of radicals and related molecules (initial phenols and molecules of quinonoid structure) is observed in the region containing carbon–oxygen and cyclic carbon–carbon stretching vibrations. The main

features of the force field of the phenoxy-radicals have been determined, and the changes in the spectra of the radicals in comparison with those of the related molecules were shown to be due mainly to change in the force field, not in the geometrical structure. Analysis of the modes of vibration of phenols, radicals, and quinonoid molecules indicates that the same coordinate makes the predominant contribution to the comparable vibrations. Hence the frequency shifts observed in the phenol–radical–quinonoid sequence are due to change in the force constants, not in the modes of vibration (Table 1). Thus it was suggested[52, 53] that the effect of the unpaired electron on the infrared spectra could be estimated by comparing the force constants of radicals and related molecules. The changes in the frequencies of out-of-plane deformation vibrations of cyclic carbon–hydrogen bonds and in the carbon–oxygen bond intensities for the series of compounds indicate a decrease in the $\pi$-electron densities on the carbon atoms forming carbon–hydrogen bonds and also an increase in polarity of the CO bond.

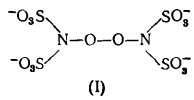


**Table 1.** Force constants ($10^6$ cm$^{-2}$) of ring carbon–carbon bonds and of carbon–oxygen bonds in phenol, the phenoxy-radical, and quinonoid molecules.

| Bond | Phenol | Phenoxyl | Cyclohexadienone | Quinone |

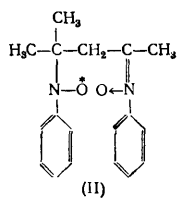
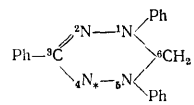
| Q′ Q′ | 10,04 | 8,66 | 7,85 | 7,85 |
| Q″ Q″ | 10,04 | 9,76 | 6,77 | 7,85 |



Infrared spectroscopy has been used to elucidate the structure of several nitroxide radicals[3, 54–61]. In the case of Frémy's salt

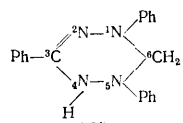
frequencies have been tentatively assigned to group vibrations for both monomeric and dimeric forms[54, 55]: the stretching frequency of the N–O* bond was assigned to the frequencies 1620 and 1260 cm$^{-1}$ in the two forms. Analysis of the infrared spectrum led to choice of (I) for the structure of the dimer.

(I)



(II)

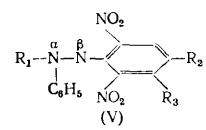
From an investigation of the infrared spectra of Benfield's radical (II), its derivatives substituted in an aromatic ring, and the initial compounds, Tüdos et al.[56] concluded that the main difference between the spectra of radicals and initial compounds is disappearance of the hydroxyl band at ~ 3300 cm$^{-1}$. They detected no other spectral features characteristic of radicals.



Piperidine nitroxide free radicals were also characterised by their infrared spectra[57–60]. The range 1300–1400 cm$^{-1}$ was studied[58] with the aim of detecting the $^{14}$N–O* bond, whose stretching frequency is 1373 ± 7 cm$^{-1}$.[60] The vibration frequency of the $^{15}$N–O* bond was also determined[60], as ~ 1353 cm$^{-1}$.

The band at 7.43 $\mu$m in the spectrum of the dimethoxydiphenylnitroxide free radical was assigned[61] to $\nu$(N–O*). The estimated force constant of this bond (8 mdyn Å$^{-1}$) is intermediate between the values for single and double bonds.

Several workers[62–64] have used infrared spectroscopy to study the verdazyls, a new class of uncharged stable radicals prepared not long ago. Kuhn and Trischmann[62] assigned the vibrations of the benzene rings in 1,3,5-triphenylverdazyl (III) and in 1,5-diphenylverdazyl, but the vibrations of the heterocycle remained almost unassigned. Qualitative examination of the infrared spectrum suggested that the radical was more symmetrical than the original leuco-base (IV), and the N–H stretching band near 3400 cm$^{-1}$ had disappeared. A fairly complete assignment of the infrared spectra of the verdazyl (III) and its derivatives substituted in one aryl ring was based[63] on the analogy with formazans investigated previously. The 1340-cm$^{-1}$ band was attributed to an NN-stretching vibration in the heterocycle. Other workers[64] assign an intense band at 1145 cm$^{-1}$ to this vibration in the verdazyl (III), and the 1340-cm$^{-1}$ band to a CN-stretching vibration in an *N*-phenyl group.



(III)

(IV)

The same paper reports the assignment of the infrared spectra of the initial leuco-base (IV), its analogue deuterated in the heterocycle, and the verdazyl cation (III), and changes in the spectrum accompanying one-electron cation-radical interconversions are traced. The spectra of the leuco-base (IV) and the radical (III) differ significantly in the frequencies of stretching vibrations of the tetrazole ring, whereas the vibration frequencies of the benzene rings remain unchanged. The spectrum undergoes appreciable changes when charged structures are formed from the radical. The frequency of the 1165-cm$^{-1}$ band due to an NN-stretching vibration rises in the spectrum of the cation, whereas that of the 1197-cm$^{-1}$ band due to the $C_{(6)}N$-stretching vibration falls, relative to those of the corresponding vibrations of the radical (1145 and 1208 cm$^{-1}$); the 1266-cm$^{-1}$ band due to vibration of the $C_{(3)}N$ bond hardly shifts. The vibration frequencies of the phenyl rings undergo little change on formation of the ion. From the frequency shifts of the $C_{(3)}N$- and NN-stretching vibrations for the cation it was assumed[64] that a considerable proportion of the positive charge was localised on the $N_{(1)}$ and $N_{(5)}$ atoms, which is consistent with the quantum-chemical calculation of the $\pi$-electron structure of the triphenylverdazyl cation.

Investigation of the infrared spectra of a series of free radicals of hydrazine type having the general formula

(V)

and of the initial hydrazines has revealed[61,65] changes in the spectra due to redistribution of electron density resulting from the appearance of the unpaired electron. The 3300-$cm^{-1}$ band due to NH-stretching vibrations has disappeared from the infrared spectra of stable hydrazyl radicals, and a series of characteristic frequencies are lower than in the original compounds. The strong bands at 1620 and 1600 $cm^{-1}$, assigned to skeletal vibrations of the picryl residue and of the monosubstituted benzene ring attached to the $\alpha$-nitrogen atom respectively, have diminished in frequency by 20 $cm^{-1}$, which is attributed to increasing conjugation resulting from the appearance of the unpaired electron on the $\beta$-nitrogen atom. The presence of the unpaired electron explains also the appearance of a new band of medium intensity in the range 1210–1250 $cm^{-1}$, assigned to stretching vibrations of the central fragment $\rangle N-N^{*}-$.

The infrared spectrum of propene adsorbed on zinc oxide at 125°C shows[66] detachment of a hydrogen atom from the methyl group and the appearance of a band at 1545 $cm^{-1}$, assigned to vibrations of CC bonds with order 1.5 in the allyl radical. The force constant of this bond was estimated as 7.54 mdyn $Å^{-1}$.

The vibrational spectrum of the benzyl radical, formed by the flash photolysis of toluene or an $\alpha$-monohalogenated derivative, was obtained by analysing the vibrational structure of the luminescence[67-73] and absorption[74,75] spectra. Emission spectra of the benzyl radical with well resolved vibrational structure were obtained both for the gas phase by means of a long-path cell[69] and for the radical trapped in various matrices at low temperatures[67,68]. The spectra of deuterated analogues of the benzyl radical were also given[70,71], and the vibrational frequencies were interpreted by analogy with toluene. More recently[72] the luminescence and absorption spectra of the benzyl and *o*-, *m*-, and *p*-fluorobenzyl radicals have been obtained in an adamantane matrix, and an analysis was given of the vibrational structure of the spectra of all these radicals. The vibrational frequencies of the benzyl radical agreed well with those obtained earlier. The infrared spectrum of the benzyl radical deposited with a neon matrix on caesium bromide and calcium fluoride windows at the temperature of liquid helium was given[73] without assignment.

The force constants of the benzyl radical were calculated[76] by means of a calibration curve from the bond orders obtained by the Hückel method and also by the self-consistent field method to a semi-empirical approximation allowing for electronic–vibrational interaction[77]. The latter were used[78] in calculating the frequencies and the forms of the normal planar vibrations of the benzyl radical, the equilibrium bond lengths of the radical being obtained by the Pariser–Parr method with variation of the resonance integral $\beta$ specified as a power function of the bond order. The satisfactory agreement between calculated and observed frequencies permits the hope that quantum-chemical estimation of bond lengths and force constants could be applied to solving the vibrational problem for free radicals. Comparison of the vibrational spectra of isoelectronic radicals—phenoxyl and benzyl—indicates that the force constants of the ring have changed more in the former than in the latter radical relative to the initial molecules[52] (Tables 1 and 2).

Quasi-line luminescence spectra have been used to provide the vibrational frequencies of radicals obtained by the photodissociation of durene[79,80], xylenes[81], ethyltoluenes[82-84], and diethylbenzenes[85]. Assignment of the frequencies of the radicals was based on analogy with the vibrational spectra of the initial molecules and of related paramagnetic species.

The vibrational frequencies 630, 1010, and 1600 $cm^{-1}$ observed[86] in the luminescence spectrum of the diphenylmethylene diradical are closely similar to those of benzene (606, 992, and 1600 $cm^{-1}$).

A vibrational structure has recently been given[87] for the fluorescence and phosphorescence spectra of the $\alpha$-indanyl free radical obtained by the $\gamma$-radiolysis of indane frozen in a neutral matrix at 77 K, and assignment of several vibrational frequencies has been attempted by analogy with indane.

The infrared spectrum of the exceptionally stable perchlorodiphenylaminyl radical has been given[88] without any attempt at interpretation.

## IV. VIBRATIONAL SPECTRA OF RADICAL-IONS

Radical-ions provide a convenient model for elucidating the influence of an unpaired electron on the force field of a molecule, since the matrices of the kinematic coefficients of a neutral molecule and of a radical derived from it should not differ greatly (the masses are the same, and the distances would not change markedly). The main changes in the vibrational frequencies are therefore determined by variation in the force constants. Until recently only the infrared spectra of radical-ions had been investigated. The first communications on the Raman spectra and the resonance Raman spectra have appeared only during recent years as a result of improvement in the method of obtaining the former spectra and the use of lasers for their excitation.

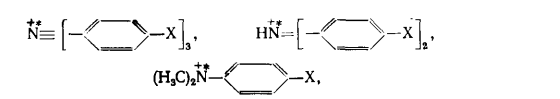
Papers on the vibrational spectra of radical-ions can be divided roughly into three groups. The most numerous group contains spectra and their qualitative description with an approximate assignment of one or two bands[61,89-101]. The second group[102-126] combines investigations of the frequency shifts in certain characteristic vibrations in a series of radical-ions of similar structure and correlations of these shifts with the variation of the parameters of the electron structure. The third group[127-137] comprises only the most recent publications, which give a fairly complete interpretation of the vibrational spectra of radical-ions based on calculation of the normal vibrations, together with an estimate of the force field and a comparison of the force constants with the parameters of the electronic structure.

Research on the infrared spectra of free radical-ions began in 1954–1955 with the work of Kainer and Otting[61,89], who obtained the spectra of various nitrogen-containing

radical-cations and compared them with those of the corresponding neutral molecules to establish the spectral variation on passing from molecules to radical-cations. The appearance of the unpaired electron in the radical salts of secondary and tertiary *para*-substituted arylamines leads to a marked strengthening of bands in the region of 6.25 μm due to stretching vibrations of the phenyl rings and of the band at 8.5 μm due to CH-deformation vibrations[61]. These effects are considerably weaker in the spectrum of pentaphenylpyrrole perchlorate, but the bands at 6.92 and 7.11 μm have become much more intense[61]. The spectrum of pyocyaninium perchlorate exhibits marked strengthening of the CH bands at 3.3 and 3.4 μm, with the appearance of two bands, at 2.90 and 2.95 μm, attributed to vibrations of OH and NH bonds respectively. With pyocyanin perchlorate it is impossible to distinguish $\nu$(OH) from $\nu$(NH) on the basis of the 3.1-μm band, owing to the bridge between the nitrogen and oxygen atoms[61].

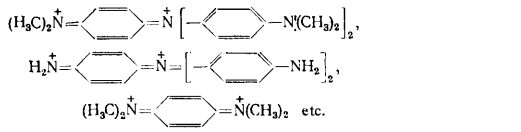
A spectral investigation was made[89] on the radical-ions obtained by reaction between the electron-donating *NNN'N'*-tetramethyl-*p*-phenylenediamine (TMPD) and electron-accepting halogenated *p*-benzoquinone derivatives. The spectrum of the radical-anions shows a decrease in the $\nu$(C=O) frequency to 6.5 μm (from 6 μm for the neutral molecule). The spectrum of the cation is characterised by weakening of the $\nu$(CH) and $\gamma$(CH) bands at 3.5 and 12.3 μm, with a marked shift in the $\delta(CH_3)$ band to 7.55 μm, while resembling the spectrum of the cation in the radical salt with the inorganic perchlorate anion (Wurster's blue).

A series of papers by Matsunaga[90-96], containing the infrared spectra of radical salts, must also be included in the first group. He examined the infrared spectra of the anions in the sodium and potassium salts of tetrachloro-*p*-benzoquinhydrone, *p*-biphenoquinhydrone, and tetrachloro- and tetrabromo-*p*-biphenoquinhydrone[90]. Using an approximate relation between the force constant and the bond order together with an empirical dependence of $\nu$(C=O) on the force constant, this worker calculated bond orders $P(C{=}O)$ and force constants for the radical-anions.



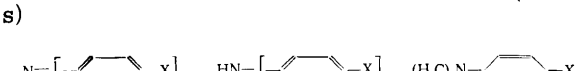
The radical-cations in salts of phenothiazine with iodine and bromine have similar spectra, differing markedly from that of the original molecule[91,92]. The infrared spectra of the radical-cations of dibenzophenothiazine remain unchanged on replacement of chloride by bromide, iodide[93], and also perchlorate anions: i.e. the spectra of the radicals are determined mainly by the absence of an electron from the highest filled orbital and are independent of the nature of the gegenion. The same conclusion applies also to the infrared spectra of the radical salts of phenoxazine, phenoselenazine, and benzophenothiazines with iodine and bromine[94]. Examination of the infrared spectra of the radical-cations of these compounds with halogenated derivatives of *p*-benzoquinone as anions shows[95] that the nature of the radical-cations remains the same with organic and with inorganic anions. From the displacement of the carbonyl band in the spectra of the anions it was concluded that this function loses ~ 30% of its double-bonded character, and the ring loses its quinonoid structure. This explains the marked difference between the infrared spectra of the radical-anions and those of the neutral molecules. The spectra of such radical-anions of semiquinones also resemble those in the alkali-metal salts. The presence of similar semiquinone radical-anions was observed[96] in the infrared spectra of complexes of dibenzophenothiazine with dichlorodicyano-*p*-benzoquinone, of 5,6 : 11,12-bisdithionaphthacene with *o*-chloranil, and of ferrocene with tetrachloro-*p*-biphenoquinone. The radical compounds investigated in this series of papers by Matsunaga have attracted attention as organic semiconductors, and their infrared spectra have been studied in parallel with their electrical conductivity.

In solutions with different gegenions the infrared spectrum of the radical-anion of 7,7,8,8-tetracyanoquinodimethane (TCQM) exhibits a bathochromic shift of $\nu(C{\equiv}N)$ (from 4.50 μm in the neutral molecule to 4.55–4.60 μm in the radical-anion[97]). Comparison of the infrared spectra of the radical salts $[TCQM]^-Li^+$ and $[TMPD]^+ClO_4^-$ recorded in Nujol with the spectrum of $[TMPD]^+[TCQM]^-$ indicates[98] that in the last salt both components are present in ionic form. Raman and infrared spectra have been obtained[99] for radical-ion complexes of tetracyanoquinodimethane with various cations; the spectra were not interpreted, but characteristic intense bands in the range 1100–1300 $cm^{-1}$ were noted.



The infrared spectra in Nujol and hexachlorobutadiene of the radical salts—triphenylammonium bromoantimonate, triphenylmethyl chlorostannate, tri-*p*-tolylammonium chloroantimonate, tri-*p*-tolylmethyl hexafluoroniobate, and tri-*p*-tolylammonium hexafluorotantalate—were given[100] without interpretation.

On examining a series of radical-anions obtained from alkylnitrobenzenes with alkali metals in dioxan, Nakai[101] found that the most significant difference between the spectra of the radical-anions and those of the neutral molecules was the enhanced intensity of the band due to antisymmetric nitro-stretching vibrations.



The second group comprises more detailed investigations[102-104] of the infrared spectra of several di- and triarylamine radical-cations

(X = $N(CH_3)_2$, $NH_2$, $OCH_3$, F, Cl, NOH, $NOCH_3$) and quinonedi-imine dyes (doubly charged cations)

With certain simplifications a relation was established[102] between the bond order calculated in the Hückel approximation and the stretching frequencies of the bonds attaching the benzene ring to the substituent and to the nitrogen atom in the arylamine radical salts, which explained the rise in these frequencies observed in the cations relative to the neutral molecules. The spectra of the above radicals and dyes were assigned[103,104] on the basis of an interpretation of those of the initial neutral molecules (leuco-bases)

Comparison of the infrared spectra indicates that singly and doubly charged cations are related in structure. Conversion of a radical into a dye does not produce such a marked change in structure as does that of the leuco-base into the radical. The changes observed in the spectra of radicals and dyes relative to those of the leuco-bases suggest that the positive charge appearing on the central nitrogen atom of the cation leads to displacement of the electrons of the lone pairs of the nitrogen, oxygen, and fluorine substituents in the CN, CO, and CF bonds, which are thereby strengthened. The consequent redistribution

of electron density changes the force constants of the CC bonds in the benzene ring. Thorough investigation of $\nu$(C–N) in radicals and dyes, together with data for many other compounds, indicated[104] that the CN bond orders had levelled out.

Savitskii and Kuznetsov[105] have since examined the infrared spectra of the Wurster salts of *p*-phenylenediamine (pPDA), *NN*-dimethyl-*p*-phenylenediamine (DMPD), and *NNN'N'*-tetramethyl-*p*-phenylenediamine (TMPD). The spectra of the radical salts were assigned by analogy with those of the initial amines and on the basis of the isotopic frequency displacements in the deuterated compounds. The range of skeletal vibrations undergoes the most considerable changes in the spectra of the radical salts in comparison with the initial amines, the frequencies tending to rise presumably owing to the more quinonoid character of the nitrogen–carbon skeleton. In the case of $[pPDA]^+$ and $[DMPD]^+$ hydrogen bonds of the anions (bromide and iodide) and amino-groups of the cations are involved in formation of the crystalline state, with a decrease in the paramagnetism of these salts. In the paramagnetic salt $[TMPD]^+$ the crystalline state is formed without the involvement of hydrogen bonds, obviously owing to steric hindrance.

Radical-anions of conjugated polycyclic hydrocarbons are obtained in high yields and are quite stable in a vacuum, which make them convenient subjects for investigation by infrared spectroscopy. Kachkurova[106–108] examined the infrared spectra of the radical-anions of naphthalene, anthracene, naphthacene, and pentacene, obtained in a vacuum by interaction with a metallic potassium mirror in oxolan. Assignment of the observed bands was facilitated by recording also the spectra of deuterated analogues. The frequencies showed a general tendency to fall on radicalisation, which was attributed to the presence of the unpaired electron in an antibonding orbital, weakening all the bonds in the radical with a decrease in force constants and increase in bond lengths. The frequency shift of the out-of-plane CH-deformation vibrations was especially large. It decreased with increase in the number of rings in the hydrocarbon, owing to the diminished electron density on the carbon atoms. With naphthacene and pentacene dianions could be obtained[108,109]. The effect on certain vibrations of the successive addition of two extra electrons could be traced by comparing the spectra of dianions and monoanions. A further fall in a series of frequencies with increase in the electron density on the ring carbon atoms is observed in the dianion spectra. The frequency shift of out-of-plane CH vibrations is larger for naphthacene than for pentacene, since the extra electron is distributed among a larger number of aromatic rings.

A preliminary assignment of several infrared bands and Raman lines of the radical-anion of naphthalene, observed by other workers[110], is consistent with Kachkurova's results[106,107].

Examination of the structure of the electronic absorption spectra of the radical-cations of naphthalene, anthracene, and phenanthrene in vitreous boric acid[111] gave the ring CC-stretching frequencies as respectively 1485, 1411, and 1356 $cm^{-1}$, with a fall in frequency in comparison with the neutral molecules. The infrared spectrum of the radical-cation of polyfluorinated naphthalene[112] also showed the disappearance of bands in the range 1600–1670 $cm^{-1}$, assigned to ring carbon–carbon vibrations, with the appearance of bands at ~ 1550–1590 $cm^{-1}$. As in the case of the radical-anions[106,107], such fall in frequencies is caused by weakening of the bonds.

The infrared and Raman spectra of the radical-anion of anthracene, obtained as a solid film by coprecipitation of anthracene and potassium vapours in a vacuum, have been investigated[113]. Films having different ratios of potassium to anthracene ($\frac{1}{2}$, 1, and 2) were identified from the vibrational and electronic spectra. Certain frequencies exhibit irregular behaviour, although in general transfer of the extra electron loosens the bonds. It was therefore considered urgently necessary to analyse the force constants both for a real interpretation of the spectra and for a quantitative estimate of the effect of the extra electron. Such irregularity in the frequency shifts was not observed by Kachkurova[106,107], obviously owing to the impossibility of observing the complete spectrum of anthracene dissolved in oxolan.

Resonance intensification of certain bands in the Raman spectrum of the radical-anion and the dianion of anthracene has been observed[114] in oxolan. According to a preliminary assignment no large differences are evident between the solid state and the solution, but the normal coordinates and results for deuteriated compounds must be examined to establish the correctness of the assignment. Later the same workers[115] observed the resonance form of the Raman spectrum of the radical-anion of biphenyl in oxolan. Assignment of the bands was based on analogy with neutral biphenyl. Both positive and negative displacements of the bands were observed. The higher stretching frequency of the central bond was associated with an increase in its order.

The radical-anions of several aromatic nitriles—benzonitrile, 1- and 2-cyanonaphthalene, *p*-cyanobiphenyl, 9-cyanophenanthrene, 1-cyanopyrene, 9-cyanoanthracene, etc.—obtained both by reaction of the nitriles with alkali metals in oxolan[116] and by cathodic reduction in dimethyl sulphoxide[117], showed a fall in the frequency of out-of-plane CH-deformation vibrations on radicalisation. The smallness of the change in polarity of the CH bonds can be judged from the almost identical intensities of these bands in the initial nitriles and in the radical-anions. Radicalisation entails weakening of CC valency bonds and hence a fall in frequency in the region of 1600 $cm^{-1}$ with an increase in intensity. The nitrile-stretching bands $\nu$(C≡N) were the most sensitive to the change in structure of aromatic nitriles on reduction. In the radical-anions their frequencies had fallen by 95–140 $cm^{-1}$, while the half-widths had increased from 7–9 to 22–45 $cm^{-1}$. The accompanying increase in the integral intensities of the nitrile bands was about tenfold.

The fall in frequency of the nitrile group on the appearance of a further electron in an antibonding orbital of a nitrile dianion[118] is 50% greater than with the singly charged anion. The half-width increases to 50–70 $cm^{-1}$, while the integral intensity is around hundredfold that observed for the neutral molecule. Such sensitivity of the C≡N vibration to variation in electronic structure gave rise to a broad investigation of the behaviour of nitrile bands on the formation of radical-anions from a number of aromatic nitriles[119,120]. The change in frequency of this vibration gives an indication of the change in order of the C≡N bond and also in its force constant: the shift in $\nu$(C≡N) correlates with the decrease in the calculated bond orders $P$(C≡N). The intense $\nu_{as}$(C≡N) band of aromatic radical-anions containing two nitrile groups is accompanied by the appearance of a weak $\nu_s$(C≡N) band at a higher frequency, not allowed in neutral molecules for reasons of symmetry, but active in radical-anions[119] owing to the unsymmetrical disposition of the gegenion.

The infrared bands of radical-anions of $^{15}N$-substituted nitriles[120] exhibit smaller isotopic displacement than in the case of the neutral molecules, which indicates that CC bonds adjacent to a nitrogen atom make a greater contribution to the vibrational energy. Inspection of the vibrations of radical-anions containing two nitrile groups leads to the conclusion that conversion of a molecule into a radical produces a considerable increase in vibrational interaction between the separated C≡N groups. The interaction force constant has been estimated on the basis of a simple vibrational model (N≡C–C...C–C≡N) as $F_{CN,CN} \simeq 0.3$ mdyn Å$^{-1}$. The main factor increasing vibrational interaction in the radical-anions is the great mobility of the unpaired electron in the antibonding orbital.

The carbonyl-stretching frequency provides a convenient indicator of change in the electronic structure of the group. It can be used[121,122] to determine the density $\rho$ of the unpaired electron on the carbonyl group in radical-anions of ketones. The displacement of the carbonyl band in the spectrum of the radical relative to its position in the neutral molecule is described by the equation

$$\Delta\nu(C=O) = A\rho, \qquad (1)$$

where $A = 250$ cm$^{-1}$ is a constant, roughly half the difference in frequency between double and single carbonyl bonds. A similar dependence extends to the nitrile and sulphonyl groups. An attempt to obtain a similar relation for the aryl group was unsuccessful, which the Reviewers regard as normal in view of the complicated form of the ring-stretching vibrations. Formula (1) is extremely useful for assigning the $\nu$(C=O) frequencies of the reduced forms of carbonyl compounds. In particular, this relation formed a guide in interpreting[123] the $\nu$(C=O), $\nu$(C=C), and $\nu$(C≡N) bands in the infrared spectra of the dianion and the radical-anion of biscarbodicyanocyclobutadiene studied in solution in dimethyl sulphoxide. The carbonyl bands showed that the frequency for the radical-anions was on the average ~ 35 cm$^{-1}$ lower than in the neutral molecule, with an additional fall of ~ 43 cm$^{-1}$ on further reduction to the dianion. The density of the unpaired electron on the carbonyl group in the radical-anion estimated by means of formula (1) is 0.17. The nitrile frequencies also fall on passing from the neutral molecule to the radical-anion and the dianion.

The magnitude and the direction of the frequency shifts of the carbonyl bands in the infrared spectra of the radical-anions and dianions of benzophenone, fluorenone, phenanthraquinone, and anthraquinone in polar solvents, on the application of Eqn. (1), give about the same order of magnitude of electron density on the carbonyl group[124] as does calculation to the Hückel approximation. The diminution in double-bonded character of the carbonyl bond with the accumulation of negative charge on the antibonding orbital is reflected in a change in the force constants calculated from the orders of the bonds and their self-polarisabilities by means of the formula of Coulson and Longuet-Higgins.

The infrared region of the carbonyl and aryl frequencies (1800–1500 cm$^{-1}$) has been examined following the reduction of several diketones on a metallic mirror in oxolan[125]. From the change in these frequencies and in the colour of the solution it was concluded that reduction of the diketones took place in two stages.

In the infrared spectrum of the dianion of tetraphenylethylene[126] the aryl frequency is 36 cm$^{-1}$ lower than in that of the neutral molecule, while $\nu$(C=C) is not observed. The large shift in the aryl frequency together with nuclear magnetic resonance data and quantum-chemical calculations of the electron density suggested an almost planar structure for the dianion and strong delocalisation of antibonding electrons.

In contrast to radical-anions in solution, stable radical-anions in the solid phase give a sufficiently complete spectrum for more reliable interpretation and estimation of the force field. Such investigations have recently been made for the radical-anions of chloranil ($p$-QCl$_4$)[127], bromanil ($p$-QBr$_4$),[128,129] 2,5-dibromo-3,6-dichloro-$p$-benzoquinone ($p$-QBr$_2$Cl$_2$),[130] and tetracyanoethylene[131,133–135]. All these compounds show significant differences between the spectra of the neutral molecules and those of the radical-anions, probably because of differences in their intramolecular force fields. The influence of the crystal field on the vibrational frequencies was assumed to be small and was disregarded. The radical-anions of the halogenated derivatives of $p$-benzoquinone were closely similar. In all three compounds the appearance of an unpaired electron in the lowest antibonding orbital was associated with a considerable fall in the stretching frequencies of the C=O and C=C bonds. In a force field this causes a decrease in the force constants of the C=O, C=C, and C–Br bonds (and also of the C–Cl bond in $p$-QBr$_2$Cl$_2$) with an increase in the force constant of the C–C bond (Table 3).

**Table 3.** Force constants (mdyn Å$^{-1}$) of the neutral molecules $p$-QBr$_2$, $p$-QCl$_2$, and $p$-QBr$_2$Cl$_2$ and of the corresponding radical-anions*.

| Bond | Neutral molecules | | | Radical-anions | | |
|---|---|---|---|---|---|---|
| | $p$-QCl$_4$[127] | $p$-QBr$_4$[128] | $p$-QBr$_2$Cl$_2$[130] | $p$-$\dot{Q}\bar{C}l_4$[127] | $p$-$\dot{Q}\bar{B}r_4$[128] | $p$-$\dot{Q}\bar{B}r_2Cl_2$[130] |
| C=O | 9.7 | 9.62 | 9.62 | 7.3 | 7.10 | 7.10 |
| C=C | 6.6 | 6.67 | 6.67 | 6.1 | 6.26 | 6.26 |
| C–C | 3.0 | 2.96 | 2.96 | 3.5 | 3.33 | 3.33 |
| C–Br | — | 2.63 | 2.63 | — | 2.17 | 2.17 |
| C–Cl | 2.67 | — | 2.67 | 2.67 | — | 2.45 |

*Q = benzoquinone.

Variation of the diagonal force constants was used to obtain the force field of the radical-anions from that of the neutral molecules. Force constants can be expressed in terms of bond orders and self-polarisabilities by means of the relation of Coulson and Longuet-Higgins. For the homopolar C=C and C–C bonds the self-polarisability term is small, which is apparent in a linear dependence of force constants on bond orders. The bond orders $P$(C=C) and $P$(C–C) estimated from known force constants agree with the results of quantum-chemical calculations for $p$-benzoquinone. For the C=O bond the order does not agree as well with those calculated quantum-chemically, but the tendency for $P$(C=O) to decrease on passing from a neutral molecule to the radical-ion is maintained here. Bond lengths obtained from the bond orders estimated in this way also agree with those calculated quantum-chemically: the C=O and C=C bonds become longer, but the C–C bonds become shorter.

The distribution of spin density has been obtained[132,129] from infrared-spectral data for the radical-anions of chloranil and bromanil on the hypothesis that the coefficients of the atomic orbitals remain the same in the molecular orbitals of the radical-anions as in the neutral molecules. The resulting spin densities are closely similar in

magnitude to those calculated from the hyperfine splitting constants on oxygen-17 in the electron spin resonance spectrum of the radical-anion of *p*-benzoquinone.

The decisive factor in the infrared frequency differences between neutral molecules and radical-anions is the difference in electronic structure[127-132]. Some difference between the bond orders obtained from the infrared spectra and calculated quantum-chemically may be due to frequency shifts under the influence of the crystal field, whose effect may be different for molecules and for radicals. Furthermore, the matrices of the kinematic coefficients of radical-anions and neutral molecules are not strictly identical, which also may make some contribution to the frequency shifts. Therefore the sets of force constants for radical-anions[127,128,130] are not the only ones possible. But the main conclusions on the electronic structure were based on an analysis of the change in the stretching frequencies, and the above effects can be neglected to a first approximation.

The infrared spectrum of the radical-anion of tetracyanoethylene proved especially interesting[131,133-135]. Apart from the C≡N stretching bands at 2208 and 2183 $cm^{-1}$, displaced to significantly lower frequencies than in the neutral molecule (2262 and 2230 $cm^{-1}$), and a very intense band at 1371 $cm^{-1}$, the spectrum of the radical-anion exhibited no appreciable absorption in the range 600–1300 $cm^{-1}$, where the most intense bands of the neutral molecule are located: only extremely weak bands are present at 1187 and 970 $cm^{-1}$, corresponding to the intense bands at 1155 and 959 $cm^{-1}$ due to C–C stretching vibrations in the neutral molecule. Since the 1371-$cm^{-1}$ band could have no other origin, it was assigned to a completely symmetrical vibration of the C=C bond (in the Raman spectrum of the neutral molecule $\nu$(C=C) = 1573 $cm^{-1}$).

Table 4. Force constants (mdyn $Å^{-1}$) of tetracyanoethylene and its radical-anion.

| Bond | Neutral molecule | | Radical-anion | |
|---|---|---|---|---|
| | Ref.131 | Ref.135 | Ref.131 | Ref.135 |
| C=C | 6.31 | 6.59 | 4.00 | 4.54 |
| C–C | 4.80 | 5.32 | 5.23 | 5.68 |
| C≡N | 16.84 | 17.04 | 15.70 | 16.34 |

The activation theory of Ferguson and Matsen and the hypothesis[134] of vibronic interaction have been used[131,133] to explain such activation of a completely symmetrical vibration in the infrared spectrum and the deactivation of antisymmetric vibrations of C–C bonds. The spectrum of the radical-anion of tetracyanoethylene has been interpreted on these assumptions, an analysis of the planar normal coordinates has been made, and the force constants of the bonds have been estimated in the Ursey–Bradley potential function of a simple field. Table 4 demonstrates the good agreement among results obtained by different workers. It shows that the extra electron in the lowest antibonding orbital of tetracyanoethylene decreases the force constants of the C=C and C≡N bonds and increases that of the C–C bond, so that this bond becomes stronger than C=C. The parallel variation in bond orders estimated from infrared spectral data is consistent with the results of quantum-chemical calculations. Investigation of the resonance Raman spectrum of the radical-anion of tetracyanoethylene[135] confirms the validity of the hypothesis of vibronic interaction and supports the earlier assignment of the infrared spectrum.

Recent conclusions[136,137] on the infrared and Raman spectra of the chloranil anion are consistent with previous results[127], although the inadequacy of varying only diagonal force constants on passing from neutral molecule to radical-anion is noted here. The infrared spectrum of the tetracyanoquinone radical-ion[137] is described satisfactorily by the force field obtained by varying the diagonal force constants of the bonds and the interaction constants of the bonds in the neutral molecule. The change in the latter constants is attributed to rearrangement of the quinonoid ring in the direction of a benzenoid structure.

The possibilities of resonance Raman spectroscopy for investigating free radicals has been demonstrated[138] in a study of the anions and dianions of several aromatic compounds (anthracene, biphenyl, terphenyl, diphenylbutadiene, perylene, and benzophenone). The differences observed in the spectra are larger on passing from the molecule to the anion than from the anion to the dianion. The appearance of several new bands with the charged forms is attributed to change in the selection rules under resonance conditions of excitation. Examination of such spectra is promising for systems having the strongest vibronic interactions, such as free radicals and multicharged ions possessing mobile electrons.

Investigation by the same workers[139] of the resonance Raman spectra of negative and positive mono- and di-ions of naphthacene revealed a considerable change in intensity on passing from neutral molecules to ionic forms, and established that the spectra were influenced mainly by the magnitude of the charge, not its sign.

A brief communication on the resonance Raman spectrum of the radical-cation of *p*-phenylenediamine[140] notes the high concentration sensitivity and the possibility of excluding the interfering effect of the solvent as advantages of the method. The spectrum is interpreted on the assumption of a cation-radical structure with the carbon–nitrogen bonds partly double-bonded in character.

A quite recent careful investigation[141] of the infrared and Raman spectra of the 7,7,8,8-tetracyanoquinodimethane radical salt $Cs_2(TCQM)_3$ and its deuterated derivatives, when compared with the results of X-ray diffraction, leads to the very interesting conclusion that the organic compound is present as two radical-anions and one neutral molecule.

Thus this survey of the literature provides evidence of the usefulness of applying methods of vibrational spectroscopy to investigate the changes of electronic structure involved in the conversion of molecules into radicals.

# Radical Reactions of Aromatic Polyfluoro-compounds

L.S.Kobrina

The review is devoted to the reactions of aromatic polyfluoro-compounds mainly with alkyl and aryl radicals. Certain features of the behaviour of compounds of this class in radical reactions are examined and the reaction mechanisms are discussed in those cases where they differ significantly from those in the corresponding reactions of non-fluorinated compounds. The bibliography includes 101 references.

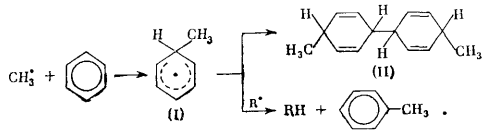
IV. Other reactions 357



## I. INTRODUCTION

Aromatic polyfluoro-compounds have been the object of continuous attention of research workers during the last 10–15 years, after convenient and easy methods for their synthesis were discovered. The data accumulated so far on the chemistry of such compounds permit the conclusion that their reactions with each of the main types of reagents (nucleophiles[1,2], electrophiles[3], and carbenes[4-9]) open general pathways to the synthesis of polyfluoro-compounds of fundamentally new structural types. In this sense, the radical reactions of aromatic polyfluoro-compounds, the study of which has been vigorously developing in recent years, constitute a striking example of the influence of fluorine atoms on the nature of the product formed and on the reactivity of aromatic compounds.

In the present review attention has been concentrated on the reactions of aromatic polyfluoro-compounds with alkyl and aryl radicals. In addition, the reactions with certain other radicals as well as photochemical and thermal reactions involving a free-radical mechanism are discussed.

## II. REACTIONS WITH ALKYL RADICALS

In contrast to homolytic arylation reactions of non-fluorinated aromatic compounds, widely described in a number of reviews and monographs[10,11], the radical alkylation reactions have not been surveyed. In order to be able to compare subsequently the available data on the action of alkyl radicals on aromatic polyfluoro-compounds and on their non-fluorinated analogues, it is useful to consider briefly the results of studies of the interaction of non-fluorinated compounds and alkyl radicals. The reactions of aromatic compounds with methyl and trifluoromethyl radicals in both liquid and gaseous phases have been studied in greatest detail. The mechanism adopted, discussed here in relation to the reaction of the methyl radical with aromatic compounds, involves the addition of the radical in the first stage with formation of a σ complex of type I:

(1)

(2)

It is assumed that direct abstraction of hydrogen from the aromatic ring with formation of the phenyl radical does not occur, since biphenyls were not detected in the reaction products[12]. Calculation has also shown that the abstraction of hydrogen from the σ complex (I) [Eqn. (2)] is energetically more favourable than the direct abstraction of hydrogen from the aromatic ring (64 and 100 kcal respectively)[13].

**Table 1.** The relative rates of methylation and phenylation of compounds of the type $C_6H_5X$.

| Relative rate | X | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | H | F | I | Br | $CH_3$ | $t\text{-}C_4H_9$ | $C_6H_5$ | $OC_6H_5$ |
| Methylation (Ref.14) | 1 | 1.51 (2.2)* | 2.11 (4.2) | 3.87 (3.6) | 1.46 | 0.68 | 7.47 | 4.89 |
| Phenylation (Ref.16) | 1 | 1.03 | 1.06 | 1.29 | 1.23 | 0.64 | 2.94 | — |

* The data of Heilman et al.[17] are indicated in brackets.

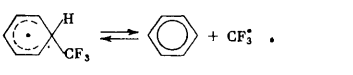
Comparison of the relative rates of methylation and arylation of benzene and its derivatives (Table 1) shows that $CH_3^{\cdot}$ is more selective than $C_6H_5^{\cdot}$, which may be attributed to the low reactivity of the intermediate σ complex (I) formed. The latter factor results in a significantly different subsequent fate of the σ complexes formed when alkyl or aryl radicals add to aromatic compounds. The σ complexes produced by the addition of alkyl radicals accumulate in the medium and vanish, dimerising in the vapour phase [Eqn. (1)], or react with the radicals of the medium, giving rise to methylbenzenes [Eqn. (2)], [14,15] while the σ complexes produced by the addition of aryl radicals disproportionate preferentially with formation of the corresponding biaryls[10].

In the reactions of aromatic compounds with sources of methyl radicals, the methylation products can be identified, while the formation of dimers of type (II) in most cases merely postulated on the grounds of general considerations[12,14,18]. Only one communication[12] reports the identification by gas–liquid chromatography (GLC) in the mixture of products of the reaction of benzene with $CH_3^{\cdot}$ of 2,2′-, 2,4′-, and 4,4′-dimethylbiphenyls, which might have been formed on dehydrogenation of the corresponding dimers. Other alkyl radicals, such as $C_2H_5^{\cdot}$, iso-$C_3H_7^{\cdot}$, and n-$C_3H_7^{\cdot}$, exhibit a reactivity in relation to aromatic

compounds analogous to that of the methyl radical, which can be inferred from the identical ratios of the isomeric alkyl derivatives obtained in the reaction of $C_6H_5Cl$ with $CH_3^{\cdot}$ and $C_2H_5^{\cdot}$,[19] and from the relative rates of addition of the ethyl[20], isopropyl[21], and n-butyl[22] radicals to aromatic compounds.

The study of the reactions of the trifluoromethyl radical with aromatic compounds showed that, as in the reaction with the methyl radical, the differences between the processes in the gas and liquid phases are insignificant[23] and that the main process is addition to the ring[24,25]. It has been found that $CF_3^{\cdot}$ is more reactive than $CH_3^{\cdot}$, which is in all probability due to its pronounced electrophilic properties (for example the rates of addition of $CH_3^{\cdot}$ and $CF_3^{\cdot}$ to benzene relative to their addition to iso-octane are 0.4 and 7.1 respectively)[26]. The relative rates of addition of $CF_3^{\cdot}$ to substituted benzenes (Table 2) also show that the trifluoromethyl radical is electrophilic.

Table 2. The relative rate constants $k_{rel}$ for the addition of the trifluoromethyl radical to substituted benzenes $C_6H_5X$.[27]



| X | H | $CH_3$ | $OCH_3$ | I | Br | Cl | F | $CF_3$ | $CCl_3$ | $NO_2$ | CN |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $k_{rel}$ | 1 | 1.43 (1.65)* | 1.93 (2.80) | — (1.65) | 0.89 (0.77) | — (0.65) | 0.35 (0.48) | 0.26 (0.30) | 0.36** — | — (0.45) | — (0.4) |

* The data of Szwarc and coworkers[28] are indicated in brackets.
** Data of Giles and Whittle[29].

The data in Table 2 show that the aromatic ring is activated with respect to the addition of the trifluoromethyl radical by electron donors and deactivated by electron acceptors. The halogens can be arranged in the following sequence in terms of the extent to which they hinder the addition to the compounds $C_6H_5Hal$: $I > Br > Cl > F$. The deactivating affect of electron-accepting substituents such as $CF_3$ and $CCl_3$ proved to be weaker than expected. The influence of other substituents resembles qualitatively the observed influence in the reactions of substituted benzenes with electrophiles and differs from the influence of these substituents in the reactions with methyl and phenyl radicals. However, the much lower dependence, compared with heterolytic reactions, of the rate of the addition reaction on the nature of the substituent in $C_6H_5X$, noted for all homolytic reactions, persists under these conditions in the reactions of aromatic compounds with the trifluoromethyl radical[11,15,30].

Fundamental differences in the behaviour of other fluorine-containing alkyl radicals in reactions with aromatic compounds have not been observed[31].

An interesting observation was made in a study of the reaction of $CF_3^{\cdot}$ and $C_2F_5^{\cdot}$ with aromatic compounds at different temperatures. When the addition of the trifluoromethyl radical to benzene at 65°C is irreversible in both gaseous and liquid phases, then at 140–150°C [32,33] (and for the perfluoroethyl radical at 110°C)[31] the process becomes reversible:

Proceeding now to the consideration of the reactions of aromatic polyfluorocompounds with alkyl radicals, we may note in the first place the appreciably reduced rate of addition of the trifluoromethyl radical to compounds of the $C_6H_nF_{6-n}$ ($n = 0-6$) series with increase of the number of fluorine atoms (Table 3).

Table 3. The Arrhenius parameters* of the reactions involving the addition of the trifluoromethyl radical to aromatic compounds[27].

| Compound | $10^{11} \cdot k_1/k_2^{1/2}$ ** | $E_1 - \frac{1}{2}E_2$ | $10^{8} \cdot A_1/A_2^{1/2}$ |
|---|---|---|---|
| $o$-$C_6H_4(CH_3)_2$ | 44.9 | 4.4 | 29.0 |
| $C_6H_5CH_3$ | 16.9 | 4.9 | 25.0 |

| 1,2,4-$C_6H_3F_3$ | 1.40 | 5.0 | 2.2 |
| 1,3,5-$C_6H_3F_3$ | 0.782 | 4.5 | 0.62 |
| 1,2,3,4-$C_6H_2F_4$ | 1.03 | 5.8 | 5.5 |
| 1,2,4,5-$C_6H_2F_4$ | 0.985 | 4.1 | 0.42 |
| $C_6HF_5$ | 0.679 | 5.1 | 1.26 |
| $C_6F_6$ | 0.484 | 5.8 | 2.8 |
| $C_6F_5CF_3$ | 0.525 | 4.6 | 0.53 |
| $p$-$C_6F_4(CF_3)_2$ | 0.143 | 4.2 | 0.069 |
| $C_6F_5CH_3$ | 0.991 | 3.7 | 0.24 |
| $C_6F_5Br$ | 0.767 | 5.2 | 2.0 |

* The kinetic method is based on the determination of the decrease of the yield of the radical recombination product relative to an internal standard (CO for the generation of the trifluoromethyl radical from hexafluoroacetone) when an aromatic substrate capable of combining with the radical is added to the reaction mixture.
** $k_1$ is the rate constant for the addition of $CF_3^{\cdot}$ to the aromatic compound and $k_2$ the rate constant for the dimerisation of trifluoromethyl radicals.

In a theoretical consideration of the addition of radicals to aromatic compounds, it is usual to assume that the changes in the rate constants are caused mainly by the changes in the activation energies for the reactions. The explanation of the deactivation of the aromatic ring by fluorine atoms in terms of electron repulsion effects or the dipolar influence of the medium also presupposes a change in activation energies. However, the data in Table 3 show that the activation energies are actually very close for all substituted benzenes, while the activation entropy (the $A$ factor) depends significantly on the number and nature of substituents.

Evidently the replacement of hydrogen atoms by fluorine in the reaction centre of the aromatic compound can influence both the activation energy and entropy of the radical addition reaction. Szwarc and coworkers[34] quote data showing that the activation entropies for hexafluorobenzene and benzene differ very little, while according to the data of Whittle and coworkers[27] the $A$ factor for aromatic polyfluoro-compounds is lower by a factor of approximately ten than for benzene derivatives without fluorine atoms. The reversibility of the addition of the trifluoromethyl radical to aromatic compounds at high temperatures (150°C for benzene and 180°C for hexafluorobenzene)[34] introduces some uncertainty into both sets of results.

Nevertheless findings such as the similarity of the ratios of the rate constants for the addition of $CF_3^{\cdot}$ to $C_6H_6$ and $C_6F_6$, obtained by Szwarc and Whittle in the temperature range 24–80°C ($k_{C_6H_6}/k_{C_6F_6} = 20$), and the observed decrease of the $A$ factor for the addition of the trifluoromethyl radical to a series of other polyfluorobenzenes (Table 3) suggest that the change in activation entropy observed by Whittle and coworkers is greater than the possible experimental error and is therefore more reliable than the data of Szwarc and coworkers. The decrease of the activation entropy for the addition of the trifluoromethyl radical occurring in the presence of substituents at the reaction centre may be a result of a partial restriction of the rotation of the trifluoromethyl group about the C–$CF_3$ axis in the transition state.

For compounds of the type $C_6F_5X$ with X = H as the standard substituent, the same effects of the substituents are observed in the addition reaction of the trifluoromethyl radical (Table 4) as for the benzene derivatives $C_6H_5X$ (Table 2).

Table 4. The relative rate constants $k_{rel}$ for the addition of the trifluoromethyl radical to compounds of the type $C_6F_5X$.[27]

| X | H | F | Br | Cl | $CF_3$ | $CH_3$ |
|---|---|---|---|---|---|---|
| $k_{rel}$ | 1 | 0.71 | 1.13 | 1.12* | 0.77 | 1.46 |

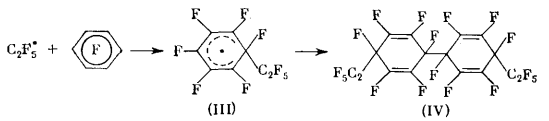
* The rate constants were calculated from the ratios $k_{C_6H_5Cl}/k_{C_6H_6} = 0.065$ [29] and $k_{C_6F_5H}/k_{C_6H_6} = 0.058$.[27]

Interesting observations have been made on the mode and ease of abstraction of hydrogen from aromatic fluorocompounds by the trifluoromethyl radical[27]. As fluorine atoms accumulate in the $C_6H_nF_{6-n}$ molecule, the abstraction of hydrogen becomes increasingly more difficult, but the addition of $CF_3^{\cdot}$ is hindered at the same time, in agreement with the earlier hypothesis that the abstraction of hydrogen in the reactions of aromatic compounds with alkyl radicals is most likely to occur from σ addition complexes of these radicals rather than directly from the ring. When the benzene ring contains a substituent such as the $CH_3$ group, hydrogen is abstracted from the latter in $C_6F_5CH_3$ with much more difficulty than in $C_6H_5CH_3$, which can be explained by the greater strength of the C–H bond in pentafluorotoluene.

The abstraction of a bromine atom is observed in the reactions of benzene derivatives such as $C_6H_5Br$ and $C_6F_5Br$ with the trifluoromethyl radical, which can be inferred from the formation of $CF_3Br$. It is then found that bromine is abstracted from bromopentafluorobenzene approximately six times more readily than from bromobenzene, but the rate constants for these reactions cannot be calculated, since there exist two alternative mechanisms of the abstraction of bromine: (1) directly from the aromatic ring and (2) from the intermediate σ complex in which $CF_3^{\cdot}$ has added to the carbon atom linked to bromine. The observations of Whittle and coworkers[27] tend to support the second mechanism. Firstly, the rate of formation of $CF_3Br$ [and $CH_3Br$?] from both $C_6F_5Br$ and $C_6H_5Br$ does not change appreciably with temperature and, secondly, the activation energies for the two reactions are less than 2 kcal mole$^{-1}$, while that for the abstraction of hydrogen is approximately 5 kcal mole$^{-1}$. Despite the low activation energy, the elimination of bromine from $C_6H_5Br$ proceeds much more slowly than that of hydrogen, probably due to steric factors, which may play a more important role in the abstraction of bromine located in the geminal position with respect to the $CF_3$ group in the σ complex than in the abstraction of hydrogen from the analogous σ complex. In contrast to the reactions of $C_6H_5Br$ and $C_6F_5Br$, an appreciable elimination of the chlorine atom was not observed in the reaction of the trifluoromethyl radical with $C_6H_5Cl$ and $C_6F_5Cl$ even at 110–120°C.[29] The calculated activation energy for the elimination of the chlorine atom is approximately 13 kcal mole$^{-1}$. On the other hand, iodine is abstracted very rapidly from $C_6H_5I$ and $C_6F_5I$ by the trifluoromethyl radical, the rate of abstraction from pentafluoroiodobenzene being approximately four times greater than from iodobenzene.

When $CF_3^{\cdot}$ interacts with pentafluorobenzaldehyde[35], the hydrogen atom is abstracted with formation of trifluoromethane and a pentafluorobenzoyl radical, which recombines with $CF_3^{\cdot}$ to form octafluoroacetophenone:

$$C_6F_5CHO + CF_3^{\cdot} \xrightarrow{h\nu} C_6F_5CO^{\cdot} + CF_3H\ ;$$
$$C_6F_5CO^{\cdot} + CF_3^{\cdot} \rightarrow C_6F_5COCF_3\ .$$



The activation energy for the abstraction of the hydrogen atom from pentafluorobenzaldehyde is higher than for benzaldehyde (8.6 and 4.6 kcal mole$^{-1}$ respectively), but the yield of octafluoroacetophenone is significantly higher than that of acetophenone in the corresponding reaction of benzaldehyde. According to the authors[35], the latter factor may be a result of the low stability of the non-fluorinated benzoyl radical (the dissociation energy of the $C_6H_5$–CO bond is only 28 kcal mole$^{-1}$), which readily dissociates with formation of $C_6H_5^{\cdot}$ and CO. On the other hand, it may be that the high yield of octafluoroacetophenone is due to the high reactivity of the pentafluorobenzoyl radical [cf. the reaction of $C_6F_5I$ with $Ni(CO)_4$, see Section V below], which reacts with the trifluoromethyl radical before dissociating with formation of $C_6F_5$ and CO.

It is of interest to compare the results of the study of the interaction of benzene and hexafluorobenzene with the chlorodifluoromethyl radical generated from 1,3-dichlorotetrafluoroacetone on photolysis[36]. The significant differences between the temperature dependences of the rates of formation of the products of the addition of $CF_2Cl^{\cdot}$ to $C_6H_6$ and $C_6F_6$ observed by the authors were interpreted in terms of the different stabilities of the corresponding σ complexes (up to 100°C for $C_6H_6CF_2Cl^{\cdot}$ and up to 250°C for $C_6F_6CF_2Cl^{\cdot}$).

The fact that the elimination of fluorine atoms was not observed in any of the reactions of aromatic polyfluorocompounds with fluorine-containing alkyl radicals may serve as evidence that the main pathway in the reaction of the σ complexes produced by the addition of the radicals to aromatic polyfluoro-compounds involves their dimerisation. We already noted previously that, in the vast majority of the reactions investigated, with both non-fluorinated and fluorinated reagents, dimeric products could not be isolated and the conclusions concerning the mechanism of the reaction of the σ complexes resulting from the addition of alkyl radicals to fluorinated and non-fluorinated aromatic compounds were based on kinetic data. In a study of the reaction of hexafluorobenzene with the perfluoroethyl radical generated from perfluoropropionyl peroxide, the isomeric compounds (IV)—the dimers

of the σ complex produced by the addition of $C_2F_5^{\cdot}$ to $C_6F_6$ (III)—were recently isolated[37] as the main reaction products:

$$(C_2F_5COO)_2 \xrightarrow{\Delta} 2C_2F_5^{\cdot} + 2CO_2 ;$$

(III) (IV)

The difference in the behaviour of benzene and hexafluorobenzene in their reactions with nitromethane at 550°C is noteworthy[38]. The main product of the reaction of benzene is biphenyl, while the remaining products consist to the extent of 80% of nitrogen compounds (aniline and *N*-methylaniline)[39]; on the other hand, the reaction with $C_6F_6$ yields mainly pentafluorotoluene and pentafluorophenol, the ratio of which varies with the molar ratio of the reactants (Table 5).

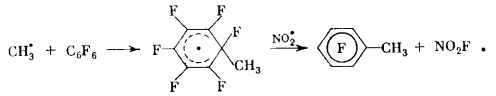


Table 5. The proportions of the products of the reaction of $C_6F_6$ with $CH_3NO_2$ (determined as percentages by GLC relative to one mole of $C_6F_6$).

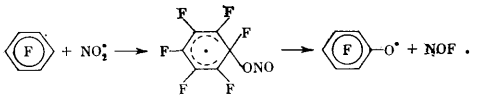
| Reaction product | Nitromethane (no. of moles) | | Reaction product | Nitromethane (no. of moles) | |
|---|---|---|---|---|---|
| | 1 | 0.1 | | 1 | 0,1 |
| $C_6F_5CH_3$ | 37.5 | 60.0 | $C_6F_5CHO$ | 6.6 | 4.6 |
| $C_6F_5OH$ | 33.0 | 3.0 | $C_{12}F_{10}$ | 6.8 | 2.9 |
| $C_6F_5OCH_3$ | 5.9 | 12.7 | unknown products | 10.2 | 16.8 |



The observed difference between the products of the reactions of nitromethane with benzene and hexafluorobenzene may be attributed to a certain amount of nucleophilic character of the methyl radical, as a result of which its attack on $C_6F_6$, which is sensitive to nucleophiles[2], becomes the preferred pathway. Possibly the degree of such preference reflects the difference between the bond dissociation energies $D(C_6F_5-CH_3) - D(C_6H_5-CH_3) = 25$ kcal mole$^{-1}$.[40] The following mechanism is proposed for the formation of the main product of the reaction of $CH_3NO_2$ with $C_6F_6$. At a high temperature nitromethane decomposes into two radicals:

$$CH_3NO_2 \rightarrow CH_3^{\cdot} + NO_2^{\cdot} .$$

The methyl radical adds to hexafluorobenzene with formation of a σ complex, from which a fluorine atom is abstracted by the $NO_2^{\cdot}$ radical:

The methyl radical apparently reacts with hexafluorobenzene so fast that there is not sufficient time for the abstraction of a hydrogen atom from nitromethane, as happens in the reaction with benzene. The role of $NO_2^{\cdot}$ in the two reactions is likewise different. The radical abstracts hydrogen from benzene, giving rise to the phenyl radical responsible for the formation of biphenyl in the phenylation of benzene or during dimerisation. Fluorine is apparently abstracted to only an insignificant extent from $C_6F_6$, since only very small amounts of decafluorobiphenyl are formed. The $NO_2^{\cdot}$ radical is most likely to play the main role in the formation of pentafluorophenol in the reaction with $C_6F_6$:

The pentafluorophenoxy-radical probably abstracts hydrogen from nitromethane, forming pentafluorophenol.

The alternative mechanism of the formation of pentafluorophenol via pentafluoronitrobenzene or possibly indirectly via pentafluorophenyl nitrite (without the preliminary dissociation of nitromethane as in the formation of phenols from different aromatic nitro-compounds at a high temperature[41]) is probably ruled out owing to the absence of $CH_3F$ from the reaction products.

Pentafluoroanisole may be formed in the reaction of hexafluorobenzene with nitromethane as a result of the attack on $C_6F_6$ by the methoxy-radical formed in the nitro-nitrite rearrangement or in the recombination–dissociation of nitromethane:

$$CH_3NO_2 \rightarrow CH_3ONO \rightarrow CH_3O^{\cdot} + NO^{\cdot}$$
$$\downarrow$$
$$CH_3^{\cdot} + NO_2^{\cdot} .$$

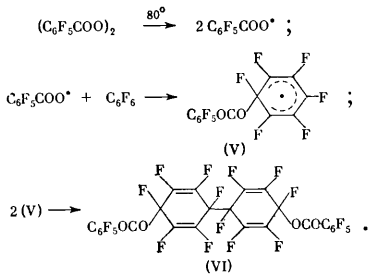
The preferential elimination of fluorine relative to that of hydrogen in the reactions with the methyl radical generated from nitromethane at high temperatures is clearly seen in the interaction of *p*-difluorobenzene with nitromethane[38]. The main product of this reaction is fluorophenol and the ratio of the yields of the products of the abstraction of fluorine and hydrogen atoms is 33 : 1.

The higher reactivity of hexafluorobenzene relative to benzene was also noted in a study of the reactivity of polyfluorinated unsaturated compounds with respect to the methyl radical generated from acetyl peroxide[43] (Table 6).

Table 6. The affinities of unsaturated compounds and their fluorinated analogues for the methyl radical[42].

| Compound | $C_6H_6$ | $CH_2=CH-CH=CH_2$ | $C_6F_6$ | $CF_2=CF-CF=CF_2$ |
|---|---|---|---|---|
| $k_1/k_2$* | 0.4[15] | 2900[43] | 3.1 | 900 |

*$k_1$ is the rate constant for the addition of $CH_3^{\cdot}$ and $k_2$ the rate constant for the abstraction of hydrogen from the solvent by $CH_3^{\cdot}$.

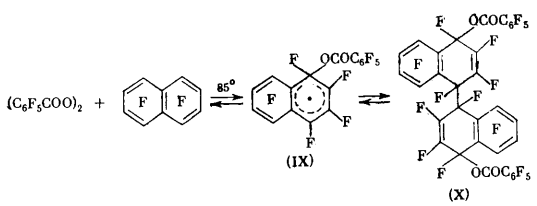


The above reactions of alkyl radicals with aromatic polyfluoro-compounds reveal certain characteristic features of the behaviour of these compounds. In the first place, one should note the higher reactivity of aromatic polyfluoro-compounds with respect to nucleophiles. No less important is the conclusion that the fluorine-containing radical σ-complexes are more stable, which follows from a comparison of the dissociation temperatures of such complexes, formed by the addition of alkyl radicals to benzene and hexafluorobenzene.

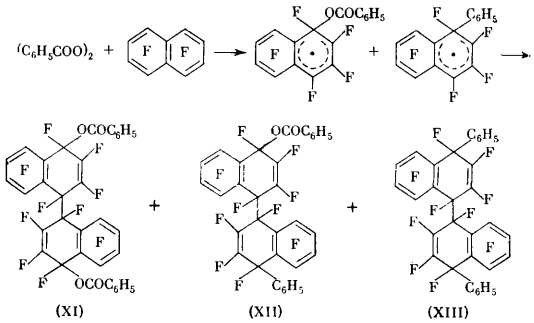
## III. REACTION WITH ARYL RADICALS

The data described in the previous Section showed that the available information about the reactions of a large set of aromatic polyfluoro-compounds with alkyl radicals

concerns mainly the process kinetics and there are almost no data concerning the synthetic possibilities of the reactions. In the studies on the interaction of aromatic polyfluoro-compounds with aryl radicals, there has been a more successful combination of investigations on these different lines, which make it possible to discover both the quantitative relations governing the behaviour of aromatic polyfluoro-compounds in these reactions as well as interesting synthetic reactions. Mainly aroyl peroxides have been used as the sources of aryl radicals in the reactions investigated, since it was observed that hexafluorobenzene does not react, for example, with the pentafluorophenyl radicals generated from $C_6F_5NHNHNH_2$[44] in the presence of oxidising agents, or from $C_6F_5I$ on photolysis[45], or with a source of $C_6F_5^{\cdot}$ such as $C_6F_5N(NO).COCH_3$, which might have been expected to be effective by analogy with the non-fluorinated compound[46].



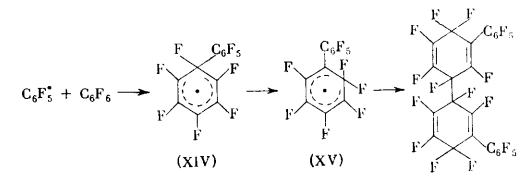
In the decomposition of pentafluorobenzoyl peroxide in hexafluorobenzene at 80°C, 4,4′-di(benzoyloxy)perfluoro-1,1′,4,4′-tetrahydrobiphenyl (VI), resulting from the dimerisation of the σ complex (V) formed by the addition of the pentafluorobenzoyloxy-radical to $C_6F_6$, is the main reaction product (60%).[47,48]



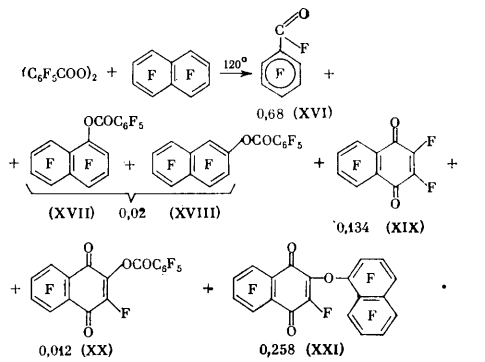
Apart from compound (VI), 3–5% of perfluorophenyl benzoate (VII) and 5–7% of tetrafluorobiphenyl (VIII) are produced. English chemists[49,50] were unable to isolate in a similar reaction any products other than compounds (VII) and (VIII).

The principal characteristics of this reaction are the virtual absence of the products of homolytic substitution and the preferential involvement of pentafluorobenzoyloxy-radicals in the reaction. We may recall that non-fluorinated reagents give rise mainly to biphenyls under these conditions. Compounds (VII) and (VIII), which are formed in insignificant amounts, can be regarded either as a result of the reaction of the radicals generated from pentafluorobenzoyl peroxide (for example the dimerisation of $C_6F_5^{\cdot}$ or the recombination of $C_6F_5^{\cdot}$ and $C_6F_5COO^{\cdot}$) or as products of the reaction of these radicals with hexafluorobenzene.

The interaction of octafluoronaphthalene (OFN) with pentafluorobenzoyl peroxide leads to results analogous to those obtained in the reaction with hexafluorobenzene. The main product at 85°C (in acetonitrile) is the dimer (X) of the σ complex resulting from the addition of the pentafluorobenzoyloxy-radical to the 1-position of OFN (IX):[51]

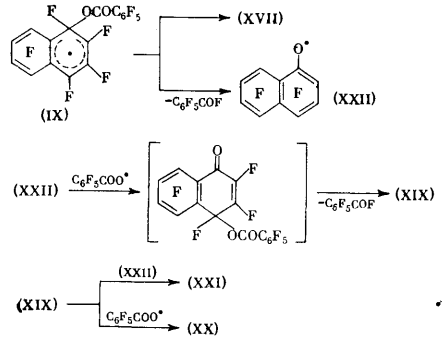


The reaction of OFN with the non-fluorinated benzoyl peroxide under the same conditions[51] probably yields a mixture of the dimers (XI), (XII), and (XIII):



The involvement of both benzoyloxy- and phenyl radicals in this reaction, in contrast to the reactions with pentafluorobenzoyl peroxide, indicates a significant influence of the introduction of the fluorine atoms into the peroxide molecule on the nature of its decomposition (this problem will be discussed below).

The exclusive involvement of the pentafluorophenyl radical in the reaction of $C_6F_6$ with $(C_6F_5COO)_2$ is observed only at high temperatures. Thus a mixture of isomeric dimers of the σ complex formed by the addition of the pentafluorophenyl radical to hexafluorobenzene is produced at 200°C.[48] The structure of these dimers, confirmed by their spectroscopic characteristics and their defluorination to perfluoro-*m*,*m*′-quaterphenyl, shows that the reaction probably involves the dimerisation of the σ complex (XV), formed as a result of the migration of the fluorine atom in the initial σ complex of type (XIV):



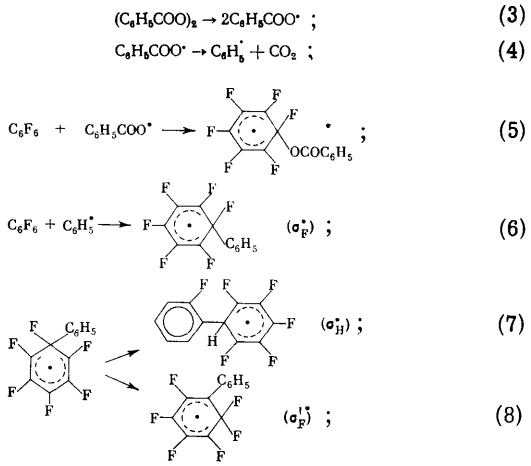
The driving force of the migration of the fluorine atom in the σ complex (XIV) is probably the considerable increase of the stability of the rearranged σ complex (XV) as a result of the possibility of the involvement of the pentafluorobenzene ring in the delocalisation of the unpaired electron.

It is of interest that an increase of temperature in the reaction of pentafluorobenzoyl peroxide with OFN does not lead to the formation of products with participation of the pentafluorophenyl radical. At 120°C this reaction already proceeds via a completely unusual pathway[65], resulting in the formation of a mixture of products in which 2-(1′-naphthoxy)perfluoro-1,4-naphthoquinone (XXI) predominates:

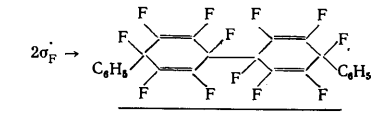
The formation of the naphthoquinone derivatives (XIX), (XX), and (XXI), which has no analogies in the familiar reactions of aroyl peroxides with naphthalene and its derivatives, is attributed to the following reactions:

The radical σ complex (IX) can, on the one hand, lose a fluorine atom and be converted into typical homolytic substitution products–perfluorobenzoyloxynaphthalenes, and, on the other hand, it can split off pentafluorobenzoyl fluoride (XVI) to give a new radical, i.e. the heptafluoronaphthoxy-radical (XXII), which is responsible for the subsequent reactions leading to the formation of compounds (XIX), (XX), and (XXI). This pathway to the stabilisation of the σ complex (IX) is probably due to the presence of the fluorine atom and the benzoyloxy-group in the geminal unit, which is confirmed by the formation of compounds (XIX) and (XXI) when OFN reacts with benzoyl peroxide at 85 °C in the absence of an inert solvent[53]. Hexafluoronaphthoquinone derivatives are formed in this reaction together with homolytic substitution products and the products of the reaction of benzoyl peroxide without the involvement of a fluorinated substrate (Table 7).

Table 7. The results of the interaction of benzoyl peroxide with octafluoronaphthalene (the yields are expressed in moles per mole of peroxide; peroxide : OFN = 1 : 4; 30 h).

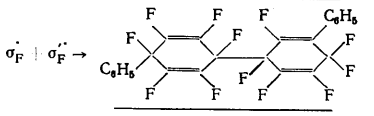


| Compound | Reaction temperature | |
|---|---|---|
| | 85° | 110° |
| 1-Benzoyloxyheptafluoronaphthalene | 0.045 | 0.019 |
| 2-Benzoyloxyheptafluoronaphthalene | 0.037 | 0.012 |
| 1-Phenylheptafluoronaphthalene | 0.104 | 0.287 |
| 2-Phenylheptafluoronaphthalene | 0.031 | 0.120 |
| 3,5,6,7,8-Pentafluoro-2-(heptafluoro-1'-naphthoxy)-1,4-naphthoquinone (XXI) | 0.056 | 0.019 |
| Hexafluoro-1,4-naphthoquinone | 0.022 | 0.018 |
| Benzoyl fluoride | 0.515 | – |
| Biphenyl | 0.051 | 0.094 |
| Phenyl benzoate | 0.566 | 0.048 |



The data in Table 7 show that a change in reaction temperature has only an insignificant effect on the qualitative composition of the reaction products, but does influence appreciably their quantitative proportions. With increase of temperature, the yield of phenylheptafluoronaphthalenes increases, as has been observed in the reaction of naphthalene with benzoyl peroxide[54]. The proportions of the isomers remain almost unchanged as the temperature is altered and indicate the greatest sensitivity of the α-position in the OFN molecule to radical attack, in agreement with the calculated radical localisation energy of OFN.

It is very remarkable that the reaction of OFN with $(C_6H_5COO)_2$ involves the homolytic substitution of a fluorine atom, which constitutes at the same time the preferred process. This may imply that the absence of products of the homolytic substitution of fluorine atoms in reactions of OFN and $C_6F_6$ with $(C_6F_5COO)_2$ is not solely due to the great strength of the C–F bond in the initial aromatic polyfluoro-compounds [$D(C_6F_5–F)$ = 140 kcal;[55] $D(C_6H_5–H)$ = 102 kcal [56]], but is also associated with the nature of the radical.



For example hexafluorobenzene reacts with $(C_6H_5.COO)_2$ [57–61] and some of its substituted derivatives[62] to form homolytic substitution products. High yields (60–80%) of the corresponding pentafluorobiphenyls were obtained in the reactions with benzoyl peroxide itself and its 3-methyl derivative but, after the introduction of electron-accepting substituents (3-chloro-, 3-bromo-, and 4-nitro-) into the peroxide molecule, the yields of the arylation products are appreciably reduced, particularly in the case of the nitroderivative of the peroxide. Williams and coworkers[62] used this mode of reaction as a basis for the conclusion that the mechanism of the arylation of aromatic polyfluoro-compounds is similar to the familiar mechanism of the arylation of non-fluorinated aromatic compounds and involves the formation of biaryls either via the disproportionation of the corresponding σ complexes or via the elimination of a fluorine atom from the latter by any radical present in the mixture.

However, a detailed study of the kinetics and products of the reaction of hexafluorobenzene with benzoyl peroxide led to the abandonment of disproportionation as a pathway to the formation of biaryls and a new mechanism was postulated for this reaction, based on the involvement of benzoic acid as a defluorinating agent. The mechanism, which also includes stages common to the reactions of non-fluorinated compounds, is given below[59–61] (the compounds which were islated from the products of this reaction are underlined):

(13)

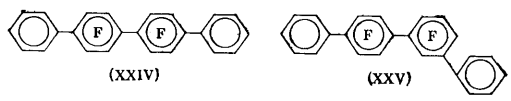
(14)

(15)

(16)

(17)

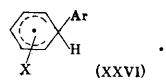
The first stages in this mechanism [stages (3) and (4)] are well known and require no explanation. Like the subsequent addition of the radicals to the substrate [Eqns. (5) and (6)], they are analogous to the stages of the interaction of aroyl peroxides with other aromatic systems. The stage involving the rearrangement of the initially formed σ complex ($\sigma_F^{\cdot}$) with migration of the fluorine atom to the unsubstituted cyclic compound [Eqn. (7)] and the subsequent reaction with benzoyl peroxide [Eqn. (9)] of the rearranged σ complex ($\sigma_H^{\cdot}$) explain in the simplest manner the formation in this reaction of small amounts of 2,2′,3,4,5,6-hexafluorobiphenyl (XXIII) and benzoic acid. The formation of compound (XXIII) was also observed in the high-temperature (600°C) reaction of hexafluorobenzene with nitrobenzene (mass-spectrometric data)[41,63], for which a radical mechanism has been proposed.



Stages (9) and (10) reflect the contribution of the induced decomposition of benzoyl peroxide to the reaction, which follows also from the analysis of the kinetic parameters of the reaction[61]. The rearrangement [Eqn. (8)] of the σ complex ($\sigma_F^{\cdot}$) with migration of the fluorine atom to a neighbouring position (a 1,2-shift), competing with the rearrangement [Eqn. (7)] to a σ complex ($\sigma_H^{\cdot}$) probably takes place to a greater extent, as can be seen from the yields of the products of dimerisation with participation of the rearranged σ complex ($\sigma_F^{\prime\cdot}$).[59]

Defluorination of the σ complex ($\sigma_F^{\cdot}$) with participation of benzoic acid [Eqn. (11)] is one of the main stages of the reaction. It leads to the formation of pentafluorobiphenyl and is a pathway to the regeneration of the benzoyloxy-radical and a source of HF. The absence of benzoic acid, an effective defluorinating agent, is probably the reason for the low yields of pentafluorobiphenyl in the reactions of hexafluorobenzene with other sources of phenyl radicals, such as phenylazotriphenylmethane[64] and $C_6H_5N=NOC_5H_{11}$.[65] The important role of benzoic acid is demonstrated by the increase of the yield of pentafluorobiphenyl when the decomposition of phenylazotriphenylmethane is carried out in hexafluorobenzene in the presence of benzoic acid[64].

The proposed mechanism for the interaction of hexafluorobenzene with benzoyl peroxide includes several pathways to the generation of benzoic acid. Apart from stage (9) mentioned above, reaction (15) and to a lesser extent reaction (16) merit attention. The required amounts of esters may be formed in subsequent reactions of the σ complex produced by the addition of the benzoyloxy-radical to hexafluorobenzene [Eqn. (5)] or via reactions (10) and (17). Since pentafluorophenyl benzoate, the formation of which may be expected when the substrate undergoes aroyloxylation initiated by reaction (5), is absent from the reaction products, all the esters are probably formed in radical–radical reactions. The most significant contribution apparently comes under these conditions from the ester $\sigma_F$–$OCOC_6H_5$, the formation of which includes the recombination of two radicals present at high steady-state concentrations.



It is of interest that the combination of stages (10), (11), and (15) ultimately leads to the formation of pentafluorobiphenyl and heptafluorodihydrobiphenyls†, i.e. to the products which can be formed also by the disproportionation of the σ complex ($\sigma_F^{\cdot}$).

The abandonment of disproportionation as one of the stages of the process was dictated by the following considerations. The disproportionation is a single-stage reaction and requires that the radical–radical combination processes resulting in dimers should not take place preferentially. However, since dimerisation and disproportionation are kinetically equivalent, the rate being equal to $k[\sigma_F^{\cdot}]^2$, the process with the lower activation energy, namely dimerisation, is the most probable, ruling out the elimination of a fluorine atom. The contribution of the dimerisation processes [Eqns. (13) and (14)] varies as a function of the reaction conditions and the yields of the dimers vary from 3 to 50%.[59] The formation on defluorination of the mixture of dimers of compounds (XXIV) and (XXV) (octafluoroquaterphenyls) confirms the rearrangement of the σ complex ($\sigma_F^{\cdot}$) formed initially to the σ complex ($\sigma_F^{\prime\cdot}$) with 1,2-migration of the fluorine atom[59]:

The results of the interaction of benzoyl fluoride with substituted aromatic polyfluoro-compounds are presented in Table 8, which includes for comparison also data for certain non-fluorinated compounds.

The transition state in the arylation of simple benzene derivatives ($C_6H_5X$) is generally believed to have a structure intermediate between that of the ground state and that of a σ complex of type (XXVI):

It is assumed that the unpaired electron is delocalised over the entire ring, including the substituent. Such delocalisation with participation of the substituent determines to a large extent the observed mode of substitution in homolytic arylation. In aromatic polyfluoro-systems ($C_6F_5X$), there is a choice between two structures in which the substituent involved in delocalisation is X or F, which may lead to differences in the isomeric composition of the arylation products $C_6F_5X$ and $C_6H_5X$.

The proportions of the isomeric biphenyls in the reactions of benzoyl peroxide with chloro- and bromo-pentafluorobenzenes are analogous to those observed in the

† The heptafluorodihydrobiphenyls were not isolated, but it was postulated that they are converted into pentafluorobiphenyl during the treatment of the reaction products, since it has been shown that the distillation of the mixture of products under severe conditions (300°/760 mmHg instead of 100°/15 mmHg) results in an increase of the yield of pentafluorobiphenyl almost by a factor of 1.5 and to the same decrease of the yield of an unidentified tarry residue[66].

non-fluorinated series, which may be a result of the similar efficiencies of chlorine, bromine, and fluorine atoms in the delocalisation of the unpaired electron in the corresponding σ complexes. The isomeric composition of the pentafluorobenzene phenylation products shows that substitution in the 1- and 3-positions takes place most readily, which apparently corresponds to a greater ease of formation of the corresponding σ complexes which are stabilised by the involvement of three fluorine atoms in the resonance, in contrast to σ complexes formed when the 2- and 4-positions are attacked. The greater ease of substitution of hydrogen compared with fluorine is probably also determined by the difference between the mechanisms of the aromatisation of the corresponding σ complexes[68]. For the same reasons as in the case of $C_6F_5H$, the 3-position is the most reactive in $C_6F_5CF_3$. The additional decrease of the reactivity of the 2-position is attributed to steric factors and the relatively greater reactivity of the 3-position relative to the 4-position is thought to be due to the presence of three fluorine atoms involved in the stabilisation of the σ complexes formed in the former case and of two such atoms in the latter[68].

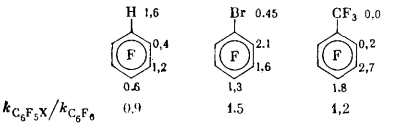


Table 8. The ratio of the isomers formed in the phenylation of aromatic compounds at 80°C (determined as percentages by GLC).

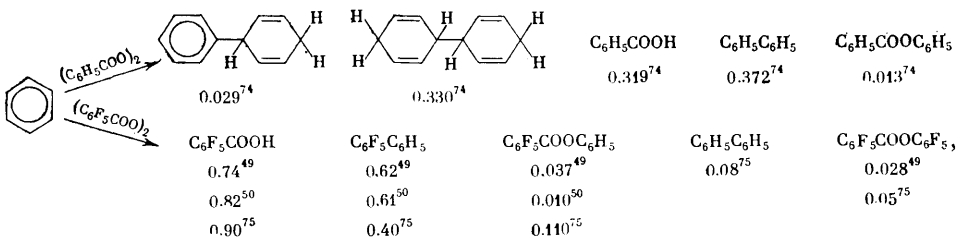
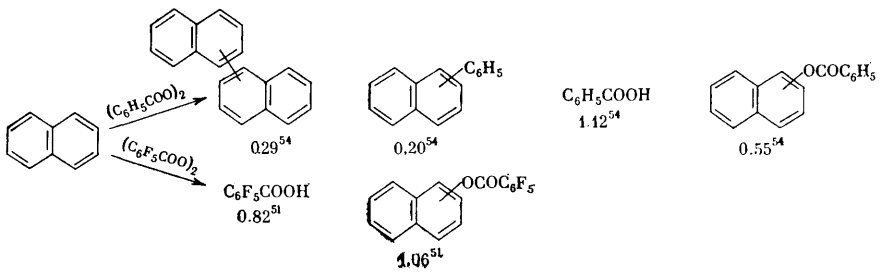
| Compound | Isomeric composition of phenylation products | | |
|---|---|---|---|
| | 2- | 3- | 4- |
| $C_6F_5Cl$[66] | 44.1 | 35.0 | 20.9 |
| $C_6H_5Cl$[67] | 50.1 | 31.6 | 18.3 |
| $C_6F_5Br$ *[66,68] | 43.6 (45.0) | 39.0 (36.0) | 17.4 (14.0) |
| $C_6H_5Br$[69] | 49.3 | 33.3 | 17.4 |
| $C_6F_5CF_3$[68] | 5.0 | 71.0 | 24.0 |
| $C_6F_5H$ **[68] | 15.0 | 45.0 | 11.0 |
| $C_5F_5N$[66] | 47.7 | 22.1 | 30.3 |
| $C_6H_5N$[70] | 54.0 | 32.0 | 14.0 |

* The data of Bolton et al.[68], according to which approximately 5% of the product resulting from the substitution of the bromine atom is also formed, are indicated in brackets.

** The formation of 29% of the product of the substitution of a hydrogen atom was also noted.

The partial rate factors for attack in different positions in $C_6F_5X$, determined by comparing the composition of the reaction products and the relative rate constants obtained from competition experiments with equimolar amounts of $C_6F_6$ and $C_6F_5X$, are indicated below[68]:





The relative rates of arylation of aromatic polyfluoro-compounds shown here differ from those obtained previously from the competing reactions of each substrate with benzene (for example $k_{C_6F_5Br}/k_{C_6F_6} = 1.0$).[11] This discrepancy is probably determined by the fact that, when benzene is used as the standard, the atoms substituted and the mechanisms of their substitution are different, and in addition there is a possibility of the formation of complexes by the mixture components[71]. For this reason, the results obtained from the competing reactions with $C_6F_6$ are more reliable[68].

It has already been stated that the high reactivity of the *meta*-position in all the compounds $C_6F_5X$ can be explained by the formation of a σ complex having three fluorine atoms capable of involvement in delocalisation. However, attack on the hexafluorobenzene itself also involves the formation of a σ complex with three stabilising fluorine atoms and yet the partial rate factors for attack in the *meta*-position are greater than unity for all the substrates. Such anomalous activation of the *meta*-position is believed to be a result of the formation of complexes of different stabilities by the precursor of the phenyl radical and the aromatic polyfluoro-substrate[68].

The greater ease of substitution of a hydrogen atom compared with a fluorine atom has been demonstrated for the reactions of $C_6F_5H$ with the phenyl radical[68]. Similar results were obtained for certain other substituted aromatic polyfluoro-compounds containing fluorine and hydrogen atoms in the molecule simultaneously. For example, the interaction of 1,2,4,5-tetrafluorobenzene[72] and 2,3,4,5,6-pentafluorobiphenyl[73] with the pentafluorophenyl radical, generated from $C_6F_5I$ on photolysis or thermal decomposition, leads to the formation in high yields only of products resulting from the substitution of hydrogen atoms: 2,2′,3,3′,4,5,5′,6,6′-nonafluorobiphenyl and three isomeric decafluoroterphenyls (14% of the *o*-isomer, 49.7% of the *m*-isomer, and 36.3% of the *p*-isomer) respectively.

In order to estimate the influence of fluorine atoms on the reactivity of aromatic polyfluoro-compounds in radical reactions, it is necessary to compare the above data for the interaction of hexafluorobenzene and octafluoronaphthalene with benzoyl and pentafluorobenzoyl peroxides with the results of the corresponding reactions of benzene and naphthalene presented in the scheme below (the yields are quoted in mole per mole of the peroxide):

The known increase of the yield of benzoyloxylation products relative to the yield of phenylation products in the case of highly reactive substrates[76] and of the formation of products of the reaction of the peroxide without the involvement of the aromatic substrate when the reactivity of the latter is low[77] may be adopted as a basis for a qualitative comparison. Analysis of all the results presented from this standpoint justifies the assumption that the reactivities of hexafluorobenzene and octafluoronaphthalene in reactions with aroyl peroxides are greatly reduced compared with those of non-fluorinated substrates. Thus, benzoyloxation products are absent in the reaction of hexafluorobenzene with benzoyl peroxide (they are formed in the corresponding reaction of benzene) and considerable amounts of biphenyl are produced. The formation of the products of the conversion of benzoyl peroxide itself (biphenyl and phenyl benzoate) is also observed in the reaction of OFN, although the relative contributions of the benzoyloxylation and phenylation processes remain the same as in the reaction of benzoyl peroxide with naphthalene.

The decrease of the reactivity of aromatic polyfluoro-compounds is characterised quantitatively by the ratio of the rates of phenylation of benzene and hexafluorobenzene found from the competing reactions of the latter with benzoyl peroxide: $k_{C_6F_6}/k_{C_6H_6} = 0.44$.[68] The reduced reactivity of aromatic polyfluoro-compounds may be caused by the influence of the fluorine atoms both in the stage involving the addition of the radical with formation of the $\sigma$ complex and in the stage where the $\sigma$ complex is stabilised by the elimination of a fluorine atom. The series based on the relative reactivities of aromatic compounds with respect to electrophilic benzoyloxy-radicals ($C_6H_5OCH_3 > C_6H_5CH_3 > C_6H_6 > C_6H_5Cl > C_6H_5NO_2$)[79,80] shows that electron-accepting substituents in the substrate hinder benzoyloxylation. On the other hand, regardless of the electronic nature, all the substituents facilitate phenylation, as shown by the following series of relative rates of phenylation of benzoyl peroxide[30]: $C_6H_6$ (1); $C_6H_5F$ (1.03); $C_6H_5Cl$ (1.06); $C_6H_5NO_2$ (2.94); 1,3,5-$C_6H_3Cl_3$ (3.68). Comparison of these two series shows that the influence of fluorine atoms in the substrate on the first stage—the addition of the radical with formation of a $\sigma$ complex—should be of the opposite types for the phenyl and benzoyloxy-radicals. However, experimental results show that the reactivity of aromatic polyfluoro-compounds is reduced both relative to the electrophilic benzoyloxy-radical and relative to the neutral phenyl radical. The latter fact may be due to the steric shielding of the reaction centre by the *ortho*-fluorine atoms, which prevent attack by phenyl radicals. An example of the influence of steric shielding of the reaction centres by the *ortho*-fluorine atoms on the reactivity is provided by the reduced reactivity of pentafluorobenzaldehyde relative to benzaldehyde in nucleophilic reactions involving the carbonyl group[81].

The influence of fluorine atoms in aromatic substrates on the stage involving the stabilisation of radical $\sigma$-complexes reflects the formation of dimerisation products of these complexes in the reactions of hexafluorobenzene and octafluoronaphthalene with benzoyl and pentafluorobenzoyl peroxides. This influence may be associated with the difference between the C–H and C–F bond dissociation energies[55,56], with the increased stability of the fluorinated radical $\sigma$ complexes, and also with the greater stability of the fluorinated dimers.

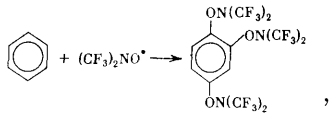
As already mentioned, one of the characteristics of the reactions of aromatic polyfluoro-compounds with aroyl peroxides is that, in the reactions of both hexafluorobenzene and octafluoronaphthalene with pentafluorobenzoyl peroxide under mild conditions (80–85°C), products involving the participation of the pentafluorobenzoyloxy-radical are formed preferentially. This may be caused by the influence of fluorine atoms on the reactivity of the radicals, which is manifested by an enhancement of their electrophilic properties.

Kurz and Pellegrini[80] showed that the benzoyloxy-radical is electrophilic and that the introduction of electron-accepting substituents into the peroxide molecule enhances the electrophilic properties of the benzoyloxy-radicals formed on its decomposition. The enhancement of the electrophilic properties of the pentafluorobenzoyloxy-radical can be explained satisfactorily by the overall inductive electron-withdrawing effect of the pentafluorophenyl group, resembling the effect of the 2,4-dinitrophenyl residue[82]. The enhanced electrophilic properties of the pentafluorobenzoyloxy-radical are reflected in a higher degree of $\alpha$-substitution in the reaction of naphthalene with pentafluorobenzoyl peroxide: the ratio of the $\alpha$- and $\beta$-naphthyl pentafluorobenzoates in this reaction is 10:1,[51] while in the reaction of naphthalene with benzoyl peroxide it is 2.7:1[54] (the $\alpha$-position in naphthalene is known to be most reactive in electrophilic reactions). The more marked electrophilic properties of the pentafluorobenzoyloxy-radical compared with the benzoyloxy-radical apparently lead to its increased reactivity in reactions with aromatic substrates. On the other hand, the high steady-state concentration of pentafluorobenzoyloxy-radicals, which can also indirectly reflect the influence of fluorine atoms on the reactivity of fluorinated radicals, may play a significant role in the preferential formation of benzoyloxylation products.

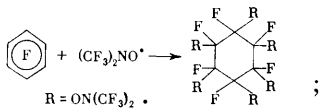
Kinetic data for the decomposition of benzoyl and pentafluorobenzoyl peroxides in benzene and hexafluorobenzene (Table 9)[83] show that pentafluorobenzoylperoxide is less resistant to unimolecular thermal decomposition than is benzoyl peroxide, since the rate constant for its decomposition in both benzene and hexafluorobenzene is greater than for the non-fluorinated peroxide. The reduced stability of the fluorinated peroxide may be associated, for example, with the appearance of an additional Coulombic repulsion between the *ortho*-fluorine

atoms in the benzene ring of the peroxide. The possibility of such a field effect has been used by Blomquist and Buselli[84] to account for the higher rate of decomposition of *ortho*-substituted symmetrical peroxides compared with their *meta*- and *para*-analogues. On the other hand, the ease of decomposition of pentafluorobenzoyl peroxide may be a result of the increased stability of the pentafluorobenzoyloxy-radical, which is confirmed by the kinetics of the decomposition of benzoyl and pentafluorobenzoyl peroxides in the absence of solvents[78]. The rate constant for the formation of $CO_2$ in the decomposition of benzoyl peroxide is greater than in the decomposition of pentafluorobenzoyl peroxide ($36.5\times10^{-2}$ and $10.1\times10^{-2}$ $min^{-1}$ respectively), i.e. pentafluorobenzoyloxy-radicals are more resistant to decarboxylation. The higher stability of pentafluorobenzoyloxy-radicals may be caused by the more effective delocalisation of the unpaired electron with participation of the benzene ring. All these factors taken together may promote a higher steady-state concentration of pentafluorobenzoyloxy-radicals.

Table 9. Kinetic parameters of the benzoyl and pentafluorobenzoyl peroxide decomposition reactions in benzene and hexafluorobenzene (80°C; initial peroxide concentration between 0.024 and 0.24 M).[83]



| Peroxide | $(C_6H_5COO)_2$ | | $(C_6F_5COO)_2$ | |
|---|---|---|---|---|
| Substrate | $C_6H_6$ | $C_6F_6$ | $C_6H_6$ | $C_6F_6$ |
| $10^3k$, $min^{-1}$ | 2.9 | 1.5 | 8.6 | 2.5 |
| $E$, kcal $mole^{-1}$ | 30 | 34 | 29 | 31 |
| $\lg A$ | 16 | 18 | 16 | 17 |

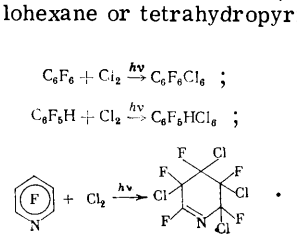


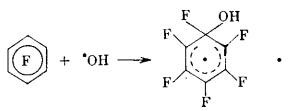
Evidently the pentafluorophenyl radical is also electrophilic, which is clearly illustrated by data for its interaction with substituted benzenes[65,85]. Thus the relative rate of the pentafluorophenylation of chlorobenzene is lower than that of its phenylation (0.72 and 1.06 respectively). However, the ratio of the degree of substitution in the *ortho*- and *para*-positions to the dgree of substitution in the *meta*-position is greater for pentafluorophenylation than for phenylation: $(o- + p-)/m- = 3.9$ and 2.9 respectively. In the reaction of the pentafluorophenyl radical with nitrobenzene, the electrophilic nature of the radical is manifested by an appreciable increase of the degree of substitution in the *meta*-position: $(o- + p-)/m- = 9.2$ ($C_6H_5^{\cdot}$) and $(o- + p-)/m- = 0.87$ ($C_6F_5^{\cdot}$). On reaction with 1,2,4,5-tetrafluorobenzene, the pentafluorophenyl radical generated from pentafluoroiodobenzene on photolysis of thermal decomposition gives a high yield of 2, 2′,3,3′,4,5,5′,6,6′-nonafluorobiphenyl, reacting at the site of the maximum electron density, which also indicates the electrophilic nature of the pentafluorophenyl radical[72].

The electrophilic properties of the pentafluorophenyl radical explain the high yield of biphenyls in the corresponding reactions of pentafluorobenzoyl peroxide and other sources of the pentafluorophenyl radical with benzene[75] and its derivatives[45,65,85,86]. On the other hand, the absence of pentafluorobenzene in these reactions and the fairly severe conditions under which the pentafluorophenyl radical reacts with hexafluorobenzene suggest a reduced reactivity of this radical, which may be attributed to the shielding of the radical reaction centre by the *ortho*-fluorine atoms.

## IV. OTHER REACTIONS

Hexafluorobenzene reacts with the bis(trifluoromethyl)-nitroxy-radical, combining with two, four, or six $(CF_3)_2NO$ residues, depending on the reaction conditions[87]. Under analogous conditions, the reaction of $(CF_3)_2NO^{\cdot}$ with benzene leads to the formation of the 1,2,4-trisubstituted product only[88]:

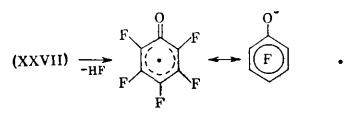




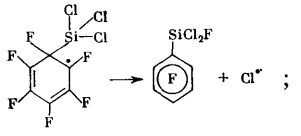
Addition takes place exclusively in the reactions of this radical with other aromatic polyfluoro-compounds. Thus the number of $(CF_3)_2NO$ groups with which the fluoro-compound combines is four for pentafluoropyridine[89], two, four, or six for chloropentafluorobenzene, four for octafluorotoluene, two, four, or six for pentafluorobenzoic acid, four or six for pentafluorobenzaldehyde, two or six for pentafluorophenol, and two, four, or six for pentafluoroaniline[90].

When perfluorodiphenylacetylene reacts with hexafluorodimethylnitrogen oxide, it is possible to identify only decafluorobibenzoyl (in 25% yield), but the unidentified reaction products include compounds containing the $(CF_3)_2NO$ group[91].

When chlorine is allowed to act on hexafluorobenzene[92], pentafluorobenzene[93], or pentafluoropyridine[89] under irradiation, it combines with the substrate, forming the corresponding cyclohexane or tetrahydropyridine derivatives:

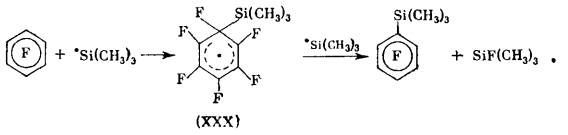


The interaction of fluorinated benzenes (1,2,3,4-$C_6H_2F_4$, $C_6F_5H$, and $C_6F_6$) with $e_{aq}^-$ and $^{\cdot}OH$ in aqueous solutions under pulse radiolysis and $\gamma$-irradiation[94] leads in the former case to the generation of the pentafluorophenyl radical and other fluorinated radicals with almost quantitative elimination of the fluoride anion: $C_6F_6 + e_{aq}^- \rightarrow C_6F_5^{\cdot} + F^-$, and in the latter case results in the addition of $^{\cdot}OH$ with formation of the $\sigma$ complex (XXVII):



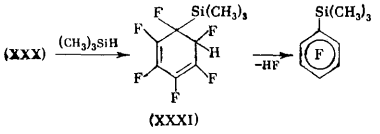
(XXVII)

The $\sigma$ complex (XXVII) is unstable, since a fluorine atom and the OH group are attached to the same carbon atom, but can be stabilised by the elimination of HF and the formation of a new radical:



A photochemical interaction of the type of substitution takes place between hexafluorobenzene and trichlorosilane[95]. The reaction results in the formation of dichlorofluoro(pentafluorophenyl)silane (XXIX) as the main product together with *o*-, *m*-, and *p*-disubstituted compounds. It is suggested that the formation of compound (XXIX) is associated with a rearrangement in the σ complex (XXVIII) formed initially followed by the stabilisation of the new σ complex as a result of the elimination of a chlorine atom which initiates the reaction:

(XXVIII) (XXIX)



$$Cl^{\cdot} + SiHCl_3 \rightarrow HCl + {}^{\cdot}SiCl_3 .$$

The photochemical reaction between hexafluorobenzene and trimethylsilane proceeds in a somewhat different manner, yielding preferentially pentafluorophenyltrimethylsilane, which indicates the stabilisation of the σ complex (XXX), [analogous to the σ complex (XXVIII)] as a result of the abstraction of a fluorine atom by a second trimethylsilyl radical[95]:

(XXX)

Nor can one exclude the possibility that pentafluorophenyltrimethylsilane is formed in the dehydrofluorination of the adduct (XXXI):

(XXXI)

Irradiation of a solution of $C_6F_6$ in cyclohexane[96] leads to a fairly complex mixture of products in which it is possible to identify cyclohexylpentafluorobenzene, pentafluorobenzene, decafluorobiphenyl, and a compound with the overall formula $C_{18}H_{22}F_4$, which is most probably dicyclohexyltetrafluorobenzene. The nature of the products shows that a free-radical process takes place in all probability. It is evident that the initial dissociation of hexafluorobenzene into a fluorine atom and a pentafluorophenyl radical is unlikely not only because $C_6F_6$ is resistant to irradiation in the absence of hydrocarbons but also owing to the high C–F bond energy in $C_6F_6$.[55] The process probably proceeds via the following mechanism:

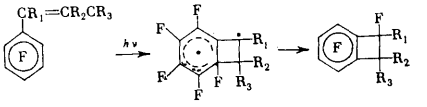
$$C_6F_6 \xrightarrow{h\nu} C_6F_6^{*}; \quad C_6F_6^{*} + HR \rightarrow C_6F_6^{\cdot} + HF + R^{\cdot} \rightarrow C_6F_5R;$$

$$2C_6F_5^{\cdot} \rightarrow C_{12}F_{10} \xrightarrow[RH]{h\nu} \text{high-molecular weight products;}$$

$$C_6F_5^{\cdot} + C_6F_6 \rightarrow C_{12}F_{11}^{\cdot} \rightarrow C_{12}F_{10}; \; C_6F_5^{\cdot} + RH \rightarrow C_6F_5H + R^{\cdot}; \; 2R^{\cdot} \rightarrow R_2.$$

A mechanism involving the formation of the pentafluorophenyl radical is postulated for the reaction of $C_6F_5I$ with $Ni(CO)_4$,[97] the main products of which are decafluorobiphenyl, decafluorobenzophenone, and pentafluorobenzene when it is carried out in dimethylformamide. The pentafluorophenyl radical may be formed as a result of the direct reaction of pentafluoroiodobenzene with nickel tetracarbonyl {in the decomposition of the complex $[C_6F_5Ni^{I}(CO)_n]$} or as the product derived from the pentafluorobenzoyl radical formed initially. The following reaction mechanism is most probable:

$$C_6F_5I + Ni(CO)_4 \rightarrow [C_6F_5CONi(I)(CO)_n] + (3-n)\,CO;$$

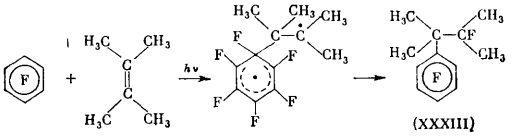


(XXXII)

$$(XXXII) \xrightarrow{-[NiI(CO)_{n+1}]^{\cdot}} C_6F_5^{\cdot}; \; C_6F_5^{\cdot} + RH \rightarrow C_6F_5H + R^{\cdot}; \; 2C_6F_5^{\cdot} \rightarrow C_6F_5C_6F_5;$$

$$C_6F_5^{\cdot} + CO \rightleftarrows C_6F_5CO^{\cdot}; \; C_6F_5CO^{\cdot} + C_6F_5^{\cdot} \rightarrow C_6F_5COC_6F_5.$$

The absence of decafluorobibenzoyl from the reaction products [bibenzoyl is the sole product of the reaction of $C_6H_5I$ with $Ni(CO)_4$] [98] demonstrates a high reactivity of $C_6F_5CO^{\cdot}$, which is present at a low concentration and reacts with the medium before dimerisation. In the analogous reaction with $Ni(CO)_4$, bromopentafluorobenzene is less reactive and hexafluorobenzene is recovered unchanged from the reaction mixture.

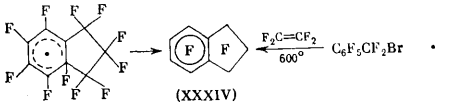


In a study of the gas-phase photolysis of polyfluorinated alkenylbenzenes, they were found to be converted into fluorine-containing benzocyclobutenes with migration of a fluorine atom from the aromatic ring to the side chain. The proposed mechanism of the photochemical rearrangement involves the intermediate formation of biradicals[99]:

(a) $R_1=R_2=R_3=F$; (b) $R_1=R_2=R_3=H$; (c) $R_1=F$, $R_2=R_3=H$; (d) $R_1=CH_3$, $R_2=R_3=H$; (e) $R_1=R_2=H$, $R_3=CH_3$.

The migration of the fluorine atom may occur as a sigmatropic, 2,3-shift concerted with the cyclisation process or following the latter, although the authors[99] do not rule out the possibility of repeated sigmatropic 1,5-shifts of the fluorine atom.

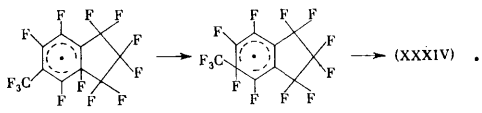
The photolysis of hexafluorobenzene in the presence of 2,3-dimethylbut-2-ene yields mainly compound (XXXIII), the formation of which is probably associated with the migration of a fluorine atom from the ring to the side chain in the intermediate biradical[100]:



(XXXIII)

The reaction of a number of substituted aromatic polyfluoro-compounds with tetrafluoroethylene at a high temperature, giving rise mainly to the formation of perfluoroindan (XXXIV), which has been described recently[101] is of interest. The mechanism proposed by the authors includes the intermediate formation of the perfluorobenzyl radical (the way in which it is generated in this reaction is still obscure):

$$C_6F_5X \xrightarrow[600-700^{\circ}]{CF_2=CF_2} C_6F_5CF_2^{\cdot} \xrightarrow{CF_2=CF_2} C_6F_5CF_2CF_2CF_2^{\cdot} \rightarrow$$



$$X = OH,\ SH,\ OCH_3,\ NH_2$$

(XXXIV)

Compound (XXXIV) is the main product also in the reaction of perfluoro-*p*-cresol and perfluoro-*p*-thiocresol with tetrafluoroethylene, which the authors attribute to the isomerisation of the intermediate σ complex (XXXV) to the σ complex (XXXVI) via a sigmatropic 1,3-shift of a fluorine

atom with subsequent elimination of the $CF_3$ group from the σ complex formed:

(XXXV) (XXXVI)

The possibility of the involvement of the perfluorobenzyl radical in these reactions has been confirmed by the formation of compound (XXXIV) (again in 80% yield) during the joint pyrolysis of tetrafluoroethylene with perfluorobenzyl bromide, which is a source of $C_6F_5CF_2^{\cdot}$.[101]

# Advances in the Chemistry of the Acetals of Acid Amides and Lactams

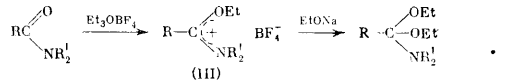
V.G.Granik, A.M.Zhidkova, and R.G.Glushkov

Data on the chemistry of the acetals of acid amides and lactams published during the period between 1969 and 1974 are surveyed. The reactions of the acetals of acid amides and lactams with various nucleophiles and electrophiles are considered, particular attention being devoted to the possibility of using such amide and lactam acetals in the synthesis of heterocyclic compounds which are of interest both chemically and biologically.
The bibliography includes 89 references.

CONTENTS

I. Introduction 361
II. The synthesis of the acetals of acid amides and lactams 361
III. The properties and reactions of the acetals of acid amides and lactams 362

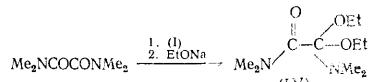
## I. INTRODUCTION



During the last two decades, the chemistry of acid amides and latcams has become enriched in new data associated primarily with the study and utilisation for synthetic purposes of "activated forms" of these compounds. Such "activated forms" include iminoesters [1], lactim ethers [2], complexes of acid amides with alkylating and acylating agents [3-6], keten *ON*-acetals [7,8], aminals [9,10], and extremely readily available at the same time very highly reactive compounds which Meerwein called the acetals of acid amides [11,12].

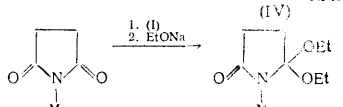
The acetals of acid amides were obtained for the first time in 1956 [11], but their properties were not described in detail until 1961. [12] In recent years, the chemistry of these compounds has been developing so vigorously that the review [13] published in 1969 no longer reflects the advances achieved in this field.

The present review surveys data on the chemistry of amide acetals published during the period between 1969 and 1974. Earlier studies are discussed only in those instances where this is required for the description of new material or when relevant studies were not considered in the review mentioned above [13].



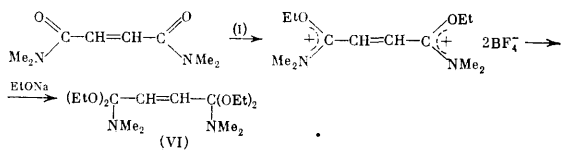
## II. THE SYNTHESIS OF THE ACETALS OF ACID AMIDES AND LACTAMS

One of the most general methods for the synthesis of the acetals of acid amides and lactams involves the interaction of amides or lactams with alkylating and acylating agents followed by the treatment of the resulting complexes with alkali metal alkoxides [13]. The most frequently used alkylating agents are triethyloxonium fluoroborate (I) and dimethyl sulphate (II). Although a quantitative comparison of the reactivities of these alkylating agents in the synthesis of amide acetals has not so far been made, one should note an important qualitative difference between them, consisting in the fact that the interaction of acid amides with compound (I), in contrast to the reaction with compounds (II), proceeds irreversibly [14]. The study of the alkylation of acid amides by compound (I) has been shown [14] that the steric effects of the substituents in the amides do not have an appreciable influence on the reactions; an exception to this rule is provided by those cases where the steric hindrance is accompanied by a significant destabilisation of the cation (III):

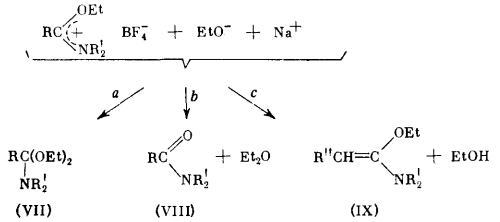


(III)

Thus $Cl_3CCON(CH_3)_2$, in which the amide group is linked to the extremely bulky and highly electronegative trichloromethyl group, does not react with compound (I). In those instances where the molecule contains two amide functional groups, the "acetalisation" of both is possible only in the presence of bridging groups between them [15]. Thus only the monoacetals (IV) and (V) can be synthesised from the bisdimethylamide of oxalic acid [14] and *N*-methylsuccinimide [16] with the aid of compound (I):

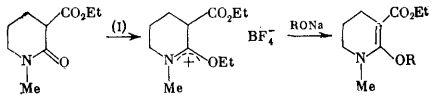


(IV)



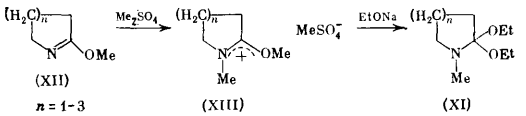
(V)

The separation of the amide groups by the -HC=CH- bridge ensures the possibility of the formation of the bisacetal (VI) [14]:



(VI)

The interaction of the intermediate complexes (III) with sodium alkoxides [14] can proceed in three ways depending on the nature of the substituent R: (a) the formation of the amide acetal (VII); (b) the regeneration of the initial amide (VIII); (c) the formation of the $\alpha$-alkoxyenamine (IX):



(VII) (VIII) (IX)

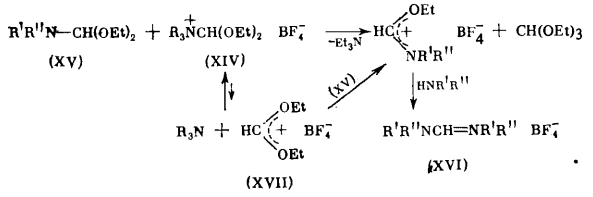
Reaction *a* should proceed most readily. This process involves the simplest ion association, since its activation energy is apparently significantly lower than in cases *b* and *c* and the acetal (VII) should be formed rapidly, provided that, for example, the steric hindrance to attack by the alkoxide anion is not too great. If R is a bulky substituent such as the t-butyl or dichloromethyl group, the reaction is directed via the thermodynamically favourable pathway *b* with formation of stable molecules such as the amide (VIII) and an ether. Finally, if R is a relatively small and highly electron-accepting group, a proton may be abstracted from the $\alpha$-position (relative to the amide group) and the $\alpha$-alkoxyenamine (IX) may be formed. One should note that the synthesis of enamines of type (IX) had also been observed earlier when 2-ethoxy-3-ethoxycarbonyl-1-methyl-3,4,5,6-tetrahydropyridinium fluoroborate (X) was treated with sodium alkoxide [17]:

(X).

A new version of the synthesis of lactam acetals (XI) involves the use of lactim ethers (XII) as the starting materials [18,19]:

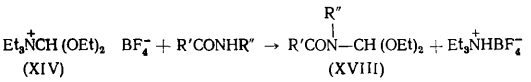
(XII) (XIII) (XI)

$n = 1$-3



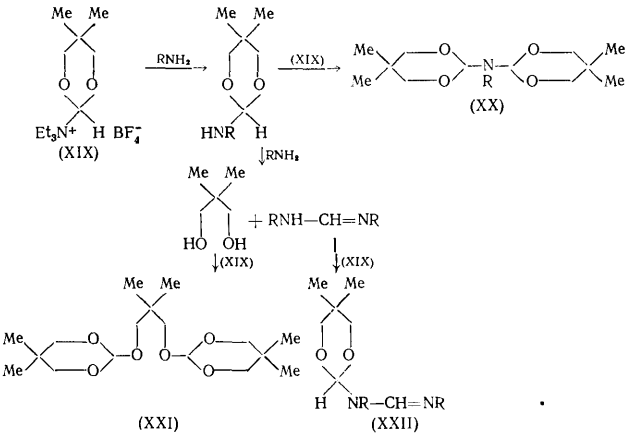
The study of the alkylation of compound (XII) by dimethyl sulphate using the method of competing reactions with analysis of the reaction mixtures by gas–liquid chromatography (GLC) showed that the rate of formation of the complexes (XIII) depends significantly on the size of the ring in compound (XII): the highest rate of alkylation is observed for *O*-methylbutyrolactim (XII, $n = 1$) and the lowest for *O*-methylcaprolactim (XII, $n = 3$). Examination of the *N*-alkylation of lactim ethers with the aid of molecular models showed that the difference between the rates of reaction is determined mainly by conformational factors [19].

New methods for the synthesis of acid amide acetals include the interaction of dialkyoxymethylammonium salts (XIV) with secondary amines [20]:



(XIV) (XV)

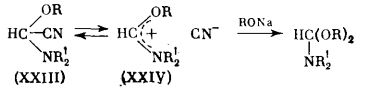
The acetals (XV) can react further with the salts (XIV) to form an orthoformate ester and amidinium salts (XVI):



(XV) (XIV) (XVII) (XVI)

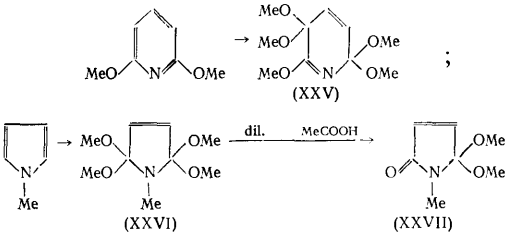
It has been suggested [20] that the above side reactions occur owing to the dissociation of the dialkyoxmethylammonium salts (XIV) into a tertiary amine and a dialkoxycarbonium salt (XVII), which reacts with the acetal (XV). This is confirmed by the finding that an excess of the corresponding tertiary amine, which displaces the equilibrium towards compound (XIV), leads to an appreciable increase of the yield of the acetals (XV). *N*-Acylamidoacetals (XVIII) have been obtained by the reaction of the salts (XIV) with acid amides [21]:

(XIV) (XVIII)



The reaction of dialkoxymethylammonium salts (XIX) with primary amines proceeds in an interesting manner and the following mechanism has been proposed [22]:

(XIX) (XX) (XXI) (XXII)

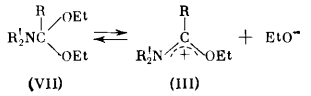


When the molar ratio of the salt (XIX) and the amine is 2 : 1, the main reaction product is the bisacetal (XX), while in the presence of an excess of the amine mainly the amidine-acetals (XXII) are formed, compound (XXI) having also been isolated as a side product.

A new method of synthesis of amide acetals, consisting in the interaction of $\alpha$-dialkylamino-$\alpha$-methoxyacetonitriles (XXIII) with sodium alkoxide has been published recently [28]. The reaction evidently proceeds via a stage involving the dissociation of compound (XXIII) with subsequent attack by the alkoxide anion on the cation (XXIV):

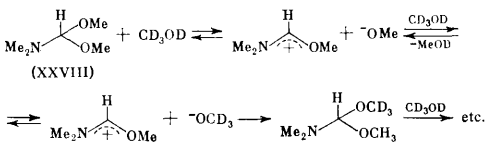
(XXIII) (XXIV)

In addition, the synthesis of the acetals of unsaturated lactams (XXV)–(XXVII) in the anodic oxidation of pyrrole and pyridine derivatives in methanol has been described [24]:



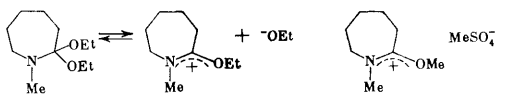
(XXV) (XXVI) (XXVII)

## III. THE PROPERTIES AND REACTIONS OF THE ACETALS OF ACID AMIDES AND LACTAMS



The structure of amide acetals, represented by formulae (VII) and (XI), does not justify the assumption that these compounds can be highly reactive in relation to nucleophiles [25] and electrophiles.

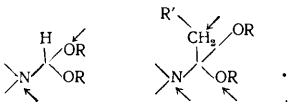
In 1961, Meerwein et al.[12] and subsequently also other investigators[13,26] showed that solutions of the acetals of acid amides and lactams are conducting. This phenomenon can be explained by the fact that amide acetals dissociate in solution into an ambident cation (III) and an alkoxide anion. It must be emphasised that the alkoxide anion is capable of interacting, for example, with compounds having an active methylene group, forming carbanions and therefore facilitating the nucleophilic addition reaction



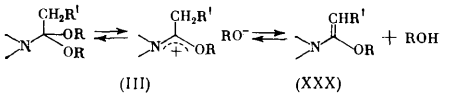
(VII) (III)

This treatment is nowadays generally accepted[13] and provides a satisfactory explanation of the properties of amide acetals. In particular, the only explanation of the readily cccurring exchange of the hydrogen atoms of the *O*-methyl groups of the dimethyl acetal of dimethylformamide (XXVIII) for deuterium in the presence of an excess of $CD_3OD$ is its preliminary dissociation[27]:

(XXVIII)



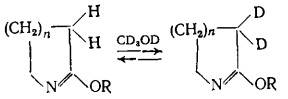
An attempt has been made[26] to estimate quantitatively by the polarographic method the degree of dissociation of the diethyl acetal of *N*-methylcaprolactam (XII, $n = 3$). Comparison of the polarographic behaviour of this acetal and the methyl sulphate complex of *N*-methylcaprolactam (XIII) showed that the content of the ambident cation (XXIX) in methanol solution does not exceed 0.3%:



(XII) $n=3$ (XXIX) (XIII)

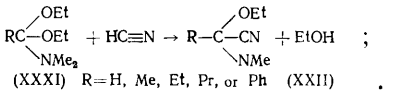
Bearing in mind the high reactivity of cations of this type in relation to reagents bearing a negative charge or having a lone electron pair, one may conclude that even the above insignificant degree of dissociation is sufficient to ensure the interaction of the acetals with various nucleophiles.

Investigations have shown that there are significant differences between the acetals of dimethylformamide, on the one hand, and their homologues and the acetals of lactams with the extremely reactive $CH_2$ groups in the $\alpha$-positions, on the other. Thus electrophiles can attack only the nitrogen atom in the acetals of dimethyl-formamide or the $RO^-$ anion formed following the dissociation of the acetal. On the other hand, together with the processes described above, the acetals of homologous amides as well as lactam acetals can undergo also reactions involving the $\alpha$-$CH_2$ groups (alkylation, acylation, etc.).



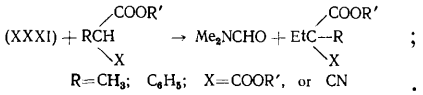
The ability of amide and lactam acetals to undergo $\alpha$-*C*-alkylation (acylation) has been explained[13,28,29] by the fact that the ambident cation (III) can interact with the alkoxide anion, the process involving the abstraction of a proton from the activated $\alpha$-$CH_2$ group in the cation (III) and the formation of an $\alpha$-alkoxyenamine (XXX), which readily reacts with electrophiles like other enamines[30]:

(III) (XXX)



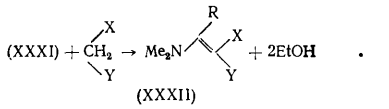
This hypothesis is supported also by data indicating a considerable mobility of the $\alpha$-protons in lactim ethers[31]:

## 1. REACTIONS OF AMIDE AND LACTAM ACETALS WITH NUCLEOPHILES



### a. Reactions of the Acetals Via Activated CH, $CH_2$, and $CH_3$ Groups

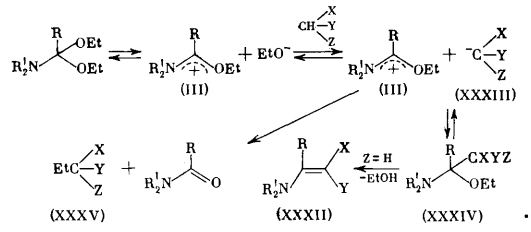
Numerous studies have been made on the reactions of amide and lactam acetals with compounds having activated methyl, methylene, or methylidyne groups[13,14,32-50]. The interaction of amide acetals with anhydrous hydrocyanic acid is accompanied by the substitution of [one of] the alkoxy-groups of the acetal by the cyano-group with formation of $\alpha$-alkoxyaminonitriles (XXIII)[32]:



(XXXI) R=H, Me, Et, Pr, or Ph (XXII)

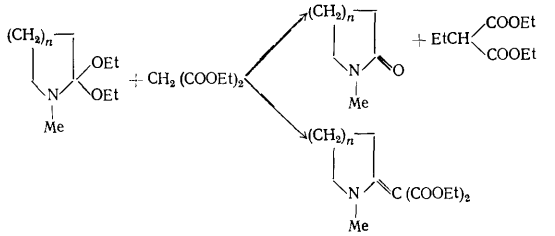
On the other hand, when the acetals react with C–H acids such as ethyl- or phenyl-malonic and cyanoacetic esters, the latter undergo *C*-alkylation[32]:

R=$CH_3$; $C_6H_5$; X=COOR', or CN



When compounds with active methylene or methyl groups are made to react with amide or lactam acetals, a third type of interaction takes place involving the formation of enamines (XXXII)[13]:

(XXXII)

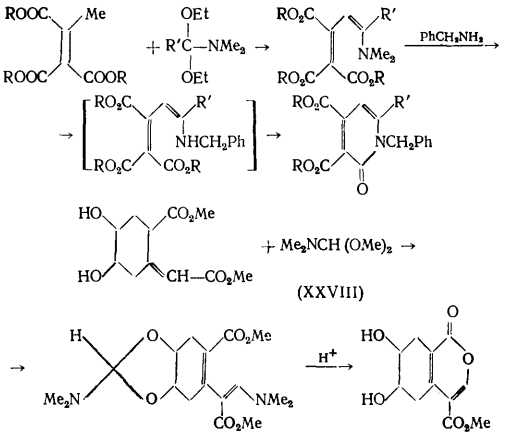


Bredereck et al.[32] believe that the first step in the interaction of amide acetals with compounds having activated CH or $CH_2$ groups involves the abstraction of a proton from the latter and the formation of the anion (XXXIII). The reaction of the anion (XXXIII) with the ambident cation (III) can proceed via the irreversible association of (III) and (XXXIII) with formation of compound (XXXIV). Subsequently, depending on the structure of the anion (XXXIV), the enamine (XXXII) (with Z = H) may be formed or *C*-alkylation may take place, which

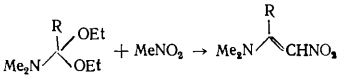
results in the formation of compound (XXXV), and the corresponding amide:

In the presence of the weakly stabilised anion (XXXIII) (for example, $^-C{\equiv}N$), the addition product (XXXIV) is thermodynamically more favourable and the equilibrium is displaced towards its formation. On the other hand, when the anion is stabilised by conjugation, compound (XXXIV) is present in the equilibrium mixture in only a small amount; if one of the substituents (X, Y or Z) is a hydrogen atom, conditions are created for the elimination of an alcohol with formation of an enamine (XXXII). Simultaneously with this process (but more slowly), the cation (III) may alkylate the anion (XXXIII) with formation of the *C*-alkyl derivative (XXXV). When the anion does not contain a hydrogen atom, the latter process becomes dominant and the main reaction product is compound (XXXV). Thus, by postulating the equilibrium (XXXIII) ⇌ (XXXIV), one can account for the possible reactions occurring when amide acetals react with CH acids. However, one must stipulate the case where the formation of compound (XXXIV) is prevented by steric factors. Under these conditions, the only reaction pathway becomes *C*-alkylation† with formation of compound (XXXV).

It follows from the above mechanism that the formation of the enamine (XXXII) must be accompanied by *C*-alkylation. Indeed, a study of the reaction of lactam acetals[33-35] with malonic ester showed that the process proceeds in two ways, C–C condensation predominating:



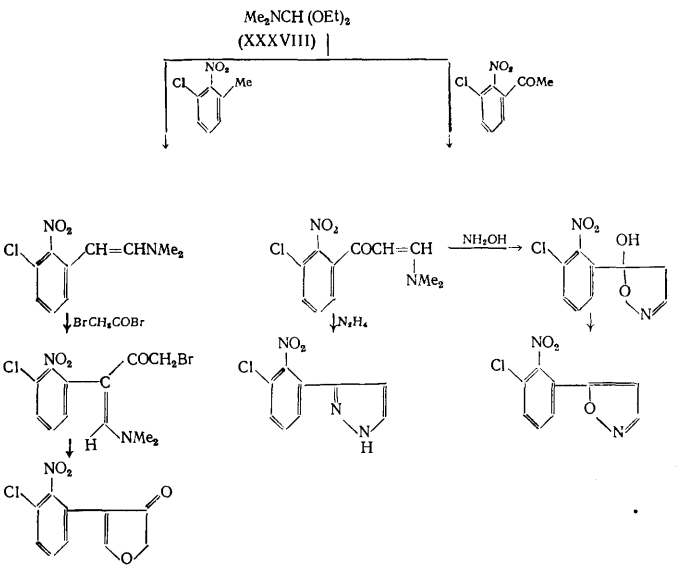
(XI), $n$=1–3



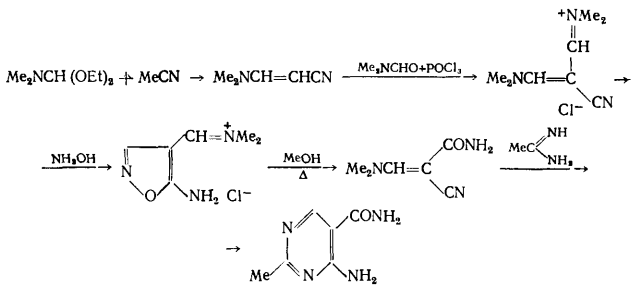
A study of the reactions of lactam acetals (XI) with compounds having active methylene or methyl groups[33-35] established that the rate of reaction depends both on the size of the lactam ring and on the strength of the CH acid: the highest reactivity is shown in this process by the diethyl acetal of *N*-methylbutyrolactam (XI, $n$ = 1), the increased mobility of the hydrogen atoms in the $CH_2XY$ group promoting a higher reaction rate.

†The initial amide and an ether may be formed in a side reaction (see above).

The ability of amide acetals to react readily with compounds having active $CH_2$ or $CH_3$ groups has been used in new syntheses of 2-pyridones[36] and condensed $\alpha$-pyrones[37]:

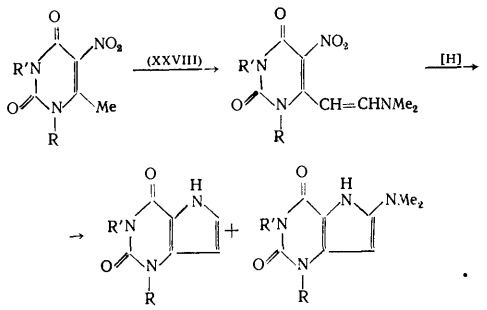


Bredereck et al.[14] compared the reactivites of the acetals (XXXVI) and (XXXVII) in condensation with nitromethane:

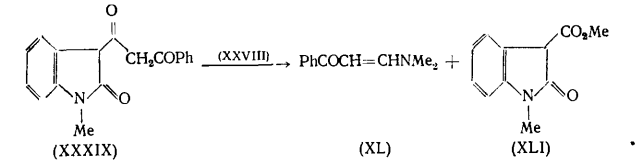


(XXXVI), R=$CONMe_2$ ;
(XXXVII), R=$CO_2Et$ .

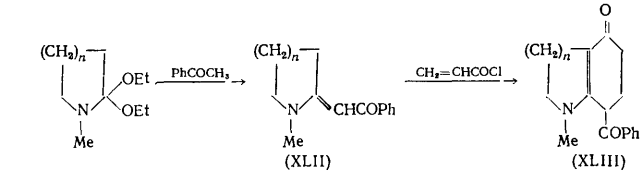
Whereas in the first case the reaction proceeds with a yield of 96% (80°C, 1 h), in the second the yield does not exceed 37% even after prolonged heating (80°C, 5 h). According to the authors, this difference between the reactivities of the acetals (XXXVI) and (XXXVII) is due to the much greater destabilising effect of the $CO_2Et$ group compared with that of the $CONMe_2$ group.



The diethyl acetal of dimethylformamide (XXXVIII) has also been used in the synthesis of pyrrolnitrin analogues[38]:



Isoxazole and pyrimidine derivatives have been synthesised from the acetal (XXVIII) [39]:



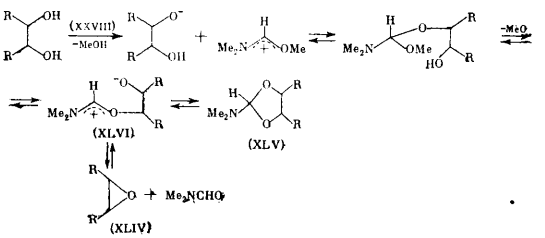
as well as pyrrolo[3,2-*d*]pyrimidines [40]:

The reaction of the acetal (XXVIII) with 3-benzoylacetyl-1-methyloxindole (XXXIX) proceeds in a very unusual manner. The C–C bond is ruptured with formation of *NN*-dimethylaminomethyleneacetophenone (XL) and 3-methoxycarbonyl-1-methyloxindole (XLI) [41]:

The interaction of the lactam acetals (XI) with acetophenone led to the synthesis of the enaminoketones (XLII) from which a new synthesis of hydrogenated derivatives of indole, quinoline, and benzazepine (XLIII) was achieved by reaction with acryloyl chloride [42]:

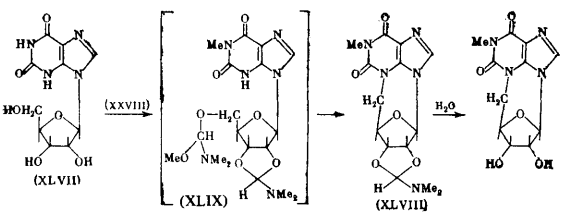
(XI), $n = 1-3$ .

A series of studies on the reactions of amide acetals with nitromethane derivatives [43], acetonitrile [44,45], malonic ester [46], and β-benzoylpropionic ester [47] have been published in recent years. They involved the synthesis of a number of substituted enamines, which can be used as the starting materials for the preparation of various heterocyclic compounds (see, for example, Spencer et al. [48]).



The above data permit the conclusion that lactam acetals react more smoothly with nucleophiles than do amide acetals [25]. A clear example is provided by the finding that lactam acetals react readily with phenylacetic ester, giving satisfactory yields [25,49], while the diethyl acetal of *NN*-dimethylacetamide could not be made to undergo this reaction [50].

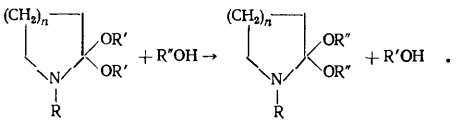
### b. Reactions with Alcohols and Mercaptans



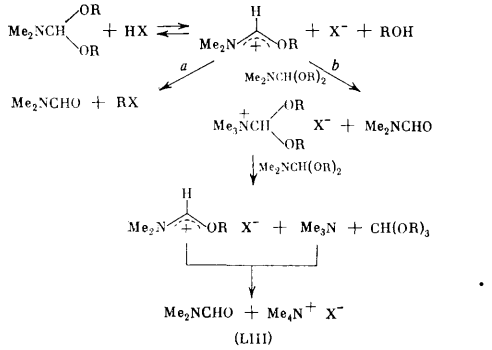
One of the methods for the synthesis of amide acetals involves the transesterification of the dimethyl acetal of dimethylformamide (XXVIII) with alcohols [13]. Compound (XXVIII) and other amide acetals react similarly with alkanethiols and arylalkanethiols, forming the thioacetals of acid amides [51]:

$$Me_2NCH(OMe)_2 + 2RSH \rightarrow Me_2NCH(SR)_2 + 2MeOH .$$

The reaction of amide acetals with alcohols constitutes the basis of a new method for the synthesis of epoxy-compounds (XLIV). [52] The process mechanism is consistent with the usual concepts concerning the interaction of amide acetals with alcohols:

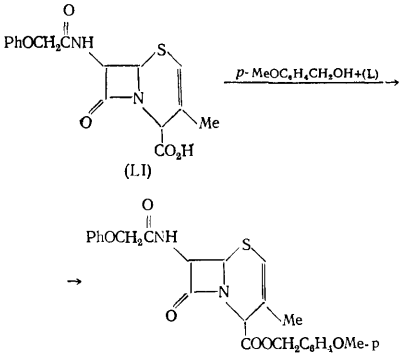


It is seen from the above mechanism that the reaction may involve the formation of cyclic amide acetals (XLV). One of the main factors determining the nature of the products formed is the configuration of the initial diol. For example, the reaction of the acetal (XXVIII) with *cis*-cyclohexanediol results in the formation of the cyclic acetal [XLV, R,R = $-(CH_2)_4-$] only, while its *trans*-isomer is converted smoothly into the epoxy-compound (XLIV). The cyclic acetal (XLVIII) has also been obtained in the reaction of xanthosine (XLVII) with the dimethyl acetal of dimethylformamide (XXVIII) [53]:

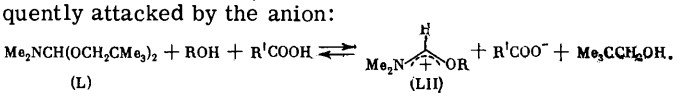


The above mechanism shows that the amide acetal (XXVIII) reacts not only with the vicinal secondary hydroxyls but also with the primary hydroxy-group. Owing to the high polarisation of the $O-CH_2$ group in the intermediate bisamide acetal (XLIX), the xanthine fragment undergoes intramolecular *N*-alkylation with formation of the cyclonucleoside (XLVIII). This is accompanied by the *N*-methylation of xanthosine by the acetal (XXVIII) (see above).

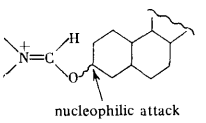
It is noteworthy that lactam acetals are readily transesterified by alcohols, like amide acetals[54,55]:



c. Reactions with Phenols and Carboxylic Acids



The esterification of carboxylic acids and phenols in their reactions with amide and lactam acetals takes place even more readily than the *C*-alkylation of compounds having an acid $CH_2$ group (see above)[12,33-35,55-57]. When the molecule contains a phenolic hydroxyl and a carboxy-group, the alkylation proceeds very selectively at the carboxy-group[56,57]. Despite its apparent simplicity, the reaction of amide acetals with carboxylic acids may be accompanied by a series of side processes[56]:

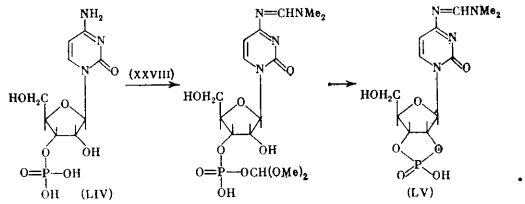


The relative contributions of the main process *a* and the side reactions *b* depend to a large extent on the nature of the substance alkylated HX.[58] Thus, in the interaction of the dimethyl acetal of dimethylformamide (XXVIII) with phenol, the reaction proceeds almost exclusively via pathway *a*. The reaction with picric acid proceeds mainly via pathway *b*. Similar behaviour has been observed also for a series of carboxylic acids: the formation of methyl benzoate predominates in the reaction involving benzoic acid, while only tetramethylammonium trifluoroacetate was isolated in the reaction with trifluoroacetic acid. However, the acidity of HX is not the only factor determining the mode of the process. The concentration of the reactants plays an important role in these processes. Thus, when solutions of the reactant are diluted and the steady-state concentration of compound (XXVIII) is reduced, it is possible to increase sharply the yield of alkylation products[56]. It was found that the rate constant for the esterification of *p*-nitrobenzoic acid by the dimethyl acetyl of *N*-formylpyrrolidine is almost twice as high as the rate constant obtained when compound (XXVIII) is used in this reaction. The dineopentyl acetal of dimethylformamide (L) has been used successfully in the alkylation of carboxylic acids[13]. Its employment for this purpose is based on the fact that derivatives of neopentyl alcohol are capable of undergoing $S_N2$ reactions to only a very slight extent[56]. As an example, one may quote the esterification of $\Delta^2$-diacetoxycephalosporin (LI), which proceeds under mild conditions[59]:

The mechanism of the esterification reaction with the aid of comopund (L) provides for the intermediate formation of the cation (LII), in which the residue R is subsequently attacked by the anion:

Naturally, when the residue R contains in this instance an asymmetric centre linked to the oxygen atom, the nucleophilic attack should involve an inversion of configuration ($S_N2$ mechanism). Epimerisation of this kind has been achieved for a series of derivatives of 3$\alpha$-hydroxycholestane and androstane[56]:

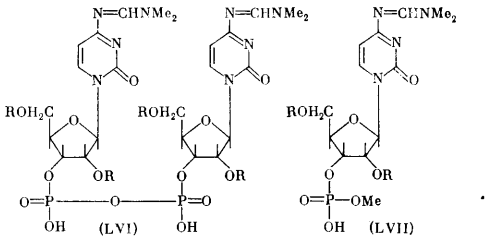
This method can probably be used for the inversion of configuration also in other optically active alcohols.



d. Reactions of Amide Acetals with Other Acid Compounds

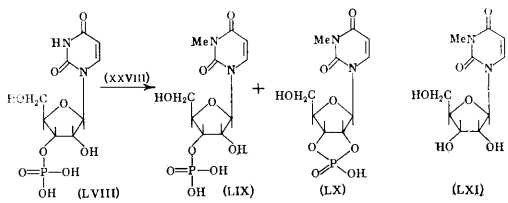
The study of the interaction of the acetal (XXVIII) with other acid agents[58] confirmed that there is a definite (although not direct) relation between the mode of reaction and the acid $pK_a$. The study of the reaction of compound (XXVIII) with amides has shown that, as a rule, both pathways *a* and *b* (see above) operate and that pathway *a* is fully inhibited only in the reaction with $Tos_2NH$. A similar behaviour has been observed for hydrochloric and phosphorus-containing acids (alkylation and the formation of quaternary salts are both observed to some extent). When toluene-*p*-sulphonic acid or $HClO_4$ are used in the reaction with compound (XXVIII), the only products are the corresponding NNN'N'-tetramethylformamidinium salts (LIII).

e. Reactions with Phosphorus-Containing Compounds



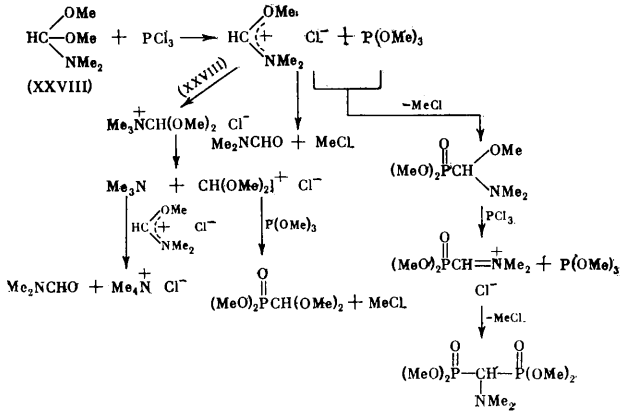
The interaction of the dimethyl acetal of dimethylformamide with nucleoside phosphates is a special case of reactions of compound (XXVIII) with OH and CH acids. When the aglycone of the nucleoside phosphate contains the $NH_2$ group, as, for example, in cytidine phosphate

(LIV), the reaction via the phosphate group is accompanied in this case also by condensation via the 4-amino-group[60]:

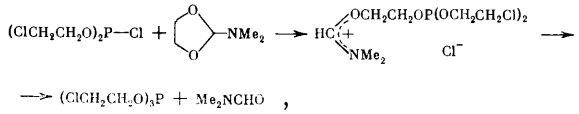


The mechanism of the formation of compound (LV) has been represented as one involving the activation of the P–O bond with subsequent closure of the five-membered ring.

The study of this reaction in other systems[60] showed that in all cases cyclic compounds of type (LV) are formed. Thus the reaction constitutes a convenient method for the synthesis of compounds containing only one unprotected OH group in the 5′-position. It is noteworthy that, in those cases where the OH groups in the 2′- and 5′-positions had been protected beforehand, the reactions of ribonucleoside phosphates with compound (XXVIII) lead to the formation of pyrophosphates (LVI) and the methyl esters (LVII) as the side products (the main reaction involves the protection of the 4-amino-group of the pyrimidine base):

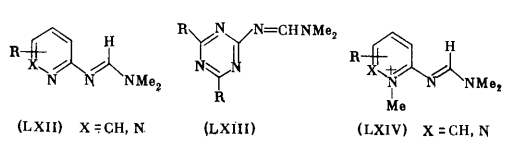


When the neopentyl acetal (L) is used in reactions with aminonucleoside phosphates, the condensation proceeds selectively via the $NH_2$ group, without involving the hydroxy-groups. It was noted that dephosphorylation with formation of compound (LX) is observed in the interaction of uridine phosphate (LVIII) with compound (XXVIII) in addition to the *N*-methylation of compound (LIX) and the cyclisation of the phosphate group at the 2′-hydroxy-group in compound (LX)[60]:



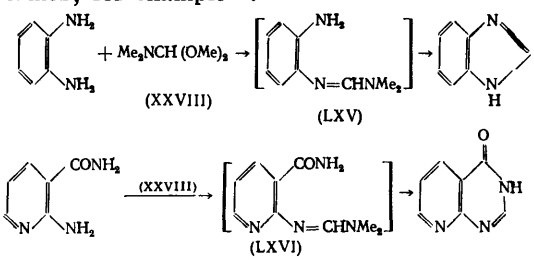
Furthermore, certain reactions of amide acetals with diribonucleoside phosphates may involve the dissociation of internucleotide linkages[61].

The reactions with phosphorus halides and with the esters of phosphorus-containing acids occupy a special place in the chemistry of amide acetals[62–64]. The following mechanism has been proposed for the reaction of the acetal (XXVIII) with $PCl_3$[62]:



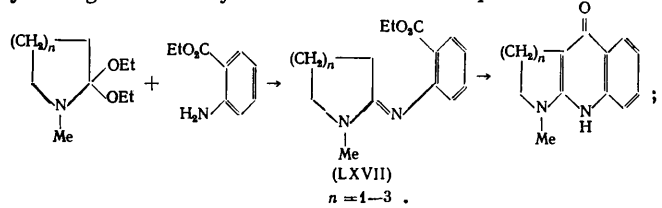
The reactions of amide acetals with other chlorophosphines have also been described[63]:

as well as the reactions with phosphite esters and phosphine oxides[63,64].



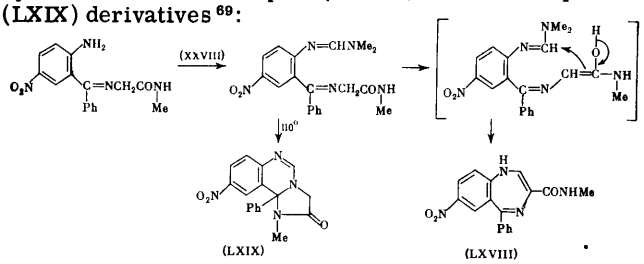
## f. Reactions with Amines

The synthesis of amidines from amide and lactam acetals has been investigated in fair detail[13]. A number of studies on the reactions of lactam acetals with aniline derivatives[25,55,65–68] and heterocyclic[60,69–73] and aliphatic[74,75] amines have been published in recent years. The interaction of amide and lactam acetals with amines constitutes a simple and convenient approach to the synthesis of various amidines, which is particularly important in connection with the fact that a number of substances exhibiting a high biological activity have been discovered in recent years among representatives of this class of compound (see, for example, Refs. 76–78). A series of 6-formamidinopenicillanic acids have been obtained by the reaction of amide acetals with aminopenicillanic acid[74]. It has been shown that animal-esters can be obtained by the interaction of compound (XXVIII) with secondary amines[75]. Various aminoheterocycles have also been successfully made to react with acetals, which led to the synthesis of the heterocyclic amidines (LXII)–(LXIV)[70]:

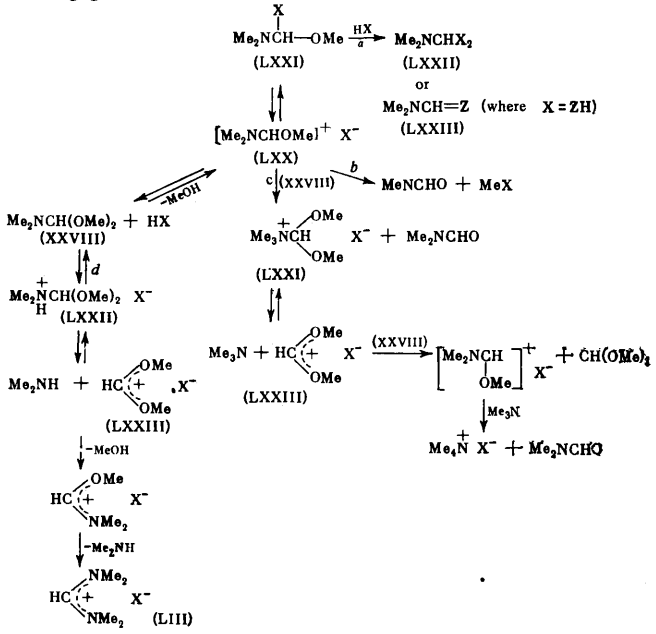


Amide acetals have been used successfully in recent years also as cyclising agents in the synthesis of various heterocyclic compounds. Thus, on heating with the dimethyl acetal of dimethylformamide, *o*-diamines or

*o*-aminocarboxamides form condensed imidazoles of pyrimidines, for example [70]:

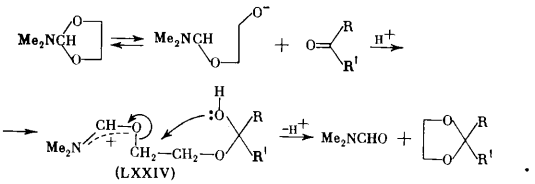


The reaction probably proceeds via the intermediate formation of the amidines (LXV) and (LXVI).



When lactam acetals react with an anthranilate ester, the corresponding amidines (LXVII) are again formed, cyclising to the tricyclic derivatives of 4-quinolone [66]:

The acetal (XXVIII) has been used successfully in the synthesis of benzodiazepine (LXVIII) and imidazoquinazoline (LXIX) derivatives [69]:

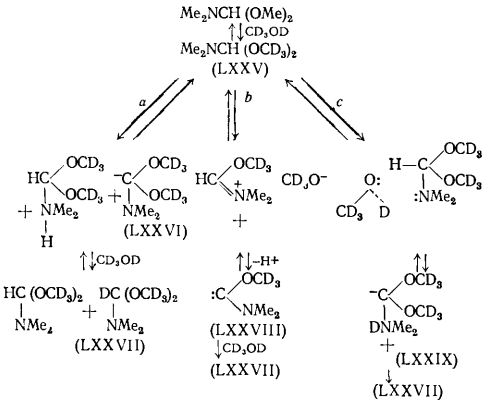


The data presented above show that the majority of studies on the reactions of amide and lactam acetals with nucleophiles are based on the interaction of amide acetals with compounds containing active C–H, O–H, S–H, and N–H groups. These reactions can be represented by the following general mechanism [58]:

As mentioned above, one of the main factors determining the mode of the process (pathways *a*–*d*) is apparently the acidity of the initial HX. Pathway *a* is characteristic of weak acids, such as HC≡CR or AlkOH [with formation of compound (LXXII)] or $H_2O$, $RNH_2$, and $RR'CH_2$ [with formation of compound (LXXIII)]. The reactions of ArOH or certain carboxylic acids proceed mainly via pathway *b*. Stronger acids ($CF_3COOH$, $Tos_2NH$, and picric acid) react via pathway *c*. Finally, pathway *d* is characteristic of sulphonic acids and $HClO_4$.

### g. Reactions with Aldehydes and Ketones

As mentioned above, amide and lactam acetals condense with compounds having activated $CH_2$ or $CH_3$ groups (including ketones [13]) with formation of enaminocarbonyl compounds. However, amide acetals are also capable of reacting with aldehydes and ketones via another mechanism—with formation of the corresponding acetals and ketals [56]:

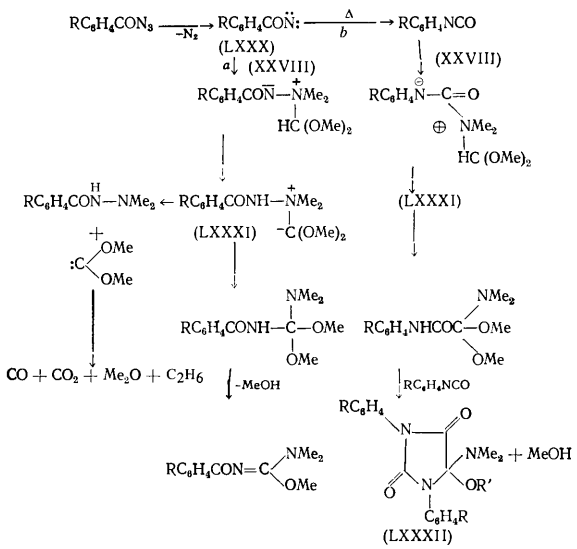


The reaction of compounds with a highly polarised carbonyl group (for example $CCl_3CHO$) is possible also in the absence of acid catalysis. It must be emphasised that the intermediate compound is sterically hindered. This factor makes it possible to use amide acetals as selective agents for the protection of keto-groups. For example, in the steroid series this process proceeds readily via the carbonyl group in the 3-position without affecting the keto-groups in the 17- and 20-positions [56].

## 2. REACTIONS OF AMIDE AND LACTAM ACETALS WITH ELECTROPHILES

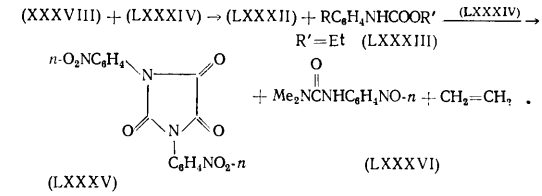
### a. Reactions Involving Dimethylformamide Acetals

The simplest reaction of amide acetals with electrophiles is deuterium exchange. It was noted previously that, in solution of the dimethyl acetal of dimethylformamide (XXVIII) in deuteromethanol, the protons of the *O*-methyl groups of the acetal are rapidly exchanged for deuterium [27]. It is of interest that the formyl proton of the acetal is exchanged for a deuteron, albeit more slowly. This process requires a detailed examination, since many features observed in the study of this phenomenon proved to be common also to the reactions of dimethylformamide acetals with other electrophiles. A mechanism has been proposed [27] for the deuteration of amide acetals via the intermediate formation of carbenes. Three possible



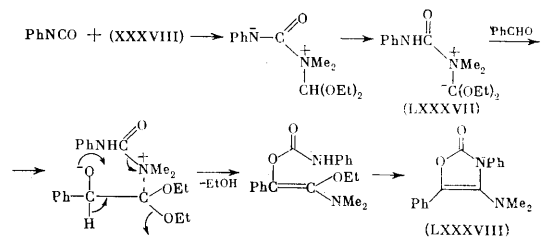
mechanisms of the deuterium exchange (pathways *a–c*) were examined in another investigation[79]:

Mechanism *a*, which provides for the abstraction of the formyl proton already in the first stage with formation of the anion (LXXVI), is unsuitable for the following reasons: under the conditions governing the formation of the deuteroacetal (LXXVII), orthoesters, in which the overall $-I$ effect of the alkoxy-groups is greater than in amide acetals, do not undergo deuterium exchange, and even chloroform is deuterated under these conditions more slowly than compound (LXXV). Mechanism *b*, according to which the intermediate is the carbene (LXXVIII), conflicts with the finding that the complexes $[MeOCH{=}NMe_2]X^-$ (where X = $MeSO_4^-$ or $BF_4^-$) do not undergoe deuterium exchange.

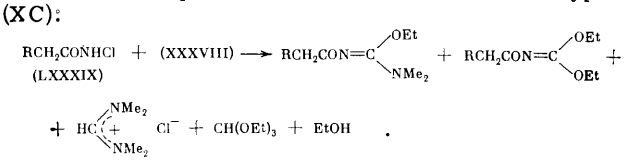


The "ylid" mechanism *c* is supported by the following data: (1) the enhancement of the electron-donating properties of the *N*-alkyl residues leads to an increase (up to a certain limit) of the rate of deuterium exchange; (2) the enhancement of the acid properties of the deuterating agent accelerates the deuterium exchange (the deuterium exchange proceeds to the extent of 25% after 196 s in $CD_3OD$ and after 705 s in t-BuOD); (3) the presence of strong bases in the system retards the deuterium exchange owing to a competing reaction.

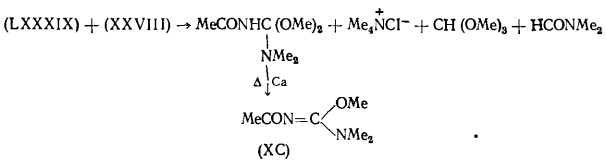
Bedereck et al.[80] proposed mechanisms for the thermal and photochemical reactions of the acetal (XXVIII) with benzoyl azides:



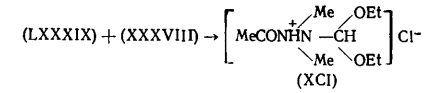
According to this mechanism, the intermediate nitrene (LXXX) interacts under mild conditions with the acetal (XXVIII), this being followed by a rearrangement to the ylid (LXXXI), from which the final reaction products are formed (photochemical reaction—pathway *a*). On heat treatment (pathway *b*), the nitrene (LXXX) rearranges to the isocyanate, which reacts further with compound (XXVIII). In this case, the synthesis on the *ON*-acetal of parabanic acid (LXXXII, R′ = Me) is also preceded by the formation of the ylid (LXXXI).



The mechanism of the reactions of amide acetals with isocyanates has been demonstrated in relation to the diethylacetal of dimethylformamide [compound (XXXVIII)].[81] It was found that, as in the thermal reaction with benzoyl azides, the main products are the *ON*-acetal (LXXXII, R′ = Et) and the carbamic ester (LXXXIII, R′ = Et). The highly reactive *p*-nitrophenyl isocyanate (LXXXIV, R = *p*-$NO_2$) reacts further, forming derivatives of parabanic acid (LXXXV), urea (LXXXVI), and ethylene:

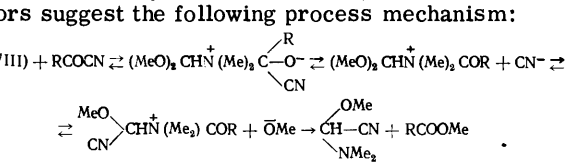


To demonstrate the intermediate formation of the ylid (LXXXVII), this reaction was carried out in benzaldehyde, a preliminary test having established that the latter does not react either with the dimethylformamide acetal (XXXVIII) or with the *ON*-acetal (LXXXII, R′ = Et). The product isolated in this reaction was 4-dimethylamino-3,5-diphenyloxazolin-2-one (LXXXVIII), for the formation of which the following mechanism has been proposed:

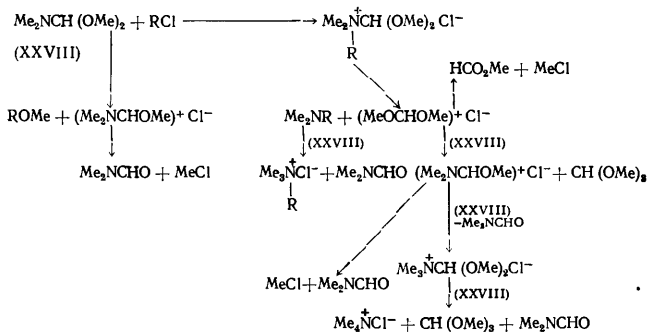


The interaction of the diethyl acetal of dimethylformamide (XXXVIII) with *N*-halogenoamides, *N*-halogenoureas, and *N*-halogenourethanes (LXXXIX)[82] proceeds with formation of multicomponent mixtures of substances, in which the main products are keten *ON*-acetals of type (XC):

It is of interest that, when the dimethyl acetal of dimethylformamide (XXVIII) is used in the reaction, the nature of the side products changes:



By allowing the acetal (**XXXVIII**) to react with *N*-chloroacetamide (**LXXXIX**, R = H), Bredereck et al.[83] succeeded in isolating the intermediate (**XCI**):

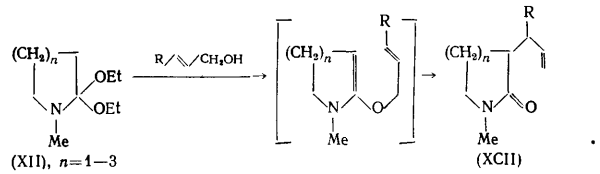


On the basis of the structure of the salt (**XCI**) and the probable formation of the ylid (**LXXXI**) from the latter, the authors suggested that the conversion of the ylid into the final product (**XC**) proceeds via an $S_E1$ or an $S_Ni$ mechanism.

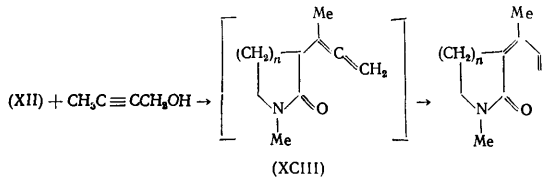
The reaction of the dimethyl acetal of dimethylformamide (**XXVIII**) with an acyl cyanide leads smoothly to the formation of α-dimethylamino-α-methoxyacetonitrile [84]. The authors suggest the following process mechanism:

The reaction of acyl cyanides with orthoesters proceeds with a much lower yield even under much more severe conditions.

A detailed study of the reactions of the dimethyl acetal of dimethylformamide (**XXVIII**) with alkylating and acylating agents has been published recently[85]. It was shown that the alkylation proceeds exclusively via the nitrogen atom of the amide acetal, while the ratio of the *O*- and *N*-acylation products depends significantly on the nature of the acyl halide used. The authors proposed the following general reaction mechanism:

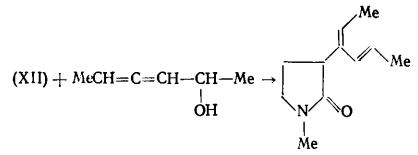


Experimental data led to the conclusion that the reactivity of acyl halides in the *O*-acylation of the amide acetal (**XXVIII**) increases in the sequence

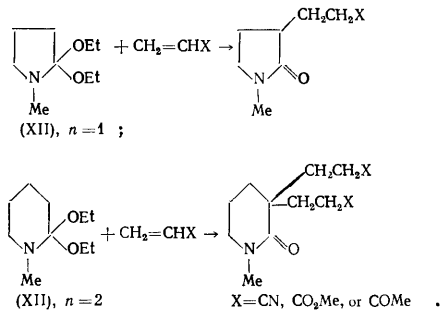


$$AlkCOCl < ArCOCl < RSO_2Cl < (RO)_2P(=O)Cl \sim R_2PCl \sim R_3SiCl .$$

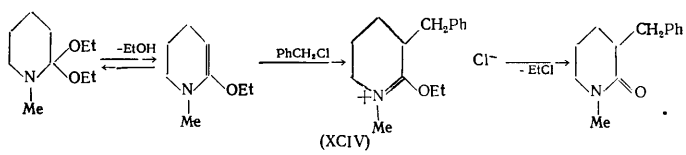
b. Reactions of the Homologues of the Dimethylformamide Acetal and Lactam Acetals



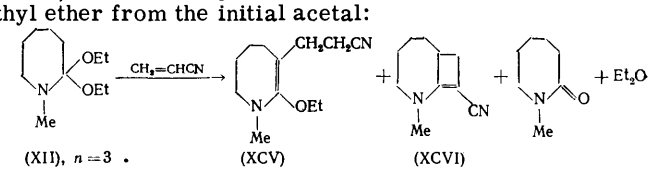
The introduction of alkyl or acyl groups in the α-positions of amides and lactams is known to proceed with difficulty as a rule. In this connection, a convenient method for the synthesis of α-alkyl(acyl)amides or α-alkyl(acyl)lactams is provided by the interaction of the corresponding amide or lactam acetals with alkylating or acylating agents. Thus the reaction of lactam acetals with unsaturated alcohols leads to the formation of 3-allyllactams (**XCII**) [54]:



The conjugated lactam (**XCII**) has been synthesised by the reaction of compound (**XII**, $n = 1$) with butynol. When the acetal of *N*-methylcaprolactam was used in this reaction, the intermediate allene (**XCIII**) could be isolated:

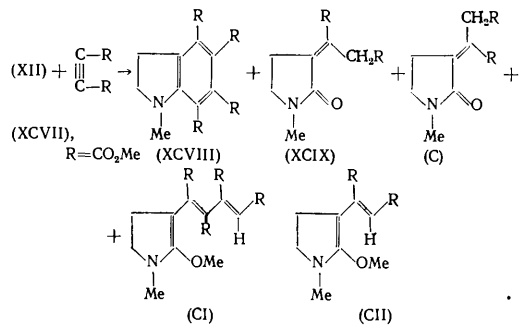


The reaction with allenes proceeds similarly[54]:



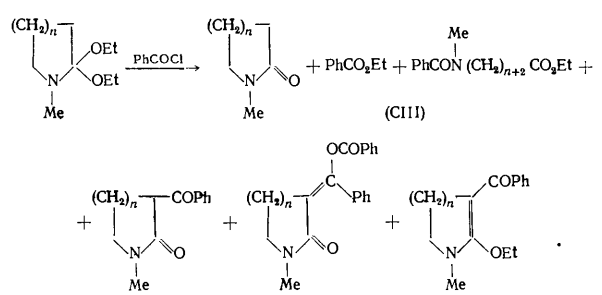
The reactions of lactam acetals with compounds such as acrylonitrile have been investigated in fair detail[29]. It has been shown that, when compound (**XII**, $n = 1$) interacts with $CH_2$=CHX (where X = CN, $CO_2Me$, or COMe), only the products of monosubstitution in the 3-position of the lactam ring are formed, while compound (**XII**, $n = 2$) forms 3,3-disubstituted lactams under these conditions:

Alkylation of compound (**XII**, $n = 2$) with benzyl chloride leads to a monoalkylation product. Such specificity of the benzylation of compound (**XII**) has been explained[29] by the ability of the intermediate immonium salt (**XCIV**) to split off ethyl chloride:



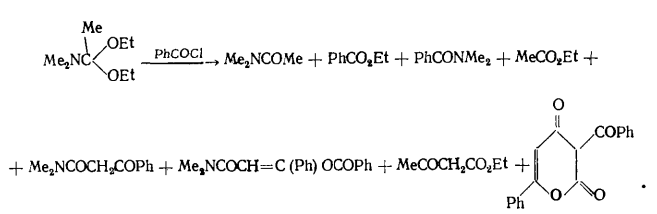
The diethyl acetal of *N*-methylcaprolactam (**XII**, $n = 3$) reacts with acrylonitrile[35], forming the $\alpha$-alkoxyenamine (**XCV**), the cyclic product (**XCVI**), and *N*-methylcaprolactam, the last compound as a result of the elimination of ethyl ether from the initial acetal:

(XII), $n=3$ . (XCV) (XCVI)



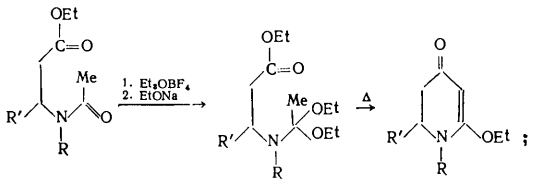
When the acetal (**XII**, $n = 1$) was allowed to react with the acetylenedicarboxylate ester (**XCVII**), a number of substances, (**XCVIII**)–(**CI**), were isolated[86]:

(XCVII), R=$CO_2$Me (XCVIII) (XCIX) (C) (CI) (CII)



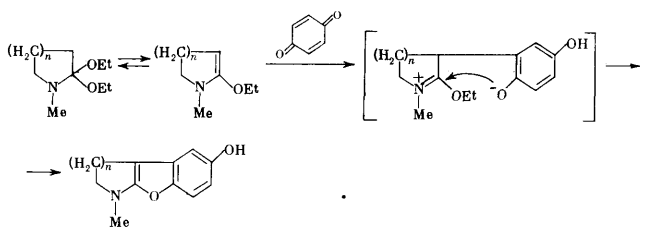
It was shown that the primary product of this reaction is the enamine (**CII**), which is converted into the isomers (**XCIX**) and (**C**) under mild conditions, for example in chromatography on silica gel, while on heating with the ester (**XCVII**) it gives rise to the indoline (**XCVIII**).

Among the reactions of amide and lactam acetals with electrophiles, those with benzoyl chloride have been investigated in greatest detail[28,35,87,88]. As was to be expected, these reactions proceed unambiguously with formation of *C*-, *N*-, and *O*- acylation products:



(CIII)

The benzoylation of the dimethylacetamide acetal (**CIV**) proceeds in an even more complex manner; its mechanism has been examined in detail[88]:



The ability of amide acetals to react with electrophiles has been used in the synthesis of heterocyclic compounds, for example for the preparation of 2,4-dioxopiperidine derivatives[50]:

R=Me, R′=H, or (RR′)=$-(CH_2)_4-$ .

It has been found recently that lactam acetals condense readily with *p*-benzoquinone, cyclising subsequently to condensed benzofurans[89]:

Thus the data described show that the discovery of amide and lactam acetals, a new class of organic compounds, initiated a new field in organic chemistry, which is of great promise from both synthetic and theoretical points of view. There is no doubt that the scope of the applications of amide acetals in organic synthesis is far from exhausted and that the chemistry of these exceptionally reactive compounds will continue to attract the attention of many organic chemists.

# α-Cyanoacetylenes

A.N.Volkov and A.N.Nikol'skaya

The problems of the synthesis, physical properties, and reactivities of α-acetylene nitriles are discussed. The bibliography includes 200 references.

## I. INTRODUCTION

α-Cyanoacetylenes are nowadays of considerable interest not only because of the wide variety of their chemical properties and synthetic possibilities, but also because of their ability to give rise to ultrahigh flame temperatures on combustion in oxygen or ozone [1]. Furthermore, cyanoacetylene has been detected in cosmic space [2-6] and it has been suggested that it was involved in the prebiological synthesis of important nitrogen compounds [7,8] (purines and pyrimidines).

However, no reviews have been published hitherto on the physical and chemical properties of these interesting compounds. This paper is the first attempt at a consideration and a systematic account of the available literature data on this problem.

## II. METHODS OF PREPARATION OF α-CYANOACETYLENES

α-Cyanoacetylenes were first detected in 1909 by Moureu, who also proposed a method for the synthesis of cyanoacetylene (CA), dicyanoacetylene (DAC), dicyanodiacetylene (DCDA), and other α-cyanoacetylenes [9-11]:

$$RC{\equiv}C{-}COOH \xrightarrow[H_2SO_4]{CH_3OH} RC{\equiv}C{-}COOCH_3 \xrightarrow{NH_4OH} \rightarrow RC{\equiv}C{-}CONH_2 \xrightarrow[-H_2O]{P_2O_5} RC{\equiv}C{-}C{\equiv}N \quad .$$

Since then, this method has been used fairly frequently in laboratory practice for the synthesis of small amounts of CA, DCA, and other substituted α-cyanoacetylenes [9-15]. Later many investigators [16-26] attempted to modify Moureu's method without altering its essential features. Thus Blomquist and Winslow [17] synthesised DCA in the following way:

$$HOOC{-}CH(Br)CH(Br)COOH \xrightarrow{KOH} HOOC{-}C{\equiv}C{-}COOH \rightarrow \xrightarrow[H_2SO_4]{CH_3OH} H_3COOC{-}C{\equiv}C{-}COOCH_3 \xrightarrow{NH_4OH} \rightarrow H_2NOC{-}C{\equiv}C{-}CONH_2 \xrightarrow{P_2O_5} N{\equiv}C{-}C{\equiv}C{-}C{\equiv}N \quad .$$

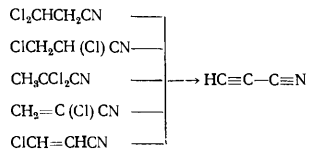
At 215°C and 2 mmHg, the diamide is dehydrated in 15 min, the yield of DCA amounting to 37%. Cookson et al. [22] succeeded in raising the yield of DCA to 40% by lowering the dehydration temperature of the diamide to 200°C. CA can also by synthesised under laboratory conditions by dehydrating the oxime of propargyl aldehyde with acetic anhydride [27].

The only method for the synthesis of DCDA consists in the treatment of the copper(I) derivative of propiolonitrile with aqueous potassium hexacyanoferrate(III).[11] Brockman [28] investigated the reaction in detail, but a high yield of DCDA was not achieved:

$$HC{\equiv}C{-}C{\equiv}N \xrightarrow[NH_4OH]{CuCl} CuC{\equiv}C{-}C{\equiv}N \xrightarrow[36\%]{K_3Fe(CN)_6;6^\circ;C_6H_6} N{\equiv}C{-}(C{\equiv}C)_2{-}C{\equiv}N \quad .$$

Other investigators [1,19,21] were also unable to make significant improvements to the method of synthesis of DCDA.

In the 1960s, various investigators [29-46] began to develop vigorously fundamentally new, in the main high-temperature methods for the synthesis of CA and DCA. Thus the possibility of synthesising CA from acetylene [29,30] or acetonitrile [31] on contact in the gas phase with hydrogen cyanide or dicyanogen at temperatures in the range 770 to 975°C has been demonstrated in a number of United States patents. Acrylonitrile and other impurities are formed together with CA, the yield of the latter increasing as the temperature is raised, while the yield of acrylonitrile falls. In order to determine whether or not acrylonitrile is an intermediate in the formation of CA, separate experiments were undertaken on the pyrolysis of acrylonitrile at 770° and 935°C. It was found that the yield of CA should be much lower if acrylonitrile were an intermediate. A simple radical reaction mechanism was therefore proposed:



$$\left.\begin{matrix} HC{\equiv}\dot{C} + HC{\equiv}N \\ N{\equiv}\dot{C} + HC{\equiv}CH \end{matrix}\right\rbrace \rightarrow HC{\equiv}C{-}C{\equiv}N + \dot{H} \quad .$$

It is suggested that the reaction is initiated by the acetonitrile present in an amount of 0.04% in the initial hydrogen cyanide:

$$CH_3CN \rightarrow \dot{H} + CH_2CN; \quad \dot{H} + HC{\equiv}CH \rightarrow HC{\equiv}\dot{C} + H_2 \quad .$$

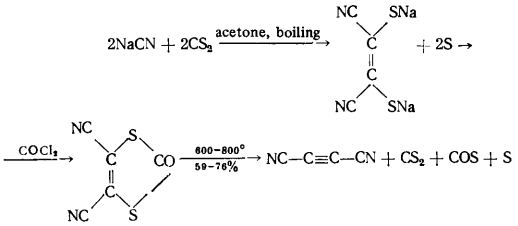
When a mixture of hydrogen cyanide and acetonitrile vapours with an inert gas is passed through a quartz tube at 700-900°C with a contact time of 5-0.01 s, malonodinitrile, acrylonitrile, and dicyanogen are formed preferentially. At 900-1100°C, CA is formed in 18% yield, but the main product is dicyanogen [31]. Comp [32] obtained CA in yields up to 95% by the non-catalytic reaction of acetylene with dicyanogen at 800-900°C. A satisfactory yield of CA is obtained when acetylene is highly diluted with dicyanogen and an inert gas. Substituted acetylenes react with dicyanogen under analogous conditions. Dehydrogenation of propionitrile and β-phenylpropionitrile over metal oxides at 600-800°C leads to CA and β-phenylpropiolonitrile, but the yield of the desired products has not been stated [33]. The formation of CA was

also noted when acetylene was added to active nitrogen, the yield of hydrogen cyanide, dicyanogen, and CA passing through a maximum as the supply of acetylene to the reaction zone was increased[34]. Morita and Hashimoto[35,36] recently synthesised CA by the pyrolytic cleavage of halogen-containing nitriles in a quartz tube in a stream of nitrogen, at 1000°C and a pressure of approximately 25 mmHg in the system. The yield of CA was 68–73%, depending on the initial nitrile:

A more detailed study of the process showed that, apart from CA, monochloroacrylonitriles and acrylonitrile are formed as impurities[37]. The addition of carbon tetrachloride accelerates the pyrolysis of dichloropropionitriles and suppresses the formation of acrylonitrile. The addition of even small amounts of β-chloropropionitrile, which is converted under these conditions into acrylonitrile, leads to a sharp decrease of the yield of CA and increases the content of monochloroacrylonitriles. According to the authors[37], these data indicate that the dehydrochlorination processes under consideration have a radical mechanism. When αα'β-trichloropropionitrile, αβ-dichloroacrylonitrile, and ββ'-dichloroacrylonitrile are pyrolysed, chlorocyanoacetylene (CCA) is formed in a high yield[37].

The gas-phase interaction of acrylonitrile and chlorine at 500–1200°C and a reduced pressure (10–100 mmHg) leads to CA without an admixture of side products[38,39].

Alkyl-substituted homologues of CA may be obtained in high yields from the corresponding lithium acetylides and chlorocyanogen[40] and aryl-substituted derivatives (yield 38%) may be synthesised from phenylethynyl bromide and copper cyanide[47] or from sodium phenylacetylide and dicyanogen[48].†



A method for the synthesis of DCA by the pyrolysis of the dichloro-derivative or its mixture with the monochloro-derivative of but-2-ene-1,4-dicarbonitrile at 300–750°C has been developed in the USA[41]:

The reaction is carried out in a pyrolysis reactor using an inert carrier gas, in particular helium (0.02–20% of the volume of the mixture). However, the pyrolysis products interact with one another so readily that the problem of their rapid separation arises even at a reduced temperature.

Zavitzanos[42,43] proposed a method for the synthesis of DCA directly from carbon and nitrogen. The latter is passed over a graphite cylinder heated to 2100–2700°C. Apart from DCA, the reaction products contain dicyanogen and DCDA. It was found that the rate of formation of DCA increases rapidly as the reaction temperature is raised from 2400 to 2700°C.

Ciganek and coworkers[40,45] obtained DCA by the pyrolysis of 4,5-dicyano-1,3-dithiol-2-one vapour:

DCA can be obtained on a preparative scale from tetracyanoethylene (yield up to 72%).[45]

DCA is also formed in the retrodiene cleavage of dimethyl 5,6-dicyano-oxabicyclo[2,2,2]hepta-2,5-dienedicarboxylate.[46] Other attempts at the synthesis of DCA, for example by the reaction of bromocyanogen with LiC≡CLi, were unsuccesful[49].

## III. PHYSICAL PROPERTIES

CA is a mobile, volatile, and readily inflammable liquid boiling at 42.5°C, easily converted on cooling into crystals melting at 5°C, which are quite stable on storage at a low temperature (−70°C).[37] There is an infinite parallel arrangement of linear chains in CA crystals owing to the formation of hydrogen bonds or charge-transfer complexes[50]. The CA vapour is highly irritant to mucous membranes and has a lachrymatory effect. On storage in air, CA rapidly darkens and on combustion in oxygen gives rise to a bright colourless flame (like acetylene). CA is sparingly soluble in water and readily soluble in alcohol and acetone. Its solutions become rapidly coloured brown.

DCA is a colourless transparent liquid boiling at 76.5°C, which crystallises[45], forming crystals melting at 20.5°C. The study of the crystal structure of DCA showed that it forms monoclinic crystals at 5°C, belonging to the space group $C_{2h}^5$–$P2_1/a$. Precision [X-ray] photography established that the unit cell contains two molecules and has the following dimensions: $a = 8.93$, $b = 6.04$, $c = 3.86$ Å, and $\beta = 99°20'$.[51]

Under the usual conditoins, DCA is a toxic and volatile substance. It is potentially explosive in the pure state and in concentrated solutions, while its dilute solutions in inert solvents are stable. Pure DCA rapidly darkens in air, because it is sensitive to the presence of oxygen, but can be stored almost indefinitely in dry ice.

DCDA sublimes in the form of fine white crystals, melting at 64.5°C, which are extremely volatile and unstable[19]. However, DCDA specimens may be stored *in vacuo* or in nitrogen at room temperature. After storage for three months, an appreciable amount of DCDA was found to have sublimed from the initial specimen[19]. Even at 100°C, only partial decomposition of DCDA is observed. DCDA solutions in $CS_2$, $CCl_4$, $CHCl_3$, furan, and hexane slowly acquire an amber colour, but in cyclohexane these changes are rapid. The solution in toluene becomes slowly coloured blue, while in benzene the same colour is acquired instantaneously.

DCDA has an irritant smell and is a powerful lachrymatory agent. The physical properties of members of the series $N{\equiv}C{-}(C{\equiv}C)_n{-}C{\equiv}N$, where $n = 0$–2, agree fairly well with the general relations governing the variation of the boiling point, melting point, and density with increasing molecular weight in a homologous series. The temperature variation of DCA and DCDA vapour pressures is significantly linear for both solid and liquid states.

†A method for the introduction of the cyano-group into bromo-substituted acetylenic alcohols by their reaction with copper cyanide was reported recently[200].

DCA and DCDA are of interest for the attainment of ultrahigh temperatures, since, on combustion in a suitable amount of oxygen, they form mainly endothermic products—CO and $N_2$. The possibility of achieving very high combustion temperatures, actually higher than in the combustion of dicyanogen, is associated with this fact[52]. Kirshenbaum and Grosse[53] found that, when DCA is burnt in oxygen, a temperature of approximately 5260 K is developed at 1 atm and 5750 K at 40 atm. It was expected that the replacement of molecular oxygen by ozone would give a temperature of 5520 K at 1 atm. Such temperatures were indeed subsequently attained[54]. (The temperature of the DCDA flame was not investigated owing to the difficulty of obtaining a sufficient amount of the latter.)

In connection with the foregoing, the heats of formation of cyanoacetylenes, measured for the first time by Moureu[11], are of interest. Subsequently Armstrong and Marantz[55] determined more accurately the heat of combustion of DCA and reported the corrected value[56] $\Delta H^\circ_{298}$(comb.) = −495.5 ± 0.2 kcal mole$^{-1}$ for the liquid substance and the heats of formation $\Delta H^\circ_{298}$(form.) of liquid and gaseous DCA calculated from it—119.6 and 126.5 kcal mole$^{-1}$ respectively.

There have been numerous studies on other physicochemical properties of α-cyanoacetylenes. The infrared spectra of CA[21,57-66], DCA, and DCDA have been investigated and discussed in detail in a collected volume[67]. The infrared spectra of CA and its deuterated derivative have been investigated in the gaseous and crystalline states (at 77 K) and measurements have been made of the integral intensities of the following absorption bands assigned on the basis of the calculation of the normal vibration frequencies: 3327 (2607) cm$^{-1}$ for the CH(CD) stretching vibrations, 2272 (2251) cm$^{-1}$ for C≡C, 2077 (1956) cm$^{-1}$ for C–N, and 863 cm$^{-1}$ for C–C (in the gase phase)[68]. Analysis of the spectra led to the conclusion that molecules of this type have a linear structure. Using the observed vibration frequencies and applying the system of valence force coordinates, Miller and Hannan[59] calculated the force constants of the C≡N ($16 \times 10^5$–$17.5 \times 10^5$ dyn cm$^{-1}$) and C–C ($6.0 \times 10^5$–$7.5 \times 10^5$ dyn cm$^{-1}$) bonds in DCA.

The infrared spectra of DCDA[21] were measured in the range 35–4000 cm$^{-1}$ in the vapour phase and in solution in carbon tetrachloride and carbon disulphide, while the Raman spectra were obtained for solutions in carbon tetrachloride, hexane, furan, and toluene. The absorption bands, assigned to the C≡N [2235 cm$^{-1}$ (Raman), 2266 cm$^{-1}$ (i.r.)] and C≡C [2183 cm$^{-1}$ (Raman), 2057 cm$^{-1}$ (i.r.)] stretching vibrations, do not interact with one another, in contrast to the two C–C vibrations with $\Sigma g^+$ symmetry. The C–C stretching vibrations give rise to a smiple intense band in the infrared spectrum in the region of 717 cm$^{-1}$.

The thermodynamic functions of DCDA have been calculated[64] for the range 200–2000 K in terms of the rigid rotator approximation. The bond polarisabilities and the average moleculer polarisability in the ground electronic state were determined using a potential δ-function. Derivatives of molecular polarisability have been calculated for fully symmetrical vibrations. The force constants of the C≡N, C≡C, and C–C bond vibrations have been obtained: $16.823 \times 10^5$, $15.614 \times 10^5$, and $6.753 \times 10^5$ dyn cm$^{-1}$ for the central bond, and $6.357 \times 10^5$ dyn cm$^{-1}$ for the bonds adjoining C≡N. The force constants have also been obtained from the overall valence-force field[65]. Moffat and Knowles[66] described a method for the calculation of various thermodynamic characteristics of dicyanogen, DCA, and DCDA: entropy, heat capacity, internal and free energy, and enthalpy (the last three quantities are determined from the dissociation energy of the molecule calculated from the heats of combustion and formation), etc.

There is extremely limited information about the rotational spectra of α-cyanoacetylenes. Westenberg and Wilson[69] analysed the purely rotational spectra of several CA and deuterated CA isotopic series in the microwave region and calculated the H–C (1.057 Å), C≡C (1.203 Å), C–C (1.382 Å), and C≡N (1.157 Å) bond lengths.

The dielectric constants of CA were determined[70] in the range 8850–9500 MHz in the gas phase at 42°C, the molecular polarisation remaining constant at 278 cm$^{-3}$. The molecular polarisation of CA at 9400 MHz is the same as at low frequencies. Measurements have been made of the $I = 1 \leftarrow 0$ and $I = 2 \leftarrow 1$ rotational transitions in the ground vibrational state[71]. Some of the lines in the rotational spectra of CA in the microwave range are quoted for the first time in the "Strelets V2" source book[3-5,72,73].

Information about the difference between the energies of the ground and excited electronic states was obtained from the electronic spectra of α-cyanoacetylenes. The spectrum of gaseous CA has many closely spaced weak bands in the range 230–260 nm.[74] The bond lengths and angles in the CA molecule have been determined from rotational spectroscopic data. The same workers[75] investigated the diffuse absorption band of CA in the gas phase in the range 200–230 nm, but its vibrational structure could not be analysed. In other investigations[76,77], the CA spectrum was obtained with a high resolution and the bands were analysed. The ionisation potential of CA has been calculated as 11.6 eV from the observed Rydberg series. Subsequently Dibeler et al.[78] measured mass spectrometrically the ionisation potentials of CA, DCA, and DCDA, which are respectively 11.6, 11.4, and 11.4 eV.

Connors et al.[79] investigated the absorption spectrum of gaseous CA in the range 105–200 nm. The first transition (61 000–66 000 cm$^{-1}$), having two main bands at 62 000 and 64 500 cm$^{-1}$, was assigned to the $\nu_2'(\sigma^+)$ or $\nu_3'(\sigma^+)$ excitation and the transition at 69 000 cm$^{-1}$ was assigned to the internal valence shell. The peak at 71 100 cm$^{-1}$, separated from the first band by 2100 cm$^{-1}$, can be regarded as due to the $\nu_2'(\sigma^+)$ or $\nu_3'(\sigma^+)$ active vibrations.

The spectra of DCA[80] in iso-octane solution and in the gas phase showed that the DCA molecule remains planar in the excited state and that its $D_{\infty h}$ nuclear configuration is preserved. DCA exhibits an intense absorption[79] in the range 150–165 nm, giving rise to three peaks separated by 2150 cm$^{-1}$, which may be assigned to the symmetrical $\nu_1'(\sigma_g^+)$ or $\nu_2'(\sigma_g^+)$ vibration. The Rydberg series (8100 to 92 440 cm$^{-1}$) has also been isolated.

The DCDA spectrum[79] in the range 105–200 nm has a more complex structure. The very intense transition in the range 175–190 nm was assigned to the $\nu_1'(\sigma_g^+)$ or $\nu_2'(\sigma_g^+)$ symmetrical vibration; in addition, three Rydberg series, giving a first ionisation potential of approximately 11.2 eV (90 300 cm$^{-1}$), were observed. A continuous absorption spectrum of gaseous DCDA[81] was also obtained in the range 230–310 nm. The fundamental characteristics of the transition suggest that the molecule is linear in both ground and excited states.

Calculations of the relative intensities in the photoelectronic spectra of CA and DCA have been published[82] and the magnetic rotation of DCA has been reported[83,84].

Analysis of the normal coordinates of CA[85,86] made it possible to determine the distribution of potential energy with respect to bonds and valence angle vibrations. Since

the application of the usual symmetry coordinates to DCA [87] leads to unduly high force constants, another set of symmetry coordinates has been proposed in which the -C-C≡C-C- chain is regarded as a system of three strongly interacting oscillators [88]. The normal DCDA coordinates have also been analysed [89] and the symmetry coordinates for the $\sigma^{+}_{g}$ and $\sigma^{+}_{u}$ symmetry types of the $L_{\infty}\omega$ group have been set up.

## IV. REACTIVITIES

α-Cyanoacetylenes are capable of entering into various chemical reactions involving both the C≡C and the C≡N bond. They are particularly reactive in reactions with nucleophiles owing to the conjugation of the triple bond with the electron-accepting cyano-group.

### 1. Hydration

The problem of orientation in the reactions involving addition to the conjugated triple bonds is naturally of considerable interest. It has been shown, for example, that diacetylene can combine with one or two water molecules, forming acetylacetylene or diacetyl respectively [90]. On the other hand, when CA is treated with 98% sulphuric acid at 20°C and then with ice, it does not undergo any changes, while chlorocyanoacetylene (CCA) gives a 75% yield of β-chloropropiolamide under these conditions [91]. Treatment of CA with sulphuric acid under controlled conditions (at 35–40°C) gave a 20% yield of propiolamide [92].

α-Aminocyanoacetylenes are readily hydrated in an aqueous solution of THF in the presence of hydrochloric acid, cyanoacetamides (I) being isolated in almost quantitative yield [93]:

$$R_2NC{\equiv}C{-}C{\equiv}N \rightarrow \underset{(I)}{R_2NCOCH_2C{\equiv}N}$$

R=Me, or Et .

CA behaves quite differently in aqueous THF in the presence of the hydrated form of Dowex-1 anion-exchange resin. Sasaki and Shoji [94] showed that di-(β-cyanovinyl) ether (II) is then formed in a yield of up to 60%:

$$HC{\equiv}C{-}C{\equiv}N \xrightarrow[\text{Dowex-1}]{THF,\ H_2O} \underset{(II)}{N{\equiv}C{-}CH{=}CHOCH{=}CHC{\equiv}N} \quad .$$

Thus, depending on the reaction conditions, water can add to α-acetylenes in different ways.

CA and CCA can enter into the Ritter reaction forming the corresponding propiolamides (III) in a yield of 10 to 80%: [91,95]

$$HC{\equiv}C{-}C{\equiv}N \xrightarrow{R^{+}} HC{\equiv}C{-}\overset{+}{C}{=}NR \xrightarrow{H_2O} \underset{(III)}{HC{\equiv}C{-}CONHR} \quad ;$$

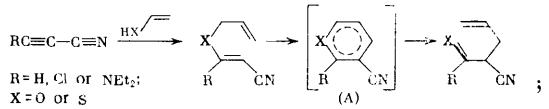
R= t-$C_4H_9$, $(C_6H_5)_2C(COOH)$, $(CH_3)_2C(CH_2Cl)$, $C_{11}H_{17}$, $C_{11}H_{15}$, or $C_6H_{11}$.

The extension of this reaction to more complex systems makes it possible to obtain heterocyclic compounds containing the ethynyl group. Thus the reaction of 2-methylpentane-2,4-diol with CA or CCA in sulphuric acid leads to 2-ethynyl- or 2-chloroethynyl-4,4,6-trimethyl-5,6-dihydro-1,3-oxazines. [96] Under these conditions, DCA and DCDA give rise to resins, which are difficult to treat.

### 2. The Addition of Alcohols and Phenols

The base-catalysed addition of methanol and ethanol to CA proceeds very readily already at 10°C, two moles of the alcohol being added with formation of ββ-dialkyoxypropionitrile (V) in 50–78% yield [18]. In the presence of KCN or potassium carbonate, it is possible to obtain a mixture of β-ethoxyacrylonitrile (IV) and diethoxypropionitrile (V):

$$HC{\equiv}C{-}C{\equiv}N \xrightarrow{ROH} \underset{(IV)}{ROCH{=}CHC{\equiv}N} \rightarrow \underset{(V)}{(RO)_2CHCH_2C{\equiv}N} \quad .$$



CA reacts similarly wtih glycols, 2-cyanomethyl-1,3-dioxolan and 2-cyanomethyl-1,3-dioxan being obtained from ethylene glycol and 1,3-propylene glycol respectively. The yields of the products were not indicated [18].

The addition of lower alcohols to CCA proceeds without catalyst at room temperature with formation of 3-alkoxy-3-chloroacrylonitrile: the reaction with allyl alcohol gave the Claisen rearrangement product (VI): [93]

$$ClC{\equiv}C{-}CN \xrightarrow{CH_2{=}CHCH_2OH} NC{-}C{\equiv}COCH_2CH{=}CH_2 \rightarrow$$

$$\xrightarrow{CH_2{=}CHCH_2OH} NC{-}CH{=}C(OCH_2CH{=}CH_2)_2 \rightarrow \underset{(VI)}{NC{-}CH(CH_2CH{=}CH_2)C(=O)CH_2CH{=}CH_2} \quad .$$

The reaction of cyanodiethylaminoacetylene with allyl alcohol in the presence of $BF_3$ etherate at room temperature gives rise to 2-cyano-*N*Λ-diethylpent-4-enamide. Sasaki et al. [93] proposed in such cases the mechanism of the Claisen rearrangement involving an intermediate with a quasi-cyclic structure (A):

CCA reacts with lower alcohols in the presence of sodium alkoxides, forming ββ-dialkoxyacrylonitriles (VII): [97]

$$ClC{\equiv}C{-}C{\equiv}N \xrightarrow[ROH]{NaOR} \underset{(VII)}{(RO)_2C{=}CHC{\equiv}N} \quad .$$

As shown by Moureu [11], DCA also interacts very readily with alcohols in the presence of alkaline agents, the reactivity of the alcohol decreasing with increasing length of its alkyl group. Winterfeldt et al. [98] investigated the stereochemistry of this reaction and showed that it leads to a mixture of *cis*- and *trans*-products (VIII) (yield 50 to 52%) in the proportions 4 : 1:

$$NC{-}C{\equiv}C{-}CN \xrightarrow{ROH} \underset{(VIII)}{NC{-}CH{=}C(OR)CN} \quad ;$$

R=Me, iso-Pr, or t-Bu

When piperidine is used at 0°C, the reaction proceeds stereospecifically (*cis*-adduct, 59% yield), while at 20°C a 9 : 1 mixture of the *cis*- and *trans*-adducts is obtained (yield 52%).

The addition of phenol to CA in the presence of sodium phenoxide proceeds sluggishly and leads to a mixture of monoadducts (IX) and diadducts (X), from which only the latter could be isolated [99]:

$$HC{\equiv}C{-}C{\equiv}N \xrightarrow{PhOH} \underset{(IX)}{PhOCH{=}CHC{\equiv}N} \rightarrow \underset{(X)}{(PhO)_2CHCH_2C{\equiv}N} \quad .$$

Having applied this reaction to halogenophenols, Miller [20] developed a method for the synthesis of halogeno-β-phenoxyacrylonitriles (IX) (in a yield of approximately 70%), which have found applications as agents effective against apple scab and as soil fungicides, insecticides, and herbicides.

### 3. The Addition of Thiols

Sasaki et al.[93] showed that the addition of propene-2-thiol to CA in the absence of a catalyst proceeds very slowly, while in the presence of sodium methoxide the reaction is accelerated and leads to a mixture of *cis*- and *trans*-β-allylthioacrylonitriles (XI) in 46% yield:

$$HC\equiv C-C\equiv N + HSCH_2CH=CH_2 \rightarrow \underset{(XI)}{H_2C=CHCH_2SCH=CHCN}$$

Like allyl alcohol, propene-3-thiol reacts with CCA and cyanodiethylaminoacetylene, forming the products of the Claisen rearrangement, for example (XII):

$$ClC\equiv C-C\equiv N + HSCH_2CH=CH_2 \rightarrow NC-CH=C(SCH_2CH=CH_2)_2 \rightarrow$$

$$\rightarrow NC-\underset{\underset{CH_2CH=CH_2}{|}}{\overset{S}{\overset{\|}{C}}}-SCH_2CH=CH_2$$

(XII)

Welle and Brandsma[40] investigated the addition of propyne-3-thiol to alkyl-α-cyanoacetylenes and found that in hexamethylphosphoramide the reaction is exothermic and proceeds without catalyst, terminating in essence at the stage of the product (XIII), which has the *cis*-configuration when R = H:

$$RC\equiv C-C\equiv N + HC\equiv C-CH_2SH \xrightarrow{20^\circ} \underset{(XIII)}{HC\equiv C-CH_2SC(R)=CHC=N} \rightarrow (HC\equiv C-CH_2S)_2C(R)CH_2C\equiv N;$$

(XIV)

R = H, or Alk .

Thiophenol readily reacts with CA in the presence of sodium methoxide on cooling, the yield of β-phenylthiolacrylonitrile (XV) reaching 75%. ββ-Di(phenylthio)-propionitrile (XVI) was obtained together with the adduct (XV) under analogous conditions in the presence of an excess of thiophenol[99]:

$$HC\equiv C-C\equiv N \xrightarrow[MeONa]{PhSH} \underset{(XV)}{PhSCH=CHC\equiv N} \rightarrow \underset{(XVI)}{(PhS)_2CHCH_2C\equiv N} .$$

CA reacts just as readily with *p*-methylbenzenethiol (at a reduced temperature in methanol solution in the presence of sodium *p*-methylbenzenethiolate), forming exclusively the *cis*-adduct in 100% yield[100,101]. Truce and Wolf[102] discovered a new reaction involving the addition of toluene-*p*-sulphonyl iodide to acetylenes, which proceeds stereoselectively and leads to the *trans*-adduct (XVII):

$$NC-C\equiv CH + n\text{-}CH_3C_6H_4SO_2I \rightarrow \underset{(XVII)}{\overset{NC}{\underset{I}{}}\!\!>C=C<\!\!\overset{SO_2C_6H_4CH_3\text{-}n}{\underset{H}{}}}$$

The reaction begins even when the components are mixed in the cold and is strongly accelerated by ultraviolet light.

### 4. The Addition of Amines, Hydrazines, and Their Derivatives

α-Cyanoacetylenes readily react with a wide variety of amines. Murahashi et al[99] obtained β-piperidinoacrylonitrile by the exothermic reaction of CA with piperidine in benzene. According to the same workers[99], the analogous reaction with aniline leads to the monoadduct (XVIII) and the diadduct (XIX):

$$HC\equiv C-C\equiv N + PhNH_2 \rightarrow \underset{(XVIII)}{PhNHCH=CHC\equiv N} \rightarrow \underset{(XIX)}{(PhNH)_2CHCH_2CN} .$$

In a later study by Sasaki et al.[103], the monoadduct (XVIII) was not obtained and the yield of (XIX) was 65%. It was shown[103] that the 1 : 1 products of the addition of cyclic secondary amines (morpholine, pyrrolidine, piperidine, aziridine, and imidazole) to CA have the *trans*-configuration. The reaction of CA with other amines proceeds similarly[104-107], the monoadducts, with both the *cis*- and *trans*-configurations, having been isolated. CA reacts with aqueous 28% ammonia solution, giving rise to β-aminoacrylonitrile.[99] The addition of ammonia and amines to DCA was first reported by Moureu and Bongrand[11], who showed that ammonia and primary and secondary amines interact vigorously with 2-cyano-1-phenylacetylene and DCA with formation of β-aminoacrylonitriles, which readily hydrolyse to β-ketonitriles (XXI):

$$RC\equiv C-CN \xrightarrow{NHR^1R^2} \underset{(XX)}{RC(NR^1R^2)=CHCN} \xrightarrow{H_2O} \underset{(XXI)}{RCOCH_2CN} ;$$

R = Ph, or CN .

Since compounds (XX) have not been characterised, Weis[108] repeated this investigation and found that 1-arylamino-1,2-dicyanoethylenes are formed quantitatively when DCA reacts with primary aromatic amines, while in the reaction with aliphatic amines the reaction mixture chars.

Sasaki et al.[109] investigated the possibility of synthesising ynamines by the reaction of CCA with secondary amines. It is known[67] that α-halogenoacetylenes enter into nucleophilic substitution reactions with trialkylamines and (mainly) into addition reactions involving the C≡C bond with secondary amines. The presence of the cyano-group in CCA suggests an increase in the reactivity of the chlorine in nucleophilic substitutions, so that treatment of CCA in ether with sodamide makes it possible to obtain malonodinitrile (XXII) in a satisfactory yield[109]:

$$NC-C\equiv CCl + NaNH_2 \rightarrow \underset{(B)}{[H_2NC\equiv C-CN]} \rightarrow \underset{(XXII)}{NC-CH_2CN} .$$

It has been suggested that the amine (B) is an intermediate in the reaction and is converted into the nitrile (XXII) as a result of prototropic isomerisation. Secondary amines (dimethylamine, diethylamine, piperidine, morpholine, and pyrrolidine) react with CCA to give the corresponding cyanoynamines (XXIII):

$$NC-C\equiv CCl + HNR_2 \rightarrow \underset{(XXIII)}{NC-C\equiv CNR_2} .$$

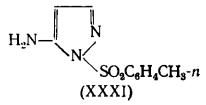
A higher yield of compound (XXIII) is achieved when the reaction is carried out at −50°C with a twofold excess of the amines. The ynamines (XXIII) readily undergo acid hydrolysis, being converted into cyanoacetamides in almost quantitative yield. They also readily react with amines, alcohols, and other compounds[109].

The interaction of CCA with allylamine[93] proceeds in a more complex manner—with formation of compound (XXIV):

$$NC-C\equiv CCl \xrightarrow{H_2NCH_2CH=CH_2} \underset{(XXIV)}{NC-CH=C(NHCH_2CH=CH_2)(NCH_2CH=CH_2)(NHCH_2CH=CH_2)} .$$

Depending on the conditions in the reaction between CCA and diallylamine, compound (XXV) or (XXVI) is obtained[93,109]:

$$\underset{(XXV)}{NC-C\equiv CN(CH_2CH=CH_2)_2}; \quad \underset{(XXVI)}{NC-CH=C[N(CH_2CH=CH_2)_2]_2} .$$



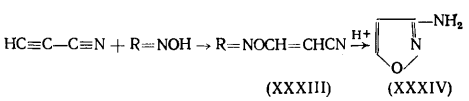
Hydrazines and semicarbazides are stronger bases and nucleophiles than amines, and can therefore react with CA

via both the triple bond and via the nitrile group or can simultaneously attack both reaction centres. For example, hydrazine hydrate in ethereal solution reacts with CA to form 1,2-di-(β-cyanovinyl)hydrazine (XXVII), while thiosemicarbazide in methanol at 20°C gives rise to β-thiosemicarbazidoacrylonitrile (XXIX)[99]:

$$\underset{\text{(XXVII)}}{NC{-}CH{=}CHNHNHCH{=}CHCN};\quad \underset{\text{(XXVIII)}}{NC{-}CH{=}CHNHNH_2};$$
$$\underset{\text{(XXIX)}}{NC{-}CH{=}CHNHNHCSNH_2};\quad \underset{\text{(XXX)}}{PhNHNHCH{=}CHCN}\ .$$

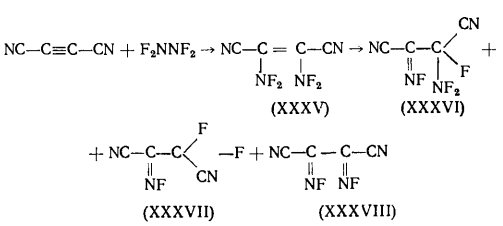
Under other conditions, CA reacts with hydrazine hydrate to give a 3 : 1 mixture of compound (XXVII) and β-cyanovinylhydrazine (XXVIII). CA and phenylhydrazine, taken in equimolar proportions in ether at −40°C, react to form a 1 : 1 adduct having the *trans*-configuration (XXX).[99]

The attempt to cyclise compounds (XXVIII) and (XXX) by heating in protic or aprotic solvents were unsuccessful[92]. However, CA reacts with tosylhydrazine to form 5-amino-1-*p*-tosylpyrazole (XXXI) in approximately 50% yield and only 23% of the non-cyclic product[97]:



(XXXI)

5-Amino-1-arenesulphonylpyrazoles, which are used as analgesics, diuretics, and chemotherapeutic agents, have been obtained by the same reaction (in benzene at 90°C).[110]



A solution of semicarbazide in methanol reacts with CA via the following mechanism and gives a 99% yield of cyanoacetaldehyde semicarbazone (XXXII):[97]

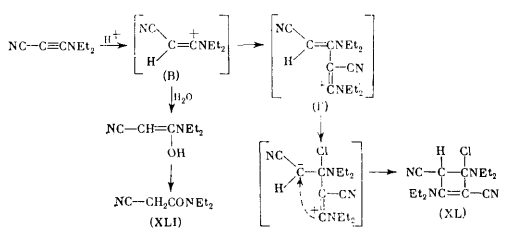
$$HC{\equiv}C{-}C{\equiv}N + H_2NNHCONH_2 \xrightarrow{MeOH} (MeO)_2CHCH_2CN \rightarrow \underset{\text{(XXXII)}}{NC{-}CH_2CH{=}NNHCONH_2}\ .$$

Alkylideneiminoxyacrylonitriles (XXXIII), which readily cyclise to 3-aminoisoxoazole (XXXIV), have been obtained by the reaction of CA with alkanone oximes[111]:

Tetrafluorohydrazine adds to DCA under more severe conditions (140°C, 5 h), which can probably be accounted for by the decrease of the nucleophilic reactivity of hydrazine when fluorine atoms are introduced into its molecule[112]. Bisdifluoroamino-1,2-dicyanoethylene (XXXV) is probably formed initially and then isomerises to the final dinitrile (XXXVI) (yield 33%) and disproportionates to side products of this reaction, namely (XXXVII) (12%) and (XXXVIII) (15):

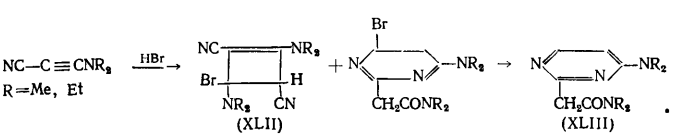
3-Aminoisoxazole was obtained by the condensation of DCA with *N*-hydroxyurethane[113] and was then converted into 3-sulphanilamidoisoxazole, which exhibits bactericidal activity.

### 5. Halogenation and Hydrohalogenation



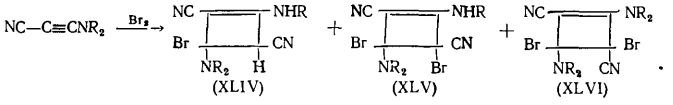
The addition of bromine and iodine to CA in alkaline solutions of KBr and KI proceeds with low yields of trihalogenoacrylonitriles[114]. Like other acetylenes, CA is readily halogenated with a high degree of selectivity at 30–60°C in alcoholic and aqueous alcoholic solutions of copper(II) chloride and bromide, forming αβ-dibromo-αβ-dichloro- and tribromo-derivatives of acrylonitrile[115,116].

Bromocyanoacetylene is halogenated under similar conditions. The halogenation of CA in methanol solutions of a mixture of $CuCl_2$ and $CuBr_2$ leads to the formation of α-bromo-β-chloroacrylonitrile. In aqueous solutions of the corresponding hydrogen halides and copper(I) halides at 30–35°C, CA readily gives rise exclusively to *cis*-β-halogeno-derivatives of acrylonitrile (XXXIX),[117] in agreement with the generally accepted ideas concerning the electron shift in CA:



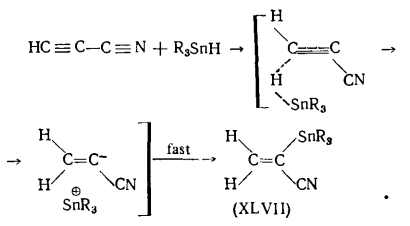
$$HC{\equiv}C{-}C{\equiv}N \xrightarrow[CuHal]{HHal} \underset{\text{(XXXIX)}}{CHHal{=}CHCN}\ .$$

The hydrohalogenation of bromocyanoacetylene and iodocyanoacetylene proceeds under analogous conditions. The addition of HCl to CA in sulphuric acid in the presence of boron trifluoride etherate leads to ββ-dichloropropionitrile[91]. In research designed to synthesise Little's model of a one-dimensional organic superconductor, the products of the addition of HBr and ICN to DCA were used to introduce 1,2-dicyanovinyl groups into azo-, cyanine, and merocyanine dyes[24].



Aminocyanoacetylenes behave quite differently in the presence of hydrogen halides[118,119]. Sasaki[118] established that the reaction of cyano-*NN*-diethylaminoacetylene in solution in methylene chloride at 0–5°C with gaseous hydrogen chloride leads to the cyclobutene (XL) in 85% yield. The mechanism of the formation of this cyclobutene apparently involves the initial protonation of the ynamine with formation of the intermediate (C), which reacts further with the nucleophilic centre of the initial compound and gives rise to the intermediate (D):

The latter is rapidly attacked by the chloride anion with subsequent cyclisation to the cyclobutene (XL). The analogous reaction in the presence of small amounts of water leads exclusively to the cyanoacetamide (XLI). The addition of hydrogen bromide to the initial ynamine at 0°C proceeds in two ways with formation of products (XLII) and (XLIII):



When these ynamines were allowed to react with bromine, cyclobutene derivatives (XLIV)–(XLVI) were again obtained in proportions which depend on the amount of bromine employed[118]:

(XLIV) (XLV) (XLVI)

## 6. The Reactions of α-Cyanoacetylenes with Metal Compounds

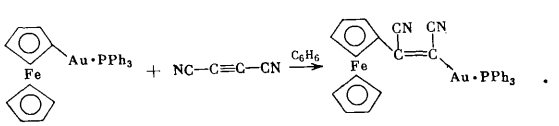
CA reacts exothermically with tin monohydrides via the *trans*-addition mechanism, which has been confirmed by experiments with deuterated transalkylstannanes[120–122]:

(XLVII)

The reaction is of second order overall: in terms of their influence on its rate, the substituents R in tin hydrides can be arranged in the following sequence: pH ≪ Me < Et, iso-Bu[121,123]. Lead hydrides[124] can also react with CA, but in this case a mixture of compounds (XLVIII)–(L) is formed:

$H_2C{=}C(PbR_3)CN$; $R_3PbCH{=}CHCN$; $R_3PbCH{=}CHCN$

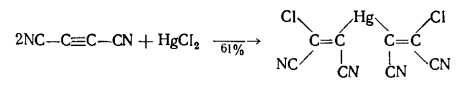
(XLVIII), 50% (XLIX), 45%, *cis*- (L), 5%, *trans*-



The stereochemistry of this process was not investigated in detail; it was suggested that compounds (XLVIII) and (XLIX) are formed via the *trans*-addition mechanism, while compound (L) is obtained as a result of the rearrangement of compound (XLIX) in the presence of the initial lead hydride[124].

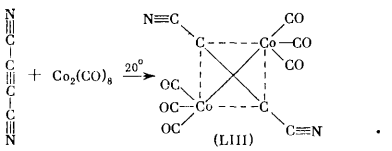
Leusink, Noltes, and coworkers observed the exchange of hydride hydrogen between organic derivatives of tin and lead. When $R_3PbOAc$ and $Ph_3SnH$ are mixed in THF at −80°C and then treated with CA, a 3 : 7 mixture of products (XLVIII) and (XLIX) is formed[125].

Quintard and Pereyre showed[126] that the reaction of DCA with tributylstannane in methanol proceeds with the reduction of the triple bond:



Nesmeyanov and coworkers[127] investigated the reactivity of the complex of ferrocenylgold with triphenylphosphine in relation to tetracyanoethylene and DCA. It was found that DCA is inserted (20°C, 15 min) in the C–Au bond with formation of 1,2-dicyano-1-ferrocenyl-2-(triphenylphosphinegold)ethylene (LI) in 76% yield:

(LI)

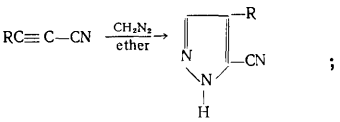


In a saturated aqueous NaCl solution, mercury(II) chloride adds to DCA (5–10°C, 20 min)[108]:

(LII)

It has been shown that in aqueous ethanol the $[Co(CN)_5]^{3-}$ ion forms stable compounds having the composition $K_6[Co_2(CN)_{10}A].2H_2O$ with acetylenes (A) having electron-accepting substituents (such compounds include DCA).[128]

Dickson and Jawhey[129] obtained hexacarbonyl-m-dicyanoacetylenedicobalt (LIII) by the reaction of DCA with dicobalt octacarbonyl in hexane:

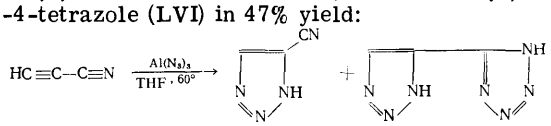


(LIII)

When DCA was allowed to react with $(Ph_3P)_2Ir(CO)Cl$ and nickelocene, complexes were obtained in low yields in which the metal atom is linked by a π-bond with the acetylenic ligand[130].

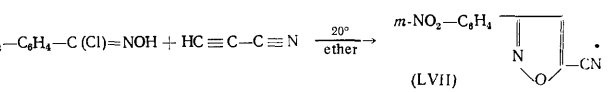
## 7. 1,3-Dipolar Cycloaddition

Numerous examples of the reactions of alkynes, particularly conjugated alkynes, with various types of dipoles are known[67]. For example, the method of synthesis of 4-R-5-cyanopyrazoles (LIV) is based on the reaction of α-cyanoacetylenes with diazoalkanes[92,131]:



R=H,Cl, or Br (LIV)

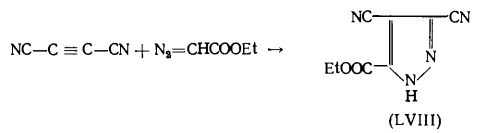
Such pyrazoles may be used to synthesise pyrazole-3,5-dicarboxylic acid, which exhibits hypoglycaemic activity.



Sasaki et al.[132] described the synthesis of 5-cyano-3-(5-nitrofuryl)pyrazole in 36% yield from CA and 5-nitro-2-furyldiazomethane in ether at 20°C in the presence of triethylamine.

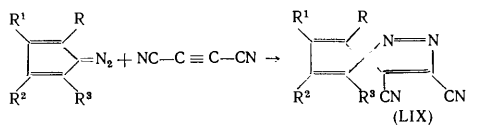
In 1969, Arnold and Thatcher[133] achieved the cyclisation of CA with aluminium azide and obtained a mixture of 4-cyano-1,2,3-triazole (LV) in 32% yield and 5-(1,2,3-triazolyl)-4-tetrazole (LVI) in 47% yield:

(LV) (LVI)



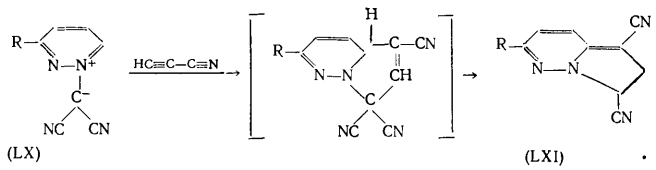
5-Cyanoisoxazole (LVII) has been obtained in 35% yield by the condensation of CA with the chloride of *m*-nitrophenylhydroxamic acid[134]:

(LVII)



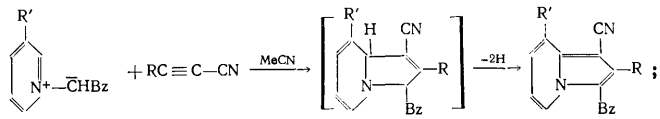
Weis[108] found that the addition of DCA to the *N*-oxide of benzonitrile or diazomethane leads respectively to 4,5-dicyano-3-phenylisoxazole in 81% yield or 3,4-dicyano-*N*-methylpyrazole in 99% yield. Ethyl 3,4-dicyanopyrazole-5-carboxylate (LVIII) has been synthesised from DCA

and ethyl diazoacetate [135] in 40% yield and then converted into 3,4,5-tricyanopyrazole:



(LVIII)

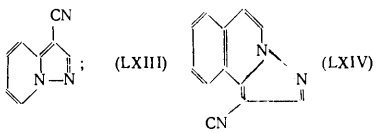
Various polycyclic adducts can be obtained by the reaction with diazo-compounds. For example, Dürr and coworkers [136,137] achieved the 1,3-dipolar cycloaddition of diazocyclopentadienes to DCA (20°C, 1–2 h) and obtained spiropyrazoles (LIX):



(LIX)

The 1,3-dipolar cycloaddition to CA to *N*-ylids (LX) in acetone (20°C, 4–12 h) results in the formation (in 30 to 80% yield) of pyrrolo[1,2-*c*]pyridazines (LXI):[138]

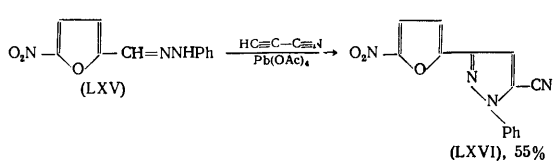
(LX) (LXI)



The analogous condensation of DCA with isoquinolinium ylid in dimethylformamide (DMF) leads to 1,2,3-tricyanopyrrolo[2,1-*a*]isoquinoline [139]. Sasaki et al. [140] achieved the 1,3-dipolar cycloaddition of CA and CCA to *N*-ylids and *N*-imines, but the yield of final products did not exceed 5–25%:

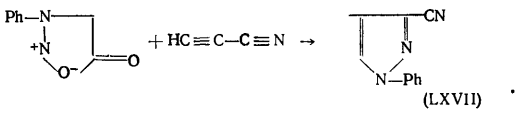
(LXII)

R=H, Cl; R′=H, or Me .



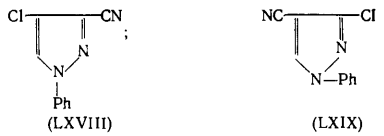
1-Aminopyridinium and 2-aminoisoquinolinium iodides react with CA in DMF (with added $K_2CO_3$) at 20°C, forming respectively 3-cyanopyrazolo[1,5-*a*]pyridine (LXIII) and 1-cyanopyrazolo-[5,1-*a*]isoquinoline (LXIV):

(LXIII) (LXIV)



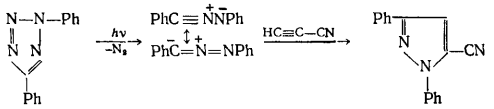
The interaction of pyridinium and triphenylphosphonium 1-cyclopentadienides with CA (−50°C, $N_2$) leads to the corresponding ylids of 1-(2-trans-β-cyanovinyl)cyclopentadiene.

5-Cyano-3-(5-nitro-2-furyl)-1-phenylpyrazole (LXVI) has been synthesised by the condensation of CA with the phenylhydrazone (XLV) in a THF–benzene mixture at 20°C in the presence of lead tetra-acetate [141]:



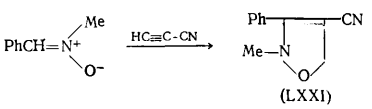
(LXV) (LXVI), 55%

Pyrazole (LXVII) has been obtained in satisfactory yield by the reaction of CA with *N*-phenylsydnone in chlorobenzene at 110°C:



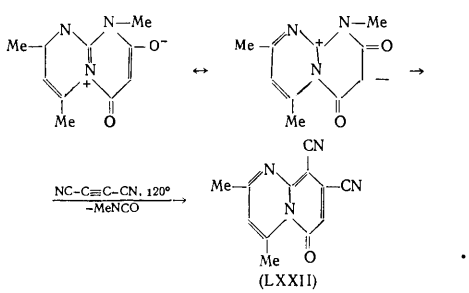
(LXVII)

Under analogous conditions, the reaction with CCA gives a 2:3 mixture of the isomeric pyrazoles (LXVIII) and (LXIX):



(LXVIII) (LXIX)

Diphenylnitrileimine [92], which was obtained by the ultraviolet irradiation of a solution of 2,5-diphenyltetrazole in THF, readily reacts with CA and yields 5-cyano-1,3-diphenylpyrazole (LXX):

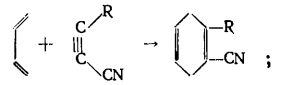


(LXX), 64%

Sims and Houk [142] established that CA reacts with *N*-methyl-*C*-phenylnitrone in benzene at 25°C to form exclusively 4-cyano-2(*N*)-methyl-3-phenylisoxazoline (LXXI), while the reaction with *N*-t-butylnitrone gives a 1:1 mixture of 4-cyano- and 5-cyano-*N*-t-butylisoxazolines:

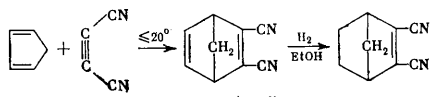
(LXXI)

DCA enters into a 1,4-cycloaddition reaction as an acetylenic dipolarophile with the anhydro-2-hydroxy-1,6,8-trimethyl-4-oxopyrimido[1,2-*a*]pyrimidinium system [143]—a new heteroaromatic betaine with condensed rings:



(LXXII)

## 8. α-Cyanoacetylenes in the Diels–Alder Reaction

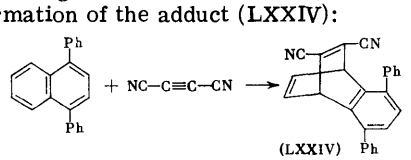


Diene synthesis is one of the convenient methods for obtaining cyclic and heterocyclic systems based on a wide variety of unsaturated compounds. CA and particularly DCA are used fairly frequently nowadays as dienophiles of the acetylenic series. The dienophilic activity of α-cyanoacetylenes is consistent with the fact that the rate of diene synthesis increases following the introduction of electron-donating substituents into the dienes and electron-accepting

substituents into the dienophiles, the reactions proceeding in accordance with the general mechanism

R=H, or CN .

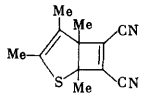
In 1945, Blomquist and Winslow [17] were the first to use DCA as a dienophile in the reaction with one of the commonest reactive dienes—cyclopenta-1,3-diene (CPD)—in order to obtain insecticides having the properties of pyrethrum:



(LXXIII), 83%

The adduct (LXXIII) was also obtained by other workers [22,144]. CA reacts with CPD with much more difficulty than does DCA: thus 1,3-dicyanobicyclo[2,1,2]hepta-1,3-diene is formed in 37% yield in petroleum ether (30°C, 12 h). [99] Subsequently numerous dienes with a wide variety of structures were introduced into diene synthesis with $\alpha$-cyanoacetylenes: butadiene [99,108], isoprene and chloroprene [93], allo-ocimene [145], cyclohexa-1,3-diene [22,108,144], 3-diphenylcyclohexa-1,4-diene [146], cyclo-octatetraene [108], fluorocyclo-octatetraene [147], furan [46,108], thiophen [148-150], benzene [151] and its derivatives (durene, veratrol, m-cresyl methyl ether, arsabenzene) [22,144,151,152], naphthalene and 1,4-diphenylnaphthalene [22,153], anthracene [22,108,154,155], 9,10-diphenylanthracene [156], naphthacene [157], dimethyl- and diphenyl-fulvenes [17,22], bicyclo[2,2,1]heptadiene [22,108], bicyclo[2,2,2]octa-2,5,7-triene [158], *cis*-bicyclo[6,1,0]nonatriene [159,160], spiro[2,6]nonatriene [161], norbornadiene [162], [2,2]paracyclophane [151], ergosteryl acetate [163], [8](2,5)furanophane [164], and 6-chloro-3-cyano-2,4-bis(dimethylamino)-pyridine [165].

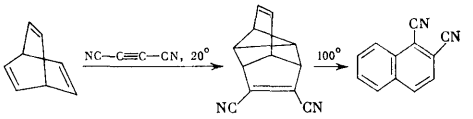
Benzene derivatives are relatively inert as dienes in Diels–Alder reactions, but are capable of condensing with DCA, the reaction having been shown by Ciganek [151] to be strongly accelerated by aluminium chloride. Thus, 2,3-dicyanobicyclo[2,2,2]octa-2,5,7-triene is formed in 14% yield in the reaction of benzene with DCA (180°C, 48 h), while in the presence of $AlCl_3$ at 20°C the yield is 63%. The condensation of DCA with hexamethylbenzene (in benzene, 130°C) is much faster than the condensation with unsubstituted benzene and gives a satisfactory yield of the desired product (83%).



DCA readily condenses with naphthalene [22], anthracene [22,108], and 1,4-diphenylnaphthalene [153], the attack in the last case being directed to the unsubstituted benzene ring with formation of the adduct (LXXIV):

(LXXIV)

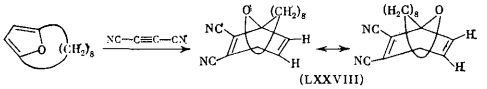
On being refluxed with anthracene (100°C, 1 h), DCA gives rise quantitatively to the 1 : 1 9,10-addition product [108], while the 2 : 1 adduct is formed in the reaction with 9,10-diphenylanthracene [156].



In contrast to benzene, thiophenes do not enter into the Diels–Alder reaction with acetylenes as dienes. In the study of the reaction of DCA and thiophen [148-150], a considerable influence of aluminium chloride on the mode of condensation was discovered. According to Wynberg and Helder [149], this involves a single-stage expansion of the thiophen ring to give thiepin (57% yield). Other workers showed by $^{13}C$ NMR that 2-thiabicyclo[3,2,0]hepta-3,6-diene (LXXV) is formed in this case, i.e. substituted thiophens undergo [2+2]-cyclo addition to DCA: [150]

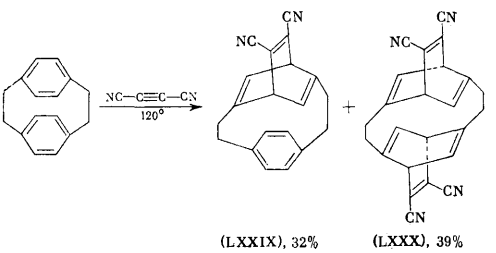
(LXXV)

The cycloaddition to $\alpha$-cyanoacetylenes of dienes such as norbornadienes [108,162], cyclohexa-1,4-diene [146], or barrelene [158] can be regarded as a kind of extension of the Diels–Alder reaction.



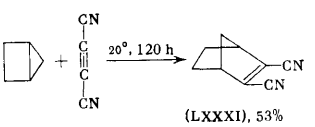
On condensation with DCA [158], barrelene is converted into the naphthalene derivative (LXXVII). The intermediate (LXXVI), isolated at lower temperatures, rearranges to 9,10-dihydronaphthalene, which is converted into the final product in 63% yield:

(LXXVI) (LXXVII)



Other cyclopolyenes [147,159-161] condense similarly with DCA.

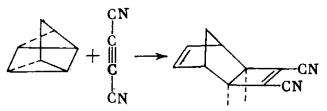
The Diels–Alder addition of DCA to certain cyclophanes [151,164] leads to unusual tricyclic systems (LXXVIII):



(LXXVIII)

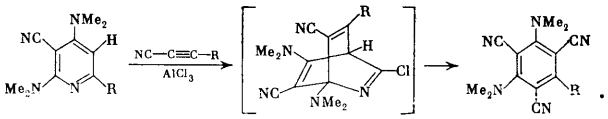
When DCA is heated with [2,2]paracyclophane [151], a mixture of the polycyclic products (LXXIX) and (LXXX) is formed:

(LXXIX), 32% (LXXX), 39%



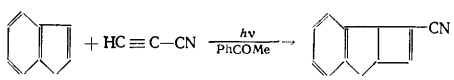
Strained alicyclic systems readily undergo the Diels–Alder reaction with DCA. Thus DCA adds to bicyclo[2,1,0]pentane [166,167] with rupture of the three-membered ring to form the adduct (LXXXI):

(LXXXI), 53%



Tricyclo[4,1,0,$0^{3,7}$]heptane [168] reacts with DCA under more severe conditions (70°C, 14 h) to form a 1 : 1 adduct (via a radical mechanism). "Propellerane" or tricyclo-[3,2,1,$0^{1,5}$]octane, synthesised by Gassman et al. [169], reacts very vigorously with DCA at 20°C and somewhat more slowly at −78°C. The reaction of quadricyclane [170] with

DCA in methylene chloride is exothermic and leads to the formation of the 1 : 1 adduct (LXXXII) in 78% yield:



(LXXXII)

On heating in the presence of a small amount of $AlCl_3$, CA reacts with 6-chloro-3-cyano-2,4-bis(dimethylamino)-pyridine[165]. The reaction proceeds via a cyclic intermediate (D) and terminates with formation of 1,3,5-tricyano-2,4-bis(dimethylamino)benzene (LXXXIII):

R = H, Cl (D) (LXXXIII), 4%

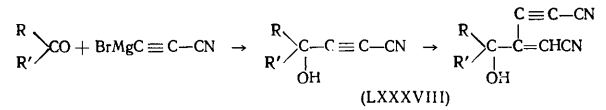
When Indene and CA were photolysed[171,172] in benzene in the presence of a sensitiser (acetophenone), cyanocyclobutene (LXXXIV) was obtained in a satisfactory yield:

(LXXXIV)

## 9. Cyanoacetylene in Substitution Reactions

The mobility of the hydrogen atom in CA is caused not only by the very nature of the acetylenic linkage but also by the presence of the electron-accepting cyano-group. Thus the acidity of the acetylenic hydrogen in CA is reflected in its distinct ability to form hydrogen bonds not only with typical basic proton acceptors, but also with the electrons of the triple bond (self-association)[50]. The tendency of CA to undergo substitution reactions is shown primarily in its reaction with metals. Thus copper cyanoacetylide[21] has been obtained as a yellow deposit when a CuCl solution in aqueous ammonia was treated with CA. The attempt to obtain the sodium derivative of CA in liquid ammonia was unsuccessful[25]. Lithium cyanoacetylide[25] has been obtained from butyl-lithium and CA at −70°C. The magnesium bromide derivative of CA (LXXXV) is formed smoothly at a reduced temperature in absolute ether and can react virtually with all reagents capable of involvement in organomagnesium syntheses[173]. In the presence of CuCl, compound (LXXXV) reacts with organic halides, for example with allyl bromide:

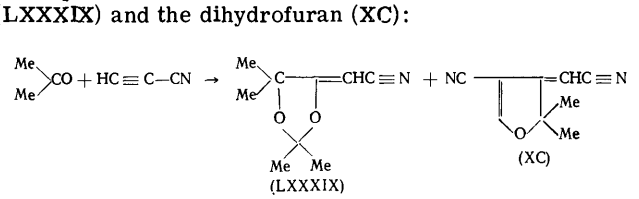
$$\underset{\text{(LXXXV)}}{BrMgC\equiv C-CN} + H_2C=CHCH_2Br \xrightarrow{THF,\ Et_2O} \underset{\text{(LXXXVI)}}{H_2C=CHCH_2-C\equiv C-CN}$$



When compound (LXXXV) is treated with phosgene, bromocyanoacetylene is formed, while treatment with ethyl chlorocarbonate results in the formation of 1,6-dicyano-3-ethoxyhex-2-en-4-yne. Acetic anhydride adds to the triple bond of complex (LXXXV) and gives rise to 2,3-diacetyl-3-bromoacrylonitrile. *trans*-Acrylonitriles (LXXXVII) have been obtained by the reactions with epoxyethane and epoxypropane:

$$BrCH_2CHOCH=CHCN$$
$$\quad\quad|$$
$$\quad\quad R$$

(LXXXVII)



R=H, or Me .

Carbonyl compounds (acetone, cyclohexanone, formaldehyde, etc.) react with compound (LXXXV) to form the corresponding carbinols (LXXXVIII), which can undergo further reactions involving the addition of another CA molecule[173]:

(LXXXVIII)

The reaction of CA with acetone[173] in the presence of a 20% aqueous solution of NaOH leads to the dioxolan (LXXXIX) and the dihydrofuran (XC):

(LXXXIX) (XC)

The magnesium iodide derivative of CA gives cyanoiodoacetylene and not CCA on treatment with toluene-*p*-sulphenyl chloride[25]:

$$IMgC\equiv C-CN + p\text{-}CH_3C_6H_4SO_2Cl \rightarrow IC\equiv C-CN$$

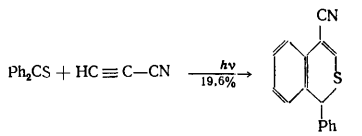
CCA can be obtained only via lithium acetylide:

$$HC\equiv C-CN \xrightarrow{BuLi} LiC\equiv C-CN \xrightarrow[30\%]{Cl_2} ClC\equiv C-CN$$

In contrast to CCA, bromo- and iodo-cyanoacetylenes are obtained by the reaction of CA with bromine or iodine respectively, in aqueous alkaline solutions of KBr and KI in yields of 40–60%[174].

The dimerisation of CA is known[27] to occur in the presence of potassium hexacyanoferrate (III). The same method can be used for asymmetric coupling. Thus, Jones and coworkers[175] described the synthesis of 7-cyanohept-2-ene-4,6-diynol from CA and pent-2-en-4-ynol. The acetylenic compounds are initially converted into copper acetylides and then treated with potassium hexacyanoferrate(III).

It has been shown recently[176] that CA can also undergo the Chodkiewicz condensation, but its use is limited by the occurrence of side reactions and the instability of the products. CA has been used successfully in the synthesis of a natural acetylene analogue (XCI):



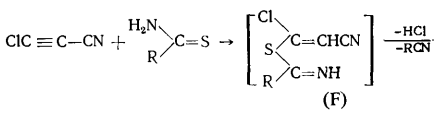
$$NC-C\equiv CH + BrC\equiv C(CH_2)_3OH \xrightarrow{CuCl,\ NH_2OH\cdot HCl,\ EtNH_2} \rightarrow [NC-C\equiv C-C\equiv C(CH_2)_3OH] \rightarrow \underset{\text{(XCI), 9\%}}{NC-C\equiv C-CH=C(CH_2)_3O}$$

5-Aminoisoxazole was isolated as a side product[176].

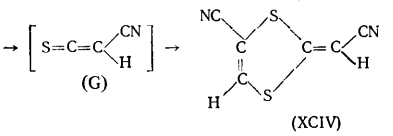
## 10. Other Reactions of α-Cyanoacetylenes

Apart from those already discussed, a number of non-general reactions of α-cyanoacetylenes have been described.

On being irradiated with light from a sodium lamp, CA undergoes photocycloaddition to diphenyl thione[177] with formation of compound (XCII):



(XCII)



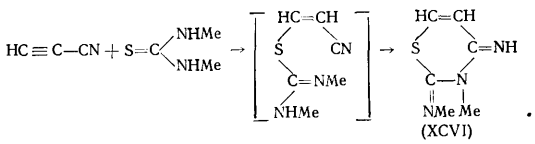
The high-temperature reaction of benzene with CA proceeds with a low conversion (1–2%), benzonitrile and biphenyl having been isolated from the reaction products[178]. When CA was allowed to react with a formate ester[179] in the presence of $HgCl_2$ or $CuCl_2$–$Zn(Ac)_2$, the cyanoacrylate (XCIII) was obtained:

$$HC\equiv C-CN + HCOOR \rightarrow NC-CH=CHCOOR \quad (XCIII)$$

Sasaki et al.[180] found that the reaction of equimolar amounts of CCA and thioacetamide in methanol at 0°C leads to 1,4-dithiofulvene (XCIV). CCA reacts similarly with other thiocarbonyl compounds: thiourea, *NN*-dimethylthiourea, and *N*-phenylthiourea:

(F)

(G)



(XCIV)

The authors believe that the reaction begins with nucleophilic attack by the thiocarbonyl group on the triple bond with formation of an intermediate (F), which loses a molecule of hydrogen chloride and RCN, is converted into the unstable thioketen (G), and dimerises to compound (XCIV).

The reaction of CA and methyl- and phenyl-cyanoacetylenes with thiourea and ammonium dithiocarbamate[181] in alcohol proceeds stereospecifically and results in the synthesis of *cis,cis*-thiodiacrylonitriles (XCV):

$$RC\equiv C-CN + H_2NCSNH_2 \text{ or } H_2NCS_2NH_4 \rightarrow NC-CH=C(R)SC(R)=CHCN \quad (XCV)$$

Sasaki et al.[180] found that other thiocarbonyl compounds (thioacetamide and *N*-phenyl-, *N*-methyl-*N'*-phenyl-, and *NN'*-diphenyl-thioureas) react with CA under analogous conditions in methanol or acetone solution to form thiodiacrylonitriles in 70–90% yield. The reaction with *NN'*-dimethylthiourea led to the isolation of 4-imino-3-methyl-2-methylimino-2,3-dihydro-1,3-thiazin (XCVI) in 60% yield:

(XCVI)

Bushby[182] described the reaction between DCA and ethers. On heating for 16 h a mixture of DCA and THF, he obtained tetrahydro-2-furylfumaronitrile (37% yield), the photochemical isomerisation of which leads to the formation of tetrahydro-2-furylmaleonitrile. 1-Ethoxyethylfumaronitrile was obtained similarly in 48% yield from diethyl ether and DCA, while 1,2-dimethoxyethane gave a mixture of 1,2-dimethoxyethylfumaronitrile (6%) and (2-methoxyethoxy)methylfumaronitrile (6% yield).

Reddy and Weis[183] obtained the product of the addition of DCA to triphenylphosphine (in acetonitrile at 25–30°C) having the structure of 1,2,3,4,5,6-hexacyanohexa-2,4-diene-1,6-diylidene-1,6-bistriphenylphosphorane according to revised data[184].

## 11. The Polymerisation of Cyanoethylenes

New polyconjugated systems have been obtained on the basis of CA [185,186], namely polypropiolonitrile and its copolymer with phenylacetylene, which exhibit a high thermal stability and electrical resistance.

A number of workers [187–191] have shown that, at a reduced temperature, CA forms low-molecular-weight polymers under the influence of anionic catalysts. For example, the polymerisation of CA and its copolymerisation with acrylonitrile are initiated by $CH_3ONa$ or KSCN.[189] It is believed that the polymerisation involves the acetylenic linkage, since the polymers readily interact with $H_2O_2$ via the cyano-group, forming amides. In another instance, the polymerisation of CA was initiated by BuLi.[191] The polymerisation of CA in the presence of Ziegler–Natta catalysts[192] leads to a mixture of trimethylsuccinonitrile and polypropiolonitrile in a low yield. It has been established by infrared spectroscopy that polypropiolonitrile has the structure $[-CH=C(CN)-]_n$.

In the presence of initiators of free-radical polymerisation in THF solution, CA forms copolymers with olefinic compounds, for example *N*-vinylcarbazole[193].

Chukhadzhyan and coworkers [194,195] showed that $\pi$-allyl derivatives of nickel are active catalysts of the polymerisation of CA. They believe that the polymerisation proceeds via the triple bond of the acetylenic group; the resulting polymer has a conjugated chain of double bonds with a *trans*-structure, which has been confirmed by infrared spectra and a number of chemical reactions.

The homopolymerisation of DCA was achieved for the first time[196] in the presence of an anionic catalyst, namely butyl-lithium (in heptane–THF at –73°C) and led to the formation of a powdered polymer in 90% yield. The infrared spectra of the latter showed absorption bands characteristic of systems of conjugated bonds with cyano-groups, while the ESR spectrum contained a single narrow signal without a definite structure (the number of unpaired electrons is approximately $10^{18}$ per gram). The polymerisation of DCA in the presence of lithionaphthalene proceeds with a large exothermic heat change, requires large amounts of the catalyst, and results in the formation of oligomers (having molecular weights in the range 400 to 500) soluble in acetone, alcohols, DMF, THF, water, and sulphuric acid and having a resistivity (*in vacuo* at 20°C) of approximately $10^9$–$10^{12}$ $\Omega$ cm.[197]

Byrd[49,198] homopolymerised DCA under free-radical conditions [in the presence of 2-azobisisobutyrodinitrile (ABIBN) for 1400 h at 55°C], the yield of the polymer being 7%. In the copolymerisation of DCA with styrene in THF, acetone, or toluene in the presence of the same catalyst, the conversion reached 80–97%.

Rembaum and Henry[199] proposed a method for the synthesis of the DCA copolymers with various vinyl (5–90 wt.%) compounds: styrene, methyl methacrylate, butadiene, isoprene, isobutene; acrylonitrile, ethylene, and propene. The polymerisation is carried out in polar organic solvents (THF, dioxan, ethyl methyl ketone, etc.) in the presence of ABIBN, benzoyl peroxide, t-butyl hydroperoxide, butyl-lithium, butylmagnesium bromide, and sodionaphthalene (for 10–30 h at 40–70°C and $10^{-5}$ mmHg, yield 70–95%). The resulting copolymers exhibit a moderate thermal stability (they are stable up to 280°C) and are semiconductors, which permits their employment in transistors and solar batteries.

# Gas-chromatographic Analysis of Metals as Volatile Complexes

D.N.Sokolov

The use of gas-chromatographic methods for analysing metals is considered. Attention is paid mainly to study of the gas-chromatographic properties of compounds of metals with various derivatives of β-diketones as well as complexes with thioketones and derivatives of β-ketoimines. Attempts to separate the rare-earth metals gas-chromatographically are examined, together with highly sensitive gas-chromatographic methods for determining traces of metals (beryllium, aluminium, chromium, etc.). A list of 78 references is included.

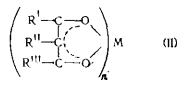
## I. INTRODUCTION

During the period covered by the Review, from the end of 1970 to the beginning of 1975, more than seventy publications appeared on the gas chromatography of volatile compounds of metals, including several reviews[1-7] and one monograph[8]. Certain changes in the general approach to the problem have been noticeable during the past five years. Whereas before 1970 the studies in this field were often in the nature of preliminary investigations, the possibilities of the method have now become clear, and the aims more definite. Most of the papers report comparative investigations of the chromatographic properties of volatile complexes of metals having a common feature (usually either complexes of a series of metals with the same ligand or, in contrast, of a series of ligands with the same metal). The authors have usually tried to find either new volatile complexes, with better properties, of metals that have already been chromatographed, or volatile compounds of metals that had previously proved impossible to chromatograph. Thermogravimetric analysis is widely used to assess the volatility of complexes. Papers on the gas-chromatographic separation of rare-earth metals form a special group. The number of papers on the practical application of the gas chromatography of chelates to the determination of traces of such metals as beryllium, aluminium, chromium, etc. has increased. Finally, a few studies have been made on the specific behaviour of metal chelates in chromatographic columns.

## II. COMPLEXES WITH β-DIKETONES

### 1. Simple β-Diketonates

Many papers have appeared on the further study of metal β-diketonates of the type



(I)

where $n$ is the charge on the metal ion. The list of complexes investigated has expanded appreciably during recent years. The interest of research workers in the hitherto popular derivatives of hexafluoropentane-2,4-dione and 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dione diminished somewhat, after which the number of investigations on non-fluorinated β-diketonates increased, especially on derivatives of 2,2,6,6-tetramethylheptane-3,5-dione (dipivaloylmethane) $CH_3.C(CH_3)_2.CO.CH_2.CO.C(CH_3)_2.CH_3$. Thermogravimetric analysis has been used[9,10] to study the volatility and investigate the chromatographic behaviour of chelates of this dione with twenty-five metals, including rare-earth elements, nickel(II), cobalt(II), and zinc(II). In a long paper on the investigation of complexes of chromium(III), aluminium(III), iron(III), palladium(II), copper(II), nickel(II), zirconium(IV), rare-earth metals, uranyl(II), and thorium(IV) with various β-diketones, Kuwamoto[11] also paid great attention to chelates with this dione. In particular, thermogravimetric analysis showed that only neodymium(III) and zirconium(IV) among the above metals, as well as sodium, give chelates that decompose partly on sublimation: all the remaining chelates sublime without decomposition. Numerous chelates of metals with pentane-2,4-dione, its hexa- and tri-fluoro-derivatives, and other β-diketones were also studied. The first chromatogram of a zinc(II) chelate with the above tetramethylheptanedione was reported in this paper.

Investigations on the gas-chromatographic properties of complexes of beryllium, aluminium, scandium, vanadyl(II), chromium(III), iron(III), copper(II), and manganese(II) with 1-thienyltrifluorobutane-1,3-dione[12] and of beryllium, aluminium, iron(III), indium, chromium(III), cobalt(III), thorium(IV), and several rare-earth elements with trifluoro-5,5-dimethylhexane-2,4-dione[13] in the main merely confirmed already known laws and gave no fundamentally novel results, apart from the first chromatogram of a chelate of cerium(IV) with the latter dione[13]. The same applies to a detailed examination[14] of chelates of aluminium, gallium, and indium with pentane-2,4-dione and its alkyl derivatives, hexafluoropentane-2,4-dione, 1-phenyltrifluorobutane-1,3-dione, 1-furyltrifluorobutane-1,3-dione, and 1-thienyltrifluorobutane-1,3-dione. The chromatographic behaviour of chelates of several metals—in particular

beryllium, aluminium, chromium, and copper—with alkylated β-diketones of the type

(II)

has been investigated for the first time [11,14,15]. Unfortunately, the replacement of hydrogen by any alkyl as R'' lowers the volatility of the complex and thereby impairs its gas-chromatographic properties, since there is evidently no accompanying improvement in thermal stability. The introduction of fluorinated radicals as R'' might have given more interesting results, but such chelates have not yet been investigated.

## 2. Complexes with Mixed Ligands

Recent years have seen a considerable increase in the number of gas-chromatographic studies of mixed-ligand metal complexes, fluorinated β-diketonates containing also one or two molecules of neutral donors such as dimethylformamide (DMF), dimethyl sulphoxide (DMSO), tributyl phosphate (TBP), diethylamine, etc. The gas-chromatographic behaviour of complexes of nickel(II) and cobalt(II) with trifluoropentane-2,4-dione and dimethylformamide having the composition $ML_2.2DMF$ (where L is a singly charged ligand anion) has been investigated [16]. Quantitative determination of each complex to 0.2 mg proved possible, with separation effected at a relatively low temperature (100°C). The gas chromatography of volatile mixed complexes of zinc $ZnL_2.A$ (where A is a molecule of tri-n-butyl phosphate or tri-n-butylphosphine oxide—TBPO) has also been described [17]. Furthermore, the same paper reported the gas-chromatographic behaviour of mixed chelates of zinc with trifluoropentane-2,4-dione and 4-methylpyridine and with pentane-2,4-dione and 2,2'-bipyridyl. The best results were obtained with the chelate having the composition $ZnL_2.TBPO$.

Investigations have been made on mixed complexes $UO_2L_2.DBSO$ and $ThL_4.DBSO$ formed by uranyl and thorium(IV) with hexafluoropentane-2,4-dione and dibutyl sulphoxide [11] and on complexes of analogous composition with 1,1,1,2,2,6,6,7,7,7-decafluoroheptane-3,5-dione, hexafluoropentane-2,4-dione, and trifluoropentane-2,4-dione with neutral donors (dibutyl sulphoxide, tributyl phosphate, and tributylphosphine oxide). [18] The best results were obtained with hexafluoropentanedione and dibutyl sulphoxide: use of these complexes enabled uranium and thallium at concentrations of 1–120 g litre$^{-1}$ to be determined in solutions with a relative error $< 10\%$. The limiting dilutions for uranium and thorium were respectively 0.6 and 0.4 g litre$^{-1}$.

Jacquelot and Thomas [19] chromatographed mixed complexes $ML_2.2(C_2H_5)_2NH$ of nickel(II) and cobalt(II) with 1-thienyltrifluorobutane-1,3-dione and diethylamine, but the form of the peaks left much to be desired. Furthermore, nickel and cobalt could not be separated, since the two complexes had almost the same retention times. It is interesting that these workers treated the solid carrier with potassium hydroxide to improve the chromatogram. This was probably the first use of this procedure in the gas chromatography of metal chelates.

The properties of complexes of iron(II) and iron(III) with hexafluoropentanedione and tributyl phosphate, as well as their chromatographic behaviour, have been examined in detail [20]. Iron(II) forms a complex $FeL_2.2TBP$, while iron(III) yields $FeL_3$ and $FeL_3.TBP$, with in the latter case one of the hexafluoropentanedione anions ($L^-$) acting as a unidentate ligand. During chromatography the compound $FeL_2.2TBP$ dissociates in the gas phase, but iron(III) present in the complex $FeL_3.TBP$ is reduced in the chromatographic column to iron(II).

Burgett [21] has studied the gas-chromatographic behaviour of complexes $ML_2.2DBSO$ of iron(II), cobalt(II), and nickel(II) with decafluoroheptanedione. He includes results for the chromatographic behaviour of the copper chelate $CuL_2$ with the same ligand. The ion $Cu^{2+}$ does not form complexes having mixed ligands. In the chromatography of small quantities the form of the peaks of all the complexes studied was distorted. The peak of the copper chelate changed form also in the presence of mixed complexes of nickel(II) and cobalt(II).

## 3. Binary Complexes

Studies have been made not only on complexes having mixed ligands but also on volatile binary complexes, which contain more than one identical ligand and ions of two different metals. The latter complexes are usually formed only from fluorinated β-diketones. Belcher et al. [22] showed that, in the presence of excess of the ligand, chelates $ML_3$ of rare-earth metals with fluorinated β-diketones react with alkali-metal cations M' to form complexes $M'ML_4$. The products sublimed in a vacuum without decomposition, but evidently could not be used for gas chromatography. Gurevich et al. [23] prepared volatile complexes $M'CoL_3$ (in which $M' = K^+$, $Rb^+$, $Cs^+$, while L represents a hexafluoropentanedione anion), obtained chromatograms of individual compounds, and effected the gas-chromatographic separation of potassium and rubidium complexes on a stainless-steel column 200 × 0.1 cm containing 1% of Silicone SE-30 on Chromaton N at 250°C. It is interesting that retention of the binary complexes diminished in the sequence from potassium through rubidium to caesium. No mention was made [23] of the possibility of using the resulting complexes for quantitative analysis.

## 4. Separation of Rare-earth Metals

The excellent results obtained when gas chromatography is used to separate compounds of closely similar properties naturally suggest the possible application of this method to solve one of the most difficult problems of analytical chemistry, separation of the rare-earth metals. Volatile complexes of these elements with dipivaloylmethane suitable for use in gas chromatography were first prepared in 1965. [24] Since then researches on the gas-chromatographic properties of various volatile rare-earth β-diketonates have been published regularly, but significant progress in this field has evidently not yet been made. Japanese workers have been responsible for the largest number of papers on the gas chromatography of the rare-earth metals; they have studied complexes with tetramethylheptane-3,5-dione [9–11,25,26], trifluorodimethylhexane-2,4-dione [13], and the latter together with a neutral donor (tributyl phosphate or tri-n-octylphosphine oxide) [27]. Interesting papers on the gas chromatography of mixed-ligand complexes of rare-earth metals have been published by Burgett and Fritz [28–30] and by Sieck and Banks [31].

However, the main task—complete separation of the whole group of rare-earth metals—remains unsolved. Only one case of the separation of chelates of two neighbouring rare-earth metals (complexes of europium and

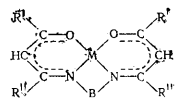
samarium with dipivaloylmethane)[22], on a column of 2% of a fluorinated silicone oil on Chromosorb G only 45 cm long with temperature programming has been reported. This work was published in 1969, but other workers have evidently been unable to repeat the separation, and publications during recent years represent in most cases the chromatograms of rare-earth metals taken singly, but in some cases as mixtures of two or three elements[25,27-29,31].

Comparison of papers by the same group of workers over several years (1968–1972) shows that the use of complexes with various β-diketones has not yielded any significant improvement in the separation of rare-earth metals[26,27,32]. Recently several investigators have again returned to the study of the dipivaloylmethane complexes, but without especial success[9,10,25]. It is stated[9,10] that a most efficient column is required for the separation of a mixture of lutetium and ytterbium chelates (> 11 000 theoretical plates), whereas 650 theoretical plates are sufficient to separate neodymium and praseodymium chelates. However, despite the availability of such an inefficient column, no attempt was made to achieve even this separation, undoubtedly owing to the additional difficulties encountered in solving the problem. In particular, attempts to improve the efficiency of separation of rare-earth chelates by lengthening the column resulted in broadening of the peaks, so that the separation not only did not improve but even deteriorated. According to other workers[29] the optimum column length is ~ 50 cm. This is probably why columns not longer than 70–75 cm have been used in most attempts at the separation of rare-earth complexes[13,25-27].

## III. VOLATILE COMPLEXES WITH LIGANDS CONTAINING OXYGEN TOGETHER WITH SULPHUR AND WITH NITROGEN

### 1. Derivatives of 4-Thionopentan-2-one

The first research on the gas chromatography of volatile chelates of metals with thioacetylacetone—a ligand containing oxygen and sulphur as donors $CH_3.CS.CH_2.CO.CH_3$—was undertaken by Stephen et al.[33] in 1969. Investigations on these lines have since been continued. In a detailed examination of bivalent compounds of nickel, zinc, cadmium, lead, palladium, platinum, and cobalt with thioacetylacetone Belcher et al.[34,35] found that most of them are monomeric $ML_2$, in contrast to the complexes of these metals with β-diketones, which in most cases are polymeric or hydrated. These workers established that the volatility of the chelates diminished in the sequence



$$\text{nickel} > \text{zinc} > \text{cobalt} > \text{palladium}$$

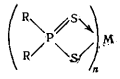
where only the nickel(II) chelate vaporised completely without decomposition. However, even it was unsuitable for the gas-chromatographic determination of small quantities of the metal. Considerably better gas-chromatographic properties were observed in chelates of several bivalent metals with fluorinated derivatives, e.g. trifluoro-4-thionopentan-2-one[35-37]. Thus chelates of the latter with nickel(II), zinc(II), and cobalt(II) sublimed completely, and those with palladium(II) and platinum(II) by 85% and 65% respectively[36]. These workers were able to separate the nickel, palladium, and platinum chelates on a column comprising 2.5% of Apiezon L on Universal B at 170°C. In a later study[38] the same workers used the nickel(II) complex of trifluorothioacetylacetone for the gas-chromatographic determination of traces of nickel (down to $5 \times 10^{-11}$ g) in alloys, tea, and fats using an electron-capture detector.

Bayer et al.[39,40] investigated the gas-chromatographic behaviour of chelates of nickel(II), palladium(II), and platinum(II) with another sulphur-containing ligand, hexafluoro-4-thionopentan-2-one. The resulting chelates were far more volatile than those with the trifluoro-derivative, and their gas-chromatographic separation was achieved on columns with 1% of SE-30 and with 3% of OV-17 on Chromosorb W at only 80°C. It is interesting that many metals that form very stable chelates with β-diketones (beryllium, aluminium, chromium, etc.) do not react at all with fluorinated β-thioketones such as trifluorothioacetylacetone.

### 2. β-Ketoiminates

The first paper on the gas chromatography of volatile β-ketoiminates of copper(II) and nickel(II) was published in 1967.[41] Since 1971 several interesting studies have appeared by Belcher, Uden, et al.[42-47] Especially promising results were obtained for the bivalent nickel, copper, palladium, and platinum complexes with quadridentate β-ketoimines

where B = $[CH_2]_2$, $[CH_2]_3$, or $CH_2.CH(CH_3)$, R′ = $CH_3$, and R″ = $CH_3$ or $CF_3$. The vapour pressure of such chelates is low, and they had to be chromatographed at high temperatures (up to 250°C), but their thermal stability resulted in almost complete absence of decomposition in the column.



Comparative studies on complexes of copper(II) and nickel(II) with bi- and quadri-dentate β-ketoimines showed that the gas-chromatographic behaviour of the latter was to be preferred, especially in the chromatography of small quantities of the complexes. In particular, the gas-chromatographic determination of copper and nickel in quantities down to $10^{-13}$ g was achieved[46,47]. An interesting fact was revealed by examination of the chelates of these metals with quadridentate ligands containing oxygen and nitrogen. The replacement of terminal alkyl by perfluoroalkyl groups in β-diketones leads in all known cases to an increase in the vapour pressure of the corresponding metal chelates, a rule which is satisfied also for bidentate β-ketoiminates. With quadridentate β-ketoimine complexes (the bivalent copper and nickel complexes were investigated), however, the opposite relation is unexpectedly observed: i.e. the introduction of terminal trifluoromethyl groups into the ligand does not increase but lowers the volatility of the copper(II) and nickel(II) β-ketoiminates[46,47]. No explanation has yet been found for this fact.

## IV. OTHER VOLATILE METAL COMPOUNDS

In 1969 D'Ascenzo and Wendlandt[48] suggested that the gas chromatography of copper, nickel, and zinc could be effected by use of the diethyldithiocarbamates, supposedly possessing adequate volatility. When tested, however, this suggestion proved unfortunate, and was rejected[49]. Barratt et al.,[50] examined the suitability for gas chromatography of volatile beryllium and zinc hydroxyacetates and hydroxypropionates $M_4OR_6$, where R = $CH_3COO^-$ or $C_2H_5COO^-$. They were able to separate the beryllium and

zinc complexes on a glass column with 5% of Apiezon L on Universal B at 150°C. However, the chromatographic properties of the compounds leave much to be desired.

Kleinmann and Neeb[51] chromatographed complexes of gold(I), cadmium(II), and zinc(II) with dialkyldithiophosphines

where R = $CH_3$, $C_2H_5$, and $C_3H_7$. They were able to obtain peaks of the individual complexes and to separate the diethyl-, dipropyl-, and dibutyl-dithiophosphinate complexes of zinc(II) on a glass column with 3% of Silicone OV-225 on Chromosorb W at 220°C. From the form of the peaks the gas-chromatographic properties of these chelates are apparently also far from ideal. Nevertheless, the chromatogram obtained is interesting in demonstrating the kinetic stability of the zinc complexes: otherwise, the chromatogram would have indicated the presence of mixed complexes formed by ligand exchange.

The possibility of the gas-chromatographic determination of certain metals as volatile trimethylsilyl derivatives of anions containing the metal is of interest. Thus a paper on the gas-chromatographic analysis of anions[52] mentions among others the possible determination of the vanadate ion $VO_3^-$. Since many metals—aluminium, chromium, manganese, niobium, tantalum, molybdenum, tungsten, bismuth, lead, tin, etc.—may occur as anions, this raises the hope that new methods may appear for the gas-chromatographic analysis of metals.

Finally, we must note the possibilities that have appeared for the quantitative determination of metals as volatile organometallic compounds. Such compounds had hitherto been regarded as of little interest for the gas-chromatographic analysis of metals, since in most cases quantitative conversion of the metal into the compound could not be achieved. Recently, however, exceptions have appeared to this rule. The first such work was published in 1968 by Bock and Monerjan on the determination of thallium as its cyclopentadienyl derivative[53]. However, as yet this is the only publication on the use of cyclopentadiene derivative in this way. Two interesting papers have appeared on the gas chromatography of several elements—thallium, selenium, tellurium, mercury, arsenic, antimony, bismuth, and tin—as their phenyl derivatives $(C_6H_5)_nM$.[54,55] It is very important that phenyl derivatives of all the above elements (other than thallium) are readily obtained quantitatively by the reaction of phenylmagnesium bromide with diethyldithiocarbamates of the metals in absolute ether. The phenyl derivatives of selenium, tellurium, mercury, arsenic, antimony, and bismuth were separated on a column comprising 5% of Carbowax 20M with added terephthalic acid on Gasochrome Q with a programmed temperature rise from 180 to 220°C (10 deg $min^{-1}$), and also those of thallium, selenium, and tellurium on a column with 3% of Silicone OV-17 on Gasochrome Q under isothermal conditions at 160°C. Further research on these lines may lead to the development of quantitative gas-chromatographic methods of analysis for the above and other elements.

## V. GAS-CHROMATOGRAPHIC ANALYSIS OF TRACES OF METALS

The chief practical value of the gas-chromatographic analysis of volatile compounds of metals consists in the high sensitivity attainable in the determination of chelates of several metals by means of such devices as an electron-capture detector or a microwave emission detector. Gas-chromatographic analysis is comparable in sensitivity with such highly sensitive methods as neutron-activation analysis, mass spectrometry with a spark source, and flameless atomic-absorption spectroscopy, sometimes even surpassing them.

During recent years several papers have been published on the practical application of the gas-chromatographic determination of traces of certain metals as volatile chelates. Descriptions have appeared of the gas-chromatographic determination of beryllium in air[56], terrestrial and lunar rocks and meteorites[57], in the leaves of trees[58], and in various biological materials[59,60], aluminium and chromium in uranium[61], aluminium in sea-water[62] and in polymers[63], nickel in alloys, tea, and fats[38], nickel and copper in biological materials[46], cobalt in vitamin $B_{12}$,[64] and chromium in aqueous solutions[65] and in various biological materials[66-69]. Chelates with trifluoropentane-2,4-dione have been most widely used, but other complexes have also found application[38,46,63,64].

Use of volatile complexes of metals in analysis of traces of elements.

| Element | Ligand | $10^{10}$ x Limit of detection, g | Ref. |
|---|---|---|---|
| Al | trifluoropentane-2,4-dione | 0,009 | 63 |
| | trifluoro-5,5-dimethylhexane-2,4-dione | 0,04 | 63 |
| As | phenyl | 4 | 54 |
| Be | trifluoropentane-2,4-dione | 0,0004 | 57 |
| Co | heptafluoro-7,7-dimethyloctane-4,6-dione | 0,4 | 64 |
| Cr | trifluoropentane-2,4-dione | 0,0025 | 68 |
| | pentane-2,4-dione | 0,03 | 71 |
| Cu | trifluoropentane-2,4-dione | 0,08 | 71 |
| | quadridentate β-ketoimines | 0,001 | 46 |
| Fe | trifluoropentane-2,4-dione | 0,13 | 71 |
| Ga | trifluoropentane-2,4-dione | 0,027 | 71 |
| Ni | trifluoro-4-thionopentan-2-one | 0,5 | 38 |
| | quadridentate β-ketoimines | 0,007 | 46 |
| Pd | trifluoro-4-thionopentan-2-one | 2 000 | 36 |
| Pt | trifluoro-4-thionopentan-2-one | 3 600 | 36 |
| Sc | pentane-2,4-dione | 0,021 | 71 |
| | trifluoropentane-2,4-dione | 0,03 | 71 |
| Th | hexafluoropentane-2,4-dione + tributylphosphine oxide | 8 000 | 18 |
| Tl | cyclopentadiene | 10 000 | 53 |
| U | hexafluoropentane-2,4-dione + tributylphosphine oxide | 12 000 | 18 |
| V | trifluoropentane-2,4-dione | 0,085 | 71 |
| Rare-earth metals | decafluoroheptane-3,5-dione + dibutyl sulphoxide | 200—300 | 28 |

Highly sensitive devices other than the electron-capture detector are beginning to be used for the determination of microquantities of chelates, including mass-spectrometric[70], microwave emission[71-74], and flame-photometric[69] detectors. An atomic-absorption spectrometer with flameless atomisation can be used for the detection of volatile compounds of metals[75]. The Table lists data on the use of metal chelates in quantitative gas-chromatographic analysis.

## VI. BEHAVIOUR OF METAL CHELATES IN A CHROMATOGRAPHIC COLUMN

Volatile complexes of metals are extremely capricious in chromatographic behaviour. Hitherto no objective methods have been available for assessing the suitability of a particular chelate for quantitative gas-chromatographic analysis. The widely used thermogravimetric

analysis permits merely comparison of the relative volatilities of two or more chelates and may indicate whether a given chelate will sublime without decomposition. Quite often a chelate that appears to be "ideal" from thermogravimetric data proves to be unsatisfactory for gas chromatography.

Especially marked departures from "ideality" are observed in work with small quantities of the substance. The literature is full of descriptions of such phenomena as irreversible sorption of the initial portions of chelates in columns[30], distortion of the form of the peak and diminution in the efficiency of the column as the sample becomes smaller[21], redox reactions in the column[20], non-linearity of the calibration curve on dilution of the test solutions (the curve does not pass through the origin)[30,34,38,73], sorption of the chelate by the surface of the liquid phase[30,76], displacement of one sorbed chelate by another[30], anomalous broadening of the chelate peaks with lengthening of the column[29], etc. The anomalous behaviour of chelates in columns has been explained[77] by their dissociation in the liquid phase, a hypothesis apparently supported by the fact that addition of a small quantity of the vapour of the ligand to the carrier gas improves the chromatograms of certain chelates[73,77,78]. Incidentally, surprisingly little attention had been paid until recently to the role of the liquid phase in the chromatography of chelates, although even the unusual fact that metal chelates can in the large majority of cases be satisfactorily chromatographed only on polysiloxane liquid phases and Apiezon L should have interested research workers. Indeed, recent results show that polysiloxanes and Apiezon L are by no means the best liquid phases for the gas chromatography of chelates. Thus the chromatograms of several chelates are considerably improved by use of the liquid phase Dexsil-300 GH based on carboranes[30,47].

Other facts difficult to explain may be mentioned. For example, it is difficult to understand the sharp differences in the sensitivity of a flame-ionisation detector to chelates of rare-earth metals having closely similar properties. Thus the sensitivity of detection of mixed-ligand complexes of erbium and ytterbium with decafluoroheptanedione and dibutyl sulphoxide differs by a factor of 8,[29] whereas that of chelates of neodymium and samarium by a factor of ~ 11![28] Another little understood phenomenon[26] is that the chelate peak gradually diminished on successive admissions to the column of the terbium complex of dipivaloylmethane, and the chromatogram became stable only after several additions of a benzene solution of the dione. The problem of the behaviour of metal chelates in a chromatographic column obviously requires further investigation.

# Thermotropic Liquid Crystals and Their Applications

E.I.Kovshev, L.M.Blinov, and V.V.Titov

The structure and the physical and physicochemical properties are discussed, with special attention paid to the relation between the chemical structure and the properties of the mesogens. The influence of external factors on liquid-crystalline phases is examined. Various fields of application of liquid crystals are reported, and requirements to be met by such materials are formulated. A list of 210 references is included.

## I. INTRODUCTION

Many synthetic organic compounds are potentially thermotropic liquid crystals[1]: i.e. over a certain temperature range, on passing into the liquid state, they retain the orientational— and in certain directions sometimes also the translational— long-range order in the disposition of molecules characteristic of crystals. By the end of 1973 more than 5000 organic and organometallic compounds having mesomorphic (liquid-crystalline) properties had been recorded[2], and their number has continually increased. The number of publications on liquid crystals has also grown rapidly during recent years. Thus, according to the publishers LOCUS, about 180 papers in this field appeared during 1968, but in 1973 this had already reached 700. During 1975 about 900 papers and patents were covered in the new journal *Liquid Crystals Abstracts*. Such intensifying interest in liquid crystals is not accidental: just recently the use of thermotropic liquid crystals has made it possible to observe visually changes in temperature[3] of 0.01-0.001 deg, and liquid-crystalline indicators, requiring hardly any energy, have enabled electronic wrist-watches to be placed on the market with an accuracy of a few seconds in a year, as well as pocket electronic calculators. Every year new effects are discovered in liquid crystals, promising great possibilities in science and technology.

The present Review has the aim of acquainting a wide circle of chemists with the fundamental ideas developed during recent years in this interesting and practically important branch of the physics and chemistry of the condensed phase. The greatest attention is paid to the chemical and physical properties of thermotropic liquid crystals that are directly related to their application in

electro-optical devices, although related problems, concerning the fundamental properties of liquid crystals and other fields of application, will be touched on. For further details on individual aspects of thermotropic liquid crystals we may recommend Chistyakov's well known book[4], which gives detailed information on structure, monographs and reviews on the chemistry[5-9], physics, and theory[10,11], electro-optical phenomena[12,13], spectroscopy[14], and thermography[15]. A whole series of short surveys on the most diverse problems of the liquid-crystalline state has been published in a special issue of the *Berichte der Bunsengesellschaft für physikalische Chemie*[16].

## II. STRUCTURE AND GENERAL PROPERTIES

### 1. Classification and Structure

It is now usual to divide thermotropic liquid crystals into three groups—nematic (filamentous), cholesteric, and smectic (soaplike)—although Friedel[17], one of the founders of the nomenclature, not without justification regarded cholesteric as a variety of nematic liquid crystals. The term "smectic" is not specific: this group comprises all liquid crystals that are neither nematic nor cholesteric.

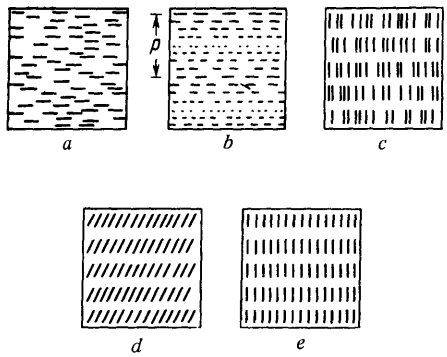

**Figure 1.** Types of thermotropic liquid crystals: *a*) nematic; *b*) cholesteric; *c*)–*e*) smectic; *P*) pitch of helix.

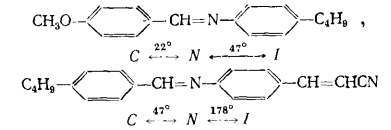

Fig. 1 shows diagrammatically, as rigid rods, the packing of molecules in the various types of liquid crystals.

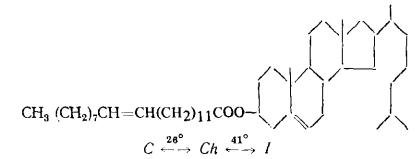
Formation of the liquid-crystalline state can be observed visually from the melting of the crystalline substance in a capillary. Transition to a homogeneous turbid liquid is then evident, followed at a different temperature by transition from the liquid-crystalline state to an isotropic liquid. A better method is to observe by means of a polarising microscope the change in the phase state of specimens when heated (or cooled). Magnifications of 100–300 are mostly used. The patterns (textures) observed can be used to identify the type of mesophase. The latter method combined with differential scanning calorimetry provides reliable identification of phase transitions, their temperatures, and the heats of transition. Phase transition points can be determined also from the temperature variation of mechanical, optical, electrical, and other properties. The types of mesophases are most reliably determined by X-ray diffraction, but the textures of individual compounds or mixtures are also used for their identification.

#### Nematic liquid crystals

Only orientational order is present in nematic liquid crystals: i.e. the long axes of the molecules forming a unit structure are approximately parallel, with the molecules able to move freely in three directions and rotate about the long axis. A large volume appears as a strongly scattering turbid liquid; in unoriented layers exceeding 0.1 mm in thickness filamentous structures (disinclinations) can be observed under crossed Polaroids; in thinner layers a schlieren texture is evident with characteristic nodes or points of intersection of disinclinations[1]. Marbled, pseudoisotropic, and homogeneous textures are encountered, as well as the filamentous (schlieren) type†. On oriented specimens ("single crystals") homotropic (pseudoisotropic) and homogeneous (planar) textures can be observed according to the direction of the long axes of the molecules (perpendicular or parallel to the walls of the cuvette).

Examples of nematic liquid crystals are *p*-butyl-*p'*-methoxybenzylidenaniline[18] and *p*-*p'*-butylbenzylidenaminocinnamonitrile[19]

(I)

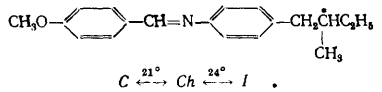


(II)

Here and subsequently *C*, *N*, and *I* denote respectively crystalline, nematic, and isotropic liquid phases, and the numerals above the arrows indicate the temperatures (°C) of the corresponding phase transitions.

#### Cholesteric liquid crystals

Cholesteric liquid crystals are formed by optically active molecules (until recently almost exclusively by esters of cholesterol). Their distinguishing feature is that the direction of the long axes of the molecules in each successive layer, consisting of molecules oriented in parallel and moving freely in two directions, forms a certain angle with the direction of the molecular axes in the preceding layer. A helix is thus formed, whose pitch *P* depends on the nature of the molecules and on external factors (Fig. 1*b*). Such twisting of the molecular axes leads to selective reflection of light, and the wavelength of maximum reflection changes with variation in the pitch of the helix, e.g. owing to slight temperature variation. The oriented layers form a confocal and planar (homogeneous) texture. An example that is colourless in the crystalline and isotropic liquid states, but changes colour (selective reflection) with change in temperature in the liquid-crystalline state, is cholesteryl erucate[20]

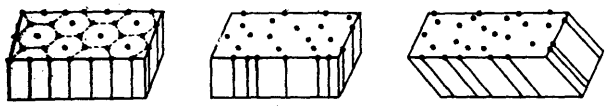


(III)

(*Ch* denotes the cholesteric phase).

†Detailed descriptions and photographs of textures will be found in e.g. Refs. 4 and 9.

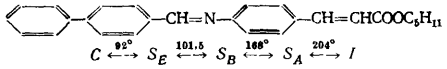
Cholesteric liquid crystals include also the so-called "chiral" nematics, which have the structure of typical nematic liquid crystals but exhibit optical activity, e.g. *D*(or *L*)-*N*-*p'*-methoxybenzylidene-*p*-(2-methylbutyl)aniline [21]



(IV)

$$C \xleftrightarrow{21^\circ} Ch \xleftrightarrow{24^\circ} I \ .$$

Smectic mesophase *A* ($S_A$)



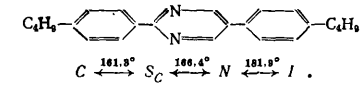
This form comprises layers moving freely relative to one another, whose surfaces are formed by the ends of parallel molecules normal to the surface (Fig. 2*a*). Within a layer the molecules have no translational order: they can move freely in two directions, and rotate about the long axis. The $S_A$ mesophase is the least "organised" among smectic liquid crystals, and may apear in confocal (of fan or polygonal type), homogeneous, or pseudoisotropic textures or as stepped drops. An attempt [22] at a more detailed classification based on crystallographic properties included in particular a variety of the $S_A$ mesophase in which the thickness of the layer was less than the length of a molecule, i.e. in which the molecules were inclined to the plane of the layer and rotated on a cone. The absence of correlation between molecular rotations in different layers leads to a uniaxial crystal as an average structure, in contrast to the biaxial inclined smectic *C*.

*a* *b* *c*

Figure 2. Structure of a layer of a smectic liquid crystal: *a*) $S_A$; *b*) $S_B$; *c*) $S_C$.

The $S_A$ modification occurs at the highest temperature among smectic phases: when heated, it passes into a nematic or a cholesteric mesophase, or else into an isotropic liquid. An example of a liquid crystal of this type is pentyl *p*-*p'*-phenylbenzylidenaminocinnamate [23] at 168–204°C

(V)



$$C \xleftrightarrow{92^\circ} S_E \xleftrightarrow{101.5} S_B \xleftrightarrow{168^\circ} S_A \xleftrightarrow{204^\circ} I$$

Smectic mesophase *B* ($S_B$)

This is a more ordered phase than $S_A$. The molecules in $S_B$ layers, while remaining mutually parallel and normal to the plane of the layer, form a hexagonal type of packing [24] within the layer (Fig. 2*b*).

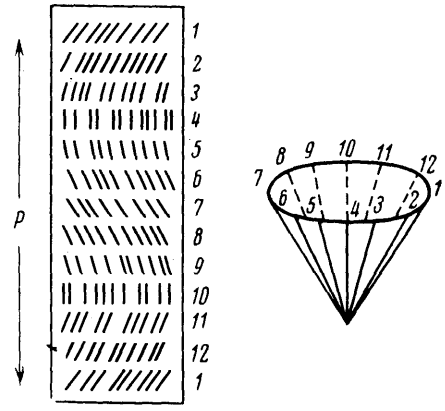
Smectic mesophase *C* ($S_C$)

This is analogous to the $S_A$ mesophase, but the mutually parallel long axes of the molecules are inclined at an angle to the surfaces of the layer (Fig. 2*c*). Such a mesophase is formed e.g. by 2,5-di-*p*-butylphenylpyrazine [25]

(VI)

$$C \xleftrightarrow{161.9^\circ} S_C \xleftrightarrow{166.4^\circ} N \xleftrightarrow{181.9^\circ} I \ .$$

As with $S_A$, different varieties of $S_C$ mesophases may exist, differing in the slope of the molecules (>40° for $S_{C1}$ and ≤26° for $S_{C2}$), its temperature dependence, and also the ability to pass into other modifications [22].



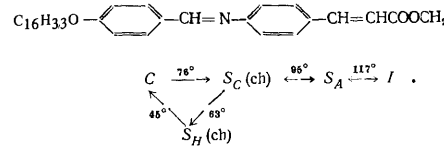


Figure 3. Structure of a ferroelectric *C* smectic, where *P* is the pitch of the "twist". Corresponding numerals on the cone and on the "section" through the layers correspond to the same angle of slope of the molecules.

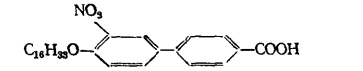
Liquid-crystalline compounds exhibiting optical activity, e.g. *D*(or *L*)-2-methylbutyl *p*-*p'*-hexadecyloxybenzylidenaminocinnamate [26], are able to form a chiral *C* smectic mesophase $S_C$(ch), in which each successive layer of molecules is turned to a certain angle relative to the preceding layer, so that a twisted structure of pitch *P* is formed (Fig. 3), which with a definite orientation of molecular dipoles possesses ferroelectric properties [26], e.g.



(VII)

$$C \xrightarrow{76^\circ} S_C(ch) \xleftrightarrow{95^\circ} S_A \xrightarrow{117^\circ} I \ .$$

$$S_C(ch) \xrightarrow{45^\circ} S_H(ch) \xleftarrow{63^\circ} S_C(ch)$$

Smectic mesophase *D* ($S_D$)

This mesophase is optically isotropic. X-Ray diffraction reveals no layer structure, but indicates a quasi-cubic lattice. Smectic liquid crystals of this type have been found with only a few compounds, e.g. 4'-hexadecyloxy-3'-nitrobiphenyl-4-carboxylic acid [27]

(VIII)

$$C \xleftrightarrow{126.8^\circ} S_C \xleftrightarrow{171.0^\circ} S_D \xleftrightarrow{197.2^\circ} S_A \xleftrightarrow{201.9^\circ} I \ .$$

The $S_D$ mesophase can exhibit not only an isotropic but also a mosaic texture [1].

Smectic mesophase *E* ($S_E$)

The degree of three-dimensional order is extremely high. The molecules in the layers form an orthorhombic lattice [28,29], from which free rotation about the long axis is absent. The $S_E$ mesophase may appear in mosaic and pseudoisotropic textures. Besides the above example (V), a detailed study has been made of the $S_E$ mesophase of dipropyl *p*-terphenyl-4,4″-dicarboxylate [28]

(IX)

$$C \xleftrightarrow{122.0^\circ} S_E \xleftrightarrow{137.1^\circ} S \xleftrightarrow{239.2^\circ} I\ .$$

Smectic mesophases *F* and *G* ($S_F$ and $S_G$)

These mesophases have been studied very little. They both have a layer structure, with an ordered arrangement of molecules in the $S_G$ layers. Schlieren and disrupted confocal textures have been observed for $S_F$, and $S_G$ exhibits a mosaic texture. An example of smectic liquid crystals having both types of mesophase is 5-*p*-pentyloxyphenyl-2-*p*′-pentylphenylpyrimidine [30]

(X)

$$C \xleftrightarrow{79^\circ} S_G \xleftrightarrow{103^\circ} S_F \xleftrightarrow{114^\circ} S_C \xleftrightarrow{144^\circ} S_A \xleftrightarrow{210^\circ} I\ .$$

Smectic mesophase *H* ($S_H$)

This is analogous to the $S_B$ mesophase, but the long axes of the molecules are inclined at an angle to the planes of the layer. As with the $S_C$ mesophase an $S_H$ mesophase formed by optically active molecules has a chiral structure $S_H$(ch) (VII), capable of spontaneous polarisation under the influence of external factors [23].

Plastic crystals

Plastic crystals constitute a special class of mesophase, not included among liquid crystals but sometimes met in the search for liquid-crystalline compounds. They were first characterised by Timmermans [31] in 1935. The molecules forming a plastic crystal were located permanently at the points of a cubic [32] (more rarely a hexagonal) lattice, but are orientationally disordered, with consequent isotropy of the optical properties, so that this type of mesophase was for a long time overlooked by research workers, who used a polarising microscope to define a mesophase. Several plastic crystals (e.g. perfluorocyclohexane) flow under their own weight, but most of them are less plastic, although they can be cut with a knife or extruded through small orifices. A plastic mesophase is formed by several compounds—tetrahedral (tetrachloromethane, silicon tetrafluoride, neopentane), octahedral (tetramethylbutane, hexabromoethane, pivalic acid), cyclic (cyclobutane, cycloheptatriene), bridged (camphor, borneol, tricyclo[2,2,2,2]decane) [33]—as well as several "classical" smectic liquid crystals, e.g. 4′-hexadecyloxy-3′-nitrobiphenyl-4-carboxylic acid [27].

In spite of the considerable number of studies on the structure and the interconversion of liquid crystals, these problems are still far from a final solution; systematic investigations on the typing of smectic liquid crystals have been undertaken only during recent years [34]. New phenomena are continually being discovered, requiring detailed investigations, e.g. the observation by Vainshtein, Chistyakov, and their coworkers that a smectic mesophase is formed when nematic liquid crystals are mixed [35].

2. Molecular–Statistical Description of the Liquid-crystalline State

The statistical distribution of molecules among orientations is described quantitatively by a series of parameters, the most important of which is that of orientational order (or degree of ordering)

$$S = \frac{1}{2}\langle 3\cos^2\theta - 1\rangle, \qquad (1)$$

introduced by Tsvetkov [36], where $\theta$ is the angle between the axis of an individual molecule in a liquid crystal and the prepared direction of the whole ensemble, and averaging is made over the whole ensemble of molecules (thermal mean). The preferred direction coincides with the optical axis of the liquid single crystal (for nematic liquid crystals, *A* smectics, or a thin layer of a cholesteric liquid crystal) or else with one of the optical axes (sloping smectics *C* and *H*). According to definition $S = 1$ for solid crystals in which the molecules are arranged in parallel, and $S = 0$ for an isotropic liquid phase. In a liquid crystal $0 < S < 1$, and *S* decreases with rise in temperature, as the isotropic phase is approached. The value of the parameter *S* is that it can easily be determined experimentally [37] (from diamagnetic measurements, dichroism, nuclear magnetic resonance spectra, etc.).

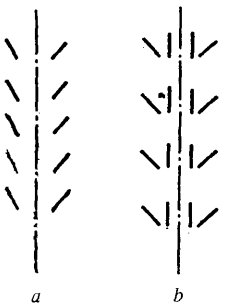


Figure 4. Hypothetical distribution of molecules with preservation of cylindrical symmetry and the same parameter *S*: *a*) dispersion absent; *b*) dispersion takes place.

A more complete statistical description of the molecular distribution is obtained by introducing also the dispersion *D*—a function of $\cos^4\theta$—and additional parameters defined in terms of higher even powers $\cos^n\theta$. The meaning of the parameter *D* can easily be understood by comparing two cylindrical distributions of molecules having the same parameter *S* (Fig. 4). The mean value of $\cos^2\theta$ is the same, but in one case the scatter (dispersion) of the molecules varies relative to the "mean" position shown in Fig. 4*a*.

The question as to which properties molecules should possess for long-range orientational order to be established in a substance occupies a central position in the theory of the liquid-crystalline state. Many attempts have

been made to derive thermodynamic characteristics of liquid crystals from the electronic structure of the molecules. A classification has been given[38] for the levels at which the structure of liquid crystals has been investigated: (*a*) at the simplest level molecules are regarded as rigid rods; (*b*) at the second level molecules are regarded as flat plates, rods with dipoles at an angle to them, or combinations of these two forms; and (*c*) the actual structure of the molecules is considered at the third level. Even at level (*a*) many questions remain unsettled, in particular the evaluation of $S$ for nematic and smectic liquid crystals, the angles of inclination of molecules in smectic $C$, the degree of bonding detween smectic layers, etc. The main problems at level (*b*) are concerned with the ability of molecules to rotate, the ordering of dipoles, etc. Level (*c*) involves the investigation mainly of the conformations of alkyl chains, the orientation of some molecular residues relative to others, internal rotations, etc.

The inadequacy of regarding molecules as rigid rods follows from the extremely graphic experiments on the probing of smectic liquid crystals by means of spin labels[10,39]. If the label belongs to the aromatic skeleton, the degree of ordering $S$ of the molecule is large. For the same label in the alkyl tail $S \to 0$ in effect. Thus the alkyl "tails" seem to be "molten", labile, which explains the "soapiness" of smectic liquid crystals (i.e. the ease of slippage of some layers relative to others).

Even at the first level (*a*), however, extremely important qualitative results have been obtained, mainly for nematic liquid crystals, which in some measure constitute a model system even for other liquid-crystal phases. It was shown in particular[40] that dispersion (van der Waals) forces of attraction between molecules play a decisive part in the organisation of nematic order[41]. The anisotropy of electron polarisability is the most important molecular characteristic governing the tendency of a specific substance to form a liquid-crystalline state. Long rodlike molecules with aromatic and heteroaromatic rings arranged in series are to be preferred in this respect. A favourable factor is the presence of a chain of conjugation along the molecular skeleton, since it will increase the longitudinal component of the polarisability. There is probably no correlation between the presence of a permanent dipole moment in the molecule and the ability of the substance to form nematic liquid crystals[5,41]. The steric factor (the length and the structure of the terminal groups) is also very significant. Theory[40] agrees with experiment in predicting a phase transition of the first kind between nematic and isotropic liquid states, as well as a regular temperature dependence of the parameter of orientational order.

An interesting criterion of the ability of a substance to form a mesomorphic state has been suggested by Ogorodnik[42] on the basis of experiments on the Raman scattering of light. He considers that only compounds that in the solid state form more than one crystalline modification (sometimes metastable) can have a nematic phase. Structural order in the mesomorphic state is then due to the superposition of "solid-crystalline clusters" of a different modification. The general applicability of this principle still lacks experimental verification.

Although the "twistedness" of the structure of cholesteric liquid crystals is due to the chirality (mirror-image asymmetry) of its component molecules, there is no clear correlation between the direction of rotation of the cholesteric helix and the sign of rotation of the individual molecules[43]. Goossens[44] attempted to explain the tendency of these liquid crystals to form a twisted structure in terms of electric dipole–quadrupole interaction between molecules on the basis of the Maier–Saupe approach‡. His calculated value for the pitch of the helix agrees with experiment. The theory of Goossens will explain also the temperature variation of the pitch if the temperature dependence of the degree of order is taken into account[45].

Another explanation of the structural twistedness and the temperature dependence of the helical pitch is based on the anharmonicity of the forces of molecular interaction[46]. However, this will explain only the increase in pitch with fall in temperature, which occurs only in the vicinity (on the temperature scale) of smectic phases, a fact that can in principle be attributed to the formation of nuclei (clusters) of a smectic in the cholesteric phase.

Yet another explanation[47] of the appearance of a cholesteric phase attributes it to long-range van der Waals forces of interaction between molecules. On this model such a phase may even be formed by molecules having mirror-image symmetry (optically inactive). This extremely untrivial case has not yet found experimental confirmation.

The first attempts at extending the Maier–Saupe approach[40] to an $A$ smectic phase involved[48,49] introducing two parameters of order, orientational (as in nematic liquid crystals) and translational. A molecular-statistical theory of more complicated types of smectic ($C$, $B$, and $H$) has been developed quite recently[50]. Here molecules are regarded as rigid rods, interactions between permanent dipoles of individual segments of the molecules must be taken into account, and the repulsion potential of the molecules within a single smectic layer must be written in explicit form. Interaction between layers is neglected. The molecular field approximation predicts theoretically[50] phase transitions of the second kind between phases $A$ and $C$, as well as between $B$ and $H$, whereas transitions between any other pairs of mesophases are of the first kind. In conformity with theory[50] smectics $A$ and $B$ are characterised by free rotation of molecules about the long axes; free rotation is absent from smectics $C$ and $H$, in which molecules are tilted relative to the smectic axes, and the dipoles are oriented in definite fashion. The suggested pattern has been subjected to criticism[38,51]. Insufficient experimental data are yet available either to support or to disprove the theoretical view[50].

## III. ANISOTROPY OF PROPERTIES

### 1. Orientation of Molecules

A liquid crystal run into a test-tube is a macroscopically homogeneous "polycrystalline" specimen (a turbid liquid). A "single crystal" must be prepared in order that the anisotropy of properties of a liquid crystal can be studied. This can be accomplished by orienting the whole molecular ensemble either by means of an external field or by the boundary conditions at the walls of the microcuvette. In the latter case planar orientation is distinguished from homotropic orientation (Section II, 1). As soon as the orientation of the molecules at the boundary has been

---

‡It must be noted that the optical activity of individual molecules is due to intramolecular interactions of the "electric dipole–magnetic dipole" type, so that it is different in nature.

firmly established, alignment of the remaining molecules parallel to the former is energetically most favourable (departure from the specified orientation increases the elastic energy).

The microrelief of a glass surface (or of electrodes) having a characteristic dimension[52] of the order of 10 Å is usually employed for the planar orientation of liquid crystals. The walls are rubbed with a cloth or polished in a definite direction (Chatelain's method[53]) or else layers of metals or dielectrics sputtered askew are used[54]. Homotropic orientation is usually effected by means of monolayers of surface-active agents such as lecithin, alkoxybenzoic acids, polyamide resins, or organosilicon compounds[55]. Fig. 5 illustrates diagrammatically the two chief modes of orientation of liquid crystals—(*a*) planar orientation due to the microrelief of a metal film sputtered askew and (*b*) homotropic orientation due to a film of a surface-active agent—where it can be demonstrated rigorously that both configurations correspond to minimum elastic energy of the liquid crystal[52].

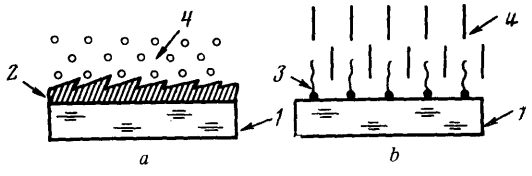

**Figure 5.** Orientation of a liquid crystal by a surface: *a*) planar; *b*) homotropic: 1) support; 2) obliquely sputtered metal film; 3) surface-active molecules; 4) rodlike liquid-crystal molecules.

If the liquid is a single crystal, almost all its properties are anisotropic, with the anisotropy more marked the greater the degree of ordering $S$. This quantity $S$ has meaning only for a single crystal, and is a thermodynamic function depending on the properties of the substance and the temperature, but independent to a first approximation of the orienting agent[11]. Thus, if a single crystal having a certain value of $S$ could be obtained by means of a magnetic field of 1 kG, increasing the field to 20 kG will not lead to an increase in $S$.[56] Incomplete orientation of a specimen (in the absence of a single crystal) can in principle be described by a different parameter—the degree of orientation—but this is not a fundamental characteristic of the substance. We cre compelled to consider this aspect in some detail, for until recently many studies were published in which the physical characteristics of the substance had been determined on unoriented specimens. This involves loss of information to the same extent as in the replacement of a solid single crystal by a polycrystalline powder.

## 2. Electrical and Magnetic Properties

Fig. 6*a* illustrates a typical temperature dependence of the degree of ordering of a nematic liquid crystal. The temperature variation of the anisotropy of the diamagnetic susceptibility $\Delta\chi = \chi_{\parallel} - \chi_{\perp}$ §, and also that of the electronic portion of the dielectric susceptibility $\Delta\alpha = \alpha_{\parallel} - \alpha_{\perp}$, are completely determined by the temperature dependence of $S$ and can be calculated from the anisotropy of these parameters in the solid phase:

$$\Delta\chi_{nlc} = S\,\Delta\chi_s; \quad \Delta\alpha_{nlc} = S\,\Delta\alpha_s \qquad (2)$$

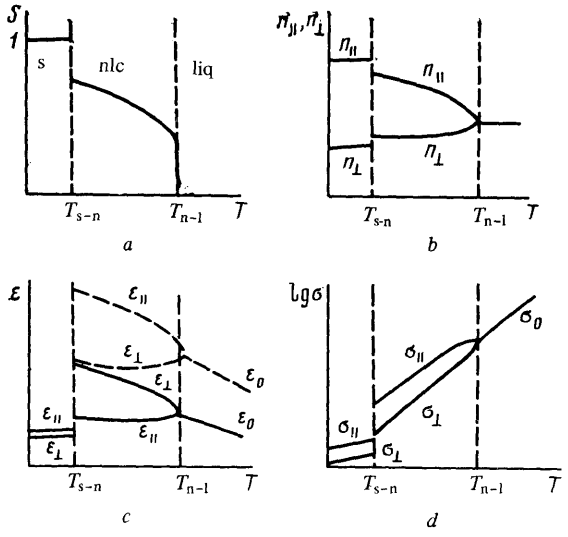

**Figure 6.** Typical temperature dependence for nematic liquid crystals (nlc) of: *a*) degree of ordering; *b*) refractive indices; *c*) dielectric constant; *d*) electrical conductivity. Here $T_{s-n}$ and $T_{n-l}$ are the solid-nematic and nematic–isotropic liquid phase transition temeratures.

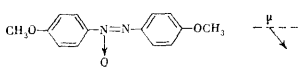
The mean values $\bar{\chi}$ and $\bar{\alpha}$ in the liquid-crystalline phase are equal to the values $\chi_i$ and $\alpha_i$ for the isotropic phase (apart from the temperature variation of $\chi$ and $\alpha$). In view of the cylindrical symmetry of distribution of molecules in a nematic liquid crystal, these average values are given by the formulae

$$\bar{\chi} = \frac{1}{3}(\chi_{\parallel} + 2\chi_{\perp}) \approx \chi_i; \quad \bar{\alpha} = \frac{1}{3}(\alpha_{\parallel} + 2\alpha_{\perp}) \approx \alpha_i \qquad (3)$$

More complicated equations hold for the anisotropy of the refractive indices $\Delta n = n_{\parallel} - n_{\perp}$, connected with $\alpha_{\parallel}$ and $\alpha_{\perp}$ by the Lorentz–Lorenz relations[57], for the total dielectric susceptibility $\Delta\epsilon = \epsilon_{\parallel} - \epsilon_{\perp}$, including the orientational component[58], and for the anisotropy of electrical conductivity $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$. However, the general rule of a monotonic fall is maintained for all these quantities: $\Delta n$, $\Delta\epsilon$, $\Delta\sigma \to 0$ as $S \to 0$. Typical temperature variations of longitudinal and transverse components of refractive indices, dielectric constants, and electrical conductivities of a nematic liquid crystal are illustrated in Fig. 6*b–d*.

§The subscripts denote directions parallel and perpendicular to the long molecular axes (to the "director" of the nematic liquid crystal).



It is noteworthy that $\Delta\chi$, $\Delta n > 0$ in all known nematic and smectic liquid crystals, in conformity with the anisotropy of the magnetic and electronic components of the electric polarisability of oblong molecules. Nevertheless, the sign of $\Delta\sigma$ is different in the two types of mesophases: in the nematic type $\Delta\sigma > 0$ (except for the temperature range in the vicinity of the smectic phase, when nuclei of smectic order are present), since the charge carriers (ions) move more readily in the direction of the long axes of the molecules; in smectic liquid crystals the mobility of the ions is greater along the smectic layers, i.e. normal to the molecular axes, so that $\Delta\sigma < 0$.

The dielectric anisotropy of a nematic liquid crystal may be either positive (Fig. 6*c*, full curves) or negative (broken curves in Fig. 6). This is determined by the components of the orientational polarisability and depends on the relation between the anisotropy of the electronic polarisability of a molecule and the permanent dipole moment $\mu$, as well as the angle $\beta$ between the dipole moment and the long axis of the molecule[58]. The quantity $\Delta\epsilon > 0$ is characteristic of molecules having a longitudinal dipole moment (i.e. with $\beta \to 0$), e.g.

(XI)

When the angle $\beta$ is sufficiently large, the case $\Delta\epsilon < 0$ is realised, e.g. in *pp'*-dimethoxyazoxybenzene

(XII)

where $\beta \simeq 60°$. As the frequency of the electric field is raised, the quantities $\epsilon_\parallel$ and $\epsilon_\perp$ exhibit dispersion in different frequency ranges[59]. Dispersion is developed by $\epsilon_\perp$ at frequencies comparable with the frequency of rotation of molecules about the long axis ($f_D^\perp \simeq 10^8$ Hz); that of $\epsilon_\parallel$ occurs at significantly lower frequencies. With long molecules[60] such as

(XIII)

the frequency $f_D^\parallel \simeq 10^4$ Hz, and is determined by hindered rotation of molecules about the short axis. Owing to the dispersion of $\epsilon_\parallel$ and $\epsilon_\perp$ the sign of $\Delta\epsilon$ may change from positive to negative in different frequency ranges[12]. This property can be used in electro-optical devices based on field effects in order to diminish the disconnection time. The dielectric anisotropy of smectic liquid crystals may change sign depending on the temperature, which is explained by pair correlations of neighbouring dipoles[61].

The local anisotropy of electrical properties of cholesteric liquid crystals (within a layer thickness, much smaller than the pitch of the helix) is characterised by the same rules as for the nematic type (e.g. there may be substances having $\epsilon_\parallel - \epsilon_\perp < 0$ and $\epsilon_\parallel - \epsilon_\perp > 0$). Sometimes, of course, anisotropy parameters are introduced to describe a macroscopic specimen having a helical structure. The components of $\epsilon_h$ and $\sigma_h$ parallel and perpendicular to the axis of the helix are then related with the components $\epsilon_\parallel$, $\epsilon_\perp$ and $\sigma_\parallel$, $\sigma_\perp$ by the self-evident formulae

$$\varepsilon_{\parallel h} = \varepsilon_\perp;\ \varepsilon_{\perp h} = \frac{1}{2}(\varepsilon_\parallel + \varepsilon_\perp);\ \sigma_{\parallel h} = \sigma_\perp;\ \sigma_{\perp h} = \frac{1}{2}(\sigma_\parallel + \sigma_\perp)\ . \quad (4)$$

## 3. Elastic Properties

The elastic properties of an ordinary liquid can be characterised by a single parameter, its compressibility. The elastic energy of a "liquid rod" is unaffected by bending, shearing, or twisting. The situation is different with an anisotropic liquid. For example, three quite different deformations—bending, splaying, and torsion, denoted for brevity *B*, *S*, and *T* deformations—can be imagined for a nematic liquid crystal[12]. Fig. 7 illustrates these three types of deformation, characterised by the respective moduli of elasticity $K_{33}$, $K_{11}$, and $K_{22}$, whose order of magnitude is $10^{-7}$–$10^{-6}$ dyn. The elastic force required for a deformation is proportional to that deformation, i.e. to the gradient of the angle of rotation of some molecules relative to others:

$$F_{\text{elast}} = K_{ii}\frac{\partial\varphi}{\partial z}, \quad (5)$$

The elastic energy is expressed in quadratic form:

$$g_{\text{elast}} = \frac{1}{2}K_{ii}\left(\frac{\partial\varphi}{\partial z}\right)^2 \quad (6)$$

A rigorous expression can be obtained for the elastic energy of combined deformation[62]. Elastic coefficients are usually determined from an electro-optical experiment[63]. Attempts have also been made to deduce the temperature dependence of moduli of elasticity from the molecular-statistical theory[64]. The same moduli of elasticity are introduced for cholesteric as for nematic liquid crystals.

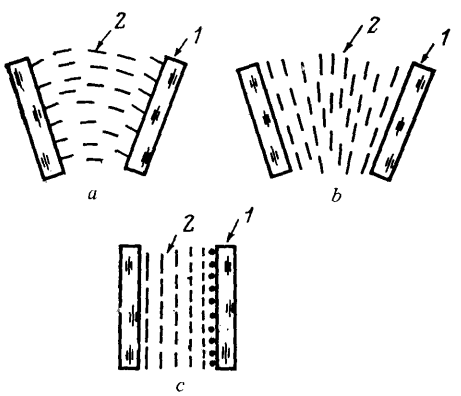


**Figure 7.** Types of deformation of nematic liquid crystals: *a*) bending; *b*) splaying; *c*) twisting: 1) oriented support; 2) liquid-crystal molecules.

A different situation is found with smectic liquid crystals[65]. In the simplest type—an *A* smectic—the moduli of elasticity for bending and torsional deformations tend to infinity, with only $K_{11}$ remaining finite. The explanation is that an *A* smectic "resists" any deformation in which the distance between the smectic layers changes. Comparing splaying and bending (Fig. 8), for example, we note that in the former case the smectic layers are curved, but the molecules remain normal to them as before, and the distance *d* between the layers is unchanged.

The deformation is described by a finite modulus $K_{11}$. In the second case the distance between the layers must change for the deformation to occur. The impossibility of such change is expressed by the condition $K_{33} \to \infty$. Torsional deformation is also difficult, as can easily be realised on trying to screw in imagination a pile of thin plates. On the other hand, in contrast to a nematic liquid crystal, it makes sense for an $A$ smectic to introduce a compressibility coefficient $\bar{B}$ representing the increase or decrease in the interlayer distances. This type of deformation does not involve the position of a "director", and the elastic energy is given by a term

$$g_{\text{elast}} = \frac{1}{2}\bar{B}\left(\frac{\partial U}{\partial z}\right)^2, \qquad (7)$$

where $U$ is the displacement of the smectic layer along the coordinate $z$ normal to the layer. The parameter $\bar{B}$ has the same dimensions and order of magnitude as the compressibility coefficients of ordinary liquids. It is interesting that in nematic phases adjacent on the temperature scale to an $A$ smectic a fall in temperature is accompanied by divergence between the moduli of bending and torsional deformations ($K_{33}$, $K_{22} \to \infty$) as these phases approach the point of transition into the $A$ smectic, a phenomenon explained by a mechanism of formation of nuclei of smectic order in the nematic phase. The modulus $K_{22}$ in a cholesteric liquid crystal also tends to infinity as a neighbouring smectic phase is approached (with change in temperature)[66].

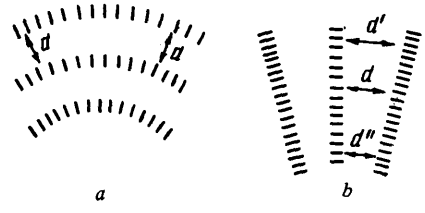

Figure 8. Deformation of an $A$ smectic: *a*) splaying; *b*) hypothetical bending.

Elasticity theory for other types of smectic is very complicated. For example, the simplest description of a $C$ smectic requires the introduction of ten elasticity coefficients (the coefficient $\bar{B}$ and nine moduli[10] are related to the orientation of the "director" and of order of magnitude $10^{-6}$ dyn).

## 4. Viscosity Characteristics

The viscosity of a liquid crystal depends on how the "director" is situated relative to the gradient of the rate of flow. This was known long ago[67], but only recently it has been shown by Leslie and by Ericksen[68] that the viscous properties of a nematic liquid crystal can be described completely by five independent coefficients $\alpha_i$ ($i = 1-5$), the Leslie coefficients. Sets of coefficients $\alpha_i$ have been determined for *pp'*-dimethoxyazoxybenzene[69] (XII) and for *p*-butyl-*p'*-methoxybenzylidenaniline (I)[70] from experiments on the Rayleigh scattering of light and on the discharge of a nematic liquid crystal from a capillary. Especially clear experiments were made by Gähwiller, who examined the rate of discharge of a nematic liquid crystal from a capillary of rectangular cross-section (50 × 40 × 0.4 mm) placed in a magnetic field (up to 4 kG) governing the orientation of the liquid-crystal molecules (this applies only at very low rates of flow, when the orienting effect of the flow is insignificant in comparison with the action of the field). Fig. 9 shows the geometry of the experiment. The corresponding viscosity coefficients $\eta_1$, $\eta_2$, and $\eta_3$ were respectively 103, 23.8, and 41.6 cP. These coefficients, together with results of an additional experiment to measure the angle of orientation of the molecules by the flow ($\tan^2\theta = \alpha_3/\alpha_2$), were used to determine all the Leslie coefficients. The great anisotropy of the viscosity of a nematic liquid crystal (e.g. $\eta_1/\eta_2 \simeq 4$) leads to appreciable anisotropy of the mobility of impurity ions, and hence to anisotropy of the electrical conductivity[71] ($\sigma_{\parallel}/\sigma_{\perp} \simeq 1-2$).

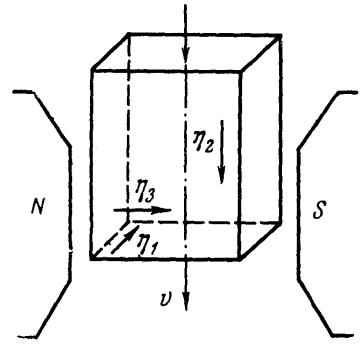

Figure 9. Geometry of Gähwiller's experiment. The "director" direction corresponding to the measured viscosity coefficients $\eta_1$ and $\eta_3$ is determined by the magnetic field; that corresponding to the measured coefficient $\eta_2$ by the material flux v with the field switched off and with an increased rate of discharge; directions of orientation of molecules are denoted by arrows.

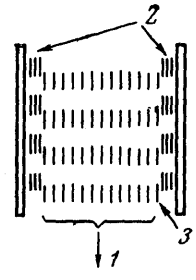

Figure 10. Outflow of $A$ smectic from a capillary: 1) outflowing liquid column; 2) layer fixed adjacent to wall; 3) site of rupture of smectic layers.

Cholesteric and smectic liquid crystals exhibit abnormally large viscosity coefficients (from measurements in capillaries), although their Leslie coefficients are of the same order as those for nematic liquid crystals (from the scattering of light). This increase in the observed

(apparent) viscosity coefficients was attributed by Helfrich[72] to a "penetration" effect (the flowing liquid crystal penetrates through the helical or layer "construction" specified by the boundary conditions at the walls of the capillary). This can be illustrated vividly for a cholesteric liquid crystal by imagining that we are trying to remove a well lubricated screw of large pitch from a threaded orifice, which may be effected by turning the screw. The force of the pressure is consumed in rotating the screw, whose rate of translational motion is small. Thus the "director" of a cholesteric liquid crystal, for which the boundary conditions determine the helical orientation of molecules on the wall of a circular capillary, is also compelled to rotate as material is discharged from the capillary. Here friction may increase the effective viscosity coefficient by factors of $10^5$. In the case of smectic liquid crystals discharge should involve the "extrusion" of smectic layers (Fig. 10), whose position is fixed on the wall of the capillary. This is an example of non-Poiseuille and non-Newtonian liquid flow. With indefinite orientation of cholesteric and smectic liquid crystals relative to the capillary (as in most experiments) the apparent viscosity coefficients are almost arbitrary (over a range of $10^5$).

## IV. INFLUENCE OF EXTERNAL FACTORS

### 1. General Considerations

Molecules of substances that form liquid crystals themselves exhibit no abnormal properties. At temperatures appreciably above the clear point of nematic liquid crystals, for example, we are dealing with ordinary liquids, whose Kerr constants are no larger than for nitrobenzene (except in the temperature range of the isotropic phase near the transition point, where the Kerr constant may either increase, decrease, or even change sign owing to the short-range order in the arrangement of the molecules[73]). Similarly, esters of cholesterol in the isotropic phase have the same specific optical rotation as have optically active liquids (alcohols, sugar, etc.), but do not form liquid-crystalline phases. The dipole moments and the components of the electrical and magnetic susceptibilities of the molecules also have the same order of magnitude for mesogenic and non-mesogenic substances.

The uniqueness of the properties of liquid crystals—their high sensitivity to external factors—is due to the extremely delicate intermolecular interactions governing the long-range orientational order in the arrangement of molecules. Which specific molecular characteristics are responsible for the tendency of molecules to form an ordered state is the main problem of a molecular-statistical theory of liquid crystals, which is still far from solution. But as soon as long-range order has been established, with the degree of order depending on external factors, the latter influence the anisotropy of almost all the parameters of the liquid crystals. Examples are the dependence of the pitch of the helix of a cholesteric liquid crystal on the temperature or the field and the pressure dependence of the optical anisotropy of a nematic liquid crystal.

Furthermore, many electro- and magneto-optical phenomena are based on reorientation of the "director" (without change in the degree of order). This process of change in optical properties can be divided into three stages. (*a*) Owing to the large anisotropy (as in solid crystals) of the electrical parameters ($\Delta\epsilon$, $\Delta\sigma$, and $\Delta\chi$) the "director" of a liquid crystal "interlocks" with an external field: an orienting moment acts on the molecules of the liquid crystal. In a magnetic field, for example, the axes of the molecules tend to arrange themselves parallel to the field. (*b*) Since a liquid crystal is liquid, the molecules actually undergo reorientation under conditions of competition with elastic forces (in some cases this reorientation is accompanied by mass transfer of liquid—by a flow). (*c*) Change of orientation is easily recorded optically owing to the great anisotropy of optical properties (refractive indices and absorption).

### 2. Examples of Electro-optical and Magneto-optical Effects

In order to simplify discussion of the three most characteristic effects—the Fréedericksz transition in nematic liquid crystals, uncoiling of the helix in cholesteric liquid crystals, and wavelike instability in smectic liquid crystals—we shall regard a liquid crystal as a pure dielectric, through which an electric current does not flow. In reality this is impossible of achievement, since even with the most careful purifications some quantity of ionic impurities will remain in the liquid crystal, and given appreciable *ionic conductivity* $\sigma \simeq 10^{-12}$–$10^{-14}$ ohm$^{-1}$ cm$^{-1}$). With perfect purification ions may still be generated by the injection of electrons from the electrode followed by their "capture" by neutral molecules of the substance. In some publications current–voltage characteristics on liquid crystals have been interpreted in terms of an electronic mechanism of conduction. Such views are incorrect, since the electronic conductance of a liquid crystal is extremely small; it should be comparable in order of magnitude with the intrinsic conductivity of impurity-free organic dielectrics such as anthracene and naphthalene. At the present time it is impossible even to state definitely what these values are; calculations give $\sigma < 10^{-19}$ ohm$^{-1}$ cm$^{-1}$. Electron currents can be observed experimentally in liquid dielectrics only under the abnormal conditions of pulse photoconduction on substances of very low electron affinity[74]. Under normal conditions we are always dealing with an ionic current, although the current carriers (ions) may not be intrinsic, but generated near the electrodes by the injection or exclusion of electrons. In this case an electrochemical process takes place on the electrode.

(*a*) Fréedericksz transition in a nematic liquid crystal

Considering now the simplest example of the reorientation of a nematic liquid crystal in an electric or magnetic field—the Fréedericksz transition[75]—we suppose that the microcuvette illustrated in Fig. 11*a* is filled with a liquid crystal of *p*-*p'*-butoxybenzylidenaminobenzonitrile (XI) and maintained at a temperature corresponding to the nematic range of this compound (64–103°C). Because of the presence of the cyano-group the molecule of (XI) has a dipole moment $\mu \simeq 4.5$ D directed along its long axis[76], so that the longitudinal component (in the direction of the axis of orientation of the molecules) of the static dielectric constant exceeds significantly the transverse component: $\epsilon_{\parallel} \simeq 25$ and $\epsilon_{\perp} \simeq 7$. Let the glasses of the microcuvette be so treated that the molecules of the adjacent layer of the liquid crystal are rigidly fixed parallel to the glass (planar orientation) and do not change their orientation in any circumstances. When an electric

field is applied, a turning moment will act on the molecules of the liquid crystal, tending to reorient them with the direction of the maximum component of the dielectric constant coinciding with that of the field. The reason is that the polarisation induced in the dielectric (the dipole moment of unit volume) is proportional to the dielectric constant; hence the polarisation is greater for the direction of $\epsilon_{\parallel}$. As a consequence, interaction of the induced moment with the external field leads to rotation of the optical axis of the single crystal, with the exception of molecules adjacent to the wall. The proportion of oriented dipoles is $\sim\exp(-\mu E/kT) \simeq 10^{-4}$–$10^{-2}$ for typical field strengths. The "director" of the ensemble of interacting molecules, i.e. the longitudinal axis of their cylindrical distribution, is oriented parallel to the field. Rotation of the molecular ensemble is opposed by the elastic energy of interaction of the molecules (Eqn.6).

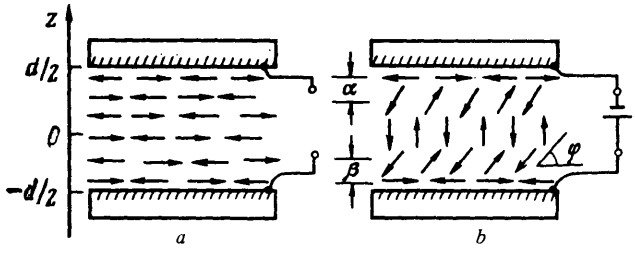

Figure 11. Illustration of the Fréedericksz effect in nematic liquid crystals: *a*) initial orientation of molecules: *b*) orientation of molecules at voltages exceeding the threshold value.

Fig. 11*b* shows regions $\alpha$ and $\beta$, in which the molecules are forced to detach themselves from their neighbours, although they "would have preferred" to remain parallel to the latter. As a result of competition between dielectric and elastic moments ($\Delta\epsilon E^2/4\pi$ and $K_{11}\partial^2\varphi/\partial z^2$), deformation has a threshold character. The threshold voltage is

$$v_0 = \pi\sqrt{4\pi K_{11}/\Delta\varepsilon} \quad . \tag{8}$$

Deformation begins from the middle of the layer ($z = 0$), and extends to the electrode with increase in the field strength, embracing more and more new layers of molecules. With the maximum field almost all molecules other than those adjacent to an electrode are reoriented perpendicular to the electrodes, which can easily be observed optically from the disappearance of double refraction by the liquid-crystal layer. Expressions for the reaction and relaxation times can be obtained[12] from the kinetics of this process taking into account the moment of viscous friction for the "director" (in addition to dielectric and elastic components).

Roughly the same pattern is observed for the twisted structure of a nematic liquid crystal (with mutually perpendicular directions of the "director" on the opposite electrodes), as well as for nematic crystals with $\epsilon_{\parallel} < \epsilon_{\perp}$, if the initial orientation was homotropic.

(*b*) Cholesteric–nematic phase transition

Fig. 12*a* represents the planar texture of a cholesteric liquid crystal when the molecules are oriented parallel to the glasses of the cuvette (in the absence of electodes), while the axis of the cholesteric helix is correspondingly perpendicular to them. Such a texture reflects circularly polarised light selectively[77] if the polarisation corresponds in sign to the twist of the helix, while the wavelength (in a vacuum) satisfies the relation $\lambda = \frac{1}{2}P\bar{n}$ (where $P$ is the pitch of the helix and $\bar{n}$ the mean refractive index of the liquid crystal). The selective reflection is caused by the diffraction of light on the cholesteric planes (analogous to the Wulf–Bragg diffraction of X-rays on ordinary crystals). Measurements of the wavelength of the selective reflection provides a method for determining the pitch $P$ of the helix.

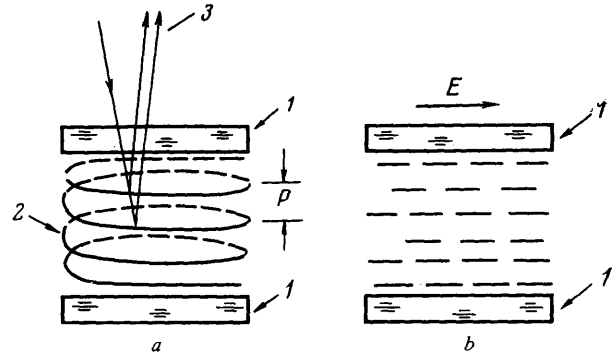

Figure 12. Cholesteric → nematic phase transition, with electric field applied along the surface of the glasses: *a*) planar cholesteric texture in absence of field; *b*) nematic phase with $E > E_0$: 1) glasses (in absence of electrodes); 2) cholesteric helix of pitch $P$; 3) diffracting light rays.

We now imagine that the dielectric anisotropy of the cholesteric liquid crystal is positive, i.e. that $\epsilon_{\parallel} > \epsilon_{\perp}$ with respect to the "director"), and that the substance is located in a field $E$ perpendicular to the axis of the helix. It is clear that all molecules will tend to orient themselves parallel to the field, which is incompatible with a helical structure and requires an increase in the elastic energy of the liquid crystal. With a sufficiently strong field the helix begins to uncoil (as is evident from the shift to longer wavelengths in the selective reflection maximum), and ultimately a phase transition takes place from cholesteric to nematic liquid crystals (Fig. 12*b*). The threshold field strength for the transition is inversely proportional to the pitch of the helix[78]:

$$E_0 = \frac{\pi^2}{P_0}\sqrt{4\pi K_{22}/\Delta\varepsilon} \quad . \tag{9}$$

(*c*) Instability of smectic liquid crystals

Formally a Fréedericksz transition occurs also with an *A* smectic, as with a nematic mesophase, and the same formula gives the threshold voltage (Eqn.8). However,

the deformation itself is too small to be recorded ("illusory" transition[79]). As already discussed in Section III, 3, the weakness of the deformation is due to the tendency of an *A* smectic to maintain unchanged the distance between the layers (whereas reorientation requires such change). Since the reorientation of molecules forms the basis of several other, more complicated electro-optical phenomena, e.g. electrohydrodynamic, the properties of smectic liquid crystals are on the whole far less subject to the influence of fields than are those of nematic and cholesteric mesophases¶.

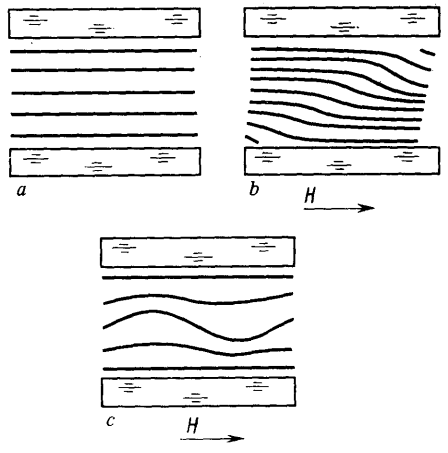

Figure 13. Instability of smectic liquid crystals in a magnetic field with $\Delta\chi > 0$: *a*) initial orientation (the lines represent smectic layers); *b*) hypothetical Fréedericksz transition leading to deformation of smectic structure with change in interplanar spacing; *c*) wavelike deformation with interplanar spacing almost unchanged.

Perhaps the most characteristic instability of a smectic liquid crystal in an external field is its wavelike deformation, which requires almost no change in the interlayer distance[10]. If $\Delta\chi > 0$ and the magnetic field is parallel to the layers, i.e. perpendicular to the axes of the molecules (Fig. 13*a*), the molecules will tend to reorient parallel to the field, which would have led to crumpling of the layers near the glasses, which is energetically disadvantageous (Fig. 13*b*). A compromise is provided by wavelike deformation, with which a minimum is reached in the total (electrical and elastic) energy (Fig. 13*c*). The period *b* of such deformation is the geometric mean of the layer thickness *d* and the "depth of penetration" $\lambda = (K_{11}/B)^{\frac{1}{2}} \simeq 20$ Å: i.e. $b = 2(\pi\lambda d)^{\frac{1}{2}}$ (~5μm for $d = 0.1$ cm), and the critical field is

$$H_c^2 = 2\pi K_{11}/\lambda\, d\,\Delta\chi \quad (\approx 60 \text{ kG}) \,. \tag{10}$$

¶This makes it difficult to measure the anisotropy of the electrical and other parameters of smectic liquid crystals.

(*d*) Electrohydrodynamic instability of nematic liquid crystals

The notion of a liquid crystal as an ideal dielectric must be rejected in considering this problem: electrohydrodynamic processes in a liquid crystal involve currents. A physical description of electrohydrodynamic instabilities is fairly complicated. The main cause of periodic liquid flows is the spatial separation of ions and consequent nonuniform distribution of ionic current in the specimen owing to the anisotropy of electrical conductivity. Because of friction the fluxes of matter break down the "monocrystallinity" of the specimen and the initial uniform distribution of the "director", causing three-dimensionally periodic deformation of this distribution. As the field becomes stronger, the periodic motion of the liquid is replaced by turbulence, which is accompanied by local changes in optical anisotropy and hence by intense scattering of light[80,81] (dynamic scattering). This effect usually develops in nematic liquid crystals having negative dielectric anisotropy (with $\Delta\sigma > 0$), but may occur even when $\Delta\epsilon > 0$, in particular when $\Delta\sigma < 0$,[82] as well as with $\Delta\epsilon = 0$.[83]

3. Effects of Temperature and Other Factors

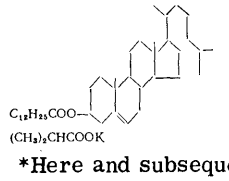
Such factors as pressure, temperature, and optically inactive additives exert a relatively weak influence on the ordered character of nematic liquid crystals, and hence on the anisotropy of their properties. A different situation obtains with cholesteric mesophases, the helical pitch of which is extremely sensitive to the above factors. The explanation is that the energy of intermolecular interaction responsible for the helical structure is only $10^5$ of that determining the nematic order[45]. A sharp change in pitch is accompanied by marked changes in optical properties, precisely at the spectral positions of maximum selective reflection[15] and the point of inversion of the sign of optical activity[84]. For example, the temperature of a layer of a cholesteric liquid crystal can be recorded optically to better than 0.02 deg.[84]

In most cases (for an exception see e.g. Ref. 85) the pitch of the helix *P* increases with fall in temperature, the relative change $P^{-1}|\,dP/dT|$ reaching 100 $\text{deg}^{-1}$ (cholesteryl nonanoate at 75°C). The reason for the variation in pitch with temperature has not been finally elucidated[44-46]. With cholesteric liquid crystals formed by optically active molecules not derived from cholesterol, such as compound (IV),[21] the temperature dependence of the pitch is very slight, and such substances are of the greatest interest for electro-optical applications. With increase in pressure from 1 to 2000 bars a considerable change has been observed[86] in the wavelength of maximum selective reflection (from the violet to the red part of the spectrum) by a cholesteric liquid crystal. The pitch of the helix can be changed also by adding optically inactive impurities to cholesteric mesophases[87].

Optically active additions to nematic liquid crystals lead to the formation of a cholesteric structure[88]. At low concentrations *c* of the additives the pitch of the helix is inversely proportional to the concentration:

$$P = (2\beta c)^{-1}, \tag{11}$$

where $\beta$ is the twisting power of a specific additive. The same effect is obtained on addition of an optically active impurity to a compensated mixture (with $P = \infty$) of cholesteric liquid crystals.



The property of twisting a nematic into a cholesteric structure is in general inherent in any chiral macroscopic species (possessing no plane of mirror-image symmetry), and the pitch of the helix is inversely proportional to the concentration $c$ of these species in the mesophase [10]. At higher concentrations $c$ the relation (11) breaks down. The twisting power $\beta$ cannot be regarded as exclusively a property of the additive [89], but depends also on the solvent. Anomalous results—such as (*a*) the production of nematic–cholesteric mixtures with the same sign of rotation (dextrorotatory) on the addition to a nematic liquid crystal of cholesteric components with a different sign of rotation [90] and (*b*) the production of a laevorotatory mixture from two dextrorotatory components [91]—can be explained by taking into account not only $\beta$ but also the twisting power of the solvent induced by the solute [92].

## V. CHEMICAL STRUCTURE AND PROPERTIES

### 1. Chemical Classes

The >5000 liquid-crystalline compounds known at the present time include representatives of various classes—acyclic, isocyclic, aromatic, heterocyclic, organometallic compounds, steroids, and salts of organic acids (Table 1)[2].

Table 1.

| Formula | Transition temperatures* | | | | |
|---|---|---|---|---|---|
| | $T_{s\text{-}sm}$ | $T_{s\text{-}n}$ | $T_{sm\text{-}n}$ | $T_{sm\text{-}c}$ | $T_{cl}$ |
| $CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH$ | 11.7 | — | — | — | 15.5 |
| $C_5H_{11}$–C$_6$H$_4$–COOH | — | 54 | — | — | 105 |
| $CH_3O$–C$_6$H$_4$–CH=N–C$_6$H$_4$–$C_4H_9$ | — | 22 | — | — | 47 |
| $C_2H_5OCO$–(C$_6$H$_4$)$_4$–$COOC_2H_5$ | 284 | — | — | — | 367 |
| $C_9H_{19}$–C$_6$H$_4$–(N=N)$_2$–C$_6$H$_4$–$C_9H_{19}$ | 140 | — | 146 | — | 151.5 |
| $(CH_3O$–C$_6$H$_4$–CH=N–C$_6$H$_4$–$)_2Hg$ | — | 209 | — | — | 285 |
|  | 63.5 | — | — | 78.8 | 84.8 |
| $C_{15}H_{23}COO$–C$_6$H$_4$–$(CH_2)_2CHCOOK$ | 240 | — | — | — | 335 |

*Here and subsequently the following subscripts are used to denote phases in the symbols for phase transition temperatures: c = cholesteric; i = isotropic; n = nematic; s = solid; and sm = smectic. As an example $T_{s\text{-}sm}$ is the temperature of transition from the solid to the smectic state. All transitions from solid to mesomorphic and from mesomorphic to the isotropic state are also denoted as melting points $T_m$ and clear points $T_{cl}$ respectively.

A small group comprises acyclic liquid crystals, mainly unsaturated aliphatic acids and their derivatives. In it may be included a few esters of carbonylbisamino-acids of general formula ROCOCHR'NHCONHCHR'COOR. These compounds are obtained from optically active esters of valine and leucine, and form a smectic phase [93].

A more representative group consists of isocyclic liquid crystals (~200 compounds [2]). Among them only 4,4″-dialkyltercyclohexanes and *trans*-4-alkylcyclohexanecarboxylic acids do not contain benzene rings. They are characterised by formation of a plastic mesophase. The remaining liquid crystals of this group contain aromatic rings together with the isocyclic residue. These are mainly 2,6-di-*p*-R-benzylidenecyclohexanones, where R = Alk, AlkO, or AcylO. Analogous derivatives of cyclopentanone and cycloheptanone have also been obtained.

More than 50% of known liquid crystals are benzene derivatives, a considerable proportion of which can be represented by the formulae

where R, R′ = Alk, AlkO, AcylO, AlkOCOO, AlkOCO, Hal, $NO_2$, or CN, while X and Y represent single bonds or the groups N:N, N:NO, CH:CH, CH:N, CH:NO, COO, C≡C, etc. *para*-Substituted benzoic and cinnamic acids are also mesomorphic, forming in the liquid-crystalline state dimers, e.g.

Certain derivatives of naphthalene [2,94], 2,7-disubstituted derivatives of fluorene and fluorenone, and also 4,4‴-disubstituted *p*-quaterphenyls possess the properties of liquid crystals. This applies also to unsubstituted *p*-quinque-, *p*-sexi-, and *p*-septi-phenyls.

Most known heterocyclic liquid crystals (~700) have an analogous structure to the benzene derivatives, but with one of the benzene rings replaced by pyridine, pyrimidine, pyrazine, pyridazine, or 1,2,4,5-tetrazine. Liquid-crystalline compounds are known also in other classes of heterocycles, e.g. quinolines [95] and benzazoles [96].

Cholesteric liquid crystals are formed by cholesterols, thiocholesterols, stigmasterols, ergosterols, and certain other sterols substituted in the hydroxy-group. Chloro-, bromo-, and iodo-cholesterols are also mesomorphic.

Around 200 liquid-crystalline compounds are salts of aliphatic or aromatic acids with alkali or alkaline-earth metals, or hydrohalides of substituted pyridines and quinolines.

### 2. Structure and Transition Temperatures

The demand by technology for liquid-crystalline materials has been the main stimulus to the establishment of rules between structure and mesogenicity and to the prediction of transition temperatures. The first requirement to be met by such materials is the occurrence of a mesophase over a wide temperature range including room temperature. Mixtures of liquid-crystalline compounds provide the best means of achieving this aim, since individual substances rarely have melting points below 40°C. However, individual liquid crystals are required to have melting points as low as possible and a wide temperature range of existence of the mesophase.

Examination of experimental data on transition temperatures and especially study of these temperatures in various homologous series have yielded several empirical conclusions on the relation between structure and mesogenicity. These rules apply to temperatures of transitions from one mesophase to another and from a mesophase to an an isotropic state, whereas temperatures of transition from the crystalline state to mesophase vary irregularly.

Only observations of a general character have been made on the latter, applicable also to melting points of non-mesomorphic compounds and consisting in a rise in such temperatures with increase in molecular weight, polarisability, polarity, and molecular symmetry, as well as on formation of intermolecular hydrogen bonds.

The occurrence of regularities in the transition points between one mesophase and another or the isotropic liquid is due primarily to the fact that the structure of a given mesophase and the relative arrangement of molecules in it are common to compounds having different structures. Yet such compounds may form solid crystals differing in structure and with different relative arrangements of the molecules in the crystal lattice. Small variations in molecular structure may lead to packing in a different three-dimensional lattice with markedly different intermolecular distances and a different arrangement of the molecules, which will produce significantly different intermolecular interactions and hence melting points. Furthermore, transition from the crystalline to the mesomorphic state will be accompanied by a greater change in energy of intermolecular interaction than in transitions between mesophases or from a mesophase to an isotropic liquid. This rule is apparent in the heats of transition: thus for *pp'*-dialkoxyazoxybenzenes the heats of transition crystal–mesophase, smectic–nematic, nematic–isotropic, and smectic–isotropic liquid are respectively 11.7–28.0, 0.02–2.30, 0.27–2.30, and 6.97–7.90 kJ mole$^{-1}$.[97] A detailed account has been given[98] of the thermodynamic properties of liquid crystals.

In investigations of the correlation between molecular structure and mesogenicity the greatest attention has hitherto been paid to transition points between mesophases and especially to the temerature $T_{cl}$ of transition from a mesophase to an isotropic liquid. At the clear point the energy of thermal motion of the molecules becomes equal to the energy of intermolecular interaction ensuring long-range orientational order. The clearing temperature is thus a measure of the mesogenicity of a compound or of the thermal stability of the mesophase (if a compound A exists as a mesophase from 70 ot 200°C, and a compound B over the range 200–201°C, the mesophase of B has the greater thermal stability). In comparisons of this kind it is unimportant whether the clear point lies above or below the melting point of the solid crystal (enantiotropic or monotropic liquid crystals respectively).

Two conclusions concerning transition temperatures follow from the Maier–Saupe theory of nematic liquid crystals (Section II, 2), which is based on dispersion forces of attraction between molecules: firstly, molecules possessing anisotropy of polarisability are necessary for establishment of the liquid-crystalline state, and the transition temperature rises with increase in such anisotropy; secondly, permanent dipoles can exert only a weak influence on transition temperatures. A comparison has been made of the variation in the anisotropy of polarisability of the substituent X and the clearing temperatures of azomethines (XIV) and esters (XV) [99]

(XIV)

(XV)

X = F, Cl, Br, $CH_3$, $CH_3O$, $C_2H_5O$, $NO_2$, CN.

According to the Maier–Saupe theory the clear point is given by

$$T_{cl} = A/4.54\,kV^2, \qquad (12)$$

where $k$ is Boltzmann's constant, $V$ is the molar volume at $T_{cl}$, and $A$ is proportional to the square of the anisotropy of polarisability of the molecule[40]. Expressing the anisotropy in terms of the sum of the polarisabilities $\Delta\alpha_M$ of the main part of the molecule and $\Delta\alpha_X$ of the substituent, we obtain

$$T_{cl} \propto (\Delta\alpha_M)^2 + 2\,\Delta\alpha_M \cdot \Delta\alpha_X + (\Delta\alpha_X)^2 \ . \qquad (13)$$

Neglecting the last term (since $\Delta\alpha_M \gg \Delta\alpha_X$), we obtain a linear relation between $T_{cl}$ and $\Delta\alpha_X$. Experimental data on esters (XV) are well represented by a straight line, and those on azomethines (XIV) also reveal a well defined tendency for $T_{cl}$ to rise with increase in $\Delta\alpha_X$. Examples for several other series

(XVI)

(XVII)

(XVIII)

(XIX)

(XX)

(Table 2) confirm this tendency, although the methoxy-derivatives may exhibit regular deviations.

Table 2. Effect of terminal substituents X on clear points.

| X | $(\Delta\alpha_X)$, Å$^3$ | Clearing temperature $T_{cl}$, °C | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | (XIV)[99] | (XV)[100] | (XVI)[101] | (XVII)[101] | (XVIII)[5] | (XIX)[2] | (XX)[2] |
| F | 0.5 | 26 | 180 | 199 | — | 265 | 198 | — |
| $CH_3$ | 1.2 | 38 | 199 | 236 | 265 | 279 | 271 | 281 |
| Cl | 2.5 | 47 | 212 | 246 | 275 | 295 | 250 | 293 |
| $CH_3O$ | 3.1 | 102 | 223 | 300 | 300 | 318 | 316 | 316 |
| Br | 3.9 | — | 213 | 252 | 277 | 294 | 275 | 292 |
| $NO_2$ | 4.0 | 82.5 | — | 281 | — | 308 | 317 | 310 |
| $C_2H_5O$ | 4.2 | 122 | — | 287 | 295 | 304 | 300 | — |
| CN | 4.4 | 119 | 249 | 353 | — | — | 322 | 327 |

Extension of the above equations to other classes is restricted both by the scarcity of data on the quantity $A$ and molar volume $V$ and by the discrepancies found sometimes between calculated and experimental values, probably resulting from the postulates made in the theory. It must be borne in mind also that a substituent introduced into a molecule not only changes the polarisability but may produce several other effects, e.g. by changing the molecular geometry, which will have a significant influence on the clearing temperature. As a consequence it is difficult to make an unambiguous interpretation of many experimental results on transition points in liquid-crystalline compounds. Clearly, however, increase in the anisotropy of polarisability should lead to a rise in the clear point. The quantity $V$ should be regarded probably as a factor representing the effect of steric forces of repulsion between molecules in the mesophase. The increase in intermolecular distance caused by these forces leads to a weakening of intermolecular forces of attraction and hence to a fall in the clearing temperature.

The anisotropy of electronic polarisability is determined to a first approximation by the geometrical anisotropy. As a consequence, mesomorphic properties are present in the *trans*-forms of *pp'*-disubstituted stilbenes

and *p*-substituted cinnamic acids, but absent from the *cis*-analogues. Among alkoxybenzoic acids only the *para*-isomers are mesomorphic, whereas the *ortho*- and *meta*-isomers are not. These facts can be used in determining molecular structure when it is necessary to choose between linear and branched configurations of isomers.

The introduction of additional benzene rings has a greater effect on the clearing temperature than have terminal substituents. In a series of esters, for example, the transition points vary as follows with increase in the number of benzene rings [102,103]:

(XXI)

$T_{s-n} = 86°$, $T_{n-i} = 91°$

(XXII)

*a*) R = Me: $T_{s-n} = 213°$, $T_{n-i} = 297°$;

*b*) R = Bu: $T_{s-n} = 153°$, $T_{n-i} = 241°$

(XXIII)

$T_{s-sm} = 171°$, $T_{sm-n} = 184°$, $T_{n-i} = 358°$.

Replacing the *p*-phenylene rings in (XXII) by the rigid but less polarisable bicyclo[2,2,2]octane rings leads to fall in the nematic–isotropic transition point [104]:

(XXIV)

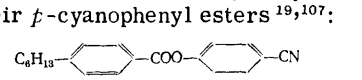
a) R = $CH_3$; $T_{s-n}$ = 185°, $T_{n-i}$ = 269°;
b) R = $C_4H_9$; $T_{s-n}$ = 152°, $T_{n-i}$ = 221°

(XXV)

$T_{s-n}$ = 189°, $T_{n-i}$ = 221°

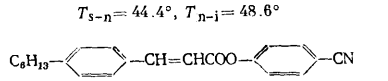
(XXVI)

$T_m$ = 209°, $T_n$ = 130°



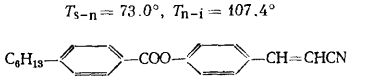
(XXVII)

$T_m$ = 197°, $T_n$ = 195°.



The width of the bicyclo-octane ring is comparable with that of the benzene ring (5.0 and 4.9 Å), but the latter is more planar (2.7 instead of 4.5 Å thick). In view of the possibility of rotation of molecules in liquid crystals about the long axis, the effect of the latter factor is neglected. The probable reason for the considerable fall in thermal stability of the mesophase (by 100 deg) on passing from (XXIV) to (XXVII) is that the cyclohexane fragment is less rigid than the bicyclo-octane ring. The diminished molecular rigidity results in disruption of linearity and thereby diminished anisotropy of polarisability of the molecule. A fall in the clear point is observed also on passing from esters of biphenyl-4,4′-diol to those of bicyclohexyl-4,4′-diol. [105]

The role of an additional double bond in a molecule of a liquid crystal has been examined in *p*-alkylbenzenzoic acids [106] and their *p*-cyanophenyl esters [19,107]:



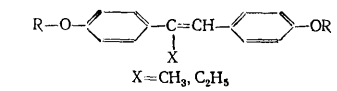
(XXVIII)

$T_{s-n} = 44.4°$, $T_{n-i} = 48.6°$

(XXIX)

$T_{s-n} = 73.0°$, $T_{n-i} = 107.4°$

(XXX)



$T_{s-n} = 97.5°$, $T_{n-i} = 147.7°$

(XXXI)

$T_{s-n} = 93.8°$, $T_{n-i} = 226.5°$

The rise in the clearing temperature in this case can also be treated as a consequence of increased anisotropy of polarisability of the molecule. The higher values for (XXX) than for (XXIX) can be explained by the longer conjugated chain containing the double bond in the former. This reflects the fact that the anisotropy of polarisability is influenced not only by the overall linear configuration of the molecule and the presence of readily polarisable structural units but also by the possibility of conjugation between various parts of the molecule (terminal and central groups, benzene rings, double bonds). Introduction of the α-alkyl group in the stilbene derivatives

(XXXII)

disrupts conjugation in the molecule, with a consequent fall in the clear point for the methyl homologue from 176 to 95°C and for the ethyl homologue [108] from 189 to 121°C. Data on the variation of the clearing temperature due to the substitution of azomethines [109] and of biphenyl derivatives [5] can be interpreted similarly.

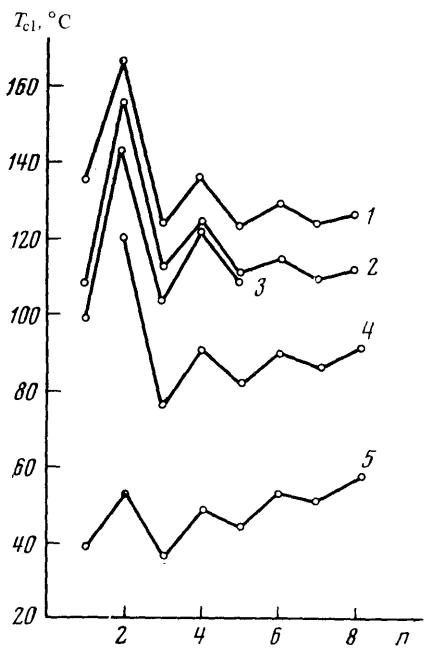


Figure 14. Clear points of the compounds [2]

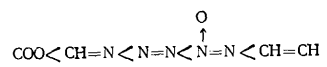
where X represents: 1) N:NO; 2) N:N; 3) CH:N; 4) COO; 5) and of



A closely related problem is the influence of the central group on the thermal stability of the nematic phase (Fig.14). Data are available also for alkylalkoxy-derivatives with one pair of substituents [110]:

(XXXIII)

| X = | CH=CH | N=N | N=N | N=CH | CH=N | N=N | N=CH | CH=N | C≡C | COO | OCO |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $T_{cl}$, °C | 121 | 77 | 74 | 70 | 53 | 49 | 49 | 46 | 37 | 24 | 22 |

With an unsymmetrical central group the isomers in the series (XXXIII) (excluding nitrones) have closely similar clear points. As appears from the above data, the central groups X can be arranged in the sequence

of increasing thermal stability of the mesophase. On passing from non-conjugated esters to partly conjugated azomethines and to planar and conjugated azo-compounds and stilbenes the anisotropy of polarisability tends to increase in the same sequence.

Table 3. Calculated parameters of central groups for determining clear points of [111]

| X | Temperature parameter, deg | X | Temperature parameter, deg |
|---|---|---|---|
| N=N | 0 | CH=N | −9 |
| CH=CH | +51 | COO | −35 |
| N=N ↓ O | +21 | C=C | −33* |
| | | CH=CCl | −32 |
| CH=N ↓ O | +8 | | |

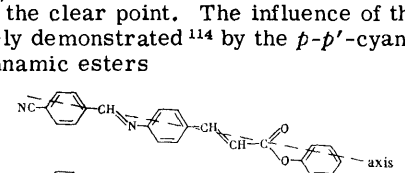
*Taken from Ref. 112.

Statistical treatment of a large quantity of experimental data [111] on the clearing temperatures of nematic liquid crystals led to suggested parameters defining the influence of central and terminal groups (Tables 3 and 4). An unknown clear point is determined as the sum of the parameters of central and terminal groups. Thus for *p*-butyl-*p'*-methoxystilbene [110]

$$T_{cl} = 55° (OCH_3) + 15° (C_4H_9) + 51° (CH=CH) = 121°;$$

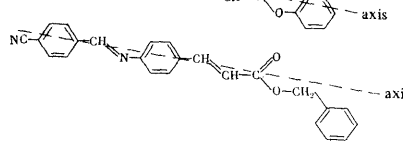
$$T_{cl}^{exp} = 121° .$$

However, considerable discrepancies between calculated and experimental values are found for the same substituents in an azomethine (61 and 47°C), an azo-compound (70 and 47°C), and an azoxy-compound (91 and 71°C). The additive approach is evidently of limited application to the determination of clear points.



The variation of the clearing temperature with growth of the alkyl chain also exhibits several peculiarities—(i) alternation, i.e. a rise in the clear point on passing from a liquid crystal having an even number of atoms (including oxygen) in the chain to a liquid crystal with an odd number of atoms, followed by a fall on subsequently passing from an odd to an even number of atoms, (ii) a fall in the case compounds whose clear points lie above 80°C, and (iii) a rise in compounds having clear points below 80°C—which can be explained by the Maier–Saupe theory [112]. For an odd atom the increment of polarisability along the long axis of the molecule is about double the increment transverse to the axis, but for an even atom in the chain the contributions to the polarisability parallel and transverse to the axis are roughly equal, which leads to the alternation in clearing temperature. The overall anisotropy of polarisability increases with growth of the alkyl chain, which causes a rise in the clear point for compounds having low clear points (increase in $A$ in Eqn.12). In compounds having high clearing temperatures the increase in mobility of the alkyl chain begins to have an effect, which increases as the chain becomes longer, with growth in the steric forces of repulsion (increase in $V$ in Eqn.12) and fall in the clear point.

Table 4. Calculated increments of terminal groups for determining clear points of [111]



| R | Temperature parameters, deg | | | | | |
|---|---|---|---|---|---|---|
| | $n=1$ | $n=2$ | $n=3$ | $n=4$ | $n=5$ | $n=6$ |
| $C_nH_{2n+1}$ | −2 | 5 | 12 | 15 | 14 | 2 |
| $C_nH_{2n+1}O$ | 55 | 75 | 56 | 61 | 55 | 58 |
| $C_nH_{2n+1}COO$ | 65 | 67 | 63 | 54 | 50 | 45 |
| $C_nH_{2n+1}OCOO$ | 68 | 61 | 42 | 41 | 43 | 35 |

The above examples of the relation between clearing temperature and structure were concerned with the variation of the anisotropy of the molecular polarisability, i.e. with the quantity $A$ in Eqn.(12). No reliable data are available on the dependence on the molar volume $V$. However, it is known that increasing the width of the molecule (defined as the diameter of the smallest cylinder into which the molecule can be placed), e.g. by introducing a side-chain, leads to a fall in the clear point [5,113]. Broadening the molecule increases the interaxial distances in the mesophase, which weakens intermolecular interactions and lowers the clear point. The influence of this factor is effectively demonstrated [114] by the *p-p'*-cyanobenzylidenaminocinnamic esters

(XXXIV)

(XXXV)

The explanation of this effect is that, when $n$ is even (e.g. in compound XXXIV), the benzene ring of the ester group fits along the long axis of the molecule, but when $n$ is odd (as in XXXV) it fits across this axis, thereby increasing the width of the molecule. A similar observation has been made on phenylalkanoates of sterols [115].

The clear points of substituted derivatives (XXXVI) vary with $n$ and the location of the substituent (Table 5). When $n$ is even, substitution at position 4″ increases the anisotropy of the molecule and hence raises the clearing temperature, but 3″-substitution widens the molecule and

lowers this temperature. When $n$ is odd, 4″-substitution also has the latter effects. With 3″-substitution conformers may apear in which the substituent widens the molecule and lowers the clear point, but the substituted benzene ring may occupy a position in which the substituent has no broadening effect ($n = 1$, X = Cl). The change in clearing temperature with the parity of $n$ in unsubstituted compounds (XXXVI) reaches 240 deg, and in 4″-substituted derivatives >360 deg (Table 5).

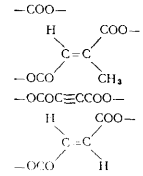
Table 5. Clear points for the compounds

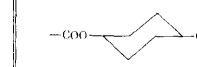
(XXXVI)

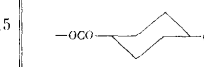
| X | Clear points, °C | | | |
|---|---|---|---|---|
| | $n = 0$ | $n = 1$ | $n = 2$ | $n = 3$ |
| H | 280.2 | 38.5 | 187.7 | 36.4 |
| 4″-Cl | 338 | —30* | 217.8 | 13 |
| 4″-$CH_3$ | 290—331 | —30* | 226.5 | 7 |
| 3″-Cl | 231.5 | 47.5 | 150.6 | 32.8 |
| 4″-$CH_3$ | 219.4 | 26 | 154.5 | 9 |

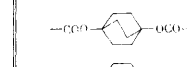
*Mesophase not observed on cooling to −30°C.

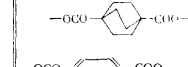
Introduction of a side-chain into the molecule of a liquid crystal lowers not only the clear point but often also the melting point, which provides a method for obtaining low-temperature liquid crystals [100]. However, melting-point depression is not observed in all cases [5,116].

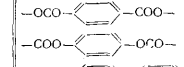












Thus the Maier–Saupe theory is useful in a qualitative discussion of the relation between structure and clear point. However, there are also other approaches to the theory of nematic liquid crystals. As a generalisation of the Maier–Saupe approach the molecular-statistical theory of such mesophases [41,117] takes into account not only dispersion forces but also interactions between permanent dipoles, induced dipole–dipole and dipole–quadrupole interactions, and also steric forces of repulsion. It has been suggested [118] that the agreement between experimental and theoretical values [41,117] is a consequence of the introduction of correcting parameters into the theory, and a general form of interaction potential between rodlike molecules is proposed.

The geometrical anisotropy of molecules is a decisive factor in the formation of nematic phases in solutions of macromolecules and viruses [119], but its role is not so obvious for thermotropic liquid crystals. Unambiguous conclusions cannot be reached from a direct comparison of the clearing temperatures with the length of the latter (Table 6). There is undoubtedly a tendency for the thermal stability of the mesophase to improve as the molecule becomes longer, but it is further influenced by the considerable differences in electronic structure and geometry of the central groups. Increase in the geometrical anisotropy of the molecule can be regarded as a factor favouring formation of a mesomorphic state, regardless of the presence of anisotropy of the $\pi$-electron polarisability.

The cholesteric liquid crystals known at the present time contain one or more asymmetric carbon atoms, although a cholesteric mesophase can probably be formed by molecules containing other chiral units. These liquid crystals are formed not only by steroids but also by compounds containing an asymmetric carbon atom in an alkyl chain, e.g. (IV). As racemates such compounds form nematic liquid crystals, but in optically active form give a cholesteric mesophase. The thermodynamic properties of the nematic (racemic) phase are identical with those of the cholesteric phase. Ideas developed for nematic liquid crystals can be applied to the relation between structure and cholesteric mesogenicity.

Table 6. Clear points of esters of *p*-n-butyoxyphenol [120]

| X | $d$, Å | $T_{cl}$, °C | X | $d$, Å | $T_{cl}$, °C |
|---|---|---|---|---|---|
|  | 3.5 | 92 |  | 10.0 | 157 |
| | 7.8 | 94 | | | |
|  | 8.15 | 99.5 |  | 10.0 | 220 |
| | 7.8 | 144 |  | 9.6 | 221 |
| | | |  | 9.75 | 226 |
| | | |  | 9.6 | 235 |
| | | |  | 9.75 | 241 |
| | | |  | 13.95 | 358 |

The general demands on structure of potentially smectic substances are the same as for nematic compounds. A specific aspect is that smectic liquid crystals consist of molecules having a longer terminal substituent. Thus in homologous series [2] the lower members are nematic, intermediate members possess smectic and nematic properties, and the higher members form smectic liquid crystals. Another feature of smectic mesophases is the significant role of permanent dipole moments in ensuring smectic ordering, as is evident both from theory (Section II, 2) and from dielectric data (Section III, 2). Specific comparisons of chemical structure and properties (in particular transition temperatures) require accurate knowledge of the structure of the smectic mesophase. Although smectic liquid crystals have been found in many classes of compounds, precise identification of the mesophase ($S_A$, $S_B$, $S_C$, etc.) has been accomplished only in rare cases, and conclusions on the relation between structure and properties cannot be correct at the present time.

## 3. Dielectric Properties of Liquid Crystals

Dielectric properties are an important characteristic of liquid crystals, determining in the case of nematics the possibility of their use in electro-optical devices. Thus those having a small negative dielectric anisotropy $\Delta\epsilon$ are used in instruments based on the dynamic scattering effect, whereas liquid crystals having a large positive or negative anisotropy $\Delta\epsilon$ are employed in devices based on field orientational effects. Threshold voltages (Eqn.8)

and connection times of field orientational effects depend on this anisotropy[12]:

$$\tau_{conn} = \frac{4\pi\gamma_1 d^2}{\Delta\varepsilon U^2 - 4\pi^3 K_i}, \quad (14)$$

where $K_i$ is the coefficient of elasticity, $\gamma_1$ the coefficient of viscosity, and $d$ the thickness of the layer of liquid crystals.

The dielectric constants of liquid crystals are determined in flat cells on specimens oriented by the walls or by an external magnetic field. Owing to the difficulties of obtaining uniformly oriented specimens of smectic liquid crystals, their dielectric properties have been studied less fully.

Application of an external electric field to an isotropic liquid causes a static polarisation $P$ equal to the sum of the orientational, electronic, and atomic polarisations and depending on the strength $E$ of the applied field and the dielectric constant $\epsilon$ of the liquid[121]:

$$P = P_o + P_e + P_a = \frac{\varepsilon - 1}{4\pi} \cdot E \quad (15)$$

The orientational polarisation $P_o$ is determined by the magnitude and direction of the permanent dipole moment, and for non-polar molecules $P_o = 0$. The electronic polarisation $P_e$ depends on the ease of displacement of the electron orbitals relative to the nuclei under the influence of the electric field, i.e. on the electronic polarisability $\alpha$:

$$P_e = \frac{4}{3}\pi N\alpha . \quad (16)$$

For organic molecules the atomic polarisation is usually taken to be $P_a = 0.1 P_e$.[121]

The dielectric constants of liquid crystals are related to the degree of ordering $S$, the mean polarisability $\bar{\alpha}$, the anisotropy of polarisability of the molecule $\Delta\alpha$, the dipole moment $\mu$, and its angle $\beta$ relative to the long axis of the molecule[58]:

$$\frac{\varepsilon_\parallel - 1}{4\pi} = NhF\left[\bar{\alpha} + \frac{2}{3}\Delta\alpha S + F\frac{\mu^2}{3kT}\{1 - (1 - 3\cos^2\beta)S\}\right] \quad (17)$$

$$\frac{\varepsilon_\perp - 1}{4\pi} = NhF\left[\bar{\alpha} - \frac{1}{3}\Delta\alpha S + F\frac{\mu^2}{3kT}\left\{1 + \frac{1}{2}(1 - 3\cos^2\beta)S\right\}\right] \quad (18)$$

$$\frac{\Delta\varepsilon}{4\pi} = NhF\left\{\Delta\alpha - F\frac{\mu^2}{2kT}(1 - 3\cos^2\beta)S\right\} \quad (19)$$

where $N$ is the number of molecules in unit volume, $T$ K is the temperature, $k$ is Boltzmann's constant, and $h$ and $F$ are factors representing the field in space and the Onsager reaction field. It follows from Eqns.(17)–(19), deduced from Onsager's theory of dielectrics, that the dielectric properties of liquid crystals are determined by the molecular parameters, the parameter $S$ characterising the liquid-crystalline state, and the temperature, where $S$ is strongly dependent on temperature, but the other parameters vary little. Equation (19) indicates that, for molecules having $\mu = 0$ and for those having $\mu \neq 0$ with $3\cos^2\beta = 1$ (i.e. with $\beta = 55°$), the anisotropy $\Delta\epsilon$ is determined by the value of $\Delta\alpha$.

Equations (17)–(19) have been tested quantitatively on *pp'*-dimethoxyazoxybenzene[122]. Comparison of the angles $\beta$ determined by three different methods gave values of 65°, 62°, and 75° obtained from dielectric measurements, the Kerr constant, and group dipole moments respectively. The first two methods yield similar values, but the high value obtained by the third method is attributed[122] to the absence of accurate data on the angle of the dipole moment of the azoxy-group. Use of these formulae to determine dielectric constants is restricted by the lack of accurate data on molecular polarisabilities, dipole moments, and the angles $\beta$. Nevertheless, Eqns.(17)–(19) can be used for a qualitative and semi-quantitative interpretation of experimental results.

Table 7. Dielectric constants of nematic liquid crystals of

*Reduced temperatures are used to eliminate the implicit dependence of $\epsilon$ on $T$ involved in the parameter $S$ in Eqns.(17)–(19).

The measured dielectric constants of liquid crystals (Table 7) clearly indicate the significant part played by permanent dipole moments in determining the dielectric properties. Non-polar molecules (No.1 and 2) have small values of $\epsilon$ and $\Delta\epsilon$, which increase somewhat on introduction into the molecule of weakly polar substituents (alkoxy-groups) or a polar central bond (azoxy, azomethine, or ester groups). The greatest effect is exerted by the nitrile group ($\mu = 4.18$), which, depending on the position at which it is introduced, may produce either a large positive anisotropy $\Delta\epsilon$ (No. 4, 8, 13, and 15) or a large negative value (No. 16).

A quantitative assessment of the role of group dipole moments in determining dielectric constants was obtained by comparing calculated molecular dipole moments with the effective values determined from dielectric measurements[123]. Calculation, which took into account the degree of order $S$, was based on projections of the dipole moment of each group on the long and short axes of the molecules ($\mu_{i\parallel}$ and $\mu_{i\perp}$):

$$\mu_\parallel^{theor} = \left[\sum \mu_{i\perp}^2 \cdot (1 - S) + (1 + 2S) \cdot \left(\sum \mu_{i\parallel}\right)^2\right]^{1/2} \quad (20)$$

$$\mu_\perp^{theor} = \left[\sum \mu_{i\perp}^2 \cdot \left(1 + \frac{S}{2}\right) + (1 - S) \cdot \left(\sum \mu_{i\parallel}\right)^2\right]^{1/2} . \quad (21)$$

The $\mu_i$ values used in the calculations are given in Table 8. Dipole moments were determined from dielectric measurements by means of formulae analogous to those proposed by Onsager for isotropic dielectrics [123]:

$$\mu_{\parallel}^{exp} = \frac{9kT}{4\pi N} \frac{(\varepsilon_{\parallel} - \bar{n}^2) \cdot (2\varepsilon_{\parallel} + \bar{n}^2)}{\varepsilon_{\parallel} (\bar{n}^2 + 2)^2} \quad (22)$$

$$\mu_{\perp}^{exp} = \frac{9kT}{4\pi N} \frac{(\varepsilon_{\perp} - \bar{n}^2)(2\varepsilon_{\parallel} + \bar{n}^2)}{\varepsilon_{\parallel} (\bar{n}^2 + 2)^2}, \quad (23)$$

where $\bar{n}$ is the mean refractive index of the liquid crystal. Measurements of the dielectric constant were made at a temperature of 0.98 $T_{cl}$ K, with the degree of order taken to be $S = 0.4$. In all the examples cited [123] $\mu^{theor}$ exceeds $\mu^{exp}$ usually by at most 30%. Thus data on group dipole moments can be used to determine the sign of $\Delta\epsilon$ and to estimate dielectric constants.

Table 8. Group dipole moments $\mu_i$. [123]

| Group | $\mu_i$ | $\mu_i$ | $\mu_{i\parallel}$ | $\mu_{i\perp}$ |
|---|---|---|---|---|
| Ph–C(=O)–O–Ph | ↗ | 1.90 | 0.89 | 0.68 |
| Ph–C(=H)–N–Ph | ↘ | 1.57 | 0.40 | 1.51 |

| Ph–CN | → | 4.18 | 4.18 | 0 |
| Ph–O–$CH_3$ | ↙ | 1.28 | −0.40 | 1.22 |
| Ph–O–C(=O)–$CH_3$ | ↖ | 1.69 | −0.69 | 1.54 |

Introduction into the molecule of a nitrile group with a dipole moment directed along the long axis leads to increases not only in $\epsilon_{\parallel}$ but also in $\epsilon_{\perp}$ (Table 7). This is a consequence of the imperfect orientation of molecules in the liquid-crystalline phase ($S \neq 1$).

Changing the sites of substituents has different effects on $\epsilon_{\parallel}$ in azomethines (Table 7, No. 13 and 14, $\epsilon_{\parallel} = 22.6$ and 17.2) and in esters (No. 8 and 9, 27.8 and 10.6). In both cases $\epsilon_{\parallel}$ is determined mainly by the group dipole moment of the nitrile group, to which is added (No. 8 and 13), or from which is subtracted (No. 9 and 14), the parallel component of the ester ($\mu_{\parallel} = 0.89$) or azomethine ($\mu_{\parallel} = 0.40$) the central group. Since the component $\mu_{\parallel}$ of an ester group is more than double that of an azomethine group, the observed effects are also more pronounced in the esters. In the case of liquid crystals having slight anisotropy $\Delta\epsilon$ transposition of substituents may lead to change not only in the dielectric constant but also in the sign of $\Delta\epsilon$. This has been observed in isomeric phenyl benzoates [126] and 4(4′)-butyl-4′(4)-methoxyazoxybenzene [127] (incidentally, our results indicate that the characteristics measured in Ref. 126 do not apply to the same isomer).

The dielectric constants of liquid crystals depend not only on molecular structure, degree of order, and temperature but also on the frequency of the applied electric field (Section III, 2).

## VI. LIQUID-CRYSTALLINE MATERIALS

### 1. General Requirements

The practical utilisation of thermotropic liquid crystals requires a set of properties that individual liquid-crystalline componds do not usually possess. For example, the working substance in indicator devices operating on the dynamic scattering effect should be in a liquid-crystalline state throughout the temperature range in which the device functions (laboratory and domestic instruments require liquid crystals melting at or below 0°C and clearing at or above 50°C). The electrical conductivity should be sufficient for an effect to appear ($\geq 10^{-10}$ ohm$^{-1}$ cm$^{-1}$) but at the same time not too high ($< 10^{-7}$ ohm$^{-1}$ cm$^{-1}$), so that electrolytic processes that would lower the operating resources of the instrument are slowed down and the consumption of energy is diminished. The working substance should have a slight negative dielectric anisotropy ($\Delta\epsilon$ from −0.2 to −0.6), with definite viscosity characteristics to ensure acceptable durability (until the appearance of scattering) and relaxation times (around 100 ms), it should be photochemically stable, and it should be oriented in the cell in a specified manner. Several less fundamental requirements (stability in moisture, atmospheric oxygen, etc.) may be satisfied by the technique of filling and hermetically sealing the indicator cell.

For indicators operating on orientational effects the working substance should usually have positive dielectric anisotropy, but the conductivity requirement is significant only in the sense that diminishing the conductivity (to $< 10^{-12}$ ohm$^{-1}$ cm$^{-1}$) may considerably increase the operating resources and decrease the consumption of current.

Cholesteric liquid crystals for thermographic purposes should operate in a specified temperature range (sometimes very narrow, $< 1$ deg), have high thermal sensitivity, and be resistant to light and chemical attack by the atmosphere.

As a consequence of the above and several other requirements, individual compounds are not used for practical application, but more or less complicated compositions or liquid-crystalline materials.

### 2. Liquid-crystalline Mixtures

Mixtures of two or more liquid crystals are used to achieve the required temperature range for a nematic mesophase. Attempts are made to find a eutectic composition, at which the melting point passes through a well defined minimum for a given combination of individual components, whereas the variation of the clear point is approximately linear. Fig. 15 shows the phase diagram for a binary mixture of *p*-cyanophenyl *p*-hexylbenzoate (A) and *p*-heptylbenzoate (B). [128] The maximum temperature range of existence of the mesophase (~30 deg) evidently corresponds to the eutectic mixture, containing ~50% of component B. The problem of finding the eutectic of binary and ternary mixtures can be solved by simple trial and error, although this is quite laborious in the latter case. With four or more components trial and error is unsuitable, and the thermodynamic constants of the components and mathematical methods must be employed to find the optimum composition.

On the assumption that mixtures of structurally similar components are nearly ideal solutions the composition and

the melting point of the eutectic of an $i$-component mixture can be calculated from a set of $i$ le Châtelier-Schröder-van Laar equations [129,130] containing $i$ unknowns

$$\begin{cases} \ln X_1 = \frac{\Delta H_1}{R} \cdot \left(\frac{1}{T_m} - \frac{1}{T_{m1}}\right) \\ \cdots\cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \ln X_i = \ln(1 - X_1 - \ldots - X_{i-1}) = \frac{\Delta H_i}{R} \cdot \left(\frac{1}{T_m} - \frac{1}{T_{mi}}\right), \end{cases} \quad (24)$$

where $X_i$, $T_{m,i}$, and $\Delta H_i$ are respectively the mole fraction, the melting point, and the heat of fusion of the $i$th component, and $R = 8.314$ J mole$^{-1}$ deg$^{-1}$. The clear point of such systems can be calculated with sufficient accuracy by means of the equation [131]

$$T_{cl} = \sum X_i T_{cl\,i}, \quad (25)$$

in which $T_{cl,i}$ is the clear point of the $i$th component.

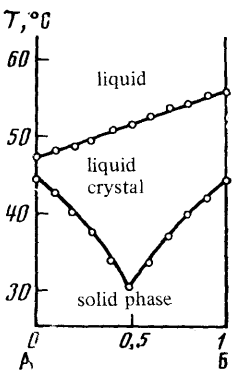

Figure 15. Diagram of phase transitions of $p$-cyanophenyl: A) $p$-hexylbenzoate; B) $p$-heptylbenzoate.

In several cases (biphenyls, azoxy-compounds) the calculated values agree well with experiment, but this method is not universally applicable. Thus clearing temperatures calculated for liquid-crystalline $p$-cyanophenyl $p$-alkylbenzoates differ considerably (by up to 20 deg) from the experimental values [132]. In these cases the problem of finding the eutectic composition can be solved by a simplex method of experiment design [133] consisting in an initially arbitrary (approximate) choice of composition and "step" for its variation, experimental determination of the melting points of $i + 1$ mixtures (where $i$ is the number of components), and mathematical treatment of the results [133], followed by choice of a new initial composition and interval of variation until a eutectic with specified properties is attained.

Even the first experiments on the use of this method have shown [128] that good results can be obtained with a comparatively small number of experiments. Thus it was necessary to measure the melting points of only eight mixtures in order to find the eutectic composition of the ternary system of mixed carbonates $p$-$C_4H_9C_6H_4COO$-$p'$-$C_6H_4OCOOR$ (R = $C_6H_{13}$, $C_7H_{15}$, $C_8H_{17}$), and the calculated melting point (68.5°C) coincided with the value determined from the thermogram. Calculation based on Eqn.(24) gave too low a melting point (63°C) for the eutectic mixture [128].

Even more complicated problems than lowering the temperature of formation of the mesophase and extending the temperature range of its existence are solved by trial-and-error selection of the component composition of liquid-crystalline mixtures. For example, materials with a relatively small positive dielectric anisotropy $\Delta\epsilon$ and a wide temperature range of the mesophase can be used in indicator devices operating on the field effect. Yet the large majority of liquid-crystalline compounds of this type are benzonitrile derivatives [134] having a large dielectric anisotropy [19] and high melting points. By mixing liquid crystals having a large positive dielectric anisotropy with low-temperature liquid crystals having a small negative dielectric anisotropy we can select a composition satisfying the above requirements. Thus mixing in different ratios $p$-$p'$-butoxybenzylidenaminobenzonitrile (BBABN) ($\Delta\epsilon = +19$ at 63°C, [135] m.p. 64°C, $T_{cl}$ = 105°C) with a 2 : 1 mixture of $p$-butyl-$N$-$p'$-methoxybenzylidenaniline (BMBA) and $p$-butyl-$N$-$p'$-ethoxybenzylidenaniline (BEBA) ($\Delta\epsilon = -0.46$ at 25°C, m.p. −12°C, $T_{cl}$ = 48°C) we can obtain the mixtures listed in Table 9 [136,137].

Table 9. Effect of additions of BBABN on phase transition temperatures and sign of dielectric anisotropy of mixtures of BMBA and BEBA.

| Mixture, mass % | | $T_m$, °C | $T_{cl}$, °C | $\Delta\epsilon$ at 24°C |
|---|---|---|---|---|
| ⅓BEBA + ⅔BMBA | BBABN | | | |
| 100 | 0 | −12 | +48 | −0.5 |
| 99.1 | 0.9 | −13 | +49 | −0.3 |
| 98.2 | 1.8 | −13 | +50 | −0.1 |
| 95.5 | 4.5 | −10 | +52 | +0.7 |
| 92.0 | 8.0 | −2 | +55 | +1.5 |
| 85 | 15.0 | +2 | +60 | +3.2 |
| 69 | 31.0 | +22 | +74 | +6.5 |
| 0 | 100 | +64 | +105 | +18.0 (64° C) |

Admixture of non-mesophasic compounds having a large dipole moment and compatible with the liquid crystal can be used to control the sign and the magnitude of the dielectric anisotropy. Thus additions of 2% and 7% of $p$-dimethylaminobenzonitrile [138] to a mixture of azoxy-compounds (Merck, m.p. = −5°C, $T_{cl}$ = +75°C, $\Delta\epsilon = -0.2$) yields respectively $\Delta\epsilon = +1.1$ and +3.8 with a fall in the clear point (67 and 48°C).

### 3. Additions for a Specified Conductivity

As already remarked above, liquid-crystalline materials in devices using dynamic scattering should have a definite electrical conductivity. Well purified liquid crystals are considerably less conducting than is required, and do not exhibit dynamic scattering of light. Unpurified substances, although scattering light on application of an electric field, cannot be used technically, since the nature and the content of their impurities are practically uncontrollable, depend on the quality and the "previous history" of the raw material, are sensitive to slight changes in the conditions of production and purification, etc.

In practice materials of specified conductivity and threshold voltage are obtained by the use of ionic additives or electron donors and acceptors [139], which probably form charge-transfer complexes with the components of the liquid-crystalline material. In the latter case the increase

in conductivity is caused by dissociation of the charge-transfer complexes into ions[71]. Acceptor additives[139] (tetracyanoquinodimethane, tetracyanoethylene, dichlorodicyanobenzoquinone), when introduced into mixtures of liquid-crystalline azoxy-compounds, effectively increase the conductivity with slight anisotropy (i.e. the ratio $\sigma_{\parallel}/\sigma_{\perp}$) and raise the threshold of dynamic scattering in an alternating current[83]. The conductivity of *p*-butyl-*N*-*p*′-methoxybenzylidenaniline was greatly increased by introduction of the charge-transfer complex of benzoquinone and quinol[142].

Tetra-alkylammonium halides can be used as ionic additives for nematic liquid crystals[140], with the anisotropy of the conductivity increasing with decrease in the ionic radius of the halogen. Choice of ions that are "compatible" with the structure of a given liquid crystal enables us to diminish such undesirable side-effects as fall in the temperature of transition to an isotropic liquid and decrease in the degree of ordering of the liquid crystals. Thus the use has recently been proposed[141] of additions of tetrabutylammonium salts of substituted benzoic acids $p$-$RC_6H_4COON(C_4H_9)_4$ (where R = $NO_2$, Cl, $NH_2$, $CH_3$, etc.) or threadlike compounds, e.g.

(XXXVII)

4. Orienting additions

As already noted above, liquid crystals in electro-optical cells should be oriented parallel or perpendicular (homotropically) to the walls. Such orientation can be attained by chemical or mechanical treatment of the surfaces, as well as by introducing into the liquid crystals orienting additives that are adsorbed on the surface[143], the orienting effect being determined in the latter case by the chemical nature of the additive, the surface, and the liquid crystal, as well as by the topology of the surface.

An example of an orienting addition is 0.5% of polyamide resin introduced into *p*-butyl-*N*-*p*′-methoxybenzylidenaniline and Schiff bases of similar structure to ensure their homotropic orientation[144,145]. Lecithin[146] and silicone oil[146,147] applied to glass have a similar effect. Addition of 0.25–2.5% of hexadecylammonium bromide to nematic liquid crystals[148] also leads to their homotropic orientation, whereas smaller quantities of the additive produce planar orientation[149], since the additive molecules are then able to "lie" on the electrode surface.

Orienting additives of various classes—amines, carboxylic acids, etc.—are known, most of which change chemically during operation of the cell, so that their orienting influence becomes weaker. At the present time, therefore, silane surface-bonding agents have found application[150]; they react chemically with the glass or quartz, which improves considerably their reliability. Various types of orientation can be obtained depending on the geometry chosen for the additive. Thus homotropic orientation of liquid crystals is ensured by $C_{18}H_{37}N^{+}(CH_3)_2 \cdot [CH_2]_3Si(OCH_3)_3Cl^{-}$ hydrolysed on glass, with vertical octadecyl groups, and planar orientation by $CH_3NH[CH_2]_3 \cdot Si(OCH_3)_3$ molecules.

It is clear from the above that the production of liquid-crystalline materials is a quite complicated scientific and technical problem. No materials have yet apeared that satisfy all the technical requirements[151]. Improvement of the chemical and electrochemical stability of liquid crystals, extension of the temperature range of existence of the mesophase (especially to lower temperatures), decrease in the threshold and working voltages, improvement of the temporal characteristics, and other aspects are still urgent problems.

## VII. FIELDS OF APPLICATION

The main peculiarity of liquid crystals is their ability to change their optical properties under the influence of almost any external factor. Therefore the number of applications suggested by various workers is immense. However, restricting consideration to those liquid crystals whose characteristics enable them to compete with traditional materials, we can distinguish the most important uses as electro-optical devices, thermography, spectroscopy, and certain others. Below we shall briefly examine several examples, with literature references only to the most typical papers, without any claim to completeness.

1. Electro-optical Devices

Because of the extremely low power consumption by the exciting source ($10^{-4}$–$10^{-6}$ W cm$^{-2}$ layer surface) nematic liquid crystals have already found wide application in indicators of numerical and graphic information for such electronic devices as wrist-watches and pocket calculators[152]. These instruments are autonomic (i.e. not connected to the mains), and in effect only liquid-crystalline "dials" are able to ensure that their batteries will function for a long time. Here it is important that not only the power input but also the supply voltage should be small (the latter a few volts), which makes it possible to use integral circuits as radio units. Indicators usually operate either on the dynamic scattering effect or on the twist effect, the latter similar to the Fréedericksz effect. The required numerals are displayed e.g. by feeding a voltage to a definite combination of segments of transparent electrodes formed into a typesetting "eight" (similar to that indicated by the postmark on envelopes). The range of possible application of indicators is, clearly, not restricted to watches and calculators. They can be used whenever information is to be displayed to human beings, e.g. in calculating machines, advertising panels, measuring instruments[153], control devices[154], etc. In all these cases the rapidity of response of the liquid crystals need not be better than 0.1 s (since the inertia of the human eye is almost the same), and liquid crystals can provide this with a symbol of high contrast range. Next is the production of coloured information indicators either by the use of dye molecules incorporated into liquid-crystalline matrices[155] or on the interference principle.

Another important trend in the electro-optics of liquid crystals is the attempt to produce a flat television screen for the reproduction of moving images[156]. Here the demands on the time characteristics of liquid crystals are far more severe, and success depends both on the development of liquid-crystalline materials with more rapid response and a more sharply defined threshold dependence of contrast on voltage and on the level of semiconductor technology necessary for the production of complicated mosaic devices for controlling the liquid-crystalline units. The preparation of new liquid crystals having diminished viscosity coefficients and increased elastic coefficients (to improve rapidity of response), is now the most important but hardly the most easily solved problem in the chemistry of nematic liquid crystals.

A third line of advance is the application of liquid crystals to optics[157], quantum electronics, holography, and equipment for the optical processing of information[158]. Here they are used to control the degree of coherence of a laser beam, for the phase modulation and deflection of beams with response in the millisecond range, for transforming an image from a cathode-ray tube (incoherent) to an image in coherent beams with subsequent registration on holograms, etc. Equipment has also been suggested for pictorial logic on liquid crystals[159].

Finally, electro-optical liquid-crystalline materials have been used to make X:ray, ultraviolet, and infrared images visible[160]. A film of the liquid crystals is placed in contact with a film of a photoconductor sensitive to the given spectral range. Variation of the electrical resistance of the photoconductor leads to variation in the voltage on the liquid-crystalline film with a corresponding change in its optical properties. The received (invisible) image can be made visible by means of an external liquid-crystalline intensifer. Procedures have also been proposed for visualisation of the emission of lasers without the use of photoconductors—by thermal effects in nematic[161], cholesteric[162], or smectic[163] liquid crystals. Defects in integral circuits can be visualised[164] by means of liquid crystals. A very complete survey of the most recent fields of application of liquid crystals has appeared[165].

## 2. Thermography

In virtue of the ability to reflect light selectively cholesteric liquid crystals find wide application in laboratories and in industry for the convenient visualisation of thermal fields and the measurement of temperature. Thermography by means of such mesophasss can be widely used also for detecting external factors leading to change in temperature, such as optical, X-ray, microwave, and radioactive emissions, currents of air, etc.

Portions of the human skin lying over malignant tumours and certain other seats of inflammatory processes have a rather higher temperature, and the use of cholesteric liquid crystals in polymer films (or applied directly to the skin) provides an effective method for locating foci of disease[4,166-168].

The high resolving power of cholesteric liquid crystals (of the order of the thickness of a layer, i.e. 20–90 $\mu$m) permits their use in microelectronics to reveal technical defects in microcircuits[171,172], the thermography of the thermal fields of transistors[173], which will reveal the "hottest" sites, so that cooling can be provided for in advance, in order to improve the reliability of the circuit.

The possible use of cholesteric liquid crystals in aerodynamic experiments[174] can be based on differences in the rate of cooling of the preheated mesophase depending on the rate of flow around the model.

Devices enabling the distribution of light flux across the diameter of a laser beam have been based on cholesteric liquid crystals[175]. The latter can be used also to determine internal stresses and defects in metals and alloys[176].

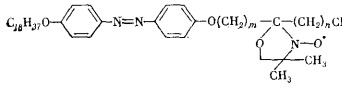
Further details of the thermographic applications of cholesteric liquid crystals can be found in Ref. 14. A detailed bibliography has been published[177] on the application of liquid crystals.

## 3. Spectroscopy

Use in spectral investigations may provide information either on the properties of the liquid crystal itself or on those of molecules dissolved in it. When liquid crystals are used as solvents, the spectra of oriented molecules can be obtained, since the long axes of dissolved molecules are oriented on the average parallel to the "director" of a nematic liquid crystal. The dissolving power of liquid crystals is almost equivalent to that of ordinary isotropic solvents, and an appropriate liquid-crystalline solvent can be selected for any substance. Such investigations are restricted by the absorption of light by the liquid crystal itself. For example, the use in ultraviolet spectroscopy of nematic mesophases containing aromatic or heteroaromatic rings is limited by the intrinsic absorption at wavelengths shorter than 350 nm. This limit can be shifted to 250 nm by using a compensated cholesteric phase as solvent[178,179] or a nematic liquid crystal based on cyclohexane. The ultraviolet or infrared spectra of oriented liquid crystals can be used to determine the polarisation of the moments of electronic or vibrational transitions in the molecules forming the liquid crystals[40,180,181], by the application of polarised radiation (parallel or perpendicular to the "director").

Examination of the dichroism of the electronic absorption by impurity molecules of dyes (or related compounds) in oriented liquid crystals and matrices[182] permits determination of the direction of the electron oscillators in these molecules, leading in several cases to conclusions on the geometrical configuration of the molecule. For example, determination of the directions of the oscillators of two long-wavelength bands due to symmetrical biscyanine dyes shows that these oscillators are mutually perpendicular[183]. The directions of oscillators in molecules of aromatic hydrocarbons have been determined by the same method[184]. Analysis of the dichroism of liquid crystals of solutions of autocomplexes of 1,4-naphthaquinone and 1,3,5-trinitrobenzene provides indications on the molecular geometry of the complexes and in several cases refinement of the specific mechanism of intramolecular charge transfer in these compounds[185]. By measuring the dichroism of rod-shaped impurity molecules, we can also investigate the structure of the liquid-crystalline matrices themselves[57].

Even at concentrations of 1–2% the dissolution of chiral compounds in a nematic liquid crystal converts the latter into a cholesteric phases (induced cholesteric liquid crystals[186,187]). Since the specific rotation of a cholesteric phase is a thousandfold that of any isotropic solution, it has been proposed to use this effect as a method of proving the chirality of molecules possessing very small specific rotations or present in small quantities. The helical pitch of an induced cholesteric liquid is in most cases so large that the selective reflection lies in the infrared[188]. The pitch and the direction of the helix have been determined from the dispersion curves of optical rotation in the infrared[189].



The addition of chiral molecules to a *C* smectic also produces a twist in its structure, the pitch in this case being about the same as for nematic–cholesteric mixtures[190].

Optically inactive molecules dissolved in a cholesteric liquid crystal exhibit in an absorption band circular dichroism induced by the liquid crystal[191,192]. This dichroism is caused not simply by the helical ordering of the dissolved molecule in the cholesteric matrix but by electronic or magnetic interactions of the chromophore of the solute molecule with the solvent[193]. The molar amplitude of the induced dichroism ($\sim 10^7$ deg cm$^2$) is tenfold that of the circular dichroism in chiral hexahelicene ($8.62 \times 10^5$ deg cm$^2$).[194] The directions of polarisation

of the moments of optical transitions have been determined for the dissolved molecule from the sign of the induced dichroism [191-193].

The largest number of spectroscopic investigations using liquid crystals have been made in the nuclear magnetic resonance range. Several reviews have been published on this aspect [14,195,199,210]. The n.m.r. spectra of a liquid-crystalline phase contain considerably more lines than do the spectra of an isotropic liquid. This is due to the presence of direct interactions between protons, which vanish in the isotropic state because of the high rotational mobility of the molecules. The degree of ordering of a liquid crystal can be determined from the n.m.r. spectra, and measurement of relaxation times will give information on the dynamics of orientational fluctuations in these systems. The fine structure of n.m.r. spectra may disappear with liquid crystals whose molecules contain many interacting protons. Such liquid crystals can be used as solvents; the resonance lines of a dissolved molecule are then observed on a smooth background. The n.m.r. spectra of simple molecules in anisotropic matrices are used to determine bond angles and lengths in the molecules.

Quite a large number of studies have been made on the use of liquid crystals in electron spin resonance spectroscopy [14,197,198]. Nematic, smectic, and compensated cholesteric liquid crystals are used as solvent. Employment of a liquid-crystalline solvent will give more complete information on the e.s.r. spectra of polyradicals. An interesting example of the use of e.s.r. spectroscopy to investigate the structures of liquid crystals is an examination of the mobility of the alkyl chains in *pp'*-dioctadecyloxyazoxybenzene [199]. Compounds of the type

(XXXVIII)

well miscible with the liquid crystal, were added (0.3%) as spin label. Transition from the solid phase of the azoxybenzene derivative to the smectic *B* phase was shown to be accompanied by increase in the mobility of the alkyl chains, and on passing from smectic *B* to smectic *C* the angle between the long axes of the molecules and the smectic plane increased.

Mössbauer spectroscopy has been used to determine the structural parameters of smectic phases [200]. The possibility has been demonstrated [201] of determining the ordering tensor of the Mössbauer label from its $\gamma$-resonance spectra in nematic and cholesteric mesophases.

## 4. Other Examples

Here we shall mention only those new trends in the application of liquid crystals on which information has appeared quite recently and which appear to be especially interesting. It has been proposed to use liquid crystals for the visualisation of ultrasonic fields and to record acoustic holograms [202], for visualisation of the distribution of mechanical stresses in various rigid objects, and to analyse gases and vapours [15].

Owing to the ordered character of a mesophase, rodlike impurity molecules dissolve in it better than do branched molecules. Ths forms the basis for the use of liquid crystals as stationary phase for the separation of isomers in gas–liquid chromatography [203,204]. Their use as anisotropic solvents in chemical reactions also is extremely promising. Both the mechanism and the kinetics of the reaction may be changed. Examples are molecular rearrangements [205,206] and polymerisations in the liquid-crystalline state [207,208].

Among important practical results may be cited the discovery of ferroelectricity in a chiral *C* smectic [26,209]. Liquid ferroelectrics may be extremely useful in nonlinear optics (e.g. for regenerators of the second harmonic of light with high resistance to laser emission); they can be used in new forms of piezo- and pyro-transducers, memory devices, etc.

# Reactions of Organic Compounds with Higher Fluorides of *f*- and *d*-Elements in Groups V and VI

V.T.Orekhov

The interaction of higher fluorides of *f*- and *d*-elements in Groups V and VI of the Periodic System with alkanes, alkenes, aromatic compounds, and also hetero-organic derivatives containing silicon, nitrogen, phosphorus, oxygen, and sulphur is surveyed. The relative oxidising powers of the inorganic fluorides are assessed. Organic donors possessing lone pairs of electrons form with penta- and hexa-fluorides of low oxidising power relatively stable adducts, least stable with the hexafluorides. Highly active inorganic fluorides undergo with organic compounds redox and substitution reactions, yielding complicated mixtures of metal-containing and fluorinated organic substances. A list of 169 references is included.

## I. INTRODUCTION

Reaction between various classes of organic compounds and inorganic fluorides such as silver(II), cerium(IV), lead(IV), bismuth(III), manganese(III), and cobalt(III) fluorides, which are selective fluorinating agents, has formed the subject of reviews[1,2] and books[3-5], and use of several of these agents has been shown to be highly effective. Hitherto, however, no summary has appeared of results on the reaction of organic compounds with higher fluorides of actinides and *d*-elements in Groups V and VI of the Periodic System, which exhibit not so much fluorinating as strongly complexing properties. Inadequate study has been made of the chemistry of complex compounds of *d*- and *f*-elements having a high formal degree of oxidation of the central atom and with coordination numbers $\geqslant 6$. The present Review represents an attempt to make certain generalisation on the basis of material published up to 1975 inclusive.

The terminology and the classification of Mulliken and Pearson[6] have been adopted in characterising donor–acceptor interactions and those of Ingold[7] and Tobe[8] for the reactions. The term "adduct" for compounds isolated individually and for those in solution is used in Cotton and Wilkinson's concept[9] as definition of a compound formed by two neutral molecules, one of which is a donor of electrons and the other an acceptor.

Towards most organic compounds not containing strongly electronegative substituents the higher fluorides of transition elements exhibit the properties of Lewis acids of various strengths (electrophilic reagents), defined by Mulliken[6] as $v$-type acceptors, having vacant orbitals on the central atom, which are able to accept the electrons of donors or abstract an electron from the reagent in the case of a redox step.

The present review discusses donors of various types[6]—$\sigma$-donors supplying electrons from a bonding orbital of a $\sigma$-bond, $\pi$-donors interacting with the acceptor by means of $\pi$-electrons of double bonds, and $n$-donors possessing lone pairs of electrons.

In order to analyse the laws governing the interaction of various classes of organic compounds with fluorides of *d*- and *f*-elements, the relative oxidising powers of the latter are assessed in Section II.

## II. RELATIVE OXIDISING POWERS OF HIGHER FLUORIDES

After formation of bonds with fluorine in a higher state of oxidation Group V pentafluorides and Group VI hexafluorides have the respective structures $M^{5+}(d^0)F_5^-$ and $M^{6+}(d^0)F_6^-$:[10,11] i.e. no unpaired *d*-electrons remain in their outer orbitals. McDiarmid has found very good agreement between experimental ultraviolet absorption bands of molybdenum and tungsten hexafluorides and the bands to be expected from ligand field theory[11]. He estimates the splitting of the *d*-orbitals of molybdenum(VI) fluoride due to the ligand field as 40 000 $cm^{-1}$, which indicates a high stabilisation energy of the bonding $t_{2g}$ orbitals. All six electronic transitions in the two hexafluorides are from $\sigma$- and $\pi$-orbitals of metal–fluorine bonds to $n(d)t_{2g}$ atomic orbitals of the metal. Pentafluorides of Group VI metals have one unpaired *d*-electron; the electronic structure of the outer shell of uranium(V), neptunium(V), and plutonium(V) fluorides is respectively $5f^0$, $5f^1$, and $5f^2$.

Molecules of the pentafluorides have a trigonal bipyramid structure[12,13] with $D_{3h}$ point group symmetry, whereas molecules of the hexafluorides form a regular octahedron[10,13,14] with symmetry $O_h$. Distortion of the structure of fluoride molecules having unpaired electrons in *d*- and *f*-orbitals of the central atom (molybdenum(V), neptunium(VI), and plutonium(VI) fluorides)—the Jahn–Teller effect—is not observed, since for transition-metal complexes it is significant only when the antibonding $e_g$ orbitals have different populations of electrons[15]. In most of the above fluorides only the $t_{2g}$ orbitals are filled, for which this effect is considerably weaker and produces no appreciable distortion of the geometry of the complex[16].

In the solid state pentafluorides exist as partly ionised tetramers of various types[12]. In the gas phase the pentafluoride of vanadium is monomeric, but those of niobium, tantalum, and molybdenum are polymers with various proportions of tri-, di-, and mono-mers, among which an equilibrium determined by the temperature is established[12,17-19]. All the hexafluorides are highly volatile monomers in the gas phase[10], which can be explained by their greater coordination saturation than that of the pentafluorides.

The hexafluorides of actinides have been arranged[20] in the sequence—plutonium(VI) > neptunium(VI) > uranium(VI)—of diminishing oxidising power. The plutonium compound is a considerably stronger fluorinating agent than is the uranium derivative, and oxidises bromine trifluoride to the pentafluoride, whereas the trifluoride converts various uranium compounds, as well as metallic uranium, into uranium hexafluoride. Sulphur tetrafluoride does not react with uranium hexafluoride, but is converted into sulphur hexafluoride by plutonium hexafluoride. Finally, plutonium hexafluoride fluorinates uranium tetrafluoride and diuranium nonafluoride to the hexafluoride[21,22]. Plutonium(VI) fluoride reacts vigorously with several organic compounds[23,24] that are stable towards uranium hexafluoride.

Few data are available on the oxidising power of neptunium hexafluoride, merely[20] that it partly oxidises bromine trifluoride to the pentafluoride. In the gas phase uranium(VI) fluoride does not react with molecular bromine, whereas the neptunium compound is reduced to the tetrafluoride[25]. A method has been patented[26] for separating a mixture of uranium and neptunium hexafluorides by reducing the latter on cobalt(II) fluoride granules at 105–220°C to the tetrafluoride. These results indicate that neptunium occupies an intermediate position between plutonium and uranium with respect to the oxidising power of its hexafluoride.

A review[2] stated that vanadium pentafluoride was unable to substitute fluorine for hydrogen atoms in organic compounds, and only in certain cases able to add fluorine to double bonds. Such a description of the oxidising capabilities of the pentafluoride does not correspond to information from other sources. Clark and Emeléus showed[27] that vanadium(V) fluoride was a stronger fluorinating agent than bromine(III) and iodine(V) fluorides, and reacted quantitatively with tetrachloromethane at room temperature to form Freons of the methane series, including tetrafluoromethane. More severe conditions—in an autoclave at 220°C—are required for the reaction between tetrachloromethane and uranium hexafluoride[28-30]. O'Donnell et al., who studied[31-35] the reactivity of fluorides of *d*-elements in Groups V and VI, as well as uranium, in redox and exchange reactions, and later Reynes et al.[36] have shown that the reaction $UF_4 + 2VF_5 \rightarrow UF_6 + 2VF_4$ already occurs at 60°C. Thermodynamic calculation of the change in Gibbs free energy $\Delta G^\circ_{298}$ of this reaction from the standard Gibbs free energies of formation $G^\circ_{f298}$ [37,38] shows that $\Delta G^\circ_{298} = -9$ kcal mole$^{-1}$: i.e. the reaction is thermodynamically possible. The results indicate that the oxidising power of vanadium pentafluoride is greater than that of uranium hexafluoride.

Uranium(VI) fluoride in turn converts tungsten(IV) and molybdenum(V) fluorides into the corresponding hexafluorides[32], and molybdenum hexafluoride oxidises[31] tungsten tetrafluoride to the hexafluoride. Furthermore, uranium hexafluoride is reduced vigorously by tetrachloroethylene[39], whereas molybdenum and tungsten hexafluorides do not react under these conditions[40]. Moreover, molybdenum hexafluoride reacts with tetrachloromethane and tetrachlorosilane, but tungsten hexafluoride does not react with these compounds right up to 220°C.[28,41] These results are consistent with conclusions reached by O'Donnell et al.[32], who arranged the hexafluorides in the reactivity sequence uranium > molybdenum > tungsten.

The oxidising power of molybdenum pentafluoride has not been studied, but the same type of structure as for niobium and tantalum pentafluorides[12] and the similar action of such reagents as ammonia[42], pyridine and its derivatives, and acetonitrile[43,44] indicate only a slight difference in chemical activity. Nevertheless, the molecule contains[5] an unpaired *d*-electron in the outer shell of the molybdenum ion, and is potentially more active. Fairbrother[45] mentions that niobium and tantalum pentafluorides, in contrast to the pentachlorides, exhibit no tendency to reduction and the elimination of halogen. Qualitative observations suggest[33,46] that niobium pentafluoride is rather more strongly oxidising than is tantalum pentafluoride. Brown[47] states that for the pentafluorides the strength of the Lewis acids decreases in the sequence tantalum > niobium > vanadium, i.e. in the reverse order to the decrease in oxidising power.

Thus on the basis of the above results the higher fluorides can be arranged in the sequence

$$PuF_6 > NpF_6 > VF_5 > UF_6 > MoF_6 > WF_6 > MoF_5 \geqslant NbF_5 \geqslant TaF_5$$

of diminishing oxidising power. This sequence is consistent with conclusions reached by Galkin and Tumanov[48] from a thermodynamic investigation of the dissociation of hexafluorides to tetrafluorides, who arranged the hexafluorides in the sequence

$$PuF_6 < NpF_6 < UF_6 < MoF_6 < WF_6,$$

of increasing thermodynamic stability. It is consistent also with an investigation[49] of the action of elementary iodine on uranium(VI) fluoride. The sequence suggests that the oxidising power of fluorides of *d*-elements in the same group becomes weaker with increase in the nuclear charge of the central ion, whereas for *f*-elements the oxidising power increases with the nuclear charge and the number of unpaired *f*-electrons in the outer orbitals.

Table 1. Force constants[50] of metal–fluoride bonds $f_d$, energies of rupture of bonds[51] $E_{M-F}$, and standard enthalpies of formation of fluorides $-\Delta H^\circ_{f,298}$.

| Fluoride | $PuF_6$ | $NpF_6$ | $VF_5$ | $UF_6$ | $MoF_6$ | $WF_6$ | $MoF_5$ | $NbF_5$ | $TaF_5$ |
|---|---|---|---|---|---|---|---|---|---|
| $f_d$, mdyn Å$^{-1}$ | 3.59 | 3.71 | — | 3.78 | 4.73 | 5.13 | — | — | — |
| $E_{M-F}$, kcal mole$^{-1}$ | — | — | 114 | 108 | 105 | 121 | — | 142 | — |
| $-\Delta H^\circ_{f,298}$, kcal mole$^{-1}$ | 407[52] | 459[53] | 341[38] | 510[37] | 372[54] | 411[55] | 347[56] | 414[57] | 435[58] |

It is not without interest to compare the sequence of higher fluorides according to their oxidising power with certain molecular constants and thermodynamic functions of the compounds. Comparison of the data in Table 1 with the suggested reactivity sequence shows that increase in oxidising power is accompanied by a decrease in the metal–fluoride stretching force constants, in the energy of rupture of the bond, and by increase in the standard enthalpies of formation for the penta- and hexa-fluorides of *d*- and *f*-elements.

The higher chlorides of most of the elements considered are regarded by Hammond[59] as stronger acceptors than are the corresponding fluorides, owing to the great electronegativity of fluorine.

In actinide hexafluorides *f*-electrons are included in the bond with the fluorine atom. Bagnall[60] notes that the different spatial configuration of *f*-orbitals from *d*-orbitals may lead to different stereochemical consequences for the octahedral

symmetry inherent in hexafluorides. This would apparently have a definite influence on the chemical properties of the actinide hexafluorides.

The reaction of fluorides of *d*- and *f*-elements with members of various classes of organic compounds will be discussed in the following Sections.

## III. ORGANIC σ-DONORS

### 1. Alkanes, Cycloalkanes, and Halogenated Alkanes

Research on the reaction between alkanes and higher fluorides of *d*- and *f*-elements was connected chronologically with the development of atomic technology, in particular with the manufacture of uranium hexafluoride, when it appeared necessary to produce organic compounds, used as greases and packing, that were resistant to the action of uranium hexafluoride, fluorine, and hydrogen fluoride[61-64].

Straight-chain alkanes right up to n-hexadecane react vigorously with uranium hexafluoride, with charring and the liberation of hydrogen fluoride, uranium tetrafluoride, and intermediate fluorides of uranium[63,64]. Reaction may or may not be accompanied by degradation of the carbon skeleton of the alkane depending on the conditions. A process has been patented[65] for fluorinating alkanes and chloroalkanes containing 1–12 carbon atoms with uranium hexafluoride at 70–600°C.

Colourless molybdenum and tungsten hexafluorides form yellow to orange solutions with n-hexane and cyclohexane. The rate of decomposition in the system formed by molybdenum hexafluoride with n-hexane is 1% $h^{-1}$.[66] Ultraviolet spectral measurements reveal the presence of weak equimolecular complexes ($K_{ass}$ = 0.3–0.6 M).

Addition of vanadium pentafluoride and uranium hexafluoride to n-heptane and cyclohexane produces brown precipitates[67], indicating reduction of the fluorides, apparently to vanadium tetrafluoride and intermediate fluorides of uranium.

In connection with the use[68] of tetrachloromethane for the preparation of uranium tetrafluoride from the hexafluoride a study was made of the reaction of this hexafluoride and several related fluorides, e.g. molybdenum and tungsten hexafluorides, with chlorinated derivatives of methane, ethane, and propane[29,30,63,64,69,70]. It was found that at 25°C uranium hexafluoride was soluble in chloroform, tetrachloromethane, dichloroethylene, pentachloroethane, and perchloroethane[63,64]. A simple eutectic containing 6.5 mole % and melting at −28.9°C occurs in the uranium(VI) fluoride–tetrachloromethane system[71]. At room temperature a solution of the hexafluoride is stable for several weeks. Heating in an autoclave to 150°C leads to an exothermic reaction[63,68], the composition of the reaction products depending on the ratio of the reactants and the temperature. With an equimolecular mixture the products are $UF_5$, $U_2F_9$, $U_4F_{17}$, chlorine, and predominantly Freon 13. A threefold excess of tetrachloromethane yields uranium tetrafluoride, chlorine, and Freon 11. No detailed study of the reaction mechanism has been made; it is suggested that the reaction is catalysed by uranium tetrafluoride[68]. Under normal pressure this reaction occurs over the range 400–500°C.

Even at room temperature plutonium hexafluoride reacts vigorously with tetrachloromethane to form the tetrafluoride with Freons 12 and 13.[22] On reaction with tetrachloromethane at 20°C vanadium pentafluoride, which also possesses strong fluorinating properties, yields[27] a series of chlorofluoro-derivatives of methane up to tetrafluoromethane, with vanadium tetrachloride and trichloride. Molybdenum hexafluoride reacts with tetrachloromethane at 150–220°C to give $Mo(Cl, F)_5$, $CCl_3F$, $CCl_2F_2$, and traces of $CClF_3$. Tungsten(VI) fluoride is inert under these conditions.

Chloro-fluorinated alkanes are considerably more inert than the hydrocarbons and their chloro-derivatives. Thus difluorodichloromethane, chlorotrifluoromethane, and dichlorotetrafluoroethane do not react with plutonium hexafluoride at room temperature[72,73], although such reaction is thermodynamically possible for the first two compounds even with uranium hexafluoride[24]. However, while inert to pure uranium hexafluoride at 150°C, dichlorodifluoromethane partly reacts at this temperature even with uranium during the reduction of plutonium from a mixture of plutonium and uranium hexafluorides[72,73]. This indicates either that reduction by this reactant has a radical mechanism or that the process is catalysed by plutonium fluorides. Study of the binary liquid–liquid systems has shown[74,75] that uranium and molybdenum hexafluorides do not react with dichlorotetrafluoroethane.

Perfluoroalkanes are stable towards all the above fluorides, the most active of which—plutonium hexafluoride—gives a stable solution in n-perfluoroheptane[22]. Vanadium(V), molybdenum(VI), tungsten(VI), and uranium(VI) fluorides are stable in solution in perfluoroalkanes of various chain lengths[61,63,64] and in perfluorinated cyclohexane[64,66], methylcyclohexane[67], and dimethylcyclohexane[76,77]. In the systems formed by tungsten hexafluoride with perfluoro-n-pentane and perfluorocyclopentane the components are miscible in all proportions to form non-ideal solutions[78,79], which indicates the presence of intermolecular interactions. Niobium and tantalum pentafluorides are almost insoluble[67] in perfluoromethylcyclohexane, apparently because of their polymeric structure in the solid state.

According to Mulliken[6] the above alkanes, cycloalkanes, and their chlorinated derivatives are weak Lewis bases or σ-type donors with almost the same basicity (judging by the ionisation potentials) for alkanes and cycloalkanes having the same number of carbon atoms. On interaction of σ-donors and *v*-acceptors such as the higher fluorides of *d*- and *f*-elements, formation of stable complexes should not be observed[6], as is fully confirmed by the above examples. During irreversible oxidative fluorination the alkanes, chloroalkanes, and their cyclic derivatives will gradually become inert to all inorganic fluorides right up to plutonium hexafluoride as the hydrogen and chlorine atoms are successively replaced by fluorine.

### 2. Organosilicon Compounds

Vacant *d*-orbitals of the silicon atom, in contrast to carbon, are closely similar in energy characteristics to the outer *s*- and *p*-orbitals, which has a corresponding effect on the behaviour of silicon.

Tetrachlorosilane reacts[80] with vanadium pentafluoride at room temperature to form vanadium monochloride trifluoride, tetrafluorosilane, and chlorine; with uranium hexafluoride[32] it forms the tetrafluoride, tetrafluorosilane, and chlorine on being heated to 100°C; and with molybdenum hexafluoride it reacts only slightly[31] even above 100°C, giving the mixed compound $Mo_2Cl_3F_6$ and tetrafluorosilane in low yield. No reaction has been detected

in the binary systems formed by tetrachlorosilane with tungsten hexafluoride[31], and with niobium and tantalum pentafluorides[33].

In tetramethylsilane molybdenum and tungsten hexafluorides form red solutions that lose their colour on being frozen, which indicates that stable adducts are absent. Niobium pentafluoride is almost insoluble in this reagent[41].

The reaction of tungsten hexafluoride with methoxytrimethylsilane yields a series of derivatives $(CH_3O)_nWF_{6-n}$ ($n = 1-6$): i.e. it results in complete replacement of fluoride ions by methoxy-groups[81]. The reaction products included tungsten oxide tetrafluoride $WOF_4$ and unidentified compounds. With phenoxytrimethylsilane the products are phenoxytungsten pentafluoride and *cis*- and *trans*-diphenoxytungsten tetrafluoride[82]. The considerable bulk of phenyl in comparison with methyl groups apparently prevents the coordination of more than two around the tungsten atom. Reaction of molybdenum hexafluoride with dimethyldimethoxy-, methyltrimethoxy-, and tetramethoxy-silane yields[83] dimethylsilicon difluoride, methylsilicon trifluoride, and tetrafluorosilane respectively, as well as tetramethoxymolybdenum difluoride and pentamethoxymolybdenum fluoride. Noble and Winfield[84] described the preparation of a series of methoxy- and phenoxy-tungsten(VI) fluorides of general formula $(RO)_nWF_{6-n}$ (where $n = 1-4$ for the methoxy-group, and 1 or 2 for the phenoxy-group) by mixing tungsten hexafluoride with methyltrimethoxy-, dimethyldimethoxy-, and dimethyldiphenoxy-silane. At 80°C *cis*-dimethoxytungsten tetrafluoride decomposes with the formation of $WOF_4.(CH_3)_2O$. The action of various proportions of tetramethoxysilane on tungsten hexafluoride at 20°C yields[85] tetrafluorosilane, methoxytungsten pentafluoride, and *cis*-tetramethoxytungsten difluoride.

When a mixture of tungsten hexafluoride and trimethylsilyldiethylamine[82] is left at 20°C for 24 h, it is converted into bisdiethylaminetungsten tetrafluoride and then into tetrakisdiethylaminetungsten difluoride, the first of these compounds being a monomer and the second a polymer having fluoride bridges. A complex having the ligands in the proportions 3 : 3 was not observed.

Table 2. Products of the reactions of higher fluorides of *d*- and *f*-elements with organosilicon compounds.

The action of trimethylsilyldiethylamine on niobium and tantalum pentafluorides yields fluorotrimethylsilane and a series of compounds (Table 2) in which one or two fluoride ions have been replaced by a diethylamino-group[86]. On treatment with pyridine or 4-methylpyridine these compounds form adducts in which the coordination number has increased to 6. Replacement of >2 fluoride ions in the pentafluorides was considered to be disadvantageous for steric and electronic reasons, since dialkylamino-ligands, being good donors for *d*-elements, in this case form considerably weaker Lewis acids than the pentafluorides—the diethylamino-tetrafluoride and the bisdiethylamino-trifluoride—which are already incapable of reaction with a base (tetrakisdiethylaminotungsten difluoride can be obtained from tungsten hexafluoride).

It follows from the above account that tetrachlorosilane reacts only with fairly strongly oxidising fluorides such as those of vanadium(V), uranium(VI), and molybdenum(VI). Higher fluorides of niobium, tantalum, molybdenum, and tungsten readily undergo substitution with organosilicon compounds containing alkoxy-, phenoxy-, and dialkylamino-groups:

$$MF_6 + R_nSi(OR)_{4-n} \rightarrow MF_{2+n}(OR)_{4-n} + R_nSiF_{4-n},$$

or

$$MF_6 + nRO^- \rightarrow MF_{6-n}(OR)_n + nF^-,$$

i.e. the substrate molecule is attacked by the nucleophilic group $RO^-$, which is a stronger nucleophile than the fluoride ion, and for this reason displaces the latter from the coordination sphere of the central ion. Thus nucleophilic substitution of the $S_N$ type occurs formally with penta- and hexa-fluorides of *d*-elements. Partial or complete substitution of fluoride ions in the electrophilic substrate molecule is observed depending on the conditions and on the steric characteristics of the entering group. Available data support rather an associative mechanism of nucleophilic substitution of the fluoride ion in pentafluorides and in tungsten and molybdenum hexafluorides. Thus exchange of fluorine is slowed down for *cis*-tetramethoxytungsten and tetrakisdialkylaminotungsten difluorides, which may indicate the formation of intermediate seven-coordinated compounds. Octahedral complexes having the electron confirguration $d^0$, $d^1$, $d^2$ and a partly covalent bond can be regarded[88] as coordinatively unsaturated compounds, capable under certain conditions of giving complexes of coordination number >6 by an $S_N2$ type of associative mechanism; on the other hand, an $S_N1$ dissociative mechanism of substitution is more typical of octahedral complexes having a large number of unpaired *d*-electrons. The definite effect of the nature of the entering group on the rate of substitution in the above reactions of pentafluorides and of tungsten and molybdenum hexafluorides with nucleophilic reagents can apparently be regarded as some confirmation of an associative mechanism.

It is of interest to examine the above reactions in terms of bond strengths and the electronic character of the reagents. The silicon–oxygen bond is thermodynamically more stable than the silicon–carbon bond (108 and 76 kcal $mole^{-1}$ respectively)[89], but the former is relatively easily cleaved by electrophilic reagents (such as the higher fluorides of *d*-elements in the present case), whereas the silicon–carbon bond is relatively inert in these reactions. Under electrophilic attack the silicon–chlorine bond (91 kcal $mole^{-1}$) is also more reactive than the less stable silicon–carbon and carbon–chlorine bonds (81 kcal $mole^{-1}$), judged by the action of tetrachlorosilane and tetrachloromethane on molybdenum(VI) fluoride[31,41]. It must be supposed that rupture of silicon–carbon bonds will be observed on attack by less electrophilic reagents than the higher fluorides of *d*-elements. Silicon–nitrogen and silicon–oxygen bonds show the same behaviour in the above reactions.

The organosilicon compounds studied are σ-donors in relation to the higher inorganic fluorides, and theoretically[6] are unable to form any stable complexes in a σ-donor–$v$-acceptor system, as is illustrated by the above results. With increase in donor strength towards the above fluorides of $d$-elements the organosilicon compounds can be arranged in the sequence

$$SiR_4 \leqslant SiCl_4 < R_3Si(OPh) < R_3Si(OR) < R_2Si(OR)_2 < RSi(OR)_3 < Si(OR)_4 < R_3Si(NEt_2),$$

which corresponds to increase in nucleophilicity of groups replacing the fluoride ion, in the sequence

$$R^- \leqslant Cl^- < PhO^- < RO^- < R_2N^-.$$

## IV. π-DONORS

### 1. Alkenes and their Halogenated Derivatives

Ethylene and trichloroethylene were tried[64,68] as reductants for uranium(VI) fluoride, and expectedly proved more active than alkanes. The hexafluoride is reduced to uranium tetrafluoride even at −50°C by liquid trichloroethylene, which adds two fluorine atoms at the double bond. In the gas phase at 75–480°C this reaction also yielded the tetrafluoride, with hexachlorobenzene as one of the organic products[28]. In both cases the precipitated tetrafluoride was contaminated with organic compounds of unknown composition[28,90].

Reduction by tetrachloroethylene at 260–315°C yields[39] uranium tetrafluoride uncontaminated by any organic impurities. Analysis of the material balance in the patent[39] shows that the organic reaction product has the empirical formula $C_2ClF_5$. However, the appearance of Freons 114 and 116 is thermodynamically most probable[24] under these conditions; perhaps the reaction products comprise an equimolecular mixture thereof. Reddish-brown and yellow solutions respectively (stable in the absence of moisture) are formed in the binary liquid–vapour systems comprising tetrachloroethylene with molybdenum and tungsten hexafluorides. Calculation of excess free energies from published data[40] indicates the presence of approximately equimolecular adducts in the liquid phase. These compounds are unstable, since the hexafluorides can be removed from the solution when dry nitrogen is blown through.

The solubility of molybdenum pentafluoride and hexafluoride in hexachlorobuta-1,3-diene has been studied[91] between −25 and +120°C, red–violet solutions being obtained in all cases. Complete miscibility between the hexafluoride and the chlorocarbon is observed at 5–30°C. The liquid pentafluoride gives with this solvent a system comprising two liquids of limited miscibility with a consolute point at 105.3°C representing 0.635 mole fraction of molybdenum(V) fluoride. Neither the pentafluoride nor the hexafluoride was reduced under the experimental conditions.

As hydrogen and chlorine atoms in alkanes are replaced by fluorine, the sensitivity to electrophilic attack diminishes, while that to nucleophilic attack increases[92–94]. For this reason the above relatively weakly oxidising inorganic fluorides—at least those to the right of uranium hexafluoride—will apparently not react with fluoroalkenes.

Alkenes and chloroalkenes act as weak π-donors towards electrophilic reagents[6]. Unstable π-complexes are formed in these systems by means of π-electrons of the double bonds supplied to the acceptor.

Equimolecular π–$v$ adducts, formed[40] by tetrachloroethylene with tungsten and molybdenum hexafluorides respectively, can apparently be regarded as intermediates in the reduction of the hexafluorides followed by addition of halogens at the double bond. The reduction of uranium hexafluoride to the tetrafluoride by chlorinated ethylenes[28,39,90] apparently takes place in two stages: addition of thorime atoms to the chloroethylenes is followed by substitution of chlorine by fluorine atoms in the chlorofluoroalkanes.

### 2. Aromatic Compounds

Benzene, toluene, and xylenes react with uranium hexafluoride at room temperature to form the tetrafluoride, hydrogen fluoride, and carbonaceous substances of unknown composition[64,95]. Nitrobenzene yields a turbid red solution[64]. Molybdenum hexafluoride is rapidly reduced in benzene and xylene to give a dark blue precipitate[95]. Binary systems of tungsten hexafluoride with benzene, toluene, and $p$- and $m$-xylenes have a red colour[41,95–97] and give equimolecular adducts. It was originally stated[98] that, in a bomb at 110°C, the hexafluoride is reduced by benzene to tungsten tetrafluoride. However, these results have not been confirmed[41], since heat-treatment of mixtures of the hexafluoride with benzene and toluene at 110°C or exposure to ultraviolet radiation has given a non-volatile, viscous dark brown liquid in which the ratio of fluorine to tungsten is ~4.7 and ~4.5 for the mixtures with benzene and with toluene respectively.

Addition of perfluorotoluene to a stable colourless solution of vanadium pentafluoride in perfluoromethylcyclohexane produces a red coloration, which then disappears. Similar changes have been observed in the absence of a diluent, as well as with hexafluorobenzene and perfluoro-$p$-xylene[67]. This indicates that the pentafluoride is reduced with preliminary formation of an unstable intermediate compound. Solutions of uranium hexafluoride in hexafluorobenzene, perfluorotoluene, and perfluoro-$p$-xylene have an orange colour[67,95,97], with those in the second solvent the most stable. A similar effect has been observed[95] with vanadium(V) and iodine(VII) fluorides. Molybdenum hexafluoride forms with hexafluorobenzene and octafluorotoluene orange-brown solutions, containing equimolecular adducts and stable for at least 24 h. The system with perfluoro-$p$-xylene is the least stable[95]. The pale yellow solutions of tungsten hexafluoride in perfluorinated benzene, toluene, and xylenes do not decompose[41,95,97] for a long time. Since niobium and tantalum pentafluorides are sparingly soluble in perfluoroarenes[67], no information is available on their behaviour in these solvents.

A recent paper[99] reports that the hydrogenation of benzene in the presence of an equimolecular mixture of hydrogen and tantalum(V) fluorides at 200°C gives high yields of toluene and ethylbenzene. Alkyl radicals are assumed[99] to be generated during the saturation of aromatic to alicyclic systems, after which ring cleavage occurs to give alkanes that interact with the radical-ions of benzene. It is noteworthy that the use of niobium and tantalum pentafluorides as Friedel–Crafts catalysts had been reported earlier[45].

Richardson and Bartlett have obtained[100] salts of the cation $C_6F_6^+$ by condensing hexafluorobenzene and tungsten hexafluoride on powdered $AsO_2F_6$, $SbO_2F_6$, and $Sb_2O_2F_{11}$ at −196°C, which are then allowed to warm up slowly to 0°C. The resulting salts have the composition $C_6F_6^+AsF_6^-$,

$C_6F_6^+SbF_6^-$, and $C_6F_6^+Sb_2F_{11}^-$, and gradually decompose at room temperature. The action of nitric oxide on the arsenic salt leads to quantitative formation of benzene and $AsNOF_6$.

The system comprising tungsten hexafluoride and a solution of naphthalene in tetrachloromethane has an orange–brown colour and equimolecular adducts[95]. In contrast, octafluoronaphthalene loses its colour when the supply of the hexafluoride ceases[82]. This is indirect evidence of the brief existence of adducts in this system. A product of the fluorination of dimethylnaphthalene, perfluoro-2-methylbicyclo[4,4,0]decane, forms stable colourless solutions with molybdenum, tungsten, and uranium hexafluorides[101].

The above results indicate that both aromatic hydrocarbons and their halogenated derivatives behave as weak $\pi$-donors towards the higher fluorides of the *d*- and *f*-elements considered, as also towards other halides, e.g. chlorides[6,102]. Interactions of such $\pi$–*v* type are characteristically weak[6]. Hammond et al.[59,103], who undertook a systematic study based on spectrophotometric measurements of equilibrium constants, enthalpies, and thermochromism of systems formed by aromatic compounds and their halogenated derivatives with various halides of *f*- and *d*-elements in Groups IV–VI of the Periodic System, described all such interactions as "extraordinarily weak or almost contact". They attribute this[59] to unfavourable steric factors involved in contact between planar aromatic systems and the sperically symmetrical hexafluoride molecules, and to the slight overlap between the orbitals of the aromatic ligands and those of the halide molecules. Plane–plane interactions would have been sterically more favourable than the plane–sphere interactions.

Stronger interactions occur in the Menshutkin complexes (of antimony trichloride with arenes)[102], apparently owing to change in the geometry of the acceptor molecule and greater availability of its orbitals for displacing the electrons of the donors. Usanovich et al.[104] have investigated Menshutkin complexes by $\gamma$-resonance spectroscopy, and shown that complex formation is due to the transfer of $\pi$-electrons of the aromatic ring to *p*-orbitals of the antimony atom. In the fluorides under consideration here such a mechanism of electron transfer, it appears, will be weakened by the greater electronegativity of fluoride ions.

## V. *n*-DONORS

### 1. Nitrogen-containing Compounds

It seens useful to begin with ammonia our consideration of the interaction of higher fluorides of *d*- and *f*-elements with nitrogen-containing organic compounds, since many of these are its derivatives. The reaction products are listed in Table 3.

Vanadium pentafluoride reacts with ammonia, ethylenediamine, tetramethylethylenediamine, and pyridine with reduction and the formation of $VF_4.L$, adducts of polymeric structure[12,105,106]. In ammoniacal uranium hexafluoride the pentafluoride is formed between −50 and −30°C, a mixture with $NH_4UF_5$ as the temperature rises to 0°C, and the latter compound at 100°C. 2-Fluoropyridine reacts[107] with uranium hexafluoride to give an adduct $UF_6.2NC_5H_4F$; in solution in dichloromethane the adduct is $UF_6.NC_5H_4F$.

A process has been patented[108] for separating a mixture of hydrogen and uranium(VI) fluorides by means of fluoroaliphatic and fluoroheterocyclic amines and diamines. The separation is based on the formation by these compounds of a stable adduct with hydrogen fluoride, while the hexafluoride is inert towards them.

At −130°C molybdenum hexafluoride is reduced by ammonia to the pentafluoride[109], which forms several ammines depending on the conditions. Keeping the

pentafluoride in an atmosphere of ammonia for a long time yields a monoammine[42,43,110]. With pyridine[107] and acetonitrile[111] the hexafluoride gives adducts of composition $MoF_6.2L$.

Tungsten hexafluoride reacts with liquid ammonia[13,112] to give the tetrammine $WF_6.4NH_3$, and with hydrazine in acetonitrile[107,111] to yield 1 : 1 and 1 : 2 compounds, whereas molybdenum hexafluoride is reduced[111] by hydrazine with separation of the tetrafluoride, the complex $MoF_4.2NH_4F$, nitrogen, and ammonia. The reaction of tungsten hexafluoride with methylamine[112] gives $WF_6.3CH_3NH_2$, and with trimethylamine[107,113] $WF_6.(CH_3)_3N$ and $2WF_6.3(CH_3)_3N$ are formed; tetramethylethylenediamine[107] gives the complexes $WF_6.C_2H_4N_2(CH_3)_4$ and $3WF_6.2C_2H_4N_2(CH_3)_4$, dimethylformamide[107] $WF_6.DMF$, and pyridine $2WF_6.3C_5H_5N$,[107,112] $WF_6.2C_5H_5N$, and $WF_6C_5H_5N$.[113] The fluorine-19 nuclear magnetic resonance spectra of the first of these pyridine complexes show that one of the fluorine atoms is not equivalent to the other five, while the octahedral symmetry of the compound is preserved[107,112]. Conductivity measurements suggest[107] the structure $2[WF_5.C_5H_5N]^+F^-.C_5H_5N$.

Fluorides of quinquevalent niobium, tantalum, and molybdenum, in contrast to other pentahalides, e.g. the chlorides, do not undergo reduction on reaction with nitrogen based[114,115]. With ammonia they form adducts[42,105,114] of the types $Nb(Ta)F_5.2NH_3$ and $MoF_5.NH_3$; with acetonitrile, chloroacetonitrile, and propionitrile[44,116] equimolecular complexes are formed, but molybdenum pentafluoride forms also[43,111] $MoF_5.2CH_3CN$. With trimethylamine niobium and tantalum pentafluorides give[13,117] equimolecular complexes. Cryoscopic measurements enabled Buslaev et al.[118] to demonstrate the establishment of the equilibrium

$$2\{NbF_5 \cdot NEt_3\} \rightleftharpoons [NbF_6]^- + [NbF_4 \cdot 2NEt_3]^+$$

results which have since been confirmed by ebullioscopic and conductometric investigations on the system[119]. Treatment of molybdenum pentafluoride with pyridine yields[43] 1 : 1 and 1 : 2 adducts, whereas those of niobium and tantalum give 1 : 2 adducts[44,114,115]; the last two compounds are stable in air, but decompose when heated. Tantalum(V) fluoride forms equimolecular adducts with 2- and 4-methylpyridines, and perhaps also a 1 : 2 adduct with the latter. Investigation of the infrared spectra suggests that $MF_5.L$ adducts are monomeric, with symmetry lower than would correspond to the $C_{4v}$ point group, whereas adducts of type $MF_5.2L$ may be ionised[44,114] $[MF_4L_4]^+[MF_6]^-$.

According to the first ionisation potentials[6] and the above experimental results the donor strength of nitrogen-containing organic compounds increases in the sequence

$$MeCN < EtCN < Py < NH_3 < MeNH_2 < EtNH_2 < Me_2NH < Et_2NH < Me_3N < Et_3N.$$

All these compounds have a lone pair of electrons on the nitrogen atom and are $n$-donors, strong Lewis bases. With the above fluorides of $d$- and $f$-elements nitrogenous compounds are able to form quite stable $n$-donor–$v$-acceptor adducts. The above sequence shows that the donor power increases on passing from heteroaromatic amines to primary, secondary, and tertiary aliphatic amines having small groups. It becomes weaker as hydrogen atoms in the alkyl groups are replaced by fluorine atoms, and in perfluoroalkylamines is almost completely absent[5]. Fluorine as a substituent has a similar effect on arylamines and heteroaromatic amines. This is supported by a patent[108] indicating that perfluorinated alkylamines, dialkylamines, peperidine, and pyrrolidine do not exhibit donor properties towards uranium hexafluoride.

Relatively strongly oxidising fluorides, such as those of vanadium(V), uranium(VI), and molybdenum(VI), are reduced by ammonia and, apparently, other organic compounds of greater basicity, and in the lower state of oxidation form quite stable adducts with excess of the organic reagent. In these complicated reactions not only does the state of oxidation of the central ion change but also the coordination number, with simultaneous substitution of ligands.

In reactions in which the inorganic fluorides do not undergo redox processes with nitrogen-containing organic compounds the coordination number increases by the addition of fresh organic ligands to the central atom. All these reactions can be included among nucleophilic additions of the $Ad_N$ type. The most characteristic coordination numbers of the metals in these adducts are $V^{IV}$ 5 and 6, $M^V$ (M = Nb, Ta, Mo) 6 and 7, $Mo^{VI}$ 8, $W^{VI}$ 7–9, $U^{IV}$ 5, and $U^{VI}$ 7 and 8. The maximum coordination numbers are observed with ligands of small bulk—ammonia, primary alkylamines—whereas ligands having less favourable steric characteristics, e.g. tertiary amines, form complexes having lower coordination numbers. Pentafluorides of $d$-elements exhibit a clear tendency to acquire a six-coordinated structure. This indicates that the adducts have an octahedral structure, which is probably the most advantageous under these conditions.

## 2. Phosphorus-containing Compounds

Tervalent phosphorus and nitrogen exhibit definite similarity in their chemistry, which is lost in states of higher oxidation. Table 4 lists products formed by several phosphorus-containing compounds with fluorides of $d$- and $f$-elements. Vanadium(V) fluoride is reduced by phosphorus trichloride[80] to vanadium chloride trifluoride, and by phosphorus trifluoride[35] to vanadium(IV) fluoride; in both cases phosphorus is oxidised to its pentafluoride. Phosphorus trichloride and trifluoride both convert uranium hexafluoride into the tetrafluoride[32,121], with temperatures of 150–300 °C regarded as optimum. Phosphorus trifluoride is used to convert molybdenum hexafluoride into the pentafluoride[31,122], and tungsten hexafluoride into the tetrafluoride[31]. Niobium and tantalum pentafluorides do not react with phosphorus trifluoride, but undergo exchange with the trichloride and tribromide, being converted ultimately into the corresponding pentabromides or pentachlorides and phosphorus trifluoride[33].

The $^{19}F$-n.m.r. spectra of the adduct $WF_6.(CH_3)_3P$ in acetonitrile show that the tungsten is surrounded by six equivalent fluorine atoms[107,113]. It is suggested[113] that, as in the corresponding adduct with trimethylamine, a loose seven-coordinated structure is present in this compound.

At temperatures above 0°C tungsten hexafluoride reacts vigorously with trimethyl phosphite to give a dark orange liquid, whose composition depends on the reaction conditions[123], in particular on the ratio of the reactants. The reaction can in general be represented by the equations

$$(MeO)_3P + WF_6 \rightarrow (MeO)_2PF + MeOWF_5$$

$$(MeO)_3P + MeOWF_5 \rightarrow [(MeO)_3PMe]^+ \cdot [WOF_5]^-.$$

The formation of methyltrimethoxyphosphonium oxopentafluorotungstate shows that, in the presence of a suitable substrate, methoxytungsten pentafluoride develops a tendency to lose the methyl group as a methyl cation, which coordinates with the nucleophilic phosphorus atom or a fluoride ion:

$$MeOWF_5 \rightarrow [Me^+ + WOF_5^-] \rightarrow MeF + WOF_4.$$

This compound reacts with benzene to give toluene[123]:

$$MeOWF_5 + C_6H_6 \rightarrow C_6H_5Me + HF + WOF_4.$$

It is assumed that such reactions do not take place with phenoxytungsten pentafluoride. At 90°C the complex phosphonium salt decomposes:

$$[(MeO)_3PMe]^+ \cdot [WOF_5^-] \rightarrow WOF_4 \cdot OP(Me)(OMe)_2 + MeF.$$

Dimethyl methylphosphonate is formed from trimethyl phosphite by a Michaelis–Arbuzov rearrangement in the presence of the electrophilic catalyst tungsten hexafluoride, and gives the tungsten oxide fluoride an adduct in which the ligand occupies a *trans*-position with respect to the oxygen atom. Methoxytungsten and phenoxytungsten pentafluorides, like tungsten hexafluoride, are Lewis acids; the phenoxy-complex is converted on treatment with trimethylamine into a non-volatile red 1 : 1 adduct; methoxytungsten pentafluoride reacts with pyridine to give $CH_3OWF_5.1.3C_5H_5N$. The above results show that the reactions of tungsten hexafluoride with alkylphosphines, which contain only carbon–phosphorus bonds, are essentially additions similar to the reactions with amines. Attack by electrophilic reagents such as the hexafluoride on alkyl and aryl phosphites leads to rupture of a phosphorus–oxygen bond and replacement of an alkoxy-group by a fluorine atom.

Walker and Winfield[124] have investigated the reaction between tungsten hexafluoride and compounds containing a four-coordinated phosphorus atom. Even in benzene at 20°C triphenyl phosphate is converted into a red precipitate of undetermined composition. At 20°C trimethyl phosphate in proportions of 3–1 relative to tungsten hexafluoride gives after 2 h a mixture of phosphoryl and methyl fluorides, methoxytungsten pentafluoride, hexafluorophosphate and $W_2O_2F_9^-$ ions, and the equimolecular adduct of tungsten oxide tetrafluoride and trimethyl phosphate. It is assumed[124] that the hexafluorophosphate ion and methyl fluoride are formed from methoxytungsten pentafluoride and trimethyl phosphate. In the authors' opinion the presence of the hexafluorophosphate ion is due to the formation of trifluorodimethoxyphosphorane, present as tetramethoxyphosphonium hexafluorophosphate. At 20°C a mixture of tungsten hexafluoride, with dimethyl methylphosphonate passes into a mixture of methyldifluorophosphine oxide, methyl fluoride, the adduct $WOF_4.CH_3PO.(OCH_3)_2$, and the salt $[(CH_3O)_3PCH_3]^+[W_2O_2F_9]^-$. With dimethyl hydrogen phosphite at −80°C the hexafluoride gives phosphorus trifluoride and a non-volatile colourless deposit, which at 20°C rapidly becomes dark blue[124,125].

The above results indicate that alkyl phosphites and phosphates with tungsten hexafluoride undergo substitution at the site of rupture of a phosphorus–oxygen bond with subsequent exchange of alkoxy-groups and a fluoride ion. In view of the considerable difference in energy between bonds formed by phosphorus with carbon and with oxygen respectively (63 and 95 kcal mole$^{-1}$) it must be supposed that in organic derivatives of phosphorus the latter are considerably more subject than the former to the action of electrophilic reagents, and readily undergo exchange.

Table 5. Products of the reactions of higher fluorides of *d*- and *f*-elements with oxygen- and sulphur-containing compounds.

In the case of triphenyl phosphate, however, cleavage of a phosphorus–oxygen bond is not observed, which may be attributable to a change in the character of the bond or in its accessibility to electrophilic attack resulting from the presence of an aromatic ring instead of an alkyl group.

The reaction of a trialkyl phosphate with tungsten hexafluoride can presumably be written

$$(RO)_3PO + 3WF_6 \rightarrow 3ROWF_5 + POF_3.$$

In the case of dialkyl alkylphosphonates the alkylphosphonic difluorides are formed, but not phosphoryl trifluoride, since the carbon–phosphorus bond is not involved in the reaction (at least at 20°C).

From theoretical considerations[126] and the above results it may be concluded that the donor power of tervalent phosphorus compounds towards the compounds surveyed here increases in the sequence

$$PF_3 < PCl_3 < PBr_3 < P(Ph)_3 < P(OMe)_3 < P(Me)_3.$$

The corresponding sequence for organic compounds of four-coordinated phosphorus is

$$(PhO)_3PO < (MeO)_3PO < (MeO)_2MePO.$$

Despite the absence of data for alkyl dialkylphosphinates and trialkylphosphine oxides in relation to tungsten hexafluoride, it may be supposed that the variation in their donor strength will be similar to that established[127] for uranyl and plutonium(VI) nitrates:

$$(RO)_3PO < (RO)_2RPO < (RO)R_2PO < R_3PO.$$

A study[128] of the reaction of niobium and tantalum pentafluorides with tributylphosphine and triphenylphosphine oxides, tributyl phosphate, and hexamethylphosphoramide revealed in all cases the formation of adducts $MF_5.L$. Tributylphosphine oxide replaces fluorine in the $MF_5$ molecule to give *cis*- and *trans*-$[MF_4((CH_4H_9)_3PO)_2]^+ . [MF_6]^-$. The donor power of the organophosphorus ligands increases in the sequence

$$(PhO)_3PO < (BuO)_3PO < Ph_3PO < [(CH_3)_2N]_3PO < Bu_3PO.$$

### 3. Oxygen- and Sulphur-containing Compounds

#### (*a*) Alcohols and thiols

Treatment of tungsten hexafluoride with ethanol produces a colourless solution[96], in which Buslaev et al.[129] established the presence of the anion $WOF_5^-$, indicating the considerable tendency of tungsten to form a multiple bond with oxygen. Other reaction products present are *cis*-diethoxytungsten tetrafluoride and $WOF_4.C_2H_5OH$ with a *trans*-arrangement of the oxygen atom and the alcohol molecule. Examination by the same workers of the stereospecificity of substitution in octahedral $d^0$ complexes[130] with ligands capable of forming multiple bonds with the central atom has established a *cis*-effect for a multiply bonded ligand, i.e. substitution primarily of a ligand in a *cis*-position relative to the multiply bonded ligand.

Treatment of a solution of ethanethiol in acetonitrile with tungsten hexafluoride yielded products analogous to those obtained with ethanol[131] (Table 5). A small excess of the thiol gives the unstable ethylthiotungsten pentafluoride, when then passes into the more stable *trans*-diethylthiotungsten tetrafluoride (with ethanol *cis*-diethoxytungsten tetrafluoride is obtained). With increase in the excess of ethanethiol adducts—$WSF_4.HSC_2H_5$ and $C_2H_5SWSF_3.HSC_2H_5$—are formed with the multiply bonded sulphur atom *trans* to the ligand molecule. Compounds of similar structure solvated by acetonitrile are present as intermediates. With benzenethiol the hexafluoride gives[131] the stable *trans*-diphenylthiotungsten tetrafluoride, which after a long time passes into the adduct $C_6H_5SWSF_3.CH_3CN$; no product having the composition $C_6H_5SWF_5$ has been observed.

In absolute ethanol niobium pentafluoride forms an electrically conducting dark red solution. The Nb-n.m.r. spectra[93] indicate the presence of the hexafluoroniobate anion, but no cation is detected[132]. Buslaev et al.[133] suggested that the complex anion is probably accompanied in this system by a cation that dissociates according to the scheme

$$[NbF_4(EtOH)_2]^+ \rightarrow NbF_4(OEt) \cdot EtOH + H^+ \rightarrow [NbF_4(OEt_2)]^- + 2H^+.$$

The latter workers studied the reaction of niobium[133] and tantalum[134] pentafluorides with the corresponding pentaethoxides $M(OC_2H_5)_5$, and obtained products $MF_{5-n}.(OC_2H_5)_n$ with $n = 1$–4 (Table 5). These compounds are oligomers containing on the average $m \simeq 2$ and 3.8 monomers for $n = 4$ and 1 respectively: i.e. the degree of polymerisation decreases with increase in the covalent character of the compound as metal–fluorine are replaced by metal–ethoxy bonds (in the solid state the pentafluorides exist as tetramers[12]).

The above results indicate that alcohols and thiols react with electrophilic fluorides—tungsten(VI), niobium(V), and tantalum(V)—by rupture of alkoxy–hydrogen (alkylthio–hydrogen) bonds with replacement of fluorine in the acceptor by an alkoxy-group under mild conditions (below 0°C). The scheme

$$WF_6 + RO{-}H \rightarrow ROWF_5 + HF$$

may be suggested. This stage apparently occurs, similarly to the reactions of organosilicon compounds[87], via formation of seven-coordinated compounds with the hexafluoride (six-coordinated for the pentafluorides) by an $S_N2$ mechanism with subsequent cleavage of a metal–fluorine bond and elimination of hydrogen fluoride. The relatively unstable[131] ethoxytungsten (or ethylthiotungsten) pentafluoride decomposes further according to the equation

$$EtOWF_5 \xrightarrow{t} WOF_4 + EtF,$$

or adds a second alkoxy-group

$$EtOWF_5 + EtO{-}H \rightarrow (EtO)_2WF_4 + HF.$$

The diethoxytungsten tetrafluoride is in turn converted into oxotungsten tetrafluoride:

$$(EtO)_2WF_4 \xrightarrow{t} WOF_4 + Et_2O$$

similarly to the dimethoxy-derivative (Ref. 85 and Table 2). The reaction mechanism with ethanethiol is apparently the same as that with ethanol[131], but the former exhibits greater donor strength, since, despite the larger bulk, three fluorine atoms in the tungsten hexafluoride molecule are replaced by an alkylthio-group, but only two by ethanol.

#### (*b*) Ethers and sulphides

Ethers, like alcohols, possess weakly basic properties: with Lewis acids, e.g. boron trifluoride, they form stable adducts by virtue of the presence of lone pairs of electrons on the oxygen. In contrast, uranium hexafluoride reacts vigorously with diethyl ether, to give uranyl and

hydrogen fluorides with a carbonaceous substance of unknown composition[64]. Hexa- and penta-fluorides of *d*-elements in Groups V and VI form with ethers the series of compounds shown in Table 5. When a 1 : 5 mixture of tungsten hexafluoride and dimethyl ether is kept in a steel bomb at 100–110°C for 5 h, the products are methyl fluoride, the adduct $WOF_4.(CH_3)_2O$, and a mixture of lower tungsten oxide fluorides and organic compounds[84,135]. Study of the volatility, infrared spectra, and $^{19}F$-n.m.r. spectra suggests[84] that the adduct is a monomer of octahedral structure with the oxygen atom *trans* to the organic ligand. From an investigation of the reaction between tungsten hexafluoride and diethyl ether Buslaev et al. concluded[129] that the complex $WOF_4.(C_2H_5)_2O$ is obtained via an unstable intermediate compound $C_2H_5OWF_5$, owing to the tendency to form the more stable multiple bond W=O. It is pertinent to mention the observation by Noble et al.[123] that $CH_3OWF_5$ is able to lose the alkyl as the methyl cation.

Below room temperature the reaction of the hexafluorides with ethers and with dialkyl sulphides and selenides yields the adducts $MoF_6.(CH_3)_2O$, $MoF_6.(CH_3)_2S$,[43] $WF_6.(C_2H_5)_2O$,[96,129,135] $WF_6.(C_2H_5)_2S$, and $WF_6.2(C_2H_5)_2Se$.[115,135] The donor power towards the hexafluorides increases in the sequence $R_2O < R_2S < R_2Se$. It is assumed that tungsten hexafluoride is partly ionised in the adducts with sulphur and selenium derivatives[115,135]. Molybdenum pentafluoride forms equimolecular adducts with dimethyl ether and dimethyl sulphide, which readily eliminate the ligand molecules in a vacuum at 60 and 20°C respectively[43].

Niobium and tantalum pentafluorides form relatively stable compounds with dimethyl ether[117,120,136–138] and with dimethyl sulphide[44,136,137] (Table 5), which in a vacuum at the melting point distil without decomposition. Equimolecular adducts of these pentafluorides with diethyl ether and sulphide have not been isolated in the crystalline state, but information on them has been obtained from a study of their solutions[43,44,97,115]. It has been concluded from the $^{19}F$-n.m.r. spectra that $NbF_5.(C_2H_5)_2O$, $NbF_5.(C_2H_5)_2S$,[116] and $TaF_5.(CH_3)_2O$ [117] are monomers with octahedral coordination. Conductivity measurements indicate a greater degree of association of adducts with sulphides than of those with ethers[139].

The above results show that under mild conditions ethers, dialkyl sulphides, and dialkyl selenides as *n*-donors[6] form with pentafluorides and hexafluorides of *d*-elements adducts that, like amines, act as nucleophilic reagents. These complexes have the structure of oxonium or sulphonium salts, as is confirmed by their conductivity. The most stable complexes are obtained with niobium, tantalum, and molybdenum pentafluorides, which are stronger Lewis acids than are the hexafluorides. Under more severe conditions (at elevated temperatures and pressures) ethers and apparently their sulphur and selenium analogues undergo cleavage by hexafluorides at the carbon–oxygen bond analogous to the cleavage of ethers by hydrohalic acids[140].

Muetterties noted[107] that the fluorine atoms are not entirely equivalent in the adducts, especially in $WF_6.R_2O$, and suggested an oxonium salt type of structure $[WF_5.R_2O]^+F^-$. If this hypothesis is correct, the course of the reaction is analogous to the cleavage of ethers:

$$1)\quad R\ddot{O}R + WF_6 \rightarrow [R{-}\underset{\underset{WF_6}{|}}{\ddot{O}}{-}R]^+ \cdot F^- \xrightarrow{t} ROWF_5 + RF.$$

Since $(RO)_2WF_4$ has been detected among the reaction products[129], an additional fluorine atom in $ROWF_5$ may be replaced:

$$2)\quad ROWF_5 + ROR \xrightarrow{t} (RO)_2WF_4 + RF.$$

The possible presence of hydrogen fluoride as an impurity in tungsten hexafluoride does not exclude the probability of another well known[140] reaction path, giving an alcohol, which then reacts more readily with the hexafluoride:

$$R_2O + HF \rightarrow [R\overset{H}{\ddot{O}}R]^+ \cdot F^- \rightarrow ROH + RF$$

$$ROH + WF_6 \rightarrow ROWF_5 + HF \text{ etc}$$

Hydrogen fluoride may thus act as a catalytic additive. On the basis of available data it is not possible to give preference to either mechanism.

Under the conditions investigated niobium, tantalum, and molybdenum pentafluorides do not undergo substitution with ethers, but form adducts usually of coordination number 6, sometimes 7. They are compounds of *n*–*v* type[6], in most cases relatively stable. Below room temperature molybdenum and tungsten hexafluorides give with ethers and sulphides less stable adducts of coordination number 7.

### (*c*) Dimethyl sulphoxide, dialkyl sulphites, and diphenyl sulphite

As regards acetone all that is known[96] is that tungsten hexafluoride forms red solutions. Dimethyl sulphoxide differs from its oxygen analogue in having a non-planar molecule and in the presence of a $p_\pi$–$d_\pi$ component of the S=O double bond. Hydrogen atoms in an $\alpha$-position with respect to the sulphur or carbon atom in a sulphoxide or a ketone are capable of substitution by halogen[89].

A study of the interaction of tungsten hexafluoride and dimethyl sulphoxide based on infrared and $^{19}F$-n.m.r. spectroscopy has established[141] that the main product, a viscous yellow oil, consists largely of two compounds—$WF_6.(CH_3)_2SO$ and $WOF_4$—accompanied by bisfluoromethyl ether, hydrogen fluoride, and $W_2O_2F_9^-$. This indicates a complicated reaction mechanism involving cleavage of S=O and C–S bonds with replacement of hydrogen by fluorine in the alkyl group.

Niobium and tantalum pentafluorides form 1 : 1 and 1 : 2 adducts with dimethyl sulphoxide[44,116,120,139,142]. On the basis of conductivity measurements and of infrared and $^{19}F$-n.m.r. spectral data it has been suggested[139,142,143] that $NbF_5.2(CH_3)_2SO$ is ionised as $[NbF_4.L_4]^+[NbF_6]^-$. This is confirmed by the known ability of dimethyl sulphoxide to solvate primarily electrophilic species, cations[89,126]. The corresponding equimolecular compound does not contain the hexafluoroniobate anion[143]. The adduct $TaF_5.2(CH_3)_2SO$ has different $^{19}F$-n.m.r. spectra from the analogous niobium compound, and is considerably more soluble in excess of the ligand. Establishment of the equilibria

$$2TaF_5 + 4L \rightleftharpoons TaF_6^- + TaF_4 \cdot L_4^+$$

$$2TaF_4 \cdot L_4^+ \rightleftharpoons TaF_6^- + TaF_2 \cdot L_n^{2+} + (8-n)\,L$$

was suggested[118].

The above results indicate that pentafluorides undergo addition reactions with dialkyl sulphoxides to form ionised complexes of coordination number 6 and 7, whereas tungsten hexafluoride, the least strongly oxidising among

hexafluorides, undergoes complicated substitution reactions, elucidation of whose mechanism requires further research.

Dimethyl sulphite converts molybdenum hexafluoride into $MoOF_4$, the organic reaction products being methyl fluoride and $CH_3O.SO.F$.[83] Apparently the mechanism is

$$MoF_6 + (RO)_2SO \rightarrow ROMoF_5 + ROS(O)F$$
$$ROMoF_5 \xrightarrow{t} MoOF_4 + RF .$$

Between −40 and +20°C dimethyl, diethyl, and diphenyl sulphites react similarly with tungsten hexafluoride[123,144]:

$$(RO)_2SO + WF_6 \rightarrow ROWF_5 + ROS(O)F .$$

Fluorosulphite esters give sulphur dioxide and the alkyl fluoride on thermal decomposition, and sulphur dioxide and hydrogen fluoride on hydrolysis. At moderate temperatures the compounds $CH_3OWF_5$ and $C_6H_5OWF_5$ are relatively stable monomers, which sublime readily in a vacuum and are soluble in benzene. At 135°C the former decomposes into $WOF_4$ and fluoromethane. The $^{19}F$- and $^1H$-n.m.r. spectra indicate[123] the presence of the adducts $WOF_4.(RO)_2SO$ and $[(RO)_3S]^+[WOF_5]^-$.

Thus dialkyl sulphites react with hexafluorides of *d*-elements with substitution of fluorine in the acceptor molecule by an alkoxy-group at the site of rupture of the sulphur–oxygen bond, by a mechanism presumably analogous to the cleavage of ethers.

### 4. Carboxylic Acids

The most characteristic reaction of carboxylic acids with halides, e.g. of phosphorus (Lewis acids), is the formation of acid halides. Molybdenum, tungsten, and uranium hexafluorides behave similarly towards acetic acid at 40–60°C,[145] giving acetyl fluoride and the corresponding oxide fluoride. The scheme

$$UF_6 + 2CH_3COOH \rightarrow UO_2F_2 + 2CH_3COF + 2HF$$
$$WF_6 + 2CH_3COOH \rightarrow WO_2F_2 + 2CH_3COF + 2HF$$
$$MoF_6 + CH_3COOH \rightarrow MoOF_4 + CH_3COF + HF$$

was suggested.

A study of the reaction of tungsten hexafluoride with acetic and thioacetic acids by $^{19}F$-n.m.r. spectroscopy has shown[131] that sulphur and oxygen atoms are detached from the latter to give tungsten oxide and sulphide tetrafluorides:

$$2WF_6 + 2CH_3COSH \rightarrow WSF_4 + WOF_4 + 2CH_3COF + 2HF .$$

With increase in the ratio of thioacetic acid to the hexafluoride the tetrafluorides pass into the dimeric anions $W_2O_2F_9^-$ and $W_2S_2F_9^-$, and obviously into $WSF_5^-$ (since $WOF_5^-$ is present in the acetic acid system). It had been shown earlier[139] that the fluorine atom *trans* to the oxygen in $WOF_5^-$, and the bridging fluorine atom in the dimer $W_2O_2F_9^-$, carry a considerable proportion of the negative charge. It is significant[131,137] that both the carbonyl C=O and the C–O or C–S bonds are ruptured in the reaction in thioacetic acid—and it must be assumed in acetic acid (more correctly in their anions)—and also that the systems contain anions of the types $WOF_5^-$, as well as the compounds $WOF_4$ and hydrogen fluoride.

On the basis of experimental results[131] the interaction of tungsten hexafluoride with thioacetic acid can be written

$$1)\quad WF_6 + R{-}C\begin{matrix}O\\ \diagdown\\ S^-\end{matrix} \rightarrow WSF_5^- + R{-}\overset{O}{\overset{\diagup}{C}}{-}F$$
$$2)\quad WSF_5^- + H^+ \rightarrow WSF_4 + HF \rightleftharpoons W_2S_2F_9^- + H^+ .$$

In the second reaction the proton apparently coordinates with the fluorine atom of the substrate on which the negative charge is concentrated[139,146]. The appearance of $WOF_4$ together with $WSF_4$ as reaction product can be attributed to the existence of resonance structures of the acid anion[89], which leads to cleavage of the bonds attaching carbon to sulphur and to oxygen.

Trifluoroacetic acid, of similar strength to hydrochloric acid, reacts with uranium hexafluoride according to the equation[145,147]

$$2UF_6 + 2CF_3COOH \rightarrow 2HUF_6 + CF_3COF + CO_2 + COF_2$$

Hexafluorouranic acid is unstable, and decomposes[145] at 60°C into uranium(V) and hydrogen fluorides. In excess of the solvent the complex acid is converted into $2UF_5.CF_3COOH$. The diminished stability of trifluoroacetic acid (which undergoes degradation, whereas acetic acid is merely dehydrated) is attributed[145] to the proximity of fluorine atoms to the carbonyl group. Indeed, the presence of uranium(V) and carbon dioxide among the reaction products indicates decarboxylation, which is known to occur readily if a strongly electron-accepting group, in the present case trifluoromethyl, is attached to an $\alpha$-carbon atom:

$$CF_3{-}C\begin{matrix}O\\ \diagdown\\ O^-\end{matrix} + UF_6 \rightarrow CF_4 + UF_5 + CO_2 .$$

On the other hand, the presence of trifluoroacetyl fluoride indicates the progress in parallel of a reaction analogous to that occurring with acetic acid[131,145]. It is evident that the reaction is actually more complicated, and further research is necessary in order to refine the mechanism.

## VI. COMPLEX FORMATION WITH ORGANIC LIGANDS

Although various compounds of *d*- and *f*-elements exhibit a strong tendency to form complexes[148], the fluorides are less strongly complex-forming than other compounds having ligands located to the left of fluorine in the spectrochemical series (e.g. chlorides, bromides). This is probably due to the greater electronegativity and the small size of fluoride ions, which form a compact screening shell diminishing the accessibility of vacant orbitals of the central atom in the fluorides for overlapping with the orbitals of organic ligands. This may explain why chlorides of *d*-elements are stronger Lewis acids than are the corresponding fluorides.

Fluorides of *d*-elements in the lower formal degrees of oxidation such as 3–5 have strong intermolecular coordinate bonds and, as Walton[149] has shown, form in the solid state lattices in which the metal is situated in an octahedral environment of six halide ions. The fall in the boiling point with increase in the number of ligands in the sequence of fluorides

$$MF_3 > MF_4 > MF_5 > MF_6$$

both for the same element and on moving from left to right along a series in the Periodic System, indicates an increase in coordination saturation and a decrease in the strength of intermolecular bonds. On the whole, hexafluorides possess a more covalent character than do tetra- and penta-fluorides. We shall examine the opportunities for inorganic fluorides in various states of oxidation to coordinate ligands containing lone pairs of electrons.

Trifluorides of *p*-elements—aluminium, gallium, indium—form[150] equimolecular adducts with diethylamine and tributylamine, and $MF_3.3NH_3$ with ammonia. Aluminium tribromide behaves similarly[151] towards dialkyl sulphides and selenides. Muetterties reported[107] that antimony and arsenic trifluorides give equimolecular adducts with dioxan and dimethylformamide, $2SbF_3.L$ is formed with pyridine and trimethylamine, and $SbF_3.2(CH_3)_2SO$ has been obtained with dimethyl sulphoxide. It may be supposed that interaction of trifluorides of *d*-elements with organic ligands will yield compounds of tetrahedral structure, since the considerable bulk of the ligands will prevent the appearance of adducts having higher coordination numbers.

Numerous examples of the preferential formation of $MF_4.2L$ adducts in reactions with amines, pyridine and its derivatives, dimethyl sulphoxide, and several other ligands have been demonstrated by Muetterties[107,152] for tetrafluorides of *d*-elements (titanium, zirconium, molybdenum) and *p*-elements (silicon, germanium, tin) and by Ennan[153] for silicon tetrafluoride. It was concluded[152] that octahedral coordination of the adducts with the metal tetrafluorides was preferred stoichiometrically. Smaller coordination numbers were observed probably because of steric hindrance in the case of bulky compounds having a metal–nitrogen bond, but this was almost completely absent from the metal–oxygen bond.

It follows from the above account that pentafluorides of *d*-elements form equimolecular adducts, considerably more rarely 1 : 2 compounds, with almost all organic ligands having lone pairs of electrons: i.e. a clear tendency to form complexes with octahedral coordination is evident in this case too.

Cotton and Wilkinson[148] point out that, in the ligand-field approximation for *d*-electrons, octahedral coordination contributes about double the energy separation of bonding $t_{2g}$ and antibonding $e_g$ orbitals in comparison with a tetrahedral field. This will obviously make octahedral coordination advantageous for complexes, including fluorides having a small number of unpaired *d*-electrons. The fluorides of *d*-elements discussed here are compounds of this type. Hence, under otherwise similar conditions, the energy of stabilisation of the ligand in an octahedral field should be the dominant factor. It is probably for this reason that tri-, tetra-, and penta-fluorides of *d*-elements undergo addition with *n*-donors possessing lone pairs of electrons, thereby acquiring a tetrahedral configuration with trifluorides (in the case of large ligands preventing a higher coordination number) and an octahedral configuration with tetra- and penta-fluorides.

Basolo and Johnson noted[154] that four-coordinated systems of *d*-elements react predominantly with the formation of new metal–ligand bonds, to which a high charge on the central ion makes a considerable contribution. Evidently there is every reason to apply this to pentafluorides. They add ligands more easily than do tri- and tetra-fluorides, in order to complete the octahedral coordination. This requires the formation of only one new metal–ligand bond, whereas in tri- and tetra-fluorides greater energy is necessary to break the considerable intermolecular forces in the condensed state and to create more than one new metal–ligand bond.

The situation is different with hexafluorides of *d*-elements, since they are structures having the energetically advantageous octahedral coordination. These hexafluorides differ greatly in oxidising and complexing properties. As shown above, the hexafluorides of *f*-elements surpass appreciably those of *d*-elements in oxidising power. This difference may be due to differences in the number of spatial configuration of *d*- and *f*-orbitals, which in turn presupposes different configurations and energies of formation of bonds. To the approximation of crystal field theory Bagnall[60] supposes that for *f*-orbitals an eight-coordinated structure is preferable, corresponding to a point group of symmetry $D_{6h}$ (a regular hexagonal bipyramid) or the octahedral $O_h$ (bonds directed from the centre towards the corners of a cube). Six-coordinated geometry of type $O_h$ or $D_{4h}$ is more favourable[148] for complexes of *d*-elements.

Matters are more complicated in the actual molecules of hexafluorides of *f*-elements, for *d*-electrons are also involved in bond formation (electronic structures—uranium $5f^36d7s^2$, neptunium $5f^46d7s^2$ or $5f^57s^2$, and plutonium $5f^67s^2$).[60] Nevertheless, available data indicate that in a six-coordinated structure hexafluorides of *f*-elements are less stable than are those of *d*-elements, and the stability of the compounds diminishes with increase in the number of *f*-electrons, an example being the decrease in stability in the sequence $UF_6 > NpF_6 > PuF_6$. For the reasons discussed above the hexafluorides of *d*- and *f*-elements will obviously differ also in complexing power, although no data are at present available providing unambiguous support for this hypothesis. It can be concluded from the work of Weinstock[10,155] that in general the stability of the hexafluorides diminishes with increase in the number of unpaired electrons—for the transition series

$$4d\text{—}MoF_6\,(d^0) > TcF_6\,(d^1) > RuF_6\,(d^2) > RhF_6\,(d^3)$$

$$5d\text{—}WF_6\,(d^0) > ReF_6\,(d^1) > OsF_6\,(d^2) > IrF_6\,(d^3) > PtF_6\,(d^4)$$

and for the actinides

$$5f\text{—}UF_6\,(5f^0) > NpF_6\,(5f^1) > PuF_6\,(5f^2).$$

The most intensive investigation has been made on the interaction of organic ligands with tungsten hexafluoride, which exhibits extremely weak oxidising properties and is more convenient for investigation than are other hexafluorides. In complexing power it is very close to the pentafluorides of *d*-elements. Jorgensen assumed[156] that the tungsten atom in the hexafluoride bore a formal charge of +5, whereas in molybdenum and rhenium hexafluorides the corresponding charge was +6. If this is in fact the case, the difference in oxidising power between molybdenum and tungsten hexafluorides is explicable: the latter is very similar to pentafluorides both in its comparatively weak oxidising power and in its tendency to form complexes, whereas molybdenum hexafluoride is a quite strong oxidant, and frequently undergoes complex formation only after reduction to the quinquevalent state.

Hexafluorides form the most stable complexes with *n*-donors having a relatively simple structure: e.g. nitric oxide gives $NO^+MoF_6^-$ and $NO^+UF_6^-$. The enthalpy of formation of the latter compound is −52 kcal mole$^{-1}$.[159] The formal state of oxidation of the metal in these compounds is +5. Tungsten hexafluoride does not react with nitric oxide.

Donors having a non-linear structure, such as nitrosyl and nitryl fluorides, give with uranium hexafluoride the compounds $NOUF_7$, $NO_2UF_7$, and $(NO_2)_2UF_8$,[160,161] with molybdenum hexafluoride $NOMoF_7$ and $NO_2MoF_7$,[161] and with tungsten hexafluoride $NOWF_7$ and $NO_2WF_7$.[162] The enthalpies of decomposition of $NOUF_7$ and $NO_2UF_7$ are respectively[161] 16.6 and 13.8 kcal mole$^{-1}$.

Uranium hexafluoride forms with alkali-metal fluorides a series of complexes varying in composition; with sodium fluoride, in particular, $NaUF_7$ [163] and $Na_2UF_8$ [164]

are obtained (having enthalpies of decomposition of 15.9 and 19.1 kcal mole$^{-1}$ respectively—given by other workers[165] as 9.4 and 23.5 kcal mole$^{-1}$). The complexes $Na_3UF_9$ and $Na_3U_2F_{15}$ are also known[166]. Molybdenum and tungsten hexafluorides also form with sodium fluoride 1 : 1 and 1 : 2 complexes[163,167]. Neptunium and plutonium hexafluorides on treatment with sodium fluoride are reduced to the quinquevalent and quadrivalent states respectively, with liberation of elementary fluorine and formation of $Na_3NpF_8$ and $Na_3PuF_7$.[166]

The enthalpies of decomposition show that the complexes of hexafluorides with the above ligands are quite stable, except in the last two cases. The alkali-metal fluorides are ionic in character, their anions acting as donors with one lone electron in their ability to form stable bonds with $\upsilon$-acceptors, in the present case halides of $d$- and $f$-elements. The nitric oxide, nitrosyl fluoride, and nitryl fluoride molecules possess a lone pair of electrons (they are $n$-donors) and a considerable capacity for polarisation, which also ensures relatively stable bonding with hexafluorides. The coordination numbers of the metals in these complexes are 7–9.

Among the classes of organic compounds considered, the following $n$-donors—amines, ethers, dialkyl sulphides, sulphoxides, and selenides, and pyridine and its derivatives—are able to form such bonds. The majority of published studies are concerned with the interactions of these donors with tungsten hexafluoride, in which it develops a coordination number 8, more rarely 7 or 9. In the case of the other hexafluorides only the adducts with pyridine and 2-fluoropyridine—$MoF_6.2C_5H_5N$, $UF_6.C_5H_4FN$, and $UF_6.2C_5H_4FN$—are known[107]. No investigations have yet been published on the structure of these compounds, their stability, or the effect of the nature and the geometrical dimensions of the ligand molecules on the properties of the adducts formed with hexafluorides.

It has been suggested in a recent publication[169] that compounds of $d$- and $f$-elements develop greater chemical differences in aqueous solution than as anhydrous halides and oxides. One might agree with this, since fluorine is located somewhat to the right of such anions as nitrate, chloride, etc. in the spectrochemical series, and theoretically have a greater levelling effect on the chemical individuality of the central ion in the adduct; on the other hand, water is situated to the right of fluorine in this series. It must also be borne in mind that the properties of halides of $d$- and $f$-elements have been studied considerably less fully in non-aqueous than in aqueous systems, so that there are as yet inadequate grounds for such a statement.

Investigation of the reactions of hexafluorides with organic $n$-donors necessitates a relatively complicated experimental technique, but the results may well make a definite contribution to the theory of complex formation by $d$- and $f$-elements and permit the use of organic donors as selective chemical reagents in fluorination, exchange, and addition reactions involving metal fluorides.

# Effect of Radioactive Emission on the Catalytic Properties of Solid Materials

D.V.Sokol'skii, K.K.Kuzembaev, and I.V.Kel'man

The general state of the problem of the radiation modification of the action of solid catalysts is discussed, in relation to various types of heterogeneous catalytic reactions, on the basis of 190 references.

CONTENTS

I. Introduction 436
II. Principal mechanisms of radiation damage 436
III. Effect of ionising radiation on the adsorptive power and the catalytic activity of solids 437

## I. INTRODUCTION

Many research workers have turned their attention to the problem of radiation heterogeneous catalysis, for solid catalysts often undergo considerable activation on irradiation. On the other hand, attempts have been made to improve the chemical efficiency of the irradiation of a reaction system by the introduction of solids, since radiolytic reactions (other than chain processes) usually give low yields of the required product. Furthermore, study of the adsorption and catalytic properties of irradiated specimens will contribute to a better understanding of general aspects of heterogeneous catalysis, in particular the relation between the activity of a solid catalyst and defects in its crystal structure.

Because of the abundance of information on this aspect, the Review will not contain any detailed discussion of the mechanisms of the radiation-catalytic processes occurring in each individual case. We have tried to report the general state of the problem, with detailed consideration only of the clearest examples with the aim where possible of revealing general features inherent in various groups of phenomena.

It is necessary to distinguish cases in which preliminary exposure of the catalyst (in the absence of reactants), by producing radiation damage in the solid specimen, confers on it new catalytic properties from cases in which a considerable proportion of the radiant energy absorbed by the catalyst during the reaction is utilised in activating gas molecules adsorbed on its surface. In the latter case thermodynamically forbidden processes may occur[1]. The radiation modifcation of solid catalysts is in some way connected with the appearance of various kinds of interior and surface defects.

## II. PRINCIPAL MECHANISMS OF RADIATION DAMAGE

The interaction of high-energy radiation with a solid result in various types of disturbance[2-5]: (1) vacancies are unoccupied lattice points; (2) interstitial atoms have been displaced from their usual position in the lattice and are located between lattice points (vacancies and interstitial atoms may be formed simultaneously by the Frenkel mechanism, i.e. by escape of an atom from a lattice point into an interstice; vacancies may arise also by a Schottky mechanism, when an atom that has vaporised from the crystal surface is replaced by an atom from a deeper layer; and vacancies may combine to form spherical pores or flat circular voids); (3) displacement peaks are regions containing up to $10^4$ displaced atoms, such defects usually arising at the end of the path of the moving particles; (4) impurity atoms are chemically foreign atoms formed as a result of nuclear reactions occurring in the solid under the influence of the radiation; (5) the non-equilibrium electrons and holes produced by the ionisation of atoms and the excitation of electrons (ionisation effects) may be localised on biographic defects to form $F$- and $V$-centres respectively, and the ionisation effects may lead to coloration, luminescence, and the formation of free radicals; and (6) thermal peaks are high-temperature regions containing a few thousand atoms and reaching 1000 K, such defects being formed along the path of a fission fragment or a dislodged charged atom.

The various types of electromagnetic and corpuscular radiation are able in general to induce any type of disturbance in a solid, but the efficiency of formation varies. Furthermore, the mechanisms of the action of radiation on metals and on semiconductors are not identical[6]. Ionisation effects, which occur with almost all types of radiation, are very short-lived in metals, since they are rapidly reduced by radiationless transitions. Relatively stable changes occur only on the direct transfer of energy to the atomic framework of the lattice, with the generation of Frenkel pairs (interstitial atom + vacancy). Therefore the most intense effect is produced by bombarding metals with neutrons or heavy charged particles. Semiconductors and dielectrics, in contrast, are distinguished by the ease of formation of diverse stable defects.

The first of three possibilities when non-metals are irradiated[7] involves only direct ionisation, i.e. the production of non-equilibrium charge carriers. Such an effect is observed when X-rays, $\gamma$-rays, fast electrons, or positrons are used. The excess concentration of free current carriers of the same sign is given by the formula $\Delta n = g\tau$, where $g$ is the rate of generation of carriers (which is proportional to the intensity of the $\gamma$-irradiation) and $\tau$ is their average lifetime[8,9]. Since $\tau$ is usually extremely short, specimens possess no radiation "memory". Under these conditions stable defects can appear only when electrons or holes are localised on biographic surface defects.

In the second case[7] irradiation (mainly neutron) initiates a nuclear reaction, which enriches the semiconductor with a donor or an acceptor impurity. This irreversible process, which is accompanied by a shift in the electron equilibrium, can become significant only when atoms having a sufficiently large capture cross-section for neutrons are present in the substance.

The third possibility is that the specimen possesses a brief "memory" owing to the appearance of interior structural defects of the Frenkel type. Atoms that have penetrated into interstices contribute new donor levels to the energy spectrum of the semiconductor, and vacancies contribute acceptor levels, which are responsible for the shift in the electron equilibrium [10]. It was suggested [11] that, as along as the energy parameter of the bombarding particle $\epsilon = mE/M$ is large in comparison with the forbidden gap $E_e$ of the crystal ($m$ is the mass of the electron, $M$ the mass of the particle, and $E$ the kinetic energy of the latter), it dissipates most of its energy on ionisation processes. When $\epsilon < E_e/8$, elastic collisions begin to predominate, leading to the displacement of lattice atoms. The number of atoms displaced in unit volume in unit time is [12] $N_d = \varphi n \sigma_d \overline{\nu}$, where $\varphi$ is the density of incident particles, $n$ the density of atoms, $\sigma_d$ the cross-section of collisions leading to displacements, and $\overline{\nu}$ the mean number of atoms displaced by a primary atom, given by [13] $\overline{\nu} = 0.5[1 + \ln(E_m/2E_d)]$, in which $E_m = 4MM'E/(M + M')^2$, while $E_d$ is the threshold energy of displacement of an atom and $M'$ its mass. The displacement of atoms in dielectrics, in contrast to semiconductors, may be caused also by ionisation phenomena, which sometimes play a leading role. Various mechanisms of formation of these defects were suggested by Varley [14] and by Seitz [12].

Diffusion of the resulting vacancies and interstitial atoms produces an annealing effect as a consequence of their mutual annihilation. Thus after a certain time specimens of $n$-germanium that had been exposed to $\alpha$-particles [15] acquired their original properties, but the annealing of specimens initially having $p$-conductance was only partial: the conductivity and the Hall coefficient did not return to the values characteristic of unexposed semiconductors. A series of theoretical studies have been made on the kinetics of the annealing of Frenkel pairs [16-19]. The saturation of radiation effects during prolonged exposure at high temperatures may be due to annealing.

## III. EFFECT OF IONISING RADIATION ON THE ADSORPTIVE POWER AND THE CATALYTIC ACTIVITY OF SOLIDS

The influence of ionising radiation on the catalytic properties of solids should be interpreted in terms of one of the current theories of heterogeneous catalysis, which involve different concepts of the primary mechanisms of the interaction of the reactants with the catalytic surface. According to Balandin's theory [20] the activity of a catalyst depends on the presence in its lattice of atomic groupings (multiplets) arranged in definite fashion, on which reactant molecules are adsorbed and thus activated. If the changes in the lattice parameters produced by the ionising radiation contribute to the establishment of such a structure, the radiation will have a promoting effect on the solid catalyst; when exposure results in the degradation of active multiplets, poisoning of the catalyst is observed.

The electronic theory of catalysis [21] is based on the hypothesis that the free electrons and holes localised on surface defects play an active part in the primary acts of adsorption and activation of reactant molecules on a semiconductor catalyst surface. Since their equilibrium concentration depends unambiguously on the position of the Fermi level in the band structure of the semiconductor, any factor (including radiation) that displaces this level will cause a change in the catalytic properties of the specimen. These concepts form the basis of theoretical studies [22,23] on the influence of radiation on the adsorptive power and the catalytic activity of semiconductors. Experimental techniques have been described in detail [24] for the oxidation of carbon monoxide on nickel(II) oxide exposed to $\gamma$-rays. Some idea of the present state of the problem of the action of radiation on the adsorption and catalytic characteristics of solids can be obtained from reviews [25,26].

### 1. Adsorption

Investigation of the adsorption properties of irradiated specimens will give a clearer idea of the disturbances, produced than will examination of catalytic reactions, which usually have a complicated mechanism.

The chemisorption of hydrogen on zinc oxide (an $n$-type semiconductor) at 20°C hardly affects the electrical conductivity of the adsorbent, whereas chemisorption under the influence of $\gamma$-rays is accompanied by a considerable increase in conductivity [27]. The explanation given was that hydrogen is adsorbed in an uncharged form in the absence of radiation, whereas in a radiation field the free holes produced are captured by hydrogen molecules. This excludes recombination with the latter of the free electrons, which are involved in conduction. In contrast, the chemisorption of oxygen in the absence of radiation leads to a sharp fall in conductance, and, when it is switched on, additional chemisorption takes place with simultaneous increase in conductivity. The probable reason is that exposure converts oxygen into a form with a smaller negative charge, and also that the concentration of excess current carriers increases in the bulk of the zinc oxide. In the absence of irradiation neither hydrogen nor oxygen was chemisorbed on aluminium oxide (in contrast to zinc oxide) at 20°C, but in the presence of $\gamma$-rays the chemisorption of oxygen was more rapid than that of hydrogen [28]. This was attributed to the presence in aluminium oxide of a considerable number of efficienct centres, which captured some of the free holes necessary for the chemisorption of hydrogen.

The quantity of hydrogen chemisorbed on a $\gamma$-alumina surface was used [29] to determine the maximum density of adsorption centres ($\sim 5.5 \times 10^{12}$ cm$^{-2}$) produced by continuous cobalt-60 $\gamma$-rays at a dosage rate of 350 rad s$^{-1}$. On preliminary irradiation this quantity was $\sim 3 \times 10^{11}$ cm$^{-2}$. Electron spin resonance established the approximate equality of the concentration of radiation defects responsible for the adsorption of hydrogen and of paramagnetic centres produced by the irradiation of aluminium oxide. A study was made [30] of the effect of such radiation on specimens of $\gamma$-alumina differing in specific surface. The intrinsic volume of one adsorption centre was found for each case from the specific surface and the number of active centres (determined kinetically). The chemisorption rate constant for hydrogen increased on passing from small to large such volumes. The rate of chemisorption is given [31] by the equation

$$-\frac{dp}{d\tau} = \alpha K p^{\frac{1}{2}} I S (1 - \theta),$$

where $p$ is the pressure of hydrogen, $\tau$ the time, $\alpha$ the surface density of adsorption centres, $I$ the dosage rate, $S$ the total area of the catalyst, and $\theta$ the proportion of adsorption centres occupied.

Despite the variation in the phase constitution and the specific surface of the adsorbents used, the initial rates of chemisorption of oxygen on the $\gamma$-irradiated aluminium

oxide were approximately the same [32], and the radiation efficiency of chemisorption of molecules was closely similar to the yield of pairs of excess current carriers. Termination of exposure led to cessation of radiation chemisorption, which indicated the short lifetime of the adsorption centres. The initial rate of chemisorption was directly proportional to the quantity of catalyst and the power of the $\gamma$-rays, but independent of the oxygen pressure [33]. The chemisorption was irreversible, the maximum number of chemisorbed molecules being $2.5 \times 10^{12}$ cm$^{-2}$.

In the Reviewers' opinion the above publications leave no doubt that free current carriers generated by the radiation are involved in the adsorption of hydrogen and oxygen on semiconducting adsorbents, with the chemisorption of hydrogen involving free holes, and that of oxygen free electrons of the semiconductor. In both cases the initial rate of chemisorption is directly proportional to the power of the radiation. The fact that the initial rate of adsorption of oxygen, in contrast to that of hydrogen, is independent of the pressure is probably due to the more efficient adsorption of oxygen by the irradiated aluminium oxide [28].

Exposure of $\gamma$-alumina in equilibrium with carbon monoxide to cobalt-60 $\gamma$-rays at 300 K results in almost complete adsorption of the gas [34]. If irradiation was terminated before adsorption was complete, a post-radiation effect was observed: with rise in temperature from 300 to 375 K the initial rate of adsorption remained unchanged, but then began to fall, owing to thermal annealing of the active centres produced by the radiation. Adsorption of carbon monoxide, nitrous oxide, and oxygen at 77 K on $\gamma$-alumina exposed to $\gamma$-rays either previously or during adsorption (dosage rate 1000 rad s$^{-1}$) produced no change in form or intensity of the electron spin resonance spectrum [35]. Thus adsorbed gases do not interact with paramagnetic centres formed on irradiation, but heating $\gamma$-alumina with carbon monoxide or oxygen to 300 K was accompanied by a change in the e.s.r. signal. In contrast to carbon monoxide, the extra quantity of carbon dioxide adsorbed in the field of the $\gamma$-rays (300 rad s$^{-1}$) was $<10\%$ of the quantity adsorbed by aluminium oxide in the thermal process [36]. The activation energy of desorption of carbon dioxide from the surface was the same (4.5 kcal mole$^{-1}$) whether or not the adsorbents had been irradiated and whatever the dosage. When specimens on which carbon dioxide had been adsorbed by means of radiation were kept for 30 days or were heated, the bonding became stronger (the activation energy increased to 11 kcal mole$^{-1}$).

Several other cases have been noted of enhanced adsorptive power resulting from the irradiation of solids. Thus silica gel exposed to cobalt-60 $\gamma$-rays was a considerably more active adsorbent for nitrogen, hydrogen, carbon monoxide and dioxide, ammonia, and ethylene than before exposure [37], which was attributed to detachment of hydroxy-groups from the surface or direct interaction of the ionising radiation with gas molecules. Exposure of $\gamma$-alumina to cobalt-60 $\gamma$-rays (300 rad s$^{-1}$) had a favourable influence on the quantity of ethylene adsorbed and strengthened its bonding with the surface [38].

The system comprising benzene and silica gel exposed to $\gamma$-rays (640 rad s$^{-1}$) at the temperature of liquid nitrogen was studied in detail [39,40]. The radiation leads to the reaction

$$\equiv Si{-}O{-}H \rightarrow \equiv Si{-}O^{\cdot} + H$$

in the silica gel; the liberated hydrogen atoms either combine to form molecules or interact with benzene molecules to form $C_6H_7^{\cdot}$ radicals. The silica-gel radicals $-Si-O^{\cdot}$ are also able to react with benzene molecules and $C_6H_7^{\cdot}$ radicals:

$$\equiv Si{-}O^{\cdot} + C_6H_6 \rightarrow \equiv Si{-}O{-}C_6H_6^{\cdot}$$

$$\equiv Si{-}O^{\cdot} + C_6H_7^{\cdot} \rightarrow \equiv Si{-}O{-}C_6H_7 \ .$$

If hexane molecules had been present on the silica-gel surface their interaction with hydrogen atoms would have yielded $C_6H_{13}^{\cdot}$ radicals [41].

Preliminary irradiation also affects the adsorption properties of solids, though usually to a less extent. Silica gel after treatment with $\gamma$-rays, for example, acquires an appreciable ability to adsorb hydrogen [42]. This is accompanied by the appearance of colour centres, which were identified [42] with holes associated with excess of oxygen in the silica. The adsorption of hydrogen involved interaction of these holes with electrons of the gas molecules, with consequent decolorisation of the colour centres. Reactor radiation, hard X-rays, $\gamma$-rays, and exposure to slow electrons from a high-frequency discharge promoted the adsorption of gases by silica gel [43] in the sequence—carbon dioxide < oxygen < hydrogen—but with proton beams and $\alpha$-rays the adsorption capacity increased from hydrogen to carbon dioxide and oxygen. No stimulation of the adsorption of argon by radiation was detected. The absorptive capacity of irradiated silica gel for hydrogen increased with its contamination by aluminium [44]. That of beryllium oxide for hydrogen was only slightly enhanced by exposure to $\gamma$-rays [45]. Exposure of $\gamma$-alumina to fast neutrons impared its adsorptive properties for krypton [46], and to n,$\gamma$-rays those for benzene and water vapour [47]. Treatment of nickel oxide in a nuclear reactor increased the subsequent sorption of hydrogen and oxygen [48].

It may be concluded from the above results that the enhancement of the adsorptive power of oxides produced by radiation is in many cases due to the appearance of non-equilibrium current carriers in their interior and on the surface. However, whereas free electrons or holes are the main agents in the continuous exposure of adsorbents, the centres of adsorption after preliminary irradiation are charge carriers produced by the radiation and trapped by biographic or radiation surface defects. Thus analysis of numerous e.s.r. spectra of irradiated sorbents before and after the adsorption of oxygen, carbon monoxide, and other electron acceptors indicates [49] that paramagnetic centres formed in a solid by the trapping in structural defects of electrons generated by the radiation are transformed into molecular ions—$O_2^-$, $CO^-$, $CO_2^-$, etc.

## 2. Isotopic Exchange and Ortho–Para Conversion of Hydrogen and the Isotopic Exchange of Oxygen

Isotope exchange is one of the simplest reactions, with a comparatively simple experimental technique. Together with the ortho–para conversion of hydrogen such exchange has therefore been used quite often as a model reaction.

Electron diffraction revealed structural disturbances in the metal lattices after the pretreatment of platinum and nickel catalysts with accelerated argon ions, which affected the rate of exchange between hydrogen and deuterium [50]. Preliminary bombardment of magnesium oxide with neutrons increased the rate of this exchange and of the ortho–para conversion of hydrogen [51,52], which e.s.r. data showed to be due to the appearance of electrons localised on surface radiation defects. On the other hand, these reactions were slower on specimens of alumina that

had first been irradiated with neutrons. If, however, the aluminium oxide contained small additions of salts of transition metals, $n,\gamma$-radiation had a considerable activating influence for the ortho–para conversion of hydrogen[54]. Enhanced catalytic activity towards deuterium–hydrogen exchange was observed[55] in irradiated powdered oxides—ZnO, MgO, $V_2O_5$, $BaTiO_3$, $CaSiO_3$, $KAlSi_3O_8$, etc.—whose treatment with neutrons in a nuclear reactor resulted in a considerable change in the rate of the process, whereas $\gamma$-irradiation was far weaker in increasing the rate, and sometimes had hardly any effect.

The rate of exchange on titanium dioxide at the temperature of liquid nitrogen increased by a factor of $10^4$ after $\gamma$-irradiation (dosage rate 120 rad $s^{-1}$, integral dose $1.7 \times 10^7$ rad).[56] When the temperature of the irradiated catalyst rose to 0°C, its activity dropped sharply and the e.s.r. signal became weaker.

Parallel variation of the e.s.r. spectrum and of the catalytic activity towards deuterium–hydrogen exchange was established also for the pretreatment of silica gel with $\gamma$-rays (integral dose from $2 \times 10^5$ to $2 \times 10^7$ rad).[57] The activity of the catalyst increased with the radiation dose, the duration and temperature of the heat-treatment preceding irradiation, and also the contamination of the specimens with aluminium. The considerably more rapid annealing of catalytic activity in hydrogen than in a vacuum was attributed to irreversible adsorption of hydrogen on active centres of the catalyst, which, according to optical and e.s.r. spectroscopy, were holes stabilised on oxygen atoms adjacent to aluminium atoms. After $\gamma$-irradiation (dosage rate $1.2 \times 10^{17}$ eV $g^{-1}$ $min^{-1}$) the activation energy of deuterium–hydrogen exchange had fallen from 9 to 2 kcal $mole^{-1}$, which was regarded[58] as due to a change in the reaction mechanism. The increase in the rate of exchange between hydrogen and deuterium observed in ethylene was attributed[59] to the appearance of unpaired electrons in the $\gamma$-irradiated aluminosilicate catalyst (dosage rate 100 rad $s^{-1}$, integral dose $1.5 \times 10^6$ rad). Their concentration was determined by e.s.r. as $4 \times 10^{18}$ spins $g^{-1}$. The enhancement of the catalytic activity of aluminosilicate cracking catalysts towards this reaction after their $\gamma$-irradiation was accompanied by an increase in optical absorption by the specimens, both parameters increasing with the radiation dose. However, no direct relation was detected between the numbers of active centres and colour centres during annealing.

$\gamma$-Irradiation ($2 \times 10^7$ eV $g^{-1}$ $min^{-1}$ for 0.5 h) had a promoting effect on the subsequent catalysis for $\gamma$-alumina of deuterium–hydrogen exchange at −78°C.[61] It is significant that radiation treatment of specimens already subjected to thermal activation at 400°C and of unactivated specimens increased their activity by factors of 7 and 1000 respectively, although in the latter case the radiation effect underwent more rapid annealing. The active centres were identified[61] with electrons or holes localised on structural defects, which was supported by results[62,63] recording the appearance of signals due to paramagnetic resonance absorption in $\gamma$-alumina after its treatment with $\gamma$-rays. The conclusion that short-lived radiation defects are not involved in deuterium–hydrogen exchange is inconsistent with data[64] indicating a sharp fall in catalytic activity of the $\gamma$-alumina after the $\gamma$-rays had been switched off. The initial reaction velocity in a system comprising 10% of hydrogen, 10% of deuterium, and 80% of helium over aluminium oxide was increased by irradiation by a factor of 1000 at 50°C, but only by factors of 4–5 at 150°C, owing to thermal annealing of the radiation active centres in the catalyst[64]. Investigation of the influence of $\beta$- and $\gamma$-rays, and also of ultraviolet radiation, on isotope exchange between benzene and heavy water on the surface of platinum dioxide[65] showed that the reaction was accelerated only by the action of radiation on the reaction mixture.

The effect of the temperature of preliminary conditioning of a catalyst on the magnitude of the radiation effect[61] has been observed by many other workers. Thus the rate of the ortho–para conversion of hydrogen on the surface of magnesium oxide that had been thermally activated at 675°C remained unchanged after irradiation of the catalyst by cobalt-60 $\gamma$-rays[66], but if the specimen had been activated at 500°C, its subsequent irradiation trebled the activity. When the system was irradiated during the reaction, the rate of the latter increased tenfold. It was concluded[66] that the action of the radiation involves neither an increase in the adsorption of hydrogen nor its radiolysis.

A detailed investigation on $\alpha$-alumina that had been exposed to cobalt-60 $\gamma$-rays ($10^{18}$ eV $g^{-1}$ $h^{-1}$) at 77 K showed[67] that specimens that had been activated at 560°C exhibited no e.s.r. signal and their catalytic activity remained unchanged after irradiation, which caused a signal to appear. Hence unpaired electrons produced during irradiation are unable to influence the course of the reaction, which supports the view[67] that the action of coupled electrons is necessary for the dissociation of hydrogen molecules. However, the activity of a specimen that had been preheated at 200°C—insufficient for its activation—and then irradiated reached that of a specimen that had been activated at 550°C.

It can thus be accepted as fully proved that the radiation sensitivity of catalysts for deuterium–hydrogen exchange diminishes with rise in the temperature of their thermal activation. A study of the effect of neutron irradiation or bombardment with $\alpha$-particles on the catalytic properties of strongly activated $\gamma$-alumina specimens even revealed a negative radiation effect[68]. This work also showed that poisoned catalysts—water, hydrogen, and acetylene were used as poisons—were more sensitive to radiation. A mechanism is therefore quite likely in which irradiation, like high-temperature evacuation, removes from the catalyst surface foreign gases blocking the active centres.

Several papers have recently appeared[1] on the action of radiation on homomolecular oxygen isotope exchange. Although this reaction does not take place on silica gel, it occurs at an appreciable rate on specimens exposed to integral doses $\geqslant 7 \times 10^6$ rad of cobalt-60 $\gamma$-rays[69,70]. The degree of conversion increases with the total catalytic surface area and the radiation dose. This effect was attributed to the formation of active centres of the type $\geq Si^{\cdot}$ or $\geq SiO^{\cdot}$ in the silica. After the action of $\gamma$-rays on lanthanum, samarium, and gadolinium oxides the rate of the process increased hundredfold[71]. More detailed study of the reaction on gadolinium oxide exposed to cobalt-60 $\gamma$-rays (integral dose $4 \times 10^5$ to $1.8 \times 10^7$ rad) at −85°C revealed an interesting relationship[72]: with increase in the integral dose the catalytic activity increased, and then somewhat diminished; after repeated growth in activity, the latter became independent of the radiation dose. The decrease in catalytic activity on exposure to doses exceeding 1.2 Mrad was explained by the association of primary defects. The secondary increase in activity was probably due to an increase in the number of association complexes.

Under a pressure of 20 mmHg at temperatures of 300° to 400°C the rate of exchange of oxygen on neodymium

oxide was approximately the same in a field of cobalt-60 $\gamma$-emission (200 rad $s^{-1}$) as in the absence of irradiation. Below 300°C there was hardly any change on the unexposed sesquioxide, but under irradiation the rate increased as the temperature fell from 300 to 20°C. This is because at low temperatures the reaction velocity on biographic active centres became incomparably smaller than the rate on radiation defects. At high temperatures the exposure of various oxides to cobalt-60 $\gamma$-rays did not lead to their activation, but at low temperatures their activity increased initially in proportion to the radiation dose, and then ceased to depend on it [74]. The radiation susceptibility diminished on passing from dielectrics to intrinsic semiconductors, and disappeared completely in substances having a forbidden gap $<2$ eV. [74] Similar results were obtained with preliminary radiation modification of the oxides. The activity of specimens that had been irradiated in an atmosphere of oxygen exceeded the activity of those that had been exposed in a vacuum.

In spite of the many experimental results on isotope exchange, it is still difficult to reach any conclusions on general aspects of the process or on its mechanism. Only the dependence of the radiation susceptibility of catalysts on the width of the forbidden gap [74] is of universal character, as we shall see later.

### 3. Decomposition of Hydrogen Peroxide and Certain Other Compounds

Study of the effect of radiation on the rate of decomposition of hydrogen peroxide was initiated [75] by recording the decrease in the catalytic activity of platinum during the reaction occurring in an X-ray field. Radiation poisoning of platinum is produced also by pretreatment with $\gamma$-rays [76]. Other workers also found [77,78] that exposure of platinum catalysts deposited on semiconductor carriers to a mercury–quartz lamp has an adverse influence on their catalytic properties in a subsequent reaction. Especially strong deactivation was observed when the dielectric silicon dioxide was used as carrier. However, direct $\gamma$-radiation of the hydrogen peroxide–platinum reaction system resulted in an appreciable increase in the rate of decomposition of the peroxide [79].

Another study [80] demonstrated the role of the carrier in the activation of a silver–silver oxalate catalyst by $\gamma$-rays (integral doses $2 \times 10^3$, $1.2 \times 10^5$, and $2.4 \times 10^5$ rad). The activity of the catalyst had changed little after irradiation, but was increased by subsequent heating. The explanation offered was that radiolytic silver, formed in the carrier on exposure, accelerated thermal decomposition of the salt with the separation of active silver. Introduction of a $\beta$-ray source (the sulphur-35 isotope) into the carrier of an iron phthalocyanine–barium sulphate catalyst improved the stability of the catalyst: the number of moles of hydrogen peroxide decomposed per mole of iron phthalocyanine decomposed increased in direct proportion to the specific radioactivity of the specimen [81]. Thus with catalysts of specific radioactivity 10.2 and 238.0 mc $g^{-1}$ the stability increased by 9% and 45% respectively.

The decomposition of hydrogen peroxide on neodymium oxide was accelerated after pretreatment of the latter in a nuclear reactor [82]. The active centres thus formed were so stable that annealing the catalyst at 110°C for 24 h, though lowering the activity, did not bring it down to that of the unirradiated specimen. The rate of decomposition of hydrogen peroxide on nickel oxide and the quantity of excess oxygen adsorbed both increased in parallel with the energy absorbed from cobalt-60 $\gamma$-rays (integral dosage $10^7$–$8 \times 10^9$ rad). [83] With a dose of $10^8$ rad the catalytic activity of the nickel oxide was double that of unirradiated specimens. The electrical conductivity of the oxide simultaneously diminished.

Many workers choose the decomposition of formic acid as model reaction. Thus the catalytic activity of copper and silica gel is somewhat improved after bombardment with fast neutrons [84]. An interesting study was made of this reaction [85,86] occurring at a high temperature on a single crystal of silver pre-irradiated with accelerated argon ions. Electron diffraction showed that the radiation treatment led to the formation of point defects and dislocations in the crystal lattice. Two competing processes—increase in the activation energy of decomposition and enhancement of the reproducibility coefficient† —were involved. Depending on which face of the single crystal was subjected to ion bombardment, one of these processes predominated, and thereby determined the sign of the radiation effect.

Preliminary irradiation of a catalyst comprising a mixture of aluminium and silicon oxides in a nuclear reactor somewhat lowered the rate of cracking of cumene at 300–450°C. [87] However, if the specimen had been "alloyed" with zinc and vanadium additions before exposure, the rate of the process was more than doubled, which indicated that impurity centres played an active part. A possible mechanism of interaction between corpuscular radiation and impurity atoms was illustrated [88] by the decomposition of nitric oxide on catalysts consisting of alumina (a dielectric), nickel monoxide (a *p*-type semiconductor), and tin dioxide (an *n*-type semiconductor) with additions of boron and lithium oxides. After exposure to neutrons (dosage rate $10^{11}$ n $cm^{-2}$ $s^{-1}$) for 3 h and standing for 1 month, the tin dioxide showed an increase, and the nickel monoxide a decrease, in catalytic activity. The reaction velocity had diminished on the catalyst comprising 90% $Al_2O_3$ + 10% $Li_2O$, but had increased on 90% $Al_2O_3$ + 10% $B_2O_3$. This was attributed to a change in the electronic properties of the oxides, both directly under the influence of the neutron irradiation and as a result of interaction with $\alpha$-particles generated in the course of the nuclear reaction of lithium-6 and boron-10 atoms with neutrons.

Pretreatment of a copper catalyst with neutrons (integral flux $3 \times 10^{18}$ n $cm^{-2}$) lowered the activation energy of the dehydrogenation of cyclohexane from 41 to 17.5 kcal $mole^{-1}$ and accelerated the process fivefold [89]. This was attributed to the appearance of foreign (probably nickel) atoms in the specimen as a consequence of a nuclear reaction. No change in activity was observed when a copper catalyst was exposed to $\gamma$-rays. The emission from a nuclear reactor changed the catalytic activity of oxides of certain amphoteric elements in the thermal decomposition of light and heavy water [90]. This phenomenon was regarded as due to change in both electronic and structural characteristics of the specimens.

The decomposition of *n*-hexane was investigated on a potassium–chromium–alumina catalyst ($Al_2O_3 : Cr_2O_3 : K_2O$ = 90.7 : 5.6 : 3.7 mole %) irradiated in a nuclear reactor with slow neutrons [flux(0.8 and 1.2) $\times 10^{13}$ n $cm^{-2}$ $s^{-1}$] and with $\gamma$-rays [91]. After the radiation treatment the yield of hydrogen diminished, while that of gaseous hydrocarbons somewhat increased, indicating more intense cracking.

---

† A reproducibility coefficient is not actually mentioned in Refs. 85 and 86 (Ed. of Translation).

Roasting the exposed catalysts did not destroy the radiation effect, but the latter disappeared completely when the experiment was repeated. The parallelism between the rate of cracking and the concentration of the radioactive chromium-51 isotope produced suggested that the latter had a promoting effect. This is confirmed by results[92] for the reaction occurring on $\gamma$-alumina to which chromium or chromium-51 (a source of $\gamma$-rays) had been added: the rate of cracking increased on introduction of the latter.

The favourable effect of induced radiation was clearly shown by a study[93] of the decomposition of n-butane (dehydrogenation, cracking, isomerisation) on alumina catalysts containing 10% of vanadium(V), molybdenum(VI), and tungsten(VI) oxides respectively, after irradiation with slow neutrons (flux $10^{13}$ n $cm^{-2}$ $s^{-1}$) in a nuclear reactor. Before irradiation the activity of these catalysts decreased in the above sequence. The catalytic activity of the first of them was unaffected by the neutron treatment (whether for 3 days or for 1 month). Prolonged irradiation of the aluminium–molybdenum oxide catalyst resulted in the appearance of the molybdenum-99 isotope, a source of $\beta$- and $\gamma$-rays, which led to a slight increase in the degree of conversion of the butane. Interaction of the aluminium–tungsten oxide catalyst with neutrons was accompanied by formation of the tungsten-185 and -187 isotopes, whose induced radioactivity far exceeds that of molybdenum-99. This was regarded as the reason why the activity of the specimens had more than doubled.

Preliminary $\gamma$-irradiation of catalysts also changed the rate of decomposition. Thus an appreciable increase in the rate for isopropylbenzene on aluminosilicate catalysts was accompanied[94] by the appearance of colour centres, formed by aluminium atoms on each of which a hole was localised. These centres were probably responsible for accelerating the reaction. An increased rate of dealkylation of isopropylbenzene was observed also after $\gamma$-irradiation of pure silica gel[95]. Here biographical defects in the catalyst surface, which trapped free holes formed under the influence of the radiation, were regarded as the active centres. The radiation treatment of silica on which a gas had been adsorbed showed that dealkylation resulted from the direct capture of free holes by the semiconductor. This yet again indicates an electronic mechanism for the radiation promotion of silicon dioxide.

Preliminary irradiation of magnesium oxide with $\gamma$-rays from a caesium-137 source (integral dose $2.5 \times 10^7$ rad) led to a decrease in the rate of decomposition of potassium perchlorate accompanied by a fall in the threshold temperature at which this reaction becomes possible[96]. Radiation was shown to produce a contraction in the crystal lattice of the oxide with the generation of free electrons. Recombination of the latter with free holes involved in the process had an adverse effect on the activity of the oxide.

Studies of decomposition occurring on solid catalysts under the influence of continuous irradiation usually attempt to elucidate how the rate of homogeneous radiolysis changes on the introduction of catalysts possessing various properties. It will be shown that such an approach enables the maximum amount of information to be extracted on the primary steps of interaction on the catalyst surface.

The rate and the degree of decomposition of potassium oxalate in aqueous solution under the influence of $\gamma$-rays increased considerably in the presence of a suspension of zinc oxide[97]. The dependence of the rate of $\gamma$-radiolysis of pentane in the presence of silica gel, magnesium oxide, or aluminium oxide on their surface coverage by the initial gas suggested[98–101] the active transfer of the emission energy absorbed by the solid to the adsorbed molecules. It was assumed that use was made of the energy evolved on the annihilation of electron–hole pairs generated in the oxides by the radiation, this process involving holes localised on adsorbed pentane molecules and free electrons.

The importance of short-lived radiation defects was confirmed[102] by the hundredfold increase in the yield of hydrogen from the $\gamma$-radiolysis of water when the process occurred on a silica-gel surface. Electron spin resonance showed that the emission was unable to create permanent defects in the catalyst but only excited states, whose energy was consumed in the decomposition of adsorbed molecules. A strong dependence of radiation-chemical yields on the surface coverage of solids by the starting material was observed also in the $\gamma$-radiolysis of heptane on aluminosilicate, aluminium–tungsten, and aluminium–molybdenum catalysts[103–105] and in the decomposition of isopropylbenzene on aluminium silicate[106,107]. The equality of the rates of homogeneous and heterogeneous processes when surface coverage by the initial molecules exceeds a monolayer indicates that the emission energy is transferred only to the first adsorbed layer. The ability of solids to transmit emission energy to adsorbed molecules is strongly dependent on their chemical nature. Thus the rate of the $\gamma$-radiolysis of ammonia on a zeolite in the sodium form exceeded considerably the rate of the homogeneous process[108–110], but when the calcium form was used the yield of hydrazine was the same in the two cases.

The view that a catalyst is an energy converter, transforming one type of motion (e.g. the kinetic energy of substrate molecules) into a different form important for the activation of molecules (e.g. into the vibrational energy of molecules), was expressed as early as the 1920s.[111] This concept formed the basis of the first theoretical interpretation of the phenomena involved in the effect of radiation on the catalytic properties of solid materials[112]. The hypothesis[113] that the radiation-catalytic activity of solids is determined by their heat capacity, increase in which should be accompanied by a decrease in activity, has not found experimental confirmation.

The rate of decomposition of carbon dioxide exposed to cobalt-60 $\gamma$-rays, X-rays, and strontium-90 $\beta$-rays is sharply increased by the introduction of silica gel, alumina, and magnesium oxide into the system[114,115]. Radiation-chemical yields are extremely slightly dependent on temperature and on the nature of the emission. Investigation of this reaction occurring under the influence of $\gamma$-rays (2.8 Mrad $h^{-1}$) on oxides having different electronic characteristics led to the conclusion[116] that the intensity of heterogeneous radiolysis diminishes from intrinsic to $n$-type and then to $p$-type semiconductors. The high-temperature $\gamma$-radiolysis of water vapour accelerated considerably in the presence of zinc oxide, with a forbidden gap of 3 eV; the effect of vanadium pentoxide, with a gap of 0.5 eV, was hardly noticeable[117].

The deduction that energy is transmitted to the adsorbed substance more efficiently in the case of dielectrics and semiconductors is supported by many investigations. Thus the degree of decomposition of azoethane fell on passing to catalysts having a narrow energy gap, to magnesium(II), silicon(IV), titanium(IV) oxides, (8.7, 8.0, and 3.0 eV respectively), etc.[118,119] This problem was examined in detail in studies[120,121] of the dehydrogenation of cyclohexane on dielectric oxides (silica, alumina, aluminium silicate), $n$- and $p$-semiconductors (zinc and nickel monoxides), and metals (nickel, 7% platinum/

/silica). In the thermal process the specific activities of the catalysts formed the sequence

$$Pt/SiO_2,\ Ni > NiO > ZnO,\ Al_2O_3 \cdot SiO_2 > MgO,\ ZrO_2,\ Al_2O_3,\ SiO_2.$$

Under the influence of continuous $\gamma$-irradiation ($3.4 \times 10^{16}$ eV $g^{-1}$ $s^{-1}$) the relation between the activities was inverted: materials having a wide forbidden gap were the most active. It is significant that, in contrast to semiconductors and metals, radiation-active dielectrics showed the presence of paramagnetic centres and $C_6H_7^{\bullet}$ radicals when cyclohexane was adsorbed during irradiation. The dependence was interpreted[120,121] on the hypothesis that the cyclohexane molecule is activated by the energy evolved on recombination of a free electron with a hole previously trapped by the molecule. This energy is equal to the difference between the width of the forbidden gap and the heat of adsorption of the gas molecule, so that substances having a wide energy gap should possess the maximum activity. The conclusion that free current carriers—not stable defects—play the main part in the decomposition of cyclohexane is supported by the fact[122] that the degree of decomposition of the initial gas on an aluminosilicate catalyst (10% $Al_2O_3$) under direct $\gamma$-irradiation exceeds considerably the extent of decomposition on a previously irradiated specimen.

While completely accepting the viewpoint of the authors[120,121], the Reviewers would like to stress that it would have been wrong to base prediction of the radiation-catalytic activity of solids solely on the width of the forbidden gap, without regard to the heat of adsorption of the molecules. Furthermore, the recombination of electron–hole pairs on adsorbed molecules may meet serious competition from their recombination on other local centres (impurities, defects), which are present in abundance on solid surfaces.

## 4. Decomposition of Alcohols and Isomerisation of Hydrocarbons

Although the catalytic decomposition of alcohols usually takes place by a fairly complicated mechanism, study of this particular class of reactions has revealed several interesting laws governing the interaction of reactants with the surface of irradiated catalysts. The dehydration of n-decanol and isomerisation of the resulting dec-1-ene were studied[123,124] on samples of alumina that had been subjected to preliminary irradiation. X-Rays had a favourable effect on the degree of conversion, treatment with cobalt-60 $\gamma$-rays and reactor $n,\gamma$-radiation lowered the catalytic activity of the oxide, and exposure to fast neutrons produced no observable change. Interesting results were reported[125] for this reaction occurring on alumina that had been exposed to neutrons ($8 \times 10^{12}$ n $cm^{-2}$ $s^{-1}$) for 1–10 days. Catalysts that had been irradiated for a few days exhibited a negative radiation effect. The yield of unsaturated hydrocarbons increased as the duration of neutron bombardment was lengthened. This was attributed to the occurrence of two competing processes—the negative influence of the direct interaction of neutrons with active centres in the alumina and the promoting effect of the high-energy radiation emitted from the short-lived aluminium-28 and oxygen-19 isotopes formed in the specimens as a result of a nuclear reaction.

The catalytic activity of silica in the isomerisation of butene and the conversion of cyclopropane into propene was increased by preliminary irradiation with X-ray bremsstrahlung[126]. The rate of the second process diminished when the catalyst was heated to 100°C, and fell sharply at 200°C, whereas the activity of the silica towards the first reaction became appreciably lower only at 400°C. This was explained by the generation of two types of active centres on the surface. The great thermal stability of the radiation active centres involved in the isomerisation of butene was noted also in the neutron pretreatment of silica gel, aluminium silicate[127], and also potassium aluminate catalysts[91], which exhibited a fifty-fold radiation activation.

Study of the thermal dissociation of ethanol on neutron-treated zinc oxide—(2.3 and 3.9) $\times 10^{13}$ n $cm^{-2}$ $s^{-1}$—showed[128] that increasing the duration of the radiation intensified dehydrogenation and tended to suppress dehydration. This effect was attributed[129] to the appearance of gallium as donor impurity in the zinc oxide, which raised the Fermi level and should thus[21] lead to a similar change in selectivity of the catalyst. The shift in the decomposition of propan-2-ol towards dehydrogenation after the irradiation of yttrium[130] and neodymium[131] oxides with thermal neutrons ($1.2 \times 10^{13}$ n $cm^{-2}$ $s^{-1}$) was explained by production of the radioisotopes—yttrium-90, terbium-166 and neodymium-147, neodymium-149.

Many studies have confirmed the decisive role of the electronic properties of irradiated catalysts in the decomposition of alcohols. For example, the rate of dehydrogenation of ethanol on copper(II) oxide increases after its $\gamma$-irradiation, with an increase in the electrical resistance, but on copper(I) oxide it falls in parallel with the latter[132]. Continuous exposure of zinc oxide (an $n$-semiconductor) to $\gamma$-rays ($4.5 \times 10^5$ r $h^{-1}$) activated it for the dehydrogenation of methanol, whereas chromic oxide (a $p$-semiconductor) was poisoned under the same conditions[133] (the increase in the rate of this reaction on zinc oxide when $\gamma$-irradiation was begun has been confirmed[134,135]). Exposure of two preparations of tungsten disulphide differing in stoichiometric composition[136]—$WS_{1.99}$ (an $n$-semiconductor) and $WS_{2.3}$ (a $p$-semiconductor)—to a flux of slow neutrons ($1.2 \times 10^{13}$ n $cm^{-2}$ $s^{-1}$) and to $\gamma$-rays ($10^4$ r $s^{-1}$) in a reactor led to the formation in the bulk of the specimens of the tungsten-187, tungsten-185, and sulphur-35 isotopes ($\beta$- and $\gamma$-sources), which activated the disulphides for the dehydration of n-decanol; the electrical conductivity of the first preparation fell, whereas that of the second preparation increased.

Among investigations on the decomposition of alcohols on solids into which radioactive isotopes had been introduced during preparation, note must be taken of a series of papers by Balandin, Spitsyn, and their coworkers. The increases in the degree of dehydration at 350°C of alcohols on magnesium sulphate catalysts containing the radioactive sulphur-35 isotope, in comparison with specimens to which non-radioactive sulphur had been added, were respectively 200%, 121%, 42%, and 26% for n-pentanol, n-hexanol, n-decanol, and n-dodecanol[136,137].

The effect of internal $\beta$-emission on the catalytic properties of solid materials was thoroughly studied[138–141] with as example the dehydration of cyclohexanol on magnesium sulphate to which had been added sodium sulphate and calcium chloride containing either non-radioactive sulphur and calcium or their radioactive isotopes sulphur-35 and calcium-45. The non-radioactive additives diminished significantly the catalytic activity of the magnesium sulphate, whereas the radioactive additions, while themselves not catalysing the reaction, increased considerably the degree of dehydration. Activation energies for the reaction on the radioactive specimens were somewhat

lower. A linear relation was observed between the activity and the dosage rate of self-irradiation of the catalysts: the degree of conversion of the alcohol increased in parallel with the specific activity of the specimens.

The mechanism of the influence of internal radioactive emission on the catalytic properties of solids evidently differs from that of external radiation. For example, the degree of dehydration of n-dodecanol on alumina diminished on continuous irradiation of the system with electrons, but introduction of a source of electrons (calcium-45) into the catalyst increased sharply the activity of the specimen [123]. The same conclusion can be reached by comparing the above results [138-141] with data [142] indicating that exposure of the cyclohexanol–magnesium sulphate system to external X-rays does not increase the degree of dehydration of the alcohol, although it produces high-energy electrons within the catalyst. Electron-microscopic investigation [143] of non-radioactive specimens of potassium, magnesium, and barium sulphates and of molybdenum trioxide, as well as specimens containing various quantities of radioactive sulphur and molybdenum isotopes, showed that the radioactive substances had considerably more developed surfaces. However, this alone is insufficient to explain the enhanced catalytic activity of radioactive specimens. The catalytic activity of specimens of magnesium sulphate containing sodium sulphate labelled with radioactive sulphur, calculated per unit surface for the dehydration of cyclohexanol, increased with the $\beta$-radioactivity [144].

Among the investigations on the decomposition of alcohols under the influence of continuous external $\gamma$-irradiation we would like to note a series of papers by Vladimirova, Zhabrova, and their coworkers. The view that dielectrics are the most active in transmitting the energy of the radiation was again confirmed [145-147]: the rate of decomposition of methanol on silica and alumina exceeded the rate of the homogeneous process by a factor of 10; the rates on the semiconducting zirconium(IV), zinc(II), magnesium(II), and nickel(II) oxides by factors of 2–3; and on metals the intensification of the reaction was hardly appreciable; but the presence of activated carbon slowed down the reaction. The radiation-catalytic activities of diamond and graphite—the same chemical substance in different electronic modifications—were compared [148]. Diamond (natural and synthetic), having a forbidden gas of 7 eV, contributed to reaction velocities exceeding the rate of the homogeneous radiolysis of methanol by a factor of 100. Graphite, whose conductance is almost metallic, was not a radiation catalyst.

With the smallest (0.7%) surface coverage of silica gel the yield of decomposition products from methanol was the highest, exceeding hundredfold the yield of homogeneous radiolysis, but with a monolayer the increase was only tenfold [149]. A more detailed investigation [150,151] revealed the interesting fact that, with the same quantity of methanol on silica and alumina surfaces, their catalytic activity was independent of the specific surface and the size of the globules. This indicates yet again that free current carriers, generated by radiation inside the solid, are involved in the decomposition of adsorbed molecules, and that their diffusion from the interior to the surface is more rapid than the primary steps in the radiation-catalytic reaction. The increase in the rate of the process observed with decrease in the quantity of substance adsorbed shows that catalytic activity is determined solely by the relation between the quantity of the compound adsorbed and the excess quantity of current carriers.

Analysis of numerous experimental data suggests that the mechanism of the decomposition of methanol is [28]

$$\text{Тв solid} \xrightarrow{\text{rad.}} K^+ + A^-$$

$$CH_3OH + K^+ \rightarrow \underset{\substack{\text{physical}\\ \text{adsorption}}}{CH_3OH^+}$$

$$\underset{\text{chemical}}{CH_3OH^+} + \ominus \rightarrow \dot{C}H_2OH + H$$

$$\dot{C}H_2OH + \dot{C}H_2OH \rightarrow (CH_2OH)_2$$

$$\dot{C}H_2OH \rightarrow CH_2O + H$$

$$H + H \rightarrow H_2 \ .$$

The energy evolved on the annihilation of an electron and a hole is consumed in the formation of a hydroxymethyl radical. These radicals recombine to form a molecule of ethylene glycol, and decompose to give a formaldehyde molecule.

## 5. Catalytic Hydrogenation

The hydrogenation of ethylene is most often chosen as model reaction, since in many cases this process does not require a high temperature. As early as 1932 a 5% increase in rate was recorded for this reaction taking place on a copper catalyst exposed to X-rays at room temperature [152].

Preliminary $\gamma$-irradiation of copper produced slight deactivation, whereas the catalytic activity of zinc oxide decreased by 80%. [153] This was attributed to a change in the charge structure of the semiconductor surface. The rate of hydrogenation of ethylene falls after zinc oxide has been exposed to $\gamma$-rays [55]. The decrease in catalytic activity of the oxide is not accompanied by change in the activation energy of the reaction, and heating the specimens restores their original properties. The active centres were assumed [154] to be interstitial $Zn^+$ cations, which are converted by ionising collisions with secondary electrons into inactive $Zn^{2+}$ cations; heat-treatment promotes the reverse process. In contrast to zinc oxide, silica gel, which is not a catalyst for this reaction, was appreciably activated after $\gamma$-irradiation for 20 h. [155]

Considerable increase in catalytic activity of copper, nickel, and platinum catalysts in the hydrogenation of ethylene was observed after their bombardment with accelerated positive argon ions [156-158]. Electron diffraction recorded significant structural disturbances in the crystal lattices. Heating the metals at 550°C annealed the defects and lowered the reaction velocity to values characteristic of unirradiated catalysts. On the other hand, structural defects generated in copper by $\alpha$-particles from a polonium-210 source caused a decrease in catalytic activity independently of the environment (hydrogen, vacuum) in which irradiation had occurred [159].

Examination of the effect of fast neutrons on the catalytic properties of zinc oxide showed [160] that the sign and the magnitude of the radiation effect depend on the chemical and thermal treatment of the catalysts preceding irradiation. The activity in the hydrogenation of cyclohexene of platinum catalysts deposited on aluminium silicate was unaffected by preliminary exposure to $\gamma$-rays [161]. However, the rate of this reaction was increased by the exposure of platinum–silica catalysts to a quartz–mercury lamp [162], the maximum increase in activity (double) being observed on illumination for 3–4 h. After exposure for 6 h the rate of the process returned to its initial value.

Passage of the catalytic activity through a maximum was recorded in the hydrogenation of nitrobenzene when a nickel catalyst was subjected to X-rays and $\beta$-particles [163]. This work also showed that the treatment of palladium with accelerated electrons increases the rate of hydrogenation of *p*-nitrotoluene in glacial acetic acid. The same result was obtained when platinum was exposed to $\beta$-rays of energy 3 MeV, whereas those of energy 2 MeV and X-rays produced no appreciable change. The radiation effect was attributed [163] to the appearance of defects in the structure of the catalysts.

The view that preliminary electromagnetic irradiation and exposure to a flux of light charged particles are unable to affect rates of hydrogenation appreciably is supported also by the hydrogenation of petroleum [164] and unsaturated hydrocarbons [165] on metals. Most investigators therefore relate the change in the rate of hydrogenation to the appearance of structural defects in the specimens. Thus work in which the rate of hydrogenation of acetone was trebled on neutron-irradiated specimens of nickel showed [166] that on thermal annealing the radiation activity of the catalysts disappears over a temperature range in which the number of point defects decreases sharply. Variation in the concentration of free current carriers probably also plays an important part in semiconductors subjected to $\gamma$-rays during the reaction. The positive radiation effect in the hydrogenation of carbon monoxide was found [167] to depend on the excess quantity of zinc in its oxide, which determined the electronic properties of the catalyst. The rate of this reaction trebled on zinc oxide at 160°C. [168] With rise in temperature the radiation effect diminished, and at 230°C disappeared altogether, probably owing to an increased rate of annealing of electron–hole pairs.

The influence of reactor radiation on the rate of the liquid-phase hydrogenation of dimethylprop-2-ynol and butynediol was studied by Sokol'skii et al. A comparison was made of the activities of platinum and osmium–platinum blacks obtained from the oxides with and without preliminary irradiation [169]. The considerably higher activity of the former was attributed to the increased degree of dispersion of the metals detected by X-ray diffraction. A similar pattern was observed in the hydrogenation of butynediol in ethanol on platinum and palladium catalysts [170]. This effect is due also to the appearance of impurity rhodium, silver, and cadmium atoms inside the platinum [171]. In the hydrogenation of the dimethylpropynol in dioxan on palladium catalysts obtained from the oxides exposed to neutrons and to $\alpha$-particles the reaction velocity increased by 100% and 60% respectively; the rate of the process in ethanol was independent of irradiation of the oxide [172].

Pretreatment in a nuclear reactor had a beneficial effect on the catalytic activity of 5% and 0.5% of platinum, palladium, and rhodium on $\gamma$-alumina in the hydrogenation of the dimethylpropynol in caustic soda [173,174]. The largest increase in activity was observed with the 0.5% platinum catalyst, when preliminary irradiation of the metal together with the carrier increased the activity of the catalyst by a factor of 5.2, but radiation treatment of the carrier separately before deposition of the active metal led to a fiftyfold increase in the rate of the process. A similar phenomenon, though less well defined, was observed also with the palladium and rhodium catalysts. Raising the temperature of the reaction diminished the radiation effect. The change in the electronic and structural properties of the carrier under the influence of radiation probably also played a part here.

Continuous $\beta$-irradiation of a platinum plate (of thickness equal to the range of a $\beta$-particle) doubled the rate of hydrogenation of benzene, which took place on platinum black deposited on the opposite side of the plate [175]. This was due to migration to the surface of defects generated inside metal by the radiation.

## 6. Catalytic Oxidation

Pretreatment of platinum black with X-rays in a moist atmosphere for 2 h increased by 16% the rate of conversion of sulphur dioxide into the trioxide at 260°C; [176] if the reaction temperature was raised to 400°C, only 1.3% activation of the catalyst was observed. Radiation treatment in dry air did not affect the catalytic activity. A similar result was obtained by workers [177] who observed an increased content of oxygen, formed by the radiolysis of air, in platinum that had been exposed to X-rays in a moist medium.

Preliminary bombardment of vanadium pentoxide with thermal neutrons ($10^{18}$ n cm$^{-2}$ s$^{-1}$) diminished its activity in the oxidation of sulphur dioxide [178]. Since this reaction took place above 500°C, the radiation effect was due to the production of stable defects, probably with the appearance of silver-110 atoms—$\gamma$- and $\beta$-sources—inside the catalyst. The rate of this process decreased on the pure pentoxide also when the latter was exposed to $\gamma$-rays during the reaction [179]. The magnitude of the radiation effect is a function of the initial properties of the catalyst. Under the influence of continuous exposure to X-rays the catalytic activity of pure titanium dioxide, which has little effect on the oxidation of sulphur dioxide, increased by 18.4%; irradiation of the more effective catalyst $TiO_2$ + $NH_4VO_3$ accelerated the reaction by only 12%, but the most active catalyst $TiO_2$ + $V_2O_5$ was poisoned [180]. Similar results were obtained for the conversion of ethanol into formaldehyde on vanadium pentoxide [181].

An electromagnetic radiation field usually has a marked effect on the ability of semiconductors to catalyse oxidation. Examples are the oxidation of propane on zinc oxide under the influence of X-rays [182] and also the oxidation of various hydrocarbons on dielectrics (silica gel, alumina, aluminium silicate) subjected to $\gamma$-rays [183]. Both effects were explained by the excitation of free current carriers in the solid. This is indicated also by the invariability of the rate of oxidation of hydrogen on platinum when the system is introduced into an X-ray field [184], since the electronic properties of a metal show little response to the influence of X-rays.

Many workers have dealt at length with the conversion of carbon monoxide into the dioxide. The effect of neutron bombardment (fluxes of thermal and fast neutrons respectively $2 \times 10^{11}$ and $7 \times 10^{9}$ n cm$^{-2}$ s$^{-1}$) of nickel oxide with 2.5 mole % of lithium oxide on the rate of this reaction has been studied [185,186]. The further intensification of the process when conducted directly in a nuclear reactor instead of on previously irradiated specimens indicates the definite roles both of short-lived defects and of stable disturbances resulting from the nuclear reaction $^{6}Li(n,\alpha)^{3}H$. A definite correlation was detected between the catalytic activity and the hole conductance of nickel oxide. Pretreatment of nickel and zinc monoxides with $\gamma$-rays had no appreciable influence on their activity [187]. However, other workers showed [188] that the $\gamma$-irradiation of nickel

monoxide in a vacuum had an adverse effect on its catalytic properties, but in an atmosphere of oxygen a beneficial effect. This was explained by the radiation-stimulated migration of activated oxygen deep into the lattice of the catalyst.

The electron bombardment—$(3-12) \times 10^{12}$ el $cm^{-2}$ $s^{-1}$—of cuprous oxide led to its deactivation, in spite of an increase in the specific surface[189]. This phenomenon is connected with decrease in the concentration in the mobility of free holes in the bulk of the catalyst. Over the temperature range 80–300°C the activation energy of the oxidation of carbon monoxide on alumina under the influence of X-rays was zero, but with further rise in temperature it reached 18 kcal $mole^{-1}$, coinciding with the activation energy of the thermal process[190].

As we have been able to see, ionising radiation is a powerful factor influencing the adsorption and catalytic properties of solids. In spite of a vast quantity of experimental results accumulated by the present time, however, scientists are still far from a generally accepted interpretation of this phenomenon, and still farther from being able to use radiation to control the activity and the selectivity of catalysts. An increasing number of authors interpret radiation effects on the basis of an electronic theory of catalysis. Such an approach permits the most productive utilisation of existing theoretical ideas on the interaction of electromagnetic and corpuscular radiation with solids.

# Methods of Synthesis of Peptides

**Yu.V.Mitin and N.P.Zapevalova**

Chemical methods for the activation of the carboxy-groups of the aminoacid used to synthesise peptides are examined, and the possible reaction mechanisms are described. Examples of the synthesis of certain peptides are presented. The bibliography includes 151 references.

III. Activation of the carboxy-group in *N*-acylaminoacids in the presence of the amino-component 453
IV. Other methods for the activation of the carboxy-group 459

## I. INTRODUCTION

This review deals with the methods for the activation of the carboxy-groups of the *N*-acylaminoacids which may be used to form the peptide linkage. It includes data published up to 1964. The methods of synthesis of peptides published up to 1965 have been examined in detail in familiar monographs devoted to the chemistry of peptides[1,2]. The review is not concerned with the methods for the detection of the functional groups of aminoacids, the problems of the isolation and purification of peptides, and the methods for the determination of the purity of synthetic peptides.

## II. ACTIVATED *N*-ACYLAMINOACID ESTERS

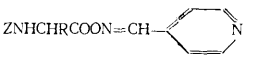
The activated esters of *N*-substituted aminoacids are extremely convenient for the synthesis of peptides. The possibility of the isolation, purification, and storage of the activated esters greatly facilitates peptide synthesis. Furthermore, there are wide possibilities for varying the properties of activated esters, in particular aryl esters, by selecting suitable substituents in the benzene ring.

One may state without exaggeration that *N*-hydroxysuccinimide esters have enjoyed the greatest popularity in recent years[3,4]. They have been used more frequently than *p*-nitrophenyl[5] and 2,4,5-trichlorophenyl esters[6]. The synthesis of *N*-hydroxysuccinimide esters presents no difficulties; they can be readily obtained with the aid of dicyclohexylcarbodiimide or mixed anhydrides[7], or from the *N*-hydroxysuccinimide esters of dichloroacetic[8] or trifluoroacetic[9] acids.

After the *N*-hydroxysuccinimide esters had been proposed for the synthesis of peptides, esters based on hydroxylamine derivatives began to attract attention because of their high reactivity, the ready availability of the reagents required, and the low degree of racemisation or its absence.

Esters derived from *NN*-dialkylhydroxylamines, in particular those derived from 1-hydroxypiperidine[10,11], which have been synthesised with the aid of carbodiimide or mixed anhydrides, have been proposed as acylating agents. The esters derived from *NN*-dialkylhydroxylamines exhibit a comparatively weak acylating capacity, but, in the presence of acetic acid as the catalyst, acylation proceeds at an appreciable rate at room temperature. The enhancement of reactivity can be explained by the protonation of the nitrogen atom of the hydroxylamine:

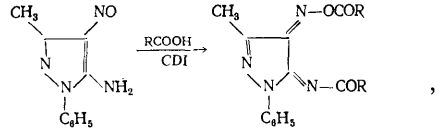
$$R{-}COONR'R'' \xrightarrow{H^+} R{-}C\overset{+}{O}ONHR'R'' \quad .$$



Certain small peptides have been synthesised with the aid of 1-piperidinyl esters[12-14], but their inadequate reactivities precluded their wide employment in peptide chemistry. Some studies have been devoted to esters derived from aldoximes and ketoximes[15-18]:

$$RCOON{=}C\begin{matrix}R'\\R''\end{matrix} \quad ,$$

where R′ = alkyl or aryl and R″ = alkyl or hydrogen. The esters of ketoximes are stable crystalline substances with a fairly high reactivity in relation to amines. When they react with aminoacid esters or free aminoacids at room temperature, peptides are obtained in 50-90% yield. The degree of racemisation in the synthesis of Anderson's tripeptide was 20%,[15,16] but this hardly reflects the properties of the activated esters, since the ester derived from 3-nitroacetophenoxime, used to study the racemisation reaction, has been synthesised with the aid of carbodiimide from Z-Gly-L-Phe-OH. There is no doubt that the racemisation occurred mainly in the synthesis of the ester itself, which, incidentally, does not rule out the formation of a racemic product also when the activated ester combines with ethyl glycinate.

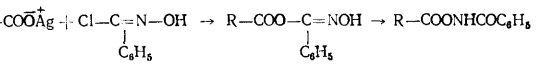


The synthesis of peptides with the aid of esters derived from ketoximes in the presence of acetic acid is more effective[17]. The addition of 1-1.5 moles of acetic acid increases the yield of peptides on average by 20-30%. Esters of ketoximes made it possible to synthesise serine and threonine peptides without protecting the hydroxy-group and also ω-nitroarginine peptides in 83-98% yield. The solubility of simple ketoximes in water facilitates the isolation and purification of peptides after the reaction. The method has been recommended for the stepwise synthesis of various peptides.

Interesting results have been obtained with esters derived from pyridine-4-aldoxime[18]:

In terms of their reactivity in the presence of acetic acid, esters derived from pyridine-4-aldoxime approach 2,4,6-trichlorophenyl esters and surpass *p*-nitrophenyl esters.

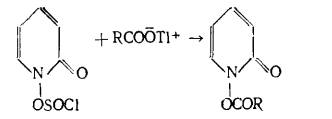
Using esters obtained from pyridine-4-aldoxime, certain peptides constituting fragments of angiotensin have been synthesised. An advantage of esters of pyridine-4-aldoxime is the ease of elimination of the reaction products and of the excess ester, since pyridine-4-aldoxime and the esters obtained from it readily dissolve in an acid medium. Esters derived from 5-amino-3-methyl-4-nitroso-1-phenylpyrazole can also be included among esters obtainable from oximes[19]:



where CDI is carbodiimide.

They exhibit a high acylating activity and make it possible to synthesise peptides in high yields (90–95%) over a period not exceeding 1 h. Certain di-, tri-, and tetrapeptides have been synthesised with the aid of esters of this type. The Weygand[20] and Izumiya[21] tests showed that there is no racemisation at all in this reaction. The esters have yet another interesting feature: they are coloured red, while the reaction product (substituted 5-amino-4-nitrosopyrazole) is green, which makes it easier to follow the condensation reaction.

Hydroxamic acid esters have also attracted attention. A study on the synthesis of benzohydroxamic acid esters and the corresponding nitriles[22] via the mechanism

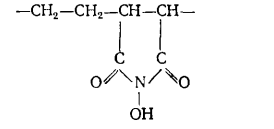


is of interest. The yield of esters in this reaction varies from 65 to 100%. Benzohydroxamic acid esters are fairly reactive and react with aminoacid esters at room temperature, giving peptides in yields not exceeding 75%. The low yields are caused by the Lossen rearrangement. Activated esters of the same type can be obtained also by the condensation of *N*-protected aminoacids with hydroxamic acids in the presence of carbodiimide[22] or by the reaction of the silver salts of *N*-protected aminoacids with the chloride of benzohydroxamic acid[23,24]; smaller yields are obtained from triethylammonium salts:

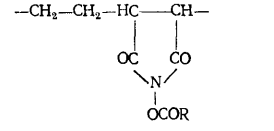
Although the majority of the esters are crystalline substances, they need not be isolated for peptide synthesis. The presence of acetic acid in the reaction of benzohydroxamic acid esters with amines appreciably accelerates the process. The authors believe[24] that the degree of racemisation does not exceed 0.1% for many peptides.

Esters based on *N*-hydroxyurethanes (for example, $HONHCOOC_2H_5$, which is both a hydroxamic acid and a carbamic acid ester) are likewise of interest. These esters have been synthesised with the aid of carbodiimide and mixed anhydrides in yields exceeding 90%.[25] A characteristic feature of these compounds is their appreciable resistance to the Lossen rearrangement. Esters based on *N*-hydroxyurethanes react readily both with aminoacid esters in an organic medium and with aminoacid salts in an aqueous medium. The yields of peptides are more than 90 and approximately 80% respectively. The use of *N*-hydroxyurethane as an additive in the carbodiimide synthesis of peptides lowers the degree of racemisation to 0–2% (Anderson's test). In contrast to *N*-hydroxysuccinimide[26], no side reactions were observed under these conditions, even if the mixture of *N*-hydroxyurethane with carbodiimide was kept at room temperature for many days[25].

Related but somewhat unusual esters are those derived from 1-hydroxy-2-pyridone[27,28]. They can be synthesised from acylaminoacid chlorides and 1-hydroxy-2-pyridone or from 2-oxo-1-pyridyl chlorosulphite and thallium salts of acylaminoacids[28]:



2-Oxo-1-pyridyl esters exhibit a high acylating activity, but, owing to their low stability and the difficulty of their synthesis, they have not so far found applications in the synthesis of peptides.

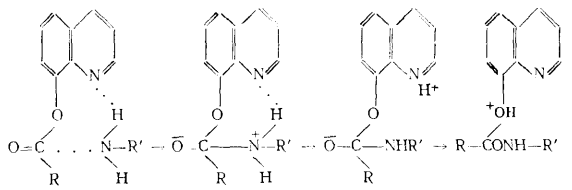


Despite the wide use of esters derived from *N*-hydroxysuccinamide in the synthesis of peptides, the search for new *N*-hydroxyimides of dibasic acids is being continued. Thus, the esters derived from *N*-hydroxyglutarimide have been synthesised and tested[29]. These esters, obtained with the aid of dicyclohexylcarbodiimide, are highly reactive, but do not have an appreciable advantage over esters derived from *N*-hydroxysuccinamide.

This can probably be also said of esters obtained from *N*-hydroxyphthalimide, first proposed in 1961[30] and recently used in the synthesis of certain peptides corresponding to the oxytocin sequence[31].

Activated esters obtained from polymers containing *N*-hydroxyimide groups are of particular interest. The copolymerisation of ethylene with maleic anhydride followed by treatment with hydroxylamine yielded a polymer containing units resembling *N*-hydroxysuccinimide:

Polymers of this type, which can be both soluble in organic solvents[32] and insoluble and cross-linked[33,34], can be obtained. An *N*-protected aminoacid RCOOH can be added with the aid of carbodiimide to the polymer, which gives rise to an activated polymeric ester:



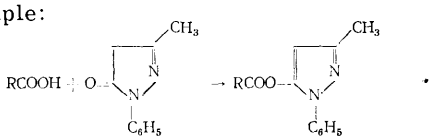
The latter can react with a solution of an amino-component in dimethylformamide. The yield of peptides in this reaction exceeds 90% as a rule if the activated ester is taken in a threefold excess. In the presence of equimolecular amounts of the reactants, the yield of peptide varies within wide limits (from 40 to 100%), depending on the nature of the aminoacid.

Polymeric activated esters are convenient because they obviate the need for the procedure involving the elimination of the excess of the activated ester and the ester component. At the same time they exhibit a high acylating activity, comparable to that of the usual esters obtained from *N*-hydroxysuccinimide. A heptapeptide corresponding to the 159–165 sequence of carboxypeptidase A (H–Ser–Pro–Cys–Ser–Glu–Thr–Tyr–OH) has been synthesised with the aid of polymeric activated esters in an overall yield of 59.5% before the elimination of protecting groups and 47.6% after their elimination[33]. The synthesis

of the octapeptide Boc–Met–Asp(OBzl)–Ser(Bzl)–Ser(Bzl)–Thr–Ser(Bzl)–Ala–Ala–OBzl has been achieved with an overall yield of 27%, the yields in the individual stages lying in the range 57–100%.[32]

Much attention has been devoted to activated esters whose reactivity can be accounted for by intramolecular base catalysis, in the first place esters derived from 8-hydroxyquinoline[35-39]. Kinetic studies on the aminolysis of these esters suggested the following reaction mechanism[36]:

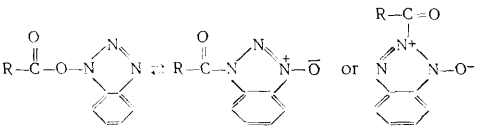
This type of influence of nucleophiles adjoining the ester carbonyl group has also been noted in other examples, which will be discussed below.



Esters are synthesised from 8-hydroxyquinolines either with the aid of carbodiimides or using mixed anhydrides, the yield being 70–90%. The esters formed by 8-hydroxyquinoline with the majority of benzyloxycarbonylamino-acids are stable crystalline substances, readily soluble in the usual organic solvents. The reaction with the amino-components proceeds at room temperature over a period of 4–20 h, the yields of peptides amounting to 75–97%. It is of interest that neither acetic acid nor heavy metal salts have any influence on the kinetics of the aminolysis reaction, which is consistent with the mechanism involving intramolecular catalysis[36]. Racemisation was not observed in the synthesis of Z–Leu–Phe–Val–OBu-t.[37] The reactivity of the esters derived from 5-chloro-8-hydroxyquinoline and 5,7-dichloro-8-hydroxyquinoline exceeds somewhat that of esters obtained from 8-hydroxyquinoline itself and they may be synthesised by the same methods[38]. Their suitability for the synthesis of peptides has been demonstrated in relation to a number of di-, tri-, tetra-, and penta-peptides, obtained in 65–97% yield. However, one should note that only comparatively simple aminoacids were used in all cases: glycine, alanine, valine, leucine, phenylalanine, and *S*-benzylcysteine.

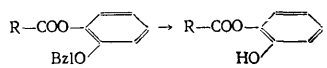
In contrast to the esters obtained from 8-hydroxyquinoline, those of 3-hydroxy- and 6-hydroxyquinolines are appreciably less reactive, particularly the esters obtained from 6-hydroxyquinoline[39]. Apart from 8-hydroxyquinoline, 8-hydroxyquinaldine has been used to synthesise activated esters[40]. Furthermore, the copolymerisation of 8-benzyloxy-5-vinylquinaldine with divinylbenzene gave a polymer containing 8-hydroxyquinaldine groups. After the removal of the benzyl group, the copolymer was used to synthesise polymeric activated benzyloxycarbonylalanine esters[40]. Aminolysis by ethyl glycinate gave the dipeptide Z–Ala–Gly–$OC_2H_5$ in 87% yield.

The effect of the intramolecular base catalysis was manifested to a greater extent for esters based on 2-hydroxypyridine[41] and 2-mercaptopyridine[42]. Esters have been synthesised from 2-hydroxypyridine with the aid of carbodiimide in pyridine. In other solvents, 2-pyridyl esters could not be synthesised. The majority of 2-pyridyl esters of t-butoxycarbonylaminoacids are crystalline, readily soluble substances with a very high reactivity. According to kinetic measurements, the time of 50% reaction with amines is between 8 and 86 min. Under these conditions, *p*-nitrophenyl esters have a half-reaction time ranging from 540 to 1900 min. However, such a high reactivity has been observed only in non-polar solvents (chloroform, methylene chloride, etc.). In polar solvents, for example, in dimethylformamide, the activity of 2-pyridyl esters is sharply reduced, which has been explained by the inactivating influence of polar solvents on the intramolecular base catalysis[41].



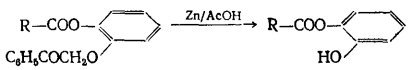
Pyridyl esters react readily with amino-components, forming peptides in 80–96% yield. They can be used to synthesise peptides on a polymeric carrier; thus oxytocin has been obtained in 70% yield using a fivefold excess of 2-pyridyl esters at each stage. Pyridyl esters react fairly readily with alcohols and hydroxyacids, so that they can be used to synthesise depsipeptides. 2-Pyridyl thio-esters, which can be readily obtained with the aid of carbodiimide, mixed anhydrides, or acid chlorides, have similar properties. They also readily react with amines and alcohols in non-polar solvents; on the other hand, in polar solvents (dimethylformamide, dimethyl sulphoxide) their reactivity falls. In contrast to 2-pyridyl esters, 3-pyridyl and 4-pyridyl esters of acylaminoacids are less reactive, which can be explained by the absence of intramolecular base catalysis. However, their reactivity is nevertheless fairly high, in particular, that of 3-pyridyl esters, which exceeds even the reactivity of *p*-nitrophenyl esters[43]. In contrast to 2-pyridyl esters, 3-pyridyl esters are very stable. Their reaction with amino-components gives rise to peptides in yields ranging from 50 to 97%.

All pyridyl esters have the advantage that the hydroxypyridines formed in the synthesis of peptides can be readily washed out of the reaction products. In a certain sense, the esters derived from the enolic form of substituted pyrazolone resemble 2-pyridyl esters[16]. They are readily obtained with the aid of carbodiimide or mixed anhydrides, for example:

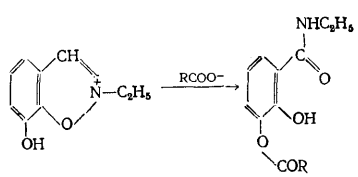


The esters obtained from the enolic form of pyrazolones have a high reactivity, similar to that of *p*-nitrophenyl esters, and readily react with amino-components, forming peptides in 70–80% yield. The esters synthesised from the pyrazolone enol can be used to synthesise peptides in an aqueous organic medium, using in the reaction aminoacid salts as the amino-component. The yields of peptides are in this case 60–73%. The degree of racemisation determined by Anderson's method proved to be 8.4%; admittedly, one must bear in mind that the activated ester Z–Gly–Phe–OPyr has been synthesised from the dipeptide Z–Gly–Phe–OH with the aid of dicyclohexylcarbodiimide, which might have involved some racemisation already in the stage involving the synthesis of the activated ester itself.

1-Benzotriazolyl esters obtained with the aid of carbodiimide are exceptionally reactive[44]. For example, the reaction of the activated ester of benzyloxycarbonylphenylalanine with the ethyl ester of valine at 0°C leads to the formation of more than 90% of the peptide after only 5 min. It is of interest that 1-benzotriazolyl esters undergo a rearrangement on crystallisation from solution. They exist in solution in the form of *O*-esters and in the crystalline state in the form of *N*-acylbenzotriazole oxide:

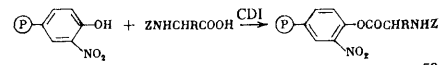


However only three 1-benzotriazolyl esters (BT) have been described hitherto: Z–Phe–OBT, Z–Gly–OBT, and Z–Thr–OBT. The high reactivity of 1-benzotriazolyl esters is apparently the reason why they are difficult to handle. 1-Hydroxybenzotriazole can probably be usefully employed as an additive in the carbodiimide synthesis, which will be discussed below.



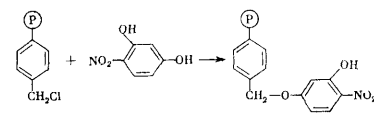
Activated esters of another type, whose enhanced reactivity can be explained by intramolecular catalysis, are those derived from catechol (*o*-hydroxyphenyl esters). They can be synthesised either from *o*-phenylene sulphite or, in a much higher yield, from *o*-benzyloxyphenol, by condensation with the aid of carbodiimide followed by the elimination of the benzyl group by hydrogenolysis or by treatment with hydrogen bromide in acetic acid[45]:

One can also begin with *o*-phenacyloxyphenol, since the phenacyl group is eliminated under milder conditions than the benzyl group[46]:



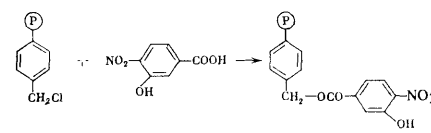
*o*-Hydroxyphenyl esters of acylaminoacids are fairly reactive. Thus the *o*-hydroxyphenyl ester of phthaloylglycine gives 91% of the peptide on reacting with ethyl glycinate at room temperature for 1 h.[45] For comparison, one may point out that phenyl phthaloylglycinate forms less than 1% of the peptide under the same conditions; the most important feature is that there is no racemisation at all when *o*-hydroxyphenyl esters are used. Because of this, *o*-hydroxyphenyl esters have been employed to synthesise polypeptides by the condensation of *o*-hydroxyphenyl esters of various tripeptides, for example, Lys–Ala–Ala[46,50]. 4,5-Dichloro-2-hydroxyphenyl esters are approximately three times as reactive as *o*-hydroxyphenyl esters, but they have not been used for the synthesis of peptides owing to the difficulty of obtaining them[45]. Esters containing the hydroxy-group in the *o*-position relative to the ester group are obtained ultimately by the reaction of the 2-ethyl-7-hydroxybenzoisoxazolium cation with acylaminoacids[51,52]:

(A number of intermediates are not indicated).

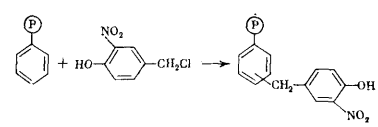


The activated esters formed are highly reactive. Thus the corresponding ester of benzyloxycarbonylglycine reacts with phenylalanine in aqueous sodium bicarbonate solution and forms 91% of benzyloxycarbonylglycylphenylalanine after 15 min. Peptide esters, in particular benzyloxycarbonylglycylphenylalanine, obtained from the 2-ethyl-7-hydroxybenzoisoxazolium cation, are very resistant to racemisation even under fairly severe conditions (12 h in 0.4 M solution of triethylamine in dimethylformamide). 2-Ethyl-7-hydroxybenzoisoxazolium fluoroborate is apparently one of the most interesting reagents for the synthesis of peptides[51]. Esters based on *o*-nitrophenol, which have been investigated in detail recently by Bodanszky and coworkers[53–56], are very promising. In contrast to *p*-nitrophenyl esters, *o*-nitrophenylesters are very reactive; the rate of their aminolysis depends less on the nature of the solvent, which can be accounted for by the intramolecular influence of the *o*-nitro-group. The high reactivity of these esters permitted their successful employment for the synthesis of protected oxytocin, the yield at each stage amounting to 80–95%.

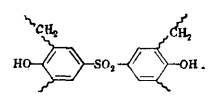
Among other types of activated esters, much attention has been devoted to esters with a polymeric base. Their advantage is that the procedure involving the isolation of the peptide synthesised is greatly facilitated. This is particularly important for activated esters based on nitrophenols, as the latter are difficult to remove from peptides by hydrolysis. Polymeric phenols are obtained either by the copolymerisation of substituted styrenes with divinylbenzene[57–59], or by a reaction involving the polymer chain[60,61], or the phenol-formaldehyde condensation is used[62]. Activated polymeric esters of acylaminoacids are synthesised with the aid of carbodiimide[59,60]:



Using such esters, certain di- and tri-peptides[59] as well as bradykynin were synthesised in an overall yield of 39%. Naturally, the method can be used only in those cases where all the protected intermediate peptides are soluble in organic solvents.

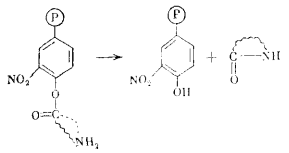


It was also found that the polymeric carrier obtained by the polymerisation of substituted styrene is not very strong mechanically, which leads to the fragmentation of polymer grains[60]. This necessitated the search for other methods whereby a polymeric carrier containing nitrophenol groups can be prepared. Chloromethylated cross-linked polystyrene was used for this purpose and nitroresocinol was attached to it in the presence of a base[61]:



This polymeric carrier was mechanically strong and was used to synthesise various peptides. In another instance, 3-hydroxy-4-nitrobenzoic acid was attached to chloromethylated polystyrene[60]:

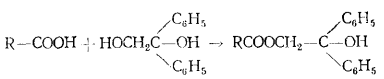
or 4-hydroxy-3-nitrobenzyl chloride was used, reacting with the styrene–divinylbenzene copolymer in the presence of aluminium chloride[63]:



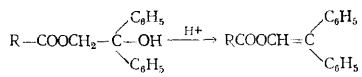
In all cases, activated esters were synthesised with the aid of carbodiimide and then, using 1.5 times the amount of the required polymeric activated ester, certain peptides were obtained, but, despite the excess of the activated ester, the yield was lower than in those cases where the synthesis was carried out in solution[60]. The polymeric activated ester, obtained on the basis of the condensation resin

had similar properties; the yield of peptides synthesised from it did not exceed 70%.[62]

Thus despite a number of useful properties, polymeric activated esters having the above structure are not appreciably advantageous compared with the analogous low-molecular-weight compounds. Their only advantage is perhaps in the case where they are used to cyclise peptides[64]. The peptide attached to polymeric nitrophenol can undergo only intermolecular cyclisation after the removal of the protecting group from the amino-group at the end of the chain; intermolecular condensation is then virtually ruled out:

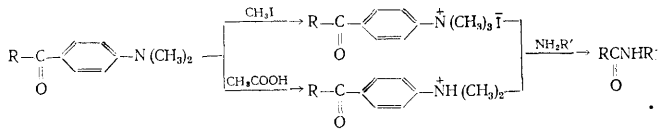


The yield of cyclopeptides was greater than in the analogous cases where a soluble activated ester is used.



Esters of acylaminoacids and peptides based on 4-methylthiophenol have interesting properties[65-68]. Methylthiophenyl esters exhibit a very weak acylating activity and the methylthiophenyl group can be regarded as a protecting group. However, when the sulphide is oxidised to sulphone by hydrogen peroxide or peracids, the reactivity of the ester increases sharply and it can be used for the effective synthesis of peptides. The applicability of esters derived from methylthiophenol (MTP) has been demonstrated in relation to the synthesis of the heptapeptide Z–Lys(Z)–Leu–Lys(Z)–Ile–Ala–Lys(Z)–Val–OMTP, which was obtained in 73% yield by the condensation of the 4-methanesulphonylphenyl ester ($MSO_2P$) of the tripeptide with the methylthiophenyl ester of the tetrapeptide[66]:

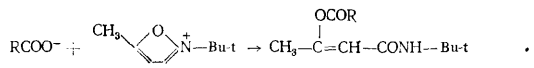
$$Z\text{—Lys(Z)—Leu—Lys(Z)—OMSO}_2\text{P} + \text{H—Ile—Ala—Lys(Z)—Val—OMTP} \rightarrow$$
$$\rightarrow Z\text{—Lys(Z)—Leu—Lys(Z)—Ile—Ala—Lys(Z)—Val—OMTP.}$$



Unfortunately this entailed a partial loss of optical activity (approximately 5%). Furthermore, this method of activation, involving the use of strong oxidants (30% $H_2O_2$ or 85% *m*-chloroperbenzoic acid), is contraindicated for peptides containing methionine, cysteine, or cystine[68]. Other aminoacids are quite stable under the activation conditions, and their methylthiophenyl and methanesulphonylphenyl esters are stable crystalline substances. After the removal of the protecting groups, the salts of the aminoacid esters may be obtained. Methylthiophenyl esters constitute an example of esters with variable reactivity. Another example of esters of this kind is provided by those derived from 1,1-diphenylethylene glycol, the primary hydroxy-group of which can be readily esterified with the aid of thionyl chloride in pyridine:[69]

This ester is inactive, but, when it has been treated with trifluoroacetic acid, it readily splits off water and is converted into the activated 2,2-diphenylvinyl ester:

This ester reacts readily with the amino-component at room temperature, forming the peptide in 80% yield after 1.5 h. The malonic ester is introduced to bind the diphenylacetaldehyde produced. Using the 2,2-diphenylvinyl ester in the last stage of the synthesis of antamanide, it was possible to achieve cyclisation in 20% yield, which is a fair result compared with other methods[69]. Esters based on *p*-dimethylaminophenol, which may be obtained with the aid of dicyclohexylcarbodiimide or by the mixed anhydride method, have similar properties[70]. Dimethylaminophenyl esters are inert with respect to amines, but, on being protonated or treated with methyl iodide, they react readily with the amino-group, forming peptides:



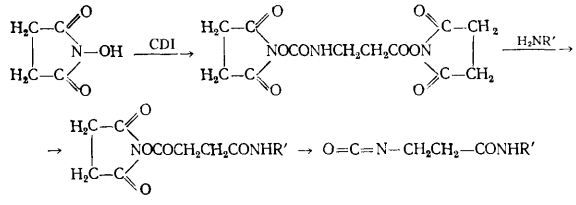
A number of di-, tri-, and tetra-peptides have been synthesised using dimethylaminophenyl esters in 50–98% yield[71].

Among activated esters of this type, the pentafluorophenyl esters, which can be synthesised either with the aid of carbodiimide or mixed anhydrides, or a complex of pentafluorophenol with dicyclohexylcarbodiimide, are of considerable interest[72]. The pentafluorophenyl esters exhibit an exceptional reactivity and permit the synthesis of peptides in yields exceeding as a rule 90%. Many peptides, including oxytocin, corticotropin, and antamanide, have been synthesised with the aid of pentafluorophenyl esters[73,74]. Presumably such esters will find extensive applications in peptide chemistry. Activated esters based on a phenol containing the sulphonamide group have been proposed[75]:

$$ZNHCHRCOO\text{—}C_6H_4SO_2NHCOCH_3$$

These esters have been synthesised with the aid of phosphoryl chloride in pyridine. Measurements of the rate of aminolysis have shown that their reactivity is equal to that of *p*-nitrophenyl esters. The yields of peptides were 65–90%; the *p*-acetylsulphamidophenol formed in the reaction can be readily removed by hydrolysis with an aqueous sodium bicarbonate solution. The addition of acetic acid to the reaction mixture has some catalytic effect.

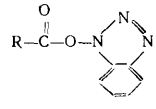
The products of the interaction of Woodward's K-reagent with acylaminoacids can also be classified as activated esters[76]:



The substituted vinyl esters of *N*-protected aminoacids obtained in this way are stable crystalline substances and exhibit an appreciable acylating activity. For example, when the activated ester of benzyloxycarbonylglycine was allowed to react with benzylamine, the amide was obtained in 98% yield[76].

## III. ACTIVATION OF THE CARBOXY-GROUP IN *N*-ACYLAMINOACIDS IN THE PRESENCE OF THE AMINO-COMPONENT

The methods for the activation of the carboxy-group in the presence of the amino-component have an undoubted advantage, since in this case the entire process is simplified and the probability of other processes (side reactions) is reduced. Although there are considerable difficulties in the selection of the reactants which interact selectively with the carboxy-group, efforts in this direction have not

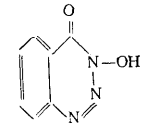


been unsuccessful. The most striking example in this field, which has played a decisive role in the development of the chemistry of peptides, is provided by various carbodiimides, in the first place by cyclohexylcarbodiimide. Studies on these lines are being successfully continued at the present time and very interesting results have been obtained in many instances. During the last five years, particular attention has been devoted to the modification of the carbodiimide synthesis by employing various additives which would tend to decrease the degree of racemisation and would eliminate side reactions. Interest in this type of modification of carbodiimide synthesis was aroused by reports concerning the favourable influence of the addition of *N*-hydroxysuccinimide in the synthesis of peptides with the aid of dicyclohexylcarbodiimide[77,78]. It was shown that the addition of one equivalent and more of *N*-hydroxysuccinimide not only prevents the formation of *N*-acylurea, but also suppresses racemisation almost completely. Some time later it was observed that, together with the favourable effect, the addition of *N*-hydroxysuccinimide can also give rise to an undesirable side process[26,79].

When *N*-hydroxysuccinimide reacts with carbodiimide, the product is the ester formed from *N*-hydroxysuccinimide and succinimido-oxycarbonyl-β-alanine, which can readily react with the amino-component and can undergo other changes:

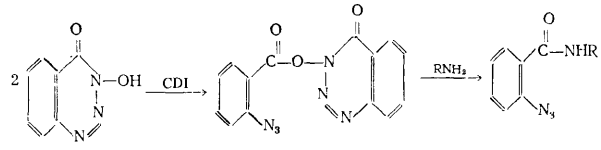
This side process is particularly dangerous when the carboxy-component is only weakly reactive owing to steric hindrance (for example, valine and isoleucine)[80] and in some cases the addition of *N*-hydroxysuccinimide does not prevent racemisation (for example, up to 46% for Z-Pro-Val-Pro-OBu-t)[81].

All these findings stimulated the search for more effective additives to carbodiimide in order to reduce the degree of racemisation and suppress side reactions. A large number of hydroxy-compounds were tested and it was established that many of them react similarly to *N*-hydroxysuccinimide[82]. Hydroxytriazoles and hydroxytriazines proved to be particularly valuable, although the effect of the additive depends also on the structure of the peptide and the nature of the solvent. 1-Hydroxybenzotriazole is the most convenient substance. Since the effect depends only slightly on the structure of the substituted hydroxybenzotriazoles, it is useful to employ unsubstituted 1-hydroxybenzotriazole[44]. It is suggested that 1-acyloxybenzotriazole



is a reaction intermediate which reacts subsequently with the amino-component forming the peptide. Certain 1-acyloxybenzotriazoles have been isolated and characterised.

Unfortunately, 1-hydroxybenzotriazole does not always rule out racemisation either. Thus, in the synthesis of Z-Pro-Val-Pro-OBu-t, it was found that the amount of racemic product is 9%.[83] However, in most cases racemisation was not observed, and, what is also important, the yields of peptides in the presence of added 1-hydroxybenzotriazole were higher than in the presence of *N*-hydroxysuccinimide.

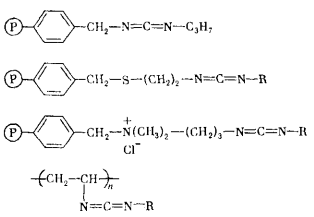


The addition of 1-hydroxybenzotriazole to carbodiimide makes it possible to add Boc-His(Bzl)-OH without racemisation[84]. Condensation with the aid of carbodiimide alone is accompanied in this instance by appreciable racemisation.

Further research led to an even more effective compound—3-hydroxy-4-oxo-3,4-dihydro-1,2,3-benzotriazine[82]:

Its addition to carbodiimide made it possible to obtain optically pure peptides even in those cases where neither 1-hydroxybenzotriazole nor *N*-hydroxysuccinimide (this is even less effective) were able to suppress racemisation completely. Thus, the degree of racemisation was 38% in the synthesis of Tfa-Pro-Val-Pro-OBu-t without any additive in the carbodiimide, in the presence of one mole of *N*-hydroxysuccinimide the degree of racemisation was 17%, the addition of one mole of 1-hydroxybenzotriazole resulted in a degree of racemisation of 3.4%, while the addition of one mole of 3-hydroxy-4-oxo-3,4-dihydro-1,2,3-benzotriazine reduced the degree of racemisation to less than 1%.[82]

However, the yield of peptides in the presence of 3-hydroxy-4-oxo-3,4-dihydro-1,2,3-benzotriazine is less than in the presence of 1-hydroxybenzotriazole, although it is higher than in the presence of *N*-hydroxysuccinide. The reduction of the yield is the result of a side reaction involving carbodiimide[84]:



It is of interest that this type of side reaction occurs when the reaction mixture contains all the components at once. On the other hand, if the synthesis is carried out initially without the amino-component (pre-activation) and the latter is added only after a certain time, the side reaction is not observed and the peptides are obtained in very high yields. Unfortunately such pre-activation does not always guarantee the absence of racemisation[82].

The introduction of additives into carbodiimide has been very popular recently. Carbodiimide synthesis with added *N*-hydroxysuccinimide and 1-hydroxybenzotriazole competes successfully with azide coupling; its use permitted a number of complex peptide syntheses (glucagon[85], thyrocalcitonin[86], and secretin[87]).

As regards the carbodiimide synthesis itself, polymeric modifications of carbodiimide are of interest. In particular, the polymeric carbodiimide $-[-(CH_2)_6-N=C=N-]_n-$ has been obtained[88,89] and the use of an excess of this compound led to the synthesis of certain simple dipeptides in high yields: Z-Gly-Gly-$OC_2H_5$ (92%), Pht-Gly-Glu$(OBzl)_2$ (89%), and Z-Cys(SZ)-Gly-OBzl (93%). However, the

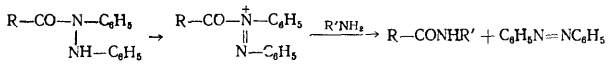
syntheses of more complex peptides have not been reported. Other polymeric carbodiimides have also been synthesised[90]:

However, only a few simple peptides have been synthesised with their aid.

In 1961 Wolman and coworkers proposed a method for the synthesis of peptides involving the oxidation of acylaminoacid hydrazides[91,92]:

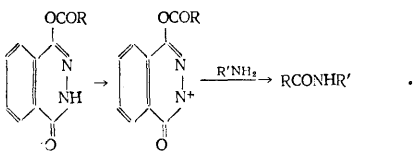
$$R{-}CONHNH_2 + NH_2R' \xrightarrow{O} RCONHR' + N_2 \quad .$$

Later it was found in 1968 that acylaminoacids phenylhydrazides can be oxidised to phenylazoacylaminoacids, which are fairly stable crystalline compounds[93]:



$$R{-}CONHNHC_6H_5 \xrightarrow{O} RCON{=}NC_6H_5 \quad .$$

Acylaminoacid phenylhydrazides have been synthesised from acylaminoacids and phenylhydrazines under the influence of papain:



$$RCOOH + NH_2NHC_6H_5 \xrightarrow{\text{papain}} RCONHNHC_6H_5 \quad .$$

This novel procedure for the preparation of hydrazides gives fairly high yield of the product and is fairly general. The hydrazides have been oxidised by *N*-bromosuccinimide and lead tetra-acetate in 70–83% yield. Phenylazoacylaminoacids and peptides react very readily with the amino-group. Thus, in the reaction of Z–Gly–Phe–N=NC$_6$H$_5$ with H–Gly–Phe–NHNHC$_6$H$_5$, the degree of conversion was 90% after 8 min. The degree of racemisation in the synthesis of the tripeptide Z–Gly–Phe–Gly–OC$_2$H$_5$ varied from 0 to 4.5%, depending on the conditions of synthesis. The best result was obtained when redistilled ethyl glycinate was used as the amino-component.

In this type of peptide synthesis, it is possible to use acylaminoacid 1,2-diphenylhydrazides, which can be oxidised by *N*-bromosuccinimide or 1-chlorobenzotriazole to azonium salts, and these readily react with the amino-component, forming peptides[69]:

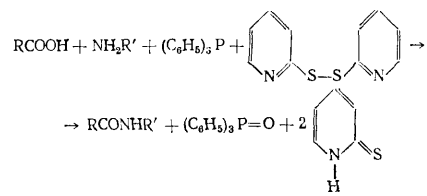
The yields of peptides amount to 70–80%. A similar result has been achieved with the aid of 4-acyloxyphthalazone[69]:

In both instances, the yield of peptides proved to be inadequate. The attempts to use these compounds for cyclisation in solution and on a polymeric carrier were unsuccessful.

A series of studies devoted to the use of phosphorus(III) compounds (phosphines and phosphites) in peptide synthesis is of particular interest. When these substances are used, unusual oxidation-reduction reactions take place during which the carboxy-group of the acylaminoacid is activated.

The reaction of a carboxylic acid, arenesulphenamide, and triphenylphosphine results in the formation of a carboxamide[94,95]. Heavy metal ions ($Cu^{2+}$, $Hg^{2+}$, etc.) are used to bind the thiophenol liberated:

$$(RCOO)_2Cu + ArSNHR' + (C_6H_5)_3P \rightarrow RCONHR' + (ArS)_2Cu + (C_6H_5)_3P{=}O \quad .$$



The arenesulphenamide can be replaced by a diaryl sulphide and an amine[96]:

$$RCOOH + (ArS)_2 + (C_6H_5)_3P + R'NH_2 \xrightarrow{Hg^{2+}} RCONHR' + (C_6H_5)_3P{=}O + (ArS)_2Hg \quad .$$

For example, Z–Phe–Gly–OC$_2$H$_5$ has been synthesised by this method in 96% yield[94].

Unfortunately, in the synthesis of a number of other peptides difficulties were encountered in their isolation from the reaction mixture. It was found that it was difficult to separate peptides from triphenylphosphine oxide and it was therefore necessary to employ in all cases chromatographic separation on silica gel, which greatly complicated the procedure[97]. The study of racemisation in the synthesis of Bz–Leu–Gly–OC$_2$H$_5$ showed that a racemic peptide is formed in appreciable amounts (3–8%).[79,80] Certain unsaturated compounds, for example, 2,3-dihydropyran and butyl vinyl ether, have been used instead of heavy metal ions to bind thiophenol[98]. The yield of peptides was then 90–97%. In order to facilitate the purification procedure and to increase the yield of peptides, the water-soluble reagents $[(CH_3)_2NC_6H_4]_3P$ and $[\overset{+}{I}(CH_3)_3NC_6H_4S]_2$ have been proposed[99]. In the synthesis of peptides, this made it possible to employ an excess of reagents, which were then readily removed by washing the peptides with water. Various dipeptides containing virtually all the natural aminoacids have been synthesised using the water-soluble reagents. The yield of peptides was 70–98%.[99]

Di-2-pyridyl disulphide proved to be a convenient compound for the oxidation-reduction condensation[98,100]. The 2-mercaptopyridine formed in the reaction with triphenylphosphine isomerises to the stable thiono-form and does not give rise to undesirable reactions:

Various dipeptides have been synthesised in 82–93% yield using di-2-pyridyl disulphide. One must note that aminoacids containing hydroxy-groups (serine, threonine, and tyrosine) do not require the protection of the hydroxy-group and the yields of peptides are high (84% for Z–Ser–Gly–OC$_2$H$_5$, 83% for 2-Thr–Gly–OC$_2$H$_5$ and 93% for Z–Tyr–Gly–OC$_2$H$_5$). In the synthesis of peptides from Z–Gln–OH and Z–Asn–OH, the dehydration of the amide groups was not observed and the yields of peptides proved to be 85–86%. The octapeptide Z–Ala–Gly–Leu–Gly–Gly–Gly–Leu–Gly–NHNHBoc was synthesised in 70% yield. The employment of di-2-pyridyl disulphide permitted the successful application of this method in solid-phase synthesis[98,101].

The influence of various additives on the degree of racemisation in the synthesis of Bz–Leu–Gly–OC$_2$H$_5$ by the oxidation-reduction condensation was investigated[102]:

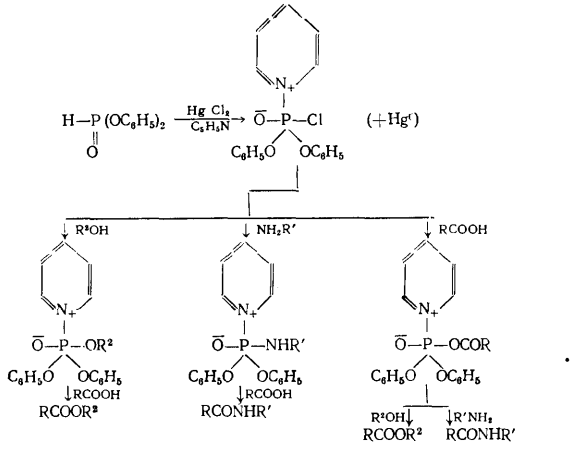
$$(Bz{-}Leu{-}O)_2Cu + NPS{-}Gly{-}OC_2H_5 + (C_6H_5)_3P \rightarrow$$
$$\rightarrow Bz{-}Leu{-}Gly{-}OC_2H_5 + (NPS)_2Cu + (C_6H_5)_3P{=}O \quad .$$

Phenol, *p*-nitrophenol, 2,4-dinitrophenol, 2,4,6-trinitrophenol, *N*-hydroxysuccinimide, and trimethylacetic acid were also used as additives.

It was found that the content of the L-isomer increases from 57 to 80% as the p$K$ of the additive is reduced from 9.89 to 0.38. However, *N*-hydroxysuccinimide deviates from this relation, the content of the L-isomer amounting to 84% for p$K$ = 9.4. A study of the dependence of the degree of racemisation on the nature of the solvent and the structure of the mercury derivatives (added to bind thiophenol) showed that there is no clear-cut trend and the degree of racemisation remains considerable (5–63%).[103] Thus the oxidation-reduction condensation method can be used only for the stepwise growth of the peptide chain. An unusual version of the oxidation-reduction condensation is the method of synthesis of peptides using anodic oxidation for the regeneration of diaryl disulphides[104]. The thiophenol formed in the reaction is oxidised to diaryl disulphide, which is thus returned to the reaction:

$$RCO\bar{O} + NH_2R' + \overset{+}{P}R_3 + ArSSAr \rightarrow RCONHR' + O{=}PR_3 + 2ArSH$$

(anodic oxidation)



This process makes it possible to introduce the diaryl disulphide into the reaction in an amount which is much less than that corresponding to stoichiometry, and the probability of the formation of side products is thereby reduced.

The use of the oxidation-reduction reaction for the synthesis of various activated esters is of interest[105]:

$$RCOOH + HOR' + (C_6H_5)_3P + \text{(2-pyridyl disulphide)} \rightarrow RCOOR' + (C_6H_5)_3P{=}O + 2\ \text{(2-pyridinethiol)}$$

Pentachlorophenyl, succinimide, and 8-quinolinyl esters have been synthesised by this procedure in 60–86% yield. This method permits the easy synthesis of activated asparagine, glutamine, and nitroarginine esters.

Another example of the oxidation-reduction reaction leading to the activation of the carboxy-group is that of diphenyl phosphite with mercury(II) salts in pyridine[106]. Using this reaction, it is possible to synthesise both acid amides and esters. The reaction is carried out in all cases in pyridine either at 45°C or on boiling and proceeds via the following mechanism:

The reaction has been used to synthesise Z–Gly–Gly–$OC_2H_5$ and Z–Gly–Gly–OH, which were obtained in 94 and 50% yields respectively.

An interesting example of the use of phosphorus(III) compounds in the synthesis of peptides is the method based on the reaction of phosphines and phosphorous acid amides with carbon tetrachloride or tetrabromide[107,108]:

$$R_3P + CX_4 \rightarrow \underset{X^-}{R_3\overset{+}{P}{-}CX_3} \xrightarrow{R'COOH} \underset{X^-}{R_3\overset{+}{P}{-}OCOR'} \xrightarrow{R''NH_2} R'CONHR'' + R_3P{=}O\ ,$$

where

$$X{=}Cl,\ Br;\ R{=}CH_3{-}\text{(N-heterocycle)}{-}N,\ C_4H_9,\ (CH_3)_2N,\ (C_2H_5)_2N\ .$$

The reaction is carried out at a reduced temperature (between −20° and 0°C) and the yield of peptides is 60–85%. A study of racemisation in the synthesis of Bz–Leu–Gly–$OC_2H_5$ showed that the amount of racemic products obtained is usually 2–8% and that the degree of racemisation is much higher (88%) only in the case of triphenylphosphine. This shows that the carboxy-group is not activated via the stage involving the formation of acid chlorides, although it is known that the acid chloride is formed readily in the reaction of a carboxylic acid, carbon tetrachloride, and phosphines[109]. When the carboxy- and amino-components are present simultaneously, the activated species is apparently an acyloxyphosphonium ion[107,110]. It has been suggested that triphenyl phosphite be used for the synthesis of peptides in the presence of imidazole[111]. The reaction proceeds via the mechanism

$$RCOOH + NH_2R' + (C_6H_5O)_3P \xrightarrow{\text{imidazole}} RCONHR' + (C_6H_5O)_2PH(=O) + C_6H_5OH\ .$$

Various peptides have been synthesised in high yields with the aid of triphenyl phosphite; the method has been used successfully in the synthesis of biologically active peptides (fragments of gastrin, corticotropin, etc.)[112]. Diphenyl phosphite, which makes it possible to synthesise peptides in 65–90% yields in the presence of pyridine, proved to be just as effective[113,114]. A similar effect was achieved also when diaryl sulphites were used instead of phosphites[115].

The employment of *o*-nitrobenzenesulphenyl derivatives of aminoacids for the synthesis of peptides is of interest. It has been found that aryl thioesters of acylaminoacids and peptides can react with salts of *o*-nitrobenzenesulphenylaminoacids, to form peptides[116]:

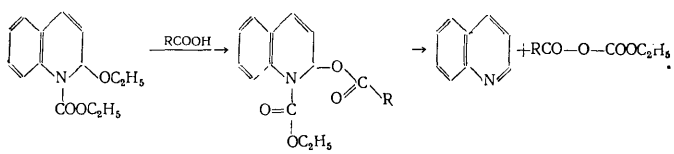
$$ZNHCHRCOSC_6H_5 + NBSNHCHR'CO\bar{O}\overset{+}{N}a \rightarrow ZNHCHRCONHCHR'CO\bar{O}\overset{+}{N}a + NBSSC_6H_5\ .$$

[where NBS is the *o*-nitrobenzenesulphenyl group]. The reaction requires fairly severe conditions: an aqueous methanol solution of the reactants was maintained for 6 h at 70°C and the yield of peptides was 56–76%. The attempts to use for this reaction the esters of *o*-nitrobenzenesulphenylaminoacids instead of the salts have not been successful. The method employing imidazole was more successful in this respect[117], which made it possible to reduce the reaction temperature to 45°C and to shorten the reaction time considerably (to 10–45 min):

$$ZNHCHRCOSAr + NBS(NHCHR'CO)_n OCH_3 \xrightarrow{4\ \text{equiv. of imidazole}} ZNHCHRCO(NHCHR'CO)_n OCH_3 + NBSSAr,$$

where Ar = $C_6H_5$, $C_6H_4NO_2$, or $C_6H_4CH_3$ and $n$ = 1–3.

The yield of peptides was about 90% and the degree of racemisation (Anderson's test) proved to be 4% for the *p*-nitrophenyl thioester. The method is convenient because it does not require the preliminary elimination of the protecting group from the amino-end of the peptide.



It was also tested in the cyclisation of certain hexa- and deca-peptides, and gave good results:

$n = 6$ or 10.

Antamanide was synthesised in this way in 30% yield[118]. It is noteworthy that this reaction occurs in pyridine or in tetrahydrofuran, while in dimethylformamide undesirable side reactions predominate. This limitation narrows the region where the reaction can be applied.

A very interesting development of the method of mixed anhydrides has been a series of studies on the application of 1,2-dihydroquinoline derivatives in the synthesis of peptides[119-122]. *N*-Ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline, which can be readily obtained from ethyl chloroformate and quinoline, is a fairly stable compound and does not react with amines; however, its reaction with carboxylic acids readily gives rise to mixed anhydrides:

Since the reaction is carried out in the presence of an amine, the mixed anhydride reacts with the latter immediately, forming an amide (peptide). Various peptides have been synthesised in yields exceeding 90% using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline. The degree of racemisation was determined in the synthesis of ethyl benzoyl-leucylglycinate (Young test), which is a very sensitive peptide; however, the racemic product was not detected. In a study of the racemisation by a more accurate method[120], only a minimal degree of racemisation was detected (approximately 0.2%). Such unusual behaviour of the mixed anhydride can be accounted for by the fact that, as soon as it is produced, it immediately reacts with the amino-component, so that its lifetime is very short and side processes do not occur.

A polymeric modification of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline has been described[121]. The polymer was obtained by the copolymerisation of 6-isopropenylquinoline with styrene, and was then converted into the active reactant by reaction with ethyl chloroformate and ethanol. The polymeric reactant makes it possible to synthesise peptides easily and rapidly in yields of 84-92%. After the reaction, the polymer can be again converted into the active reactant.

*N*-Isobutoxycarbonyl-2-isobutoxy-1,2-dihydroquinoline has been recommended for use in ordinary solid-phase synthesis of peptides (Merrifield's method)[122]. This reagent is just as effective as *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline. Certain peptides containing serine, threonine, and asparaginine have been obtained in yields of 80-95%. The octapeptide has been synthesised from Z(OCH$_3$)-Asp(OBzl)-Phe-Cys(Bzl)-Leu-Glu(OBzl)-Pro-OH and H-Gly-Ala-O-polymer (fourfold excess) as an example of the use of this reagent in the solid-phase synthesis. The latter was carried out over a period of 48 h and the yield was nearly quantitative. In order to determine the degree of racemisation, the dipeptide Ac-Ile-Gly-OCH$_3$ was used[123], the degree of racemisation found amounting to 4.1%. In the synthesis of the tripeptide Z-Gly-Ala-Leu-OBzl with the aid of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline, the degree of racemisation was only 0.2%.[120]

The ynamines $R-C\equiv C-NR_2'$ have been suggested for the stepwise synthesis of peptides[124,125]:

$$RCOOH + NH_2R' + R''-C\equiv C-NR_2''' \rightarrow RCONHR' + R''CH_2CONR_2''' .$$

The reaction is carried out at 40°C in tetrahydrofuran, the yields of certain dipeptides amounting to 83-99%. However, the attempts to synthesise Z-Leu-Phe-Val-OCH$_3$ gave a poor yield of the tripeptide (25%) and the degree of racemisation was high, varying from 17 to 27% depending on the reaction temperature. It appears that ynamines must be used with caution in the synthesis of peptides. They proved to be much more effective in the preparation of symmetrical anhydrides used subsequently to synthesise peptides[124].

Diphenylphosphoryl azide[127], which can be readily obtained from diphenylphosphoryl chloride and sodium azide in acetone, proved to be a very interesting reagent for the synthesis of peptides. It is a stable non-explosive liquid, which can be distilled at a reduced pressure. When it is allowed to react with a solution containing carboxy- and amino-components, peptides are obtained at 0°C easily and in high yields:

$$RCOOH + NH_2R' + N_3PO(OC_6H_5)_2 \rightarrow RCONHR' .$$

It is suggested that the carboxylic acid azide RCON$_3$ is an intermediate. This is confirmed by the fact that, when a carboxylic acid, diphenylphosphoryl azide, and alcohols are heated, the corresponding urethanes are obtained:

$$RCON_3 \rightarrow RN=C=O \xrightarrow{R'OH} RNHCOOR' .$$

Diphenylphosphoryl azide is a universal reagent permitting the synthesis of peptides containing virtually any amino-acids in high yields. The following peptides have been synthesised with its aid (the yields are indicated in brackets):

Z—Asn—Phe—OCH$_3$ (80%); Z—Gln—Ser—OCH$_3$ (80%);
Z—Val—Tyr—OCH$_3$ (69%); Z—Thr—Phe—OCH$_3$ (72.5%);
Z—Met—Gly—OC$_2$H$_5$ (90%); Boc—Trp—Gly—OC$_2$H$_5$ (89.5%);
Z—Arg(NO$_2$)—Leu—OCH$_3$ (83%); Z—His—Leu—OCH$_3$ (95%).
Z—Leu—Leu—Val—Phe—OCH$_3$ (87%);

Racemisation was not observed in the synthesis of the tetrapeptide Z-Leu-Leu-Val-Phe-OCH$_3$, but Young's test showed that the degree of racemisation is about 5%.

## IV. OTHER METHODS FOR THE ACTIVATION OF THE CARBOXY-GROUP

Mixed anhydrides obtained from the esters of chlorocarbonic acids are very important in the synthesis of peptides. Despite the fact the method of mixed anhydrides was developed at the beginning of the 1950s, interest in this procedure has still not weakened; new studies in which new versions of the method are proposed are published fairly frequently.

A new method for the preparation of mixed anhydrides, based on the use of stable *N*-alkoxycarbonyl-*NNN*-trialkylammonium salts, is of interest[128]. Certain salts of this type are fairly stable and can be used to form mixed *N*-acylaminoacid anhydrides, for example:

$$BF_4^-R_3\overset{+}{N}-\underset{\underset{O}{\|}}{C}OC_4H_9 + ZNHCHR'COOH \rightarrow ZNHCHR'CO-O-CO-OC_4H_9 .$$

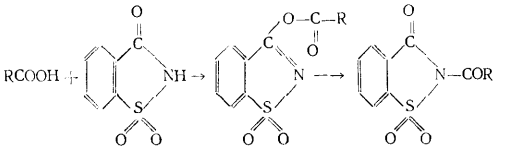
Certain di- and tri-peptides have been synthesised in this way in yields of 70-97%.

Another example of a new method of synthesis of mixed anhydrides involves the use of dihydroquinoline derivatives, which were considered in Section III.[119-122]

Among the methodological developments devoted to the use of mixed anhydrides, special attention should be given to the method based on the use of a large excess of the mixed anhydride[129]. This approach permits the synthesis of peptides in a nearly quantitative yield and makes it possible to carry out the process without the isolation and purification of the intermediate peptides. The method has been successfully applied in the synthesis of a fragment of the growth hormone[128], secretin[129], and other peptides.

Despite the fact that the mixed anhydrides with certain carboxylic and alkylcarbonic acids were introduced into peptide chemistry long ago and have gained general recognition by virtue of their high reactivity and the simplicity of their synthesis, the search for new types of mixed anhydrides is still being continued. The necessity for such search probably arises due to the instability of mixed anhydrides and the side reactions which occur in many instances. Admittedly the number of new types of mixed anhydrides is not all that large and they can hardly compete with the generally recognised mixed anhydrides.

One of such new mixed anhydrides proposed is the compound obtained by the reaction of toluene-*p*-sulphonic acid anhydride with hexamethylphosphoramide[131]:



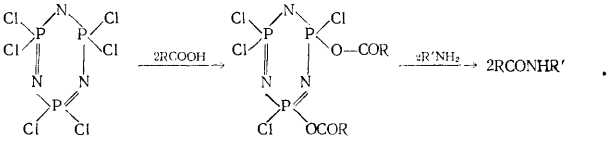
$$[(CH_3)_2N]_3PO + Tos_2O \rightarrow [(CH_3)_2N]_3\overset{+}{P}-O-\overset{+}{P}[N(CH_3)_2]_3 \cdot 2Tos\bar{O} \rightarrow$$
$$\xrightarrow{RCO\bar{O}} RCO-O-\overset{+}{P}[N(CH_3)_2]_3\,Tos\bar{O} \xrightarrow{R'NH_2} RCONHR' + [(CH_3)_2N]_3PO \quad .$$

The resulting acyloxytris(dimethylamino)phosphonium tosylate is fairly stable in solution and rapidly reacts with the amino-component, forming peptides in a high yield for the majority of aminoacids (81–96%). Aliphatic aminoacids containing hydroxy-groups (serine and threonine) cannot be used in this reaction without protecting the hydroxy-group. Histidine also gives unsatisfactory results. However, the absence of racemisation (less than 1%) is of interest; it can probably be accounted for by the impossibility of the formation of the oxazolone ring owing to the steric hindrance caused by the dimethylamino-groups. At the same time, the presence in solution of chloride or bromide ions may promote the appearance of the racemic product, which was noted previously[132].

The absence of racemisation permitted the use of this method for the coupling of large peptide fragments. The hexapeptide Z–Ile–Gly–Val– –Gly–Ala–Pro–$NH_2$ (the double dash indicates the junction of the fragments), the octapeptide Z–Gly–Leu–Leu–Gly–Gly– –Phe–Ala–Gly–$OCH_3$, and the octapeptide Z–Thr(t-But)–Ala– –Ile–Gly–Val–Gly–Ala–Pro–$NH_2$ have been obtained in yields of 84, 86, and 81% respectively. The reaction is carried out in hexamethylphosphoramide, which is an effective solvent for various peptides. Mixed anhydrides based on boric acid[133] have not been found to be quite so effective, for example:

$$RCO\bar{O} + ClB(OCH_3)_2 \rightarrow RCOOB(OCH_3)_2 \xrightarrow{R'NH_2} RCONHR' \quad .$$

By allowing the sodium salt of benzoylphenylalanine to remain in contact with chlorodimethoxyborane for 18 h at room temperature and then introducing freshly distilled ethyl glycinate into the mixture, the peptide Bz–L–Phe–Gly–$OC_2H_5$ was obtained in 31% yield. The analogous reaction at 55°C led to the formation of the racemate. The mixed anhydride acyloxydimethoxyborane undergoes a number of reactions, for example it gives rise to triacyloxyborane $(RCOO)_3B$, the symmetrical anhydride RCOOCOR, and other products. All these factors are responsible for the low yields of peptides[134]. A novel application of saccharin is its use in the synthesis of mixed anhydrides with acylaminoacids[135]:



The mixed anhydrides are obtained with the aid of carbodiimide or thionyl chloride in 74–95% yield. They are readily crystallisable, highly fusible compounds with a considerable stability on storage. At the same time, they are very reactive, reacting readily with the amino-components at 0°C and forming peptides in 86–95% yield. They can be employed to synthesise peptides in an aqueous medium, using solutions of aminoacids and peptides in aqueous potassium bicarbonate. The yields of peptides are 63–95%, and the saccharin liberated in the reaction can be readily washed away with water.

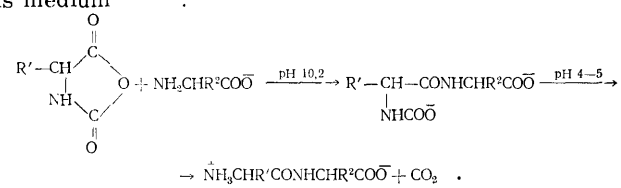
The use of acylguanidine for the synthesis of peptides is of interest[136]. Acylguanidines are obtained in satisfactory yields by the reaction of methyl esters of acylaminoacids with free guanidine. Acylguanidines are crystalline compounds with fairly high melting points (150–190°C) and are soluble in polar solvents. They react fairly effectively with amines, forming amides (peptides); the protonation of guanidine is postulated in this process:

$$RCO-NH-\overset{\overset{\cdots}{NH}}{\overset{\|}{C}}-NH_2 \xrightarrow{H^+} R-CO-NH-\overset{\overset{+}{NH_2}}{\overset{\|}{C}}-NH_2 \xrightarrow{NH_2R'} RCONHR' + \overset{\overset{+}{NH_2}}{\overset{\|}{NH_2CNH_2}} \quad .$$

The reaction is carried out in an aqueous or aqueous organic medium at room temperature at pH 8. The yields of dipeptides are 68–90%.

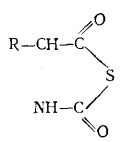
The comparatively low yields of peptides and complete racemisation were noted when polyphosphoric acid esters $(C_2H_5O_3P)_n$ were used[137]. Peptides were synthesised by refluxing a solution in $CHCl_3$ or $CH_3CN$; their yield did not exceed 75% and the peptides of comparatively simple aminoacids were obtained: glycine, alanine, phenylalanine, and leucine. The method can be hardly used to synthesise even small peptides owing to the unduly severe condensation conditions. The application in the synthesis of peptides of hexachlorocyclotriphosphatriazine, which can react with two molecules of the acylaminoacid to form an unusual mixed anhydride, has been described[138]:

The symmetrical anhydrides of Boc-aminoacids, obtained with the aid of ynamines at 0°C[126]:



$$2R-COOH + CH_3C{\equiv}C-N(C_2H_5)_2 \rightarrow RCOOCOR + CH_3CH_2CON(C_2H_5)_2 \quad ,$$

or with the aid of phosgene at −40°C,[136,137] proved to be very effective. The reaction of the symmetrical anhydrides with the amino-component terminates after 10–30 min. All these factors make it possible to achieve a single peptide coupling after each 2–3 h in a yield exceeding 90% at each stage. The excess of the anhydride (an



excess by a factor of 1.5 is used) and the Boc-aminoacid formed in the reaction can be readily regenerated after washing with a solution of sodium bicarbonate. Using symmetrical anhydrides, it has been possible to synthesise rapidly and in a satisfactory yield the nonapeptide Boc–Leu–Ile–Ile–Leu–Val–Pro–Pro–Phe–Phe–OBzl without isolating and identifying the intermediates[126].

The symmetrical anhydrides of t-butoxycarbonylaminoacids proved to be convenient reagents for the synthesis of peptides on a polymeric carrier[141]. The use of anhydrides ensures a high yield at each stage. An advantage of this synthesis is also that a comparatively simple regeneration of the excess anhydride is possible. A linear decapeptide, corresponding to antamanide, has been synthesised in 96% yield using symmetrical anhydrides.

The employment of internal anhydrides–*N*-carboxyanhydrides, which can be readily obtained from aminoacids by treatment with phosgene[142], proved to be very productive in the synthesis of peptides. Until recently, *N*-carboxyanhydrides were used mainly to obtain polypeptides and statistical copolypeptides. It was found that, under strictly controlled conditions, *N*-carboxyanhydrides can be used for the stepwise synthesis of peptides in an aqueous medium[142-145]:

For effective synthesis, it is necessary to maintain the pH within a narrow range, since at pH $< 10$ the carbamate of the dipeptide already loses $CO_2$, and the resulting dipeptide may react with the *N*-carboxyanhydride to form a side product. On the other hand, at pH $> 10.5$ the *N*-carboxyanhydride hydrolyses and other side reactions take place. When the pH is maintained rigorously in the range 10.2–10.5, peptides are synthesised at a very high rate. It is important that, among all the aminoacids, only lycine and cysteine require the protection of side groups. The C-terminal tetrapeptide gastrin H–Trp–Met–Asp–Phe–$NH_2$ has been synthesised in 1 h with the aid of *N*-carboxyanhydrides. For certain aminoacids (for example, histidine and glycine), it is useful to use thio-analogues of *N*-carboxyanhydrides (thiazolidine-2,5-diones)[146,147]:

In this case, the peptide synthesis can be carried out at lower pH values. The *N*-carboxyanhydride method can be conveniently used to synthesise peptide fragments consisting of 4–8 aminoacid residues. It has been applied successfully in the synthesis of ribonuclease fragments[148].

A disadvantage of this method is the low stability of the *N*-carboxyanhydrides, which cannot be synthesised before their immediate requirement and stored for a long time. Furthermore, serious difficulties are encountered in the synthesis of certain *N*-carboxyanhydrides and their thio-analogues. Efforts have been made recently to overcome these difficulties. It was found that *N*-carboxyanhydrides with a substituent at the nitrogen atom are much more stable than the unsubstituted *N*-carboxyanhydrides; they do not polymerise and at the same time react readily with the amino-components, forming *N*-protected peptides. The following protecting groups have been used: NBS[149,150], benzyl, 2,4-dimethoxybenzyl, 2,4,6-trimethoxybenzyl, diphenylmethyl, bis-(4-methoxyphenyl)methyl, and 9-xanthenyl[151]. Protected *N*-carboxyanhydrides have been synthesised either from unprotected *N*-carboxyanhydrides[149] or from protected aminoacids and phosgene[151]. Certain small peptides have been synthesised with the aid of protected *N*-carboxyanhydrides both in solution and on an insoluble polymeric carrier, the yield of peptides being very high in certain instances[150].

# Vinyl Fluoride Polymers

Kh.U.Usmanov, T.S.Sirlibaev, and A.A.Yul'chibaev

Results obtained on the polymerisation, copolymerisation, and graft copolymerisation of vinyl fluoride, various properties of the polymers thus produced, and also possible fields of application are discussed on the basis of 435 references published up to the beginning of 1976

## I. INTRODUCTION

The polymerisation and copolymerisation of vinyl fluoride, as well as various properties of the resulting polymers, have been very intensively studied during recent years. Poly(vinyl fluoride) possesses good heat resistance, thermal stability, and chemical inertness, while being readily processed. Films of this polymer are distinguished by high mechanical strength, durability, flexibility, transparency, and enhanced resistance to the atmosphere and to light. Several copolymers and graft copolymers possess similar qualities. In virtue of these valuable properties polymers based on vinyl fluoride are currently among the principal types of fluorinated polymers widely employed in various branches of modern technology, building construction, agriculture, and everyday life.

A few review papers have been published on vinyl fluoride and its polymers [1-3], a subject that has been partly covered also in several books [4-6]. However, attention is paid in these publications mainly to the preparation and properties of vinyl fluoride itself, with little space devoted to the synthesis of its polymers and their properties. Moreover, they contain no results published during the past 4–5 years.

## II. POLYMERISATION OF VINYL FLUORIDE

Vinyl fluoride was prepared as early as 1901 by Swarts [7], but its polymerisation was accomplished only in 1934. [8] Quite detailed information both on the kinetics of the polymerisation of vinyl fluoride and on the properties of the polymer was published in 1946 by Newkirk [9].

Vinyl fluoride is more difficult to polymerise [8,10] than are e.g. vinyl chloride, vinylidene chloride, and vinylidene fluoride, owing to the appreciable inertness of the double bond and the great activity of vinyl fluoride radicals. The process is therefore very sensitive to the presence of impurities that may inhibit polymerisation [8,11-14]. The failures and difficulties met by the early investigators in their attempts to polymerise vinyl fluoride were due mainly to inadequate purity of the monomer, although the low reactivity of the double bond in vinyl fluoride was also quite important. The diminished activity of the double bond was due to a mesomeric effect weakening the inductive effect of the fluorine atom [15-18].

The successful development during recent years of methods for obtaining vinyl fluoride in a high state of purity has enabled its free-radical polymerisation to be achieved both by chemical initiation and under the influence of radiation.

### 1. Chemically Initiated Polymerisation of Vinyl Fluoride

Various organic peroxides have been most widely used to initiate the polymerisation of vinyl fluoride. Newkirk [9] obtained poly(vinyl fluoride) of density 1.39 g $cm^{-3}$, soluble in hot dimethylformamide, in dioxan, chlorobenzene, and several other solvents, by employing benzoyl peroxide as initiator. This polymerisation initiator was used also by other workers [12,19-23]. Other peroxides that have been widely used to polymerise vinyl fluoride are acetyl, diethyl, di-t-butyl [12], isobutyl [25], lauroyl [24,26], and polyperfluoropropylene, as well as t-butyl hydroperoxide [27].

The polymerisation of vinyl fluoride in the presence of peroxide initiators is strongly inhibited by oxygen [12]. Acetylene has a similar effect: the yield of poly(vinyl fluoride) in the presence of 2% of acetylene does not exceed 3%. [10,22] Polymerisation in the presence of 2.5% of 1,1-difluoroethane, initiated by benzoyl peroxide, gave a normal yield [12]. Traces of propene help to control the molecular mass, and the resulting polymer has a constant melt flow index [28].

The influence of benzene, methanol, propan-2-ol, and 1,3-dioxolan on the polymerisation of vinyl fluoride was studied [12]. All the organic solvents examined interacted with the monomer, and thus caused a sharp decrease in the molecular mass of the resulting polymer. This is shown especially clearly in the polymerisation of vinyl fluoride in tetrachloromethane in the presence of a peroxide [29]. The telomerisation of vinyl fluoride by chloroformates [30], iodotrifluoromethane [18], perfluorochloroalkenes [31], and perhalogenoethanes [32] has been studied in the presence of peroxides. The telomers obtained are used as plasticisers for poly(vinyl fluoride); they do not bleed and do not cause opacity in the polymer when bent [18].

Polymers of higher molecular mass are formed in the presence of water than in the presence of acetone [33,34].

Initiation of polymerisation by benzoyl or lauroyl peroxide in a fluorinated solvent—1,1,2-trichlorofluoroethane or iodotrifluoromethane—gave poly(vinyl fluoride) soluble in hot dimethylformamide[18]. A polymer of high molecular weight is formed also when the peroxide of a fluorinated acid[35] or trifluoromethyl peroxide[36] is used as initiator.

Two-stage polymerisation in aqueous suspension in the presence of benzoyl peroxide was suggested[37] for the preparation of light-resistant poly(vinyl fluoride). Processes were also developed for the continuous polymerisation of vinyl fluoride in aqueous suspension[38,39] and methods for separating the resulting polymer from water, which was subsequently recycled[28,37,39]. The polymerisation of vinyl fluoride was studied in the presence of various surface-active agents and stabilisers of suspensions—methylcellulose[40-42], glucose ethers and esters, water-soluble copolymers of ethylene, 2-ethylhexyl acrylate, and 2-ethylhexyl methacrylate[43], and also copolymers of vinyl acetate and allyl alcohol with maleic acid or anhydride[44].

Emulsion polymerisation had been most widely used for the preparation of poly(vinyl fluoride) used especially in coatings. Water alone or mixed with organic solvents was the dispersion medium[21,26,45-47]. The emulsifiers were magnesium dodecanesulphonate[40], sodium ditridecyl sulphosuccinate[27], sorbitol ethers or esters, or $C_{12-18}$ aliphatic acids[48].

As the polymerisation of vinyl fluoride in the presence of the usual peroxide initiators requires temperatures above 50°C and hence high pressures, the possibility of polymerisation at relatively low temperatures and pressures has been intensively examined during recent years. Use of various alkyl peroxodicarbonates as initiators has proved especially fruitful for this purpose. A most detailed study has been made of the polymerisation of vinyl fluoride in the presence of the di-isopropyl ester[21,49-53]. As the ester content increases from 0.28 to 0.98 wt.% on the weight of the monomer the rate of polymerisation in heptane solution increases in conformity with the equation $v = kc^{0.58}$, where $k$ is the overall polymerisation rate constant and $c$ the initiator concentration; the corresponding equation when the concentration of vinyl fluoride in heptane solution increases from 3.07 M to 9.20 M is $v = kc^{0.60}m^{1.10}$, in which $m$ is the monomer concentration.

The activation energy of polymerisation is ~17 kcal mole$^{-1}$. Methylcellulose[54], poly(vinyl alcohol)[55], and mixtures of water-soluble cellulose ethers and partly hydrolysed poly(vinyl acetate)[48] have been suggested as peptising agents for the suspension polymerisation of vinyl fluoride in the presence of di-isopropyl peroxodicarbonate. In order to improve the compatibility of poly(vinyl fluoride) with plasticisers the suspension polymerisation of vinyl fluoride is conducted in the presence of 0.05–2% (on the weight of the monomer) of carboxymethyl-, hydroxypropyl-, or hydroxyethyl-cellulose[56,57].

The emulsifiers used in the emulsion polymerisation of vinyl fluoride are dodecyl benzenesulphonate[54] and such non-ionogenic surface-active agents as alkyl or alkylphenyl ethers or esters of polyoxyethylene and polyoxypropylene[58], sorbitol and its ethers, and also esters of $C_{12-18}$ aliphatic acids[48]. Not only di-isopropyl peroxodicarbonate but also the dipropyl ester[59] and didecanoyl peroxide[26] have been used for the emulsion polymerisation of vinyl fluoride. An 85% yield of poly(vinyl fluoride) is obtained when polymerisation is initiated by 0.05–1.0 mole % of bis-2-t-butylcyclohexyl peroxodicarbonate[60].

The polymerisation of vinyl fluoride at ordinary temperatures and pressures can also be initiated by various redox systems, among which the most efficient are organoelementary compounds in the presence of oxygen, e.g. alkylboranes at 25–40°C.[23,26,61] The activation energy of polymerisation depends on the nature of the group in the alkyl borane: it is 6 and 15 kcal mole$^{-1}$ for triethylborane and tri-isobutylborane respectively. With increase in the ratio of molecular oxygen to the trialkylborane the rate of polymerisation passes through a maximum. Rise in temperature increases the probability of the formation of groups such as $CH_2.CHF.CHF.CH_2$.[18]

A kinetic study of the polymerisation of vinyl fluoride has been made in the presence of tri-n-butylborane[53,62]. The reaction velocities are given by the equations $v = kc^{0.61}$ and $v = kc^{0.65}m^{1.24}$ in the mass and in ethyl-acetate solution respectively. The activation energy of polymerisation is 10 kcal mole$^{-1}$. Polymer samples of crystallinity <30% are obtained by using as initiators organoboron compounds of the type $BR_3$ (where R represents a $C_{1-12}$ group) or RR'BX (where X = OR) with oxygen[63-66], and their coordination compounds with ammonia, hydrazine, hydroxylamine, and amines[67-71]. Trialkylboranes with hydrogen peroxide in the molar proportions 0.05–0.6 are also effective initiators[72,73].

Vinyl fluoride can be polymerised at ordinary temperatures by the use not only of alkylboranes but also of triethylaluminium, di-isopropylcadmium, diethylcadmium, di-isopropylzinc, diethylzinc, ethylzinc isobutoxide, or butylethylzinc in the presence of oxygen or a peroxide, e.g. benzoyl peroxide, 1-hydroxycyclohexyl peroxide, or cyclohexyl hydroperoxide[19,74]. The binary systems formed by diethylaluminium bromide or triethylaluminium with titanium tetrachloride[75,76] and by tri-isopropylaluminium with tetraisopropoxytitanium[77] have been tested. In the presence of tetraethyl-lead with sodium persulphate vinyl fluoride underwent polymerisation only at high temperatures and pressures (40–100°C above 150 atm)[78].

Heterogeneous catalysts comprising aluminium alkyls and titanium or vanadium halides proved ineffective for the polymerisation of vinyl fluoride[79,80]. However, soluble halogen compounds of vanadium combined with aluminium mono- or di-alkyls in the presence of polar solvents, e.g. vanadium acetylacetonate and an alkylalkoxyaluminium chloride in dimethylformamide, initiate the polymerisation of vinyl fluoride very vigorously at 20–50°C.[81] The activation energy of polymerisation fluctuates from 11 to 16 kcal mole$^{-1}$ depending on the nature of the radical R attached to the aluminium atom. Manganic acid and various of its salts are effective initiators of the polymerisation in aqueous suspension[82].

The systems formed by potassium peroxodisulphate with sodium sulphite and with sodium hydrogen sulphite have also proved effective[83]. In their presence vinyl fluoride undergoes emulsion polymerisation at relatively low temperatures (50–60°C), the resulting polymer does not settle on the walls, and it is readily removed from the reaction vessel.

With azo-compounds as initiators the polymerisation of vinyl fluoride is usually conducted at temperatures of 50–100°C and pressures exceeding 30 atm.[84] Thus in the presence of α-azoisobutyramidine[85,86] polymerisation takes place in aqueous medium at 70–90°C and 30 atm. A continuous process has been developed for polymerisation in aqueous suspension initiated by α-azoisobutyramidine hydrochloride[12,29,38,87-89]. 2,2'-Diguanyl-2,2'-azopropane dihydrochloride[28,37,39,90,91], 2,2'-diguanyl-2,2'-azobutane dihydrochloride, and azo-α-cyclopropylpropionamide hydrochloride[92] have also been used for this purpose. Polymerisation of vinyl fluoride has been initiated also by

$\alpha\gamma\gamma'$-trimethyl- and $\alpha\gamma$-dimethyl-$\alpha$-azovaleronitrile[93], 1-azocyclohexanecarbonitrile, $\gamma$-ethyl-$\gamma'$-hydroxyethyl-azobutyronitrile, and azo-disulphonates of alkali and alkaline-earth metals[45]. The most commonly used initiator for the polymerisation of vinyl fluoride has been azoisobutyronitrile[12,53,64,93,94], when the order of reaction with respect to the initiator is 0.55 in the mass.

### 2. Polymerisation of Vinyl Fluoride by Irradiation

When exposed to ultraviolet radiation in the absence of a sensitiser, vinyl fluoride does not polymerise but decomposes into acetylene and hydrogen fluoride[95], which is eliminated by a molecular mechanism. In the early work[9] polymerisation was effected by ultraviolet exposure in the presence of benzoyl, lauroyl, or acetyl peroxide in a quartz capillary. Several other publications appeared later[33,34,96]. Thus exposure of vinyl fluoride in acetone solution to ultraviolet radiation of wavelength 2537 Å at 27°C for 8 h gave 36% of the polymer[33,34].

The polymerisation of vinyl fluoride under the influence of cobalt-60 $\gamma$-rays has been studied in the greatest detail[97-109]. The first reports of the possibility of the radiation polymerisation of this monomer appeared as early as 1962–1963.[99-102] The laws governing such polymerisation in the mass, in the gas phase, and in the presence of various solvents have now been investigated in detail.

The polymerisation of vinyl fluoride in the mass has been conducted at dosage rates of 13–100 rad $s^{-1}$.[103] At and above 70 rad $s^{-1}$ the rate curves have a well developed sigmoid form, which is attributed to heterophase occurrence of the process. The rate of polymerisation passes through a maximum at a polymer yield of 45–65%. In the mass at 38°C the rate of polymerisation is proportional to the dosage rate to the power 0.42. The radiation-chemical yield lies in the range 8000–30 000 mol./100 eV, as a consequence of the chain character of the process.

Under the influence of $\gamma$-rays vinyl fluoride polymerises at less than half the rate for vinylidene fluoride and trifluoroethylene, but more rapidly than chloro-trifluoroethylene, hexafluoropropene, and perfluoroisobutene[110]. As with chemical initiation, the radiation polymerisation of vinyl fluoride is strongly inhibited by oxygen and by acetylene[99,111]; increasing the acetylene content of the monomer from 0.5% to 1% diminishes the rate of polymerisation almost to one-third.

In the first study of the gas-phase polymerisation of vinyl fluoride[112,113] irradiation with cobalt-60 $\gamma$-rays was employed at dosage rates of 10, 20, 70, and 100 rad $s^{-1}$. The increase from 10 to 100 rad $s^{-1}$ increases the rate of polymerisation from 1.29 to 22–23 g $litre^{-1}$ $h^{-1}$. Such a sharp increase is attributed to generation by the radiation of active centres in the product, polymerisation at which results in branched polymers. The radiation-chemical yield lies between 1670 and 15 670 mol./100 eV.

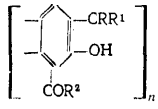
Detailed studies have been made also of the radiation polymerisation of vinyl fluoride dissolved in tetrachloromethane, benzene, dimethylformamide, dichloroethane[114,115], and a series of fluorinated hydrocarbons[116-118]. In the presence of tetrachloromethane the rate of polymerisation passes through a maximum at a monomer concentration of 0.80 M, exceeding by 50% the rate in the mass. With an initial monomer concentration of 0.26–0.35 M a colourless, viscous, oily product of molecular weight 320–540 is formed. Mole fractions of vinyl fluoride of 0.77 and above yield a solid polymer. The constant of chain transfer to tetrachloromethane is 0.0196. The infrared spectra[119] exhibit maxima in the regions of 790 and 712 $cm^{-1}$, indicating partial incorporation of the trichloromethyl group into the poly(vinyl fluoride) macromolecules.

The relative rate of polymerisation of vinyl fluoride is strongly dependent on the nature of the solvent[115]. Thus in benzene the rate drops sharply, and in dimethylformamide it is almost a linear function of the monomer concentration, but in dichloroethane the rate is higher than in the mass. Such variation in the rate of polymerisation of vinyl fluoride is due both to differences in the radiation-chemical yields of radicals from these solvents and to a redistribution between monomer and solvent of the energy absorbed from the radiation.

The dependence of the rate of the radiation polymerisation of vinyl fluoride on the dosage rate $I$ and the monomer concentration is described by different equations: in benzene $v = kI^{0.73}m^{2.7}$; in dimethylformamide $v = kI^{0.76}m^{2.2}$; in dichloroethane $v = kI^{0.86}m^{1.2}$; and in tetrachloromethane $v = kI^{0.80}m^{1.2}$. The activation energies of radiation polymerisation in the mass, in dimethylformamide, in dichloroethane, and in tetrachloromethane are respectively 5.7, 4.8–5.3, 5.5–6.1, and 5.0–5.5 kcal $mole^{-1}$ depending on the solute concentration. These values are 10–11 kcal $mole^{-1}$ smaller than the activation energy in the presence of material initiators, which is one of the advantages of radiation polymerisation.

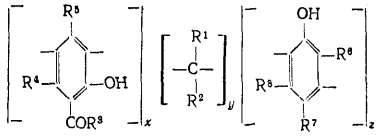
Vinyl fluoride has been polymerised also in a plasma[120].

## III. STRUCTURE AND PROPERTIES OF POLY(VINYL FLUORIDE)



Poly(vinyl fluoride) gives relatively sharp X-ray diffraction patterns[121-124]. The crystallinity of specimens lies in the range 35–47% depending on the conditions of preparation. The unit cell possesses hexagonal symmetry. The macromolecules, like those of polyethylene or polyvinyl alcohol, have a planar zigzag conformation[65]. The interplanar spacing is 4.95 Å, and the repeat distance along the chain is 2.53 Å.[125,126].

One of the main factors determining many properties of poly(vinyl fluoride) is the sequence in which one unit is added to another in the macromolecule. "Head to tail" addition of monomer units was noted at an early stage by Newkirk[9]. Groupings of the CHF.CHF type, resulting from "tail to tail" addition, have been identified[127] in the nuclear magnetic resonance spectra. Bovey et al.[128] established by high-resolution n.m.r. spectroscopy the presence of a resonance line having a chemical shift of 8.33 ppm (on the $\tau$ scale), which may be due to "head to head" structures. The possibility of the presence of such units in the polymer chain is admitted by other workers who have studied the infrared and n.m.r. spectra of this polymer[129-135].



A distinguishing feature of poly(vinyl fluoride) is its great photostability[136], which is due to the complete transparency of its films in the ultraviolet and visible regions of the spectrum. Thus transparent films remained colourless and retained 50% of their original tensile strength after exposure to sunlight for 10 years[122]. Films 0.13 mm thick transmit $>90\%$ of radiation in the wavelength range 2350–1950 Å.[137]

Because of this great transparency, however, articles coated with such films are not always effectively protected from the action of ultraviolet radiation. Ultraviolet-absorbers must be introduced into the film, widely used

examples being triazoles [138,139], polymers of acrylic derivatives of acetophenones or benzophenone [140,141], polymers of general formula [142]

($R = R^1 = H$, $R^2 = C_6H_5$, and $n = 2$ or 3), and linear polymers having the structure [143]

($R^1$ and $R^2$ = H, $C_{1-6}$-Alk, chloroalkyl, furyl, vinyl, propenyl, or phenyl; $R^3 = C_{1-6}$-Alk or Ar; and $R^4$, $R^5$ = H, OH, Hal, Ar, aryloxyalkyl, or cyclohexyl). The same purpose can be achieved also by copolymerising [144] vinyl fluoride with a small quantity of the acrylic-acid derivative $CH_2:CR.COO.C_6H_4.CO.CH_2.CO.R'$ (R = H or $C_{1-3}$-Alk and $R' = C_{1-18}$-Alk or substituted phenyl). Other proposed ultraviolet-absorbers are benzophenone [146]†, various hydroxy-derivatives thereof [147-150], and the polyester obtained from adipoyl dichloride and 2,4,4'-trihydroxybenzophenone [151,152].

Poly(vinyl fluoride) films possess extremely good mechanical properties. Great strength is combined with elasticity and resistance to multiple bending even at low temperatures [122]. These properties are only slightly impaired by the prolonged action of water vapour [153]: thus at 99°C no appreciable deterioration in the elongation of films and their stability on multiple bending had occurred after 100 h. The films are characterised also by enhanced abrasion resistance [154-158], in which they are inferior only to polytetrafluoroethylene [159]. This property is fully consistent with the swellability, wettability, and surface free energy of poly(vinyl fluoride) [160].

Poly(vinyl fluoride) possesses great chemical resistance. The stability of the physical structure of films and their characteristic resistance to oxidation and hydrolysis were studied from the variation in properties on ageing in moist and dry atmospheres at high temperatures [122]. During ageing the tensile strength of a highly oriented film approaches that of films having less orientation of the molecules [161]. The polymer is stable towards caustic soda, hydrochloric and sulphuric acids, and primary and secondary amines [161,162]. It far surpasses in chemical stability poly(ethylene terephthalate), and is not inferior to a polyamide film. Treatment with nitrogen trifluoride or monofluoride at 80–100°C leads to the formation of cross-links in poly(vinyl fluoride) and improves the mechanical properties of the film [163,164]. The polymer can be chlorinated [165] and fluorinated [166] by the action of the gaseous halogens.

The product of the chemically initiated polymerisation of vinyl fluoride at temperatures above 100–110°C dissolves in such strongly polar solvents as *N*-substituted amides, dinitriles, thiolan dioxide, tetramethylurea, *N*-methylpyrrolidone, and γ-butyrolactone [12], the polymer separating out when the solution is cooled below 100°C. At room temperature poly(vinyl fluoride) dissolves well in hexamethylphosphoramide [167-169], perfluoropropane-2,2-diol, and 1,3-dichloro-1,1,3,3-tetrafluoropropane-2,2-diol [170]. The product of radiation polymerisation is considerably less soluble [171]. The conditions of preparation—dosage rate and radiation dose, temperature, presence of impurities and additives, and state of aggregation of the monomer during polymerisation—than have a marked effect on the solubility of the polymer. The solubility in boiling solvents of polymer samples obtained in the mass is respectively 30–35%, 22–27%, 10–15%, and 1–5% in dimethylformamide, hexamethylphosphoramide, cyclohexanone, and dioxan respectively [97]. Gas-phase polymerisation yields a product of enhanced solubility [113], and a polymer obtained in tetrachloromethane dissolves still better [172].

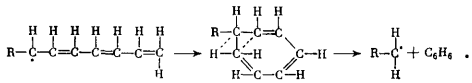
Because of the poor solubility of poly(vinyl fluoride) simple and reliable methods for determining its molecular mass were lacking until recently, so that only estimates were available [9,12,22]. In the first detailed study of the properties of solutions in dimethylformamide quantitative relations were deduced for determining the molecular mass and other characteristics of the polymer. The specimens used had been obtained in the presence of 0.003–0.2% of azoisobutyramidine at 67–97°C. The weight-average molecular mass of 9 samples studied varied from 143 000 to 654 000, and the number-average value from 76 400 to 218 000. The relation between the intrinsic viscosity and the molecular mass was given by $[\eta] = 6.42 \times 10^{-5} M_S^{0.80}$. More recently [50] molecular masses have been determined and the molecular-mass distribution has been studied for samples of the polymer obtained in the presence of α-azoisobutyronitrile, di-isopropyl peroxodicarbonate, and tributylboron monoperoxide as initiators, when the resulting polymer solutions had intrinsic viscosities of 1.58, 1.75, and 1.20 dl $g^{-1}$ respectively.

All the solvents for poly(vinyl fluoride) contain both groups that solvate the hydrocarbon portion and groups that interact with the polar part of the monomer units. Since interaction is probably of the nature of hydrogen bonding, the possibility of the latter must be taken into account in studying the interaction of various solvents with the polymer. It was established [174], for example, that replacing a hydrogen atom in polyethylene by a fluorine atom enhances its wettability by polar liquids capable of forming hydrogen bonds, whereas its wettability by non-polar liquids diminishes. A film of poly(vinyl fluoride) possesses relatively slight permeability to gases [175-177]. Its permeability to the vapours of organic solvents is also insignificant, except in the case of ketones, which probably cause the polymer to swell [178].

Sivadjian and his coworkers found [179] that at 25°C the water permeability of poly(vinyl fluoride) films is fourfold that of polyethylene, and sevenfold that of a Kel-F film. The probable reason is the possibility of free rotation of monomer units and larger segments in the crystal lattice of poly(vinyl fluoride) [137,162].

In its adhesive properties poly(vinyl fluoride) surpasses polytetrafluoroethylene by a factor of 4 and approaches polyvinyl alcohol [180]. Because of the vigorous growth in its application as a coating on various articles, however, various methods for improving its adhesive properties have recently been widely studied. In particular, this has been achieved by impregnating the surface

† Reference 145 appears to be missing and out of context: it is concerned with the heat-treatment of polymer films (Ed. of Translation).



of a film of the polymer with a thermosetting resin[93] or by activating it by means of an electric discharge in the presence of such electrophilic substances as boron trifluoride, aluminium trichloride, chlorine, fluorine, etc.[168,181] The adhesion of a film of the polymer was improved also on bombardment with helium or hydrogen atoms[182]. The adhesion of a film was increased by factors > 100 when the surface was treated with substances capable of abstracting hydrogen and fluorine atoms, such as boron trifluoride, its hydrates, or etherates in the gas or liquid phase in the presence of oxygen at normal or elevated temperatures[161,162,183-185]. The adhesive properties of a poly(vinyl fluoride) film can be improved by treating its surface with a flame[186], nitrogen, an activated plasma[187], a diazo-compound[71,188-190], concentrated sulphuric acid, or hot alkali[191]. Polyurethanes[192] and polyamides[193] have been deposited on the film surface for the same purpose. In several cases adhesion is improved by modifying not the film itself but the metal surface to which the film adheres[186,194]. Thus treating an aluminium surface with a solution of trishydroxyethylamine increases the adhesion of a film of the polymer from zero to 1.1 kg.

Poly(vinyl fluoride) belongs to a class of polymers characterised by high melting points (197°C)[12,22] with relatively low heats of fusion, as follows from its thermodynamic parameters[93]—$\Delta H_M$ = 1800 cal mole$^{-1}$ and $\Delta S_M$ = 3.87 cal mole$^{-1}$ deg$^{-1}$.

This polymer is characterised also by great thermal stability, a consequence of the strength of the carbon–fluorine bond, the regularity of structure of the main chain, and the high energy of interchain interaction. The thermal stability depends on the method and conditions of preparation of the polymer. The product of free-radical initiation in the mass begins to decompose in a vacuum at 300°C, and in air at 170°C,[195] with respective activation energies of 44.0 and 21.0 kcal mole$^{-1}$. Thermal breakdown of the product of emulsion polymerisation begins in a vacuum at 290°C, with an activation energy of 51.0 kcal mole$^{-1}$.

The thermal stability of poly(vinyl fluoride) prepared by the radiation method has been studied in the greatest detail[195-198]. The polymer obtained in the mass begins to decompose in a vacuum above 300°C, and in air at 175°C, the activation energy being respectively 61.1 and 24.0 kcal mole$^{-1}$.[197] The product of gas-phase polymerisation begins to decompose at 300°C,[196] like that obtained in the mass. With further rise in temperature, however, the former polymer undergoes more intense breakdown than does the latter. The activation energy of degradation is also lower in the first case: 36.0 and 20.0 kcal mole$^{-1}$ in a vacuum and in air respectively. The enhanced thermal stability of the polymer obtained in the mass by the radiation method is explained both by its great purity and by the partial formation of three-dimensional structures during polymerisation.

The main product of the decomposition of poly(vinyl fluoride at 310–325°C is hydrogen fluoride[199-203]. Further rise in temperature changes the composition of the degradation products: at 332°C they comprise 10 components, and at 350°C about 13 components[198]. The infrared spectra of the polymeric residues show[198] that they consist of macromolecules cross-linked one to another and containing conjugated and isolated double bonds together with fused aromatic structures. It has been suggested that the elimination of hydrogen fluoride in the thermal degradation of poly(vinyl fluoride) takes place by a molecular mechanism. The presence of considerable quantities of benzene among the decomposition products is explained[198] as a result of secondary decomposition, probably following the formation and isomerisation of polyene radicals:

Toluene and xylene are formed similarly.

In spite of the enhanced stability of poly(vinyl fluoride) its successful processing and use of the resulting articles under various conditions require at present that it should be stabilised by means of various compounds[200]. These agents should meet various requirements[199]: (i) they should be good acceptors of hydrogen fluoride; (ii) they should be dienophilic, i.e. capable of Diels–Alder reactions; and (iii) they should possess antioxidant properties. Amines and amides containing mobile hydrogen atoms[203], glycerol monolaurate[204], and salicylate salts containing one or two substituents in the benzene ring[205] have been proposed as stabilisers for poly(vinyl fluoride). Substituted 1–8-octahydro-6-methylenenaphthalenes proved to be highly effective stabilisers[206]; they also lower the viscosity of the polymer melt, are fully compatible with it, and are insoluble in water. Terpenes, thiols, and disulphides are used as stabilisers when a film of the polymer is formed by extrusion[207]. Alkyl($C_{2-6}$) hydrogen fumarates and maleates raise to 250°C the temperature at which poly(vinyl fluoride) begins to decompose in air[208].

Other compounds that can be used as thermal stabilisers are urea and its derivatives[209], 1,1-diphenylcyclohexane-*pp'*-diol[210,211], thiobismethyl-t-butylphenol[212], terpenes and certain alkenoylamides and alkenoyloxyphenylbenzotriazole-containing polymers[207], polyvinylpyridine[213], polymers of *ortho*-hydroxylated and *para*-substituted phenol[214], 2,2'-thiobisalkylphenols, phenoxides, or salts of a carboxylic acid of a bivalent organometallic phosphite and tin 2-ethylhexanoate, dialkyl pentaerythritol phosphites or their mixtures, polyhydroxylated compounds either pure or combined with sulphur- or phosphorus-containing compounds[215], and compounds of type Zn(S.$PSR_2)_2$, where R is an aliphatic (normal or branched), cyclic, or aromatic radical containing 2–18 carbon atoms[216].

Copolymerisation of vinyl fluoride with bicyclo[2,2,1]-heptadiene[214] will raise by 20 deg the temperature at which poly(vinyl fluoride) begins to decompose. Alkali-metal formates are effective thermal stabilisers for the polymer. The potassium and sodium salts have proved the best[198]: addition of 0.5% of potassium formate raises to 270°C the start of decomposition; similar results are obtained with sodium formate. Certain cross-linking agents, such as amines, ammonia[217], and *cis*-dinitrogen difluoride, are suitable for improving the thermal stability of the polymer[164].

Poly(vinyl fluoride) differs from polytetrafluoroethylene and polychlorotrifluoroethylene in possessing high radiation resistance[218,219]. Whereas ionising radiation depolymerises the second polymer with cleavage of carbon–carbon bonds in the chain, poly(vinyl fluoride), as a polymer containing hydrogen, is cross-linked. Films of the latter remain unchanged at radiation doses up to 32 Mrad, whereas a polytetrafluoroethylene film becomes appreciably shorter even with a dose of 8 Mrad.[26] Irradiation with cobalt-60 $\gamma$-rays liberates various gaseous products, mainly hydrogen fluoride[220], the rate of evolution of which depends on the dosage rate in conformity with the equation $v = kI^{0.55}$. Exposure lowers the flow point of the polymer considerably[221], which is attributed to partial degradation

of chains, amorphisation of the polymer, the plasticising effect of simple substances formed by radiolysis, and the decrease in the energy of intermolecular interaction due to the decrease in polar groups.

Study of the relaxation properties of the polymer has begun only recently. Specimens obtained in different ways exhibit structural transition temperatures of −70.43 [−70 to −43 (?) (Ed.of Translation)], 125−150, and 195−235 °C.[49, 221] In order to interpret the mechanism of these transitions, a method of forced resonance vibrations was used to examine the dynamic mechanical properties of the polymer[221]. The temperature dependence of the dynamic Young's modulus $E$ and the mechanical loss factor $\tan\delta$ correlate well with the above values. The stress−strain curves are peculiar in character[49]: the polymer breaks without necking even at temperatures up to 80 °C. The curves do not exhibit a region of rubberlike elasticity.

Pure poly(vinylfluoride) melts in air with partial decomposition. The introduction of various plasticisers to lower the melting point is therefore of direct practical interest for its processing into films, sheets, and fibres. An investigation[222] of plasticisation within and between blocks used as plasticisers dimethyl, diethyl, dibutyl, and dioctyl phthalates, tritolyl phosphate, butyl stearate, castor oil, and fluorinated hydrocarbon oils. A specimen of the polymer containing 25−30% of dibutyl phthalate does not undergo degradation cross-linking and flows irreversibly at 165 °C. Similar results have been obtained for other plasticisers. Different methods of polymerisation result in different effects of plasticisation, which is more efficient for specimens obtained by the suspension method than by other processes. The tensile strength of the plasticised polymers[223] passes through a maximum when containing 5−6% of dioctyl phthalate, 2% of castor oil, or 1% of butyl stearate. In contrast, the elongation of the specimens at break passes through a minimum. X-Ray diffraction shows[223] that the crystallinity increases on the introduction of up to 2% of a plasticiser, owing to increased mobility of the chains, but begins to diminish with further increase in the plasticiser content.

The combination of good electrical properties with enhanced thermal stability, chemical inertness, photostability, and adhesive properties makes poly(vinyl fluoride) one of the first choices for use in electrical insulation[224]. In contrast to many polymers, the rate of charge accumulation is independent of the applied voltage and the ambient humidity[225], because of the low hygroscopicity of the polymer. Surface films are coated with bishydroxyalkylamides to prevent the accumulation of static charge[226,227]. The dielectric constant and the dielectric losses are tenfold those for the corresponding polymeric chloride and bromide[228-230]. The dielectric constant usually increases with rise in temperature, but diminishes with increase in frequency[231]. The reason is that, because of the comparatively small radius of the fluorine atom, the polymer chains, are able to perform rotational movements (of small amplitude) in which the monomer units rotate, which can be regarded as segmental motion[232-234].

## IV. COPOLYMERISATION OF VINYL FLUORIDE

Methods of preparation analogous to those used for poly(vinyl fluoride) have produced many diverse copolymers with novel properties of practical value.

The copolymerisation of vinyl fluoride with ethylene was first studied by Coffman[235,236], and later by Roedel[237], in the presence of carboxylated initiators over the range 50−150 °C. A more detailed investigation was made by Burkhart et al.[27,238] in the presence of various peroxides and by means of radiation at 160 °C and 100 atm. The copolymers were in all cases enriched with ethylene, independently of the ratio of the monomers in the initial mixture. A copolymer suitable for the production of films and fibres was obtained by conducting the process in solution and in suspension[239,240]. The initiators used were tri-isobutylboron, triethylboron monammine, sodium peroxodisulphate, iron(III) hydrogen sulphate, alkylalkoxyaluminium chlorides, benzoyl peroxide, and di-isopropyl peroxodicarbonate with molecular oxygen. The radiation copolymerisation of vinyl fluoride with ethylene was also studied[241].

Products of diverse properties are obtained by copolymerising vinyl fluoride[242-245] with propene, isobutene, bicycloheptane[246], and styrene[239,247]. A copolymer of vinyl fluoride with vinyl chloride was obtained by Thomas[11] as early as 1944, and was one of the first copolymers of vinyl fluoride. Copolymers with vinyl chloride suitable for the production of films, fibres, and coatings have been prepared by the use of benzoyl peroxide[11], organoboron initiators[247,248], di-isopropyl peroxodicarbonate[249,250], sodium persulphate, iron(II) salts[64,66,247,251-255], and catalysts of Ziegler−Natta type[247].

The radiation copolymerisation of vinyl fluoride with vinyl chloride has been studied in the greatest detail[256-263]. Under otherwise similar conditions the rate of copolymerisation is considerably lower than the rate of separate polymerisation of either component. Copolymers containing up to 50 mole % of vinyl fluoride are completely soluble in dimethylformamide, dioxan, cyclohexanone, 1,1-dichloroethane, and butan-2-one, but those having a higher content of the fluoride are only partly soluble at the boiling points of these solvents. They are transparent to ultraviolet radiation, but absorb strongly in the infrared[257]. The presence of vinyl fluoride units in the copolymers leads to the appearance of infrared absorption bands in the range 1035−1175 $cm^{-1}$. Ultraviolet exposure results in new infrared bands in the region of 1610, 1700, and 1720 $cm^{-1}$, which can be assigned to vibrations of the carbonyl group and of isolated and conjugated ethylenic bonds[258]. However, the bands at 690 and 1175 $cm^{-1}$, due to vibrations of carbon−chlorine and carbon−fluorine bonds respectively, become weaker.

Copolymers of vinyl fluoride and chloride are more wear-resistant than poly(vinyl chloride)[259]. Heat-treatment at 150 and 175 °C causes loss of fluidity owing to cross-linking of the macromolecules. The losses in weight in a vacuum at 200 °C are respectively 36%, 15%, and 9% for poly(vinyl chloride) and copolymers containing 12.1 and 21.6 mole % of vinyl fluoride[261]. The respective activation energies of thermal decomposition are 27.5, 30.2, and 37.5 kcal $mole^{-1}$: i.e. increase in the proportion of vinyl fluoride in the copolymer is accompanied by a parallel improvement of thermal stability. Copolymers obtained by the radiation method were thermally more stable than those resulting from chemical initiation. Thus for a copolymer containing 21.9 mole % of vinyl fluoride the loss in weight in a vacuum at 250 °C for 6 h was 35% and 46% for samples obtained by means of radiation and chemically.

The copolymerisation of vinyl fluoride with vinylidene chloride has been initiated by various peroxides[239,247] and organoboron compounds[239] in solution or in aqueous suspension in the presence of a dispersing agent. Kinetic study of the copolymerisation in the presence of di-iso-

propyl peroxodicarbonate[260] has revealed certain laws: initially the yield of copolymer is a linear function of time, and the rate of copolymerisation is proportional to the initiator concentration to the power 0.53; at high degrees of conversion the rate curves are sigmoid; and the copolymers are enriched with vinylidene chloride whatever the ratio of the monomers in the initial mixture.

The copolymerisation of vinyl fluoride with tetrafluoroethylene can be initiated by peroxides[240,246-266], organoboron catalysts[267], and di-isopropyl peroxodicarbonate dissolved in benzene, chloroform, or dimethylformamide[65]. The copolymer containing 85 mole % of vinyl fluoride has a glass point of 212–213°C; it is soluble in cyclohexanone and dimethylformamide[19].

Copolymerisation of vinyl fluoride with chlorotrifluoroethylene has been accomplished in the mass, in solution, and in suspension in the presence of benzoyl peroxide, di-isopropyl peroxodicarbonate, organoboron compounds, and also sodium persulphate and iron(II) sulphate[247,267-269]. The resulting copolymers dissolve in acetone, form transparent films, and have good electrical and thermal stability[270]. The presence of hydrogen and halogen atoms enables these copolymers to be cross-linked by ethyl cyanoacetate, hexanonitrile, acetonitrile, cyanoacetic acid, acrylonitrile, cyanoacetamide, etc.[271]

Vinyl fluoride copolymerises with trifluoroethylene in the presence of inorganic and organic peroxides, di-isopropyl peroxodicarbonate, and organoboron initiators in the mass, suspension, emulsion, and solution[66,240,267,272]. These copolymers are characterised by enhanced heat resistance and are suitable for the production of films[273].

The copolymerisation of vinyl fluoride with vinylidene fluoride has been studied in greater detail[29,65,239,272-274]. The reaction is initiated by benzoyl peroxide, sodium persulphate, di-isopropyl peroxodicarbonate, organoboron catalysts—triethylboron, tributylboron tri-isopropylboron, diethylboron ethoxide, diethylboron chloride, diborane—and oxygen. The resulting copolymers are soluble, and have been used to obtain thin films and coatings[275,276]. Exposure of a mixture of vinyl and vinylidene fluorides to $\gamma$-rays (dose 7.2 rad) yields a copolymer containing 52.7% of vinyl fluoride units[277].

Vinyl fluoride copolymerises readily with perfluoromethacryloyl fluoride—a monomer that does not polymerise alone—both in the presence of chemical initiators and on exposure to $\gamma$-rays[278]. The products are partly soluble in dimethylformamide. The thermal stability of the copolymer improves with increase in the content of the acid fluoride.

Products that are thermally more stable than poly(vinyl fluoride) are obtained by copolymerising vinyl fluoride with 1,1-difluoroisobutene[273], perfluoropropene[29,240,247], 1,1,2,4-tetrafluorobuta-1,3-diene[279], 1,1,2- and 1,1,3-trifluorobuta-1-diene [sic][280], fluorinated ketones[281,282], perfluoronitroisomethane [sic][283,284], halogenotrifluorocyclopropanes[283], and dichlorodifluoroethylene[285].

Vinyl fluoride copolymerises with vinyl acetate in bulk, solution, or aqueous dispersion in the presence of benzoyl peroxide[251,254,268,286,287] or on ultraviolet irradiation[288]. At 0–80°C copolymerisation takes place readily in the presence of di-isopropyl peroxodicarbonate and organoboron initiators[195,239,247]. The products possess great resilience and resistance to sunlight[289]. Aqueous solutions of partly hydrolysed copolymers of vinyl fluoride with vinyl acetate yield thermally reversible gels[286]. Detailed studies have been made of the radiation copolymerisation of vinyl fluoride and acetate in the mass and dissolved in 1,1-dichloroethane, acetone, dimethylformamide, and several other solvents[290,291]. The rates of copolymerisation in the mass and in 1,1-dichloroethane solution are proportional to the dosage rate to the power 0.78 and 0.55 respectively. Increase in the vinyl fluoride content of the copolymer is accompanied by an increase in its density, rises in the glass and flow points, and strengthening of the films formed from it. The activation energy of the thermal degradation of poly(vinyl acetate) and of copolymers containing 14% and 35% of vinyl fluoride is respectively 32.0, 40.7, and 43.5 kcal mole$^{-1}$.[209]

Under the influence of $\gamma$-rays vinyl fluoride copolymerises with vinyl propionate in the mass and in 1,1-difluoroethane solution[251,254]. The product is transparent and rubberlike, softens at 140°C, and decomposes at 285°C. Vinyl fluoride has been copolymerised also with 3,5-dichloromethylstyrene[255]. The suspension copolymerisation of vinyl fluoride has been accomplished also with vinyl butyrate, benzoate, and succinate, diethyl and dibutyl maleates, and dioctyl fumarate in the presence of lauroyl peroxide[43,44,251,254]. The resulting copolymers possess enhanced resistance to heat and light with good electrical insulation.

Investigation of the copolymerisation of vinyl fluoride with acrylic and methacrylic acids and esters in the presence of free-radical initiators has established[52,239,241,292-299] that the esters are less active than are the corresponding acids. A similar rule is observed in their radiation copolymerisation[297]. The rate of copolymerisation is proportional to the dosage rate to the power 0.55 to 0.80, and increases on passing from acrylates having large groups to the acid itself. The copolymers are enriched with the acrylic monomers in all the systems studied. Copolymers of vinyl fluoride with acrylic and with methacrylic acids, whether obtained chemically or by the radiation method, do not exhibit fluidity, though the glass point falls as the vinyl fluoride content increases. The copolymers with the esters develop rubberlike elasticity, and both glass and flow points rise with increase in the vinyl fluoride content, which is attributed to the strengthening of intermolecular interaction by the presence of the polar carbon–fluorine bond. The copolymers are intermediate in thermal stability between the corresponding homopolymers of the acrylic monomer and poly(vinyl fluoride)[209].

A copolymer of vinyl fluoride with *N*-vinylpyrrolidone has been prepared by a radiation method[300]. The latter component is more reactive than the former by a factor of 63, on interaction both with its own radical and with that of vinyl fluoride. The solubility of the copolymer depends on the dosage rate and on the integral dose. Chemically prepared copolymers are completely soluble in polar solvents[301].

The copolymerisation of vinyl fluoride with acrylonitrile has been widely studied in the mass, in solution, and in suspension in the presence of benzoyl and lauroyl peroxides, di-isopropyl peroxodicarbonate, perfluoroacyls, and organoboron compounds at 0–50°C.[44,248] Water-soluble copolymers of maleic anhydride with ethylene or vinyl acetate served as dispersing agent for the suspension copolymerisation[44]. A radiation method has also been used for the copolymerisation of vinyl fluoride with acrylonitrile in the mass and in solution in benzene and dimethylformamide[256,302]. Examination of the influence of rate of irradiation on rate of copolymerisation established the same rules as for the binary systems of vinyl fluoride with vinyl chloride, vinylidene chloride, and *N*-vinylpyrrolidone. Copolymers of irregular structure are formed, but with a high content of vinyl

fluoride in the initial monomer mixture short segments comprising vinyl fluoride and acrylonitrile units alternate. The copolymers are obtained in cross-linked forms, so that they are only partly soluble; the insoluble portions of the copolymers are enriched with acrylonitrile units.

Waxlike solid copolymers of vinyl fluoride with hydrogen cyanide [303] are obtained in the presence of free-radical initiators at 135°C and 1000 atm. Copolymers of vinyl fluoride can be obtained with methylenemalononitrile, $\alpha$-cyanoacrylamide, methylenemalonamide [304], and $\alpha$-acetamidoacrylamide [305,306].

Several studies have been made also on ternary copolymers of vinyl fluoride. Thus readily soluble, non-flammable products are obtained by copolymerising vinyl fluoride and tetrafluoroethylene with chlorotrifluoroethylene [307], vinyl chloride, and vinylidene fluoride respectively. The ternary copolymer comprising 60% of vinyl fluoride, 25% of tetrafluoroethylene, and 15% of vinyl chloride possesses good physicochemical and adhesive properties [308]. Copolymerisation of vinyl fluoride with chlorotrifluoroethylene and vinylidene fluoride under the influence of $\gamma$-rays has been described [254]. Polymers that melt with decomposition are obtained by copolymerising vinyl fluoride with bishydroxyalkyl maleates and vinylidene halides [267]. Heat-resistant copolymers of vinyl fluorides with bicyclo-[2,2,1]hept-2-ene and *N*-carboxylated bicyclo[2,2,1]hept-2-ene derivatives have been prepared [309]. Copolymers having good cross-linking properties are obtained from vinyl fluoride with acrylates and $\alpha\beta$-alkenes [310]. Vinyl fluoride can be copolymerised with a small quantity of vinyl acetate and itaconic acid or with maleic anhydride and isobutyl vinyl ether to improve the dyeing properties of poly(vinyl fluoride) fibres [309]. A copolymer of high adhesive power, soluble in cheap solvents, is obtained from vinyl fluoride with vinyl benzoate, bis-2-chloroethyl vinylphosphonate, itaconic acid, and tetrafluoroethylene [311]; the product melts at 182°C.

Radiation copolymerisation of equimolecular ternary mixtures of vinyl fluoride and vinyl acetate with vinyl chloride and with methyl methacrylate respectively has been studied in the greatest detail [312-316] with the use of cobalt-60 $\gamma$-rays at dosage rates of 16, 70, and 100 rad $s^{-1}$ for various lengths of time. The order of reaction with respect to the dosage rate is respectively 0.74 and 0.64 for the two ternary systems. Copolymers obtained in the initial stages are in all cases enriched with the more active monomers—vinyl acetate with vinyl chloride and methyl methacrylate respectively—but as they are consumed the content of vinyl fluoride in the monomer mixture increases, with a consequent increase in its content in the copolymer also. The infrared spectrum [315,316] of the ternary copolymer of vinyl fluoride with vinyl chloride and acetate shows a sharp drop in intensity of carbon–chlorine stretching vibrations in comparison with the spectrum of the binary copolymer of the latter components. Furthermore, bands in the range 1000 to 1200 $cm^{-1}$ are broadened by the presence of bands due to stretching vibrations of ester carbon–oxygen–carbon bonds and of carbon–fluorine bonds. The nuclear magnetic resonance spectrum [315,316] of this copolymer contains three groups of signals, in the ranges 1.7–2.5, 4.0–4.7, and 4.9–6.5 ppm: the sharp peak at 2.0–2.05 ppm corresponds to methoxy-groups in vinyl-acetate segments; and the signal in the range 4.0–5.5 ppm is due to the superposition of signals of tertiary protons in fluoromethylene, chloromethylene, and acetoxymethylene groups. The ternary copolymers of vinyl fluoride and acetate with vinyl chloride and with methyl methacrylate respectively have lower glass points than have the corresponding binary copolymers, and these fall with increase in the vinyl fluoride content of the copolymer [314].

## V. GRAFT POLYMERISATION OF VINYL FLUORIDE

At the end of the 1960s, when the valuable properties of poly(vinyl fluoride) had become clear, intensive study began both of the preparation and of the properties of graft copolymers based on vinyl fluoride [317,318]. The low boiling point, resistance to polymerisation in the presence of material initiators, and inertness towards most polymers hinder considerably the graft polymerisation of vinyl fluoride by chemical and mechanochemical methods. The most effective has proved to be the radiation method, by which has now been accomplished the graft polymerisation of vinyl fluoride to cellulose and its derivatives, natural silk, wool, kapron fibre, polyalkenes, and halogenated and several other polymers [98,113,319-340].

The radiation graft polymerisation of vinyl fluoride to cotton cellulose and cellulose hydrate has been conducted in the mass in the presence of dimethylformamide, ethanol, and water [325,326]. With increase in the time of irradiation both the overall conversion of vinyl fluoride and the yield of the graft copolymer increase.

Graft polymerisation of vinyl fluoride from the vapour phase goes best on mercerised and "inclusion" cellulose [326]. This is due to enhancement of the reactivity of cellulose by the loosening of its structure during mercerisation and inclusion. The increase in weight due to the grafted poly(vinyl fluoride) is larger in the presence of the vapours of such "including" substances as dimethylformamide or isopentanol than on an already "included" specimen. The larger gain in the first case is due to the grafting of vinyl fluoride at the instant at which the cellulose swells.

The grafting of poly(vinyl fluoride) to cotton cellulose weakens the infrared absorption band in the range 1325 to 1350 $cm^{-1}$, due to deformation vibrations of primary hydroxy-groups [330]. This indicates that active grafting centres are located at these groups. The band in the region of 900 $cm^{-1}$ also diminishes in intensity, which is attributed to loosening of the structure of compact segments of cellulose under the influence of the grafted poly(vinyl fluoride) chains.

The infrared spectra of cellulose hydrate [330] exhibit the same changes as in cotton cellulose, but the weakening of vibrations in the range 3200–3300 $cm^{-1}$ is most clearly evident. Absorption diminishes also in the range 1000 to 1020 $cm^{-1}$, which suggests that active centres may well be formed not only at primary but also at secondary hydroxy-groups. Modified cellulose hydrate containing 8% of poly(vinyl fluoride) resists the action of sulphuric acid for 1 month, whereas an unmodified specimen breaks down completely within a few minutes. Increase in the content of the grafted polymer diminishes the sorption of water vapour, which is attributed to the strongly hydrophobic character of the poly(vinyl fluoride) side-chains.

Study of the thermal stability of graft copolymers of cotton cellulose with poly(vinyl fluoride) in a vacuum and in air over the temperature range 270–370°C has established [333] that the initial rates of decomposition of the copolymers are considerably lower than those of the initial cellulose.

The graft polymerisation of vinyl fluoride on cellulose triacetate fibre is more rapid than on the diacetate [327], which is due to the greater radiation sensitivity of the

former. Graft copolymers of the diacetate and the triacetate containing >40% of poly(vinyl fluoride) dissolve neither in acetone nor in chloroform, and undergo partial swelling in dimethylformamide and cyclohexanone.

Graft polymerisation of vinyl fluoride to natural silk does not take place in the absence of solvents [331]. The presence of such liquids as water, methanol, and ethanol has a sensitising effect on grafting, and the increase in weight reaches 20% on the weight of the silk. The grafting of vinyl fluoride effects a marked improvement in the acid resistance of natural silk, which is attributed to shielding of the peptide links by the grafted polymer chains [332,333]. Furthermore, grafting improves the resistance of silk to heat and light, as well as its oil- and water-repellent properties. Electron microscopy has established that the grafting of vinyl fluoride to natural silk diminishes the fibrillarity characteristic of the original fibre [335,341]. Individual globular structures are also observed, whose presence is due to the grafted chains of lyophobic poly(vinyl fluoride).

Vinyl fluoride has been grafted from the vapour phase to kapron fibre at dosage rates of 12–100 rad $s^{-1}$, [113,317,323] when the resulting copolymers contain up to 31% of the grafted polymer. In the presence of water vapour the gain in weight increases to 60%. [336] This may be due to the great swelling of kapron fibre in water vapour and to the sensitising action of radicals formed in the radiolysis of water. The yield of graft copolymer is lower in the presence than in the absence of methanol and ethanol vapours. Grafting is influenced also by the fibre structure [336]: the gain in weight is larger on an unoriented than on an oriented fibre and a tyre cord. The grafting of vinyl fluoride enhances the light, heat, and chemical resistance of kapron [113].

Radiation vapour-phase grafting of vinyl fluoride has been accomplished also on natural wool [333]. Grafting is greatest in the presence of water vapour. At 90°C modified wool containing 10% of a poly(vinyl fluoride) graft dissolves more slowly than unmodified wool in caustic soda by a factor of almost 400.

Detailed studies have been made on the radiation graft polymerisation of vinyl fluoride to polyethylene, polypropylene, and polyisobutylene. Vinyl fluoride has been grafted to polyethylene (in film or powder form) from the vapour phase at 38°C and 27.5 atm [98,113] with dosage rates varying from 10 to 100 rad $s^{-1}$. The radiation-chemical yield fluctuates within the range 100–3800 mol./100 eV in the case of a film, and 870–9540 mol./100 eV for a powder. A graft copolymer containing <30% of poly(vinyl fluoride) is completely soluble in boiling toluene and in xylene [113]. With further increase in the content of the graft the solubility diminishes, and a gel is formed consisting of a graft copolymer of polyethylene containing very long poly(vinyl fluoride) side-chains. The grafting of vinyl fluoride increases the density of polyethylene to 1.082 g $cm^{-3}$ for a copolymer containing 50.2% of poly(vinyl fluoride). The splitting of the absorption band due to vibrations of the methylene group in the region of 720 and 730 $cm^{-1}$ in the infrared spectra of the copolymer [98] gradually disappears with increase in the poly(vinyl fluoride) content. This shows that grafting takes place both in amorphous and in crystalline regions of polyethylene, and leads to breakdown of the crystal structure of the latter. In graft copolymers containing ≥25% of poly(vinyl fluoride) fluidity is completely absent owing to cross-linking of the side-chains of the latter by the elimination of hydrogen fluoride under the influence of temperature [98].

As with polyethylene the modification of polypropylene by the grafting of vinyl fluoride increases its density while diminishing its solubility and swellability [329]. Graft copolymers of polyisobutylene with vinyl fluoride has been prepared in cyclohexanone with equimolecular proportions of polymer, monomer, and solvent and dosage rates of 9–126 rad $s^{-1}$. [338] As in the other cases, the poly(vinyl fluoride) content of the copolymer increases with the dose whatever the dosage rate. This is accompanied by increase in the heat and chemical resistance of the copolymer.

Vinyl fluoride has been grafted to polytetrafluoroethylene with the aim of improving the adhesive properties and diminishing the cold flow of the latter [338]. When polytetrafluoroethylene is irradiated in liquid vinyl fluoride, the homopolymer is formed preferentially. Better results are obtained by conducting the graft copolymerisation from the vapour phase. The resulting graft copolymers are readily wetted by polar liquids while retaining all the valuable properties of the original polytetrafluoroethylene.

Radiation grafting to poly(vinyl chloride) has been accomplished both in pure vinyl fluoride vapour and in the presence of vapours of various solvents [338–340], among which the presence of 1,1-dichloroethane gave the largest degree of grafting. With increase in the poly(vinyl fluoride) content of the copolymer from 6.7% to 35.8% the loss in weight in a vacuum and in air decreases by factors of 1.5–4, and 1.5–6 respectively [342]. Vinyl fluoride has been grafted also on khlorin fibre, obtained from chlorinated poly(vinyl chloride) [113,317,343]. The rate of the graft copolymerisation is proportional to the dosage rate to the power 0.61. Improvement in the heat, light, and chemical resistance of khlorin is noted.

Vinyl fluoride has been grafted on polystyrene [338], polyvinyl alcohol [98,113], poly(vinyl acetate) [98,338,340], and poly(methyl methacrylate) [98,337,338]. With polystyrene dosage rates of 9–126 rad $s^{-1}$ were used in 1,1-dichloroethane and chloroform. Increase in the poly(vinyl fluoride) content of the copolymer was accompanied by decrease in its swellability in toluene and fall in its glass point. A copolymer containing 5.6% of grafted poly(vinyl fluoride) decomposes at little more than one-sixth of the rate of decomposition of the original polystyrene.

Under identical conditions vinyl fluoride can be grafted considerably more rapidly to kapron than to polyvinyl alcohol [98,113]. This is explained by the low activity of the macroradical from the polymeric alcohol and by the formation of a very compact, oriented jacket on the surface of the fibre during its formation. Fluidity is completely absent from graft copolymers containing 28% of poly(vinyl fluoride), as from graft copolymers of polyethylene, owing to cross-linking at the time of the thermal test.

The radiation grafting of vinyl fluoride on poly(methyl methacrylate) has been accomplished in benzene and in 1,1-dichloroethane [98,338]. The glass points of the resulting graft copolymers were lower than that of the original methacrylate polymer, which is attributed to the plasticising action of the grafted chains. The grafting of vinyl fluoride on poly(vinyl acetate) strongly enhances the resistance of the latter to organic solvents and mineral acids [338], as well as raising the flow point. Thus graft copolymers containing 11.2% and 59.0% of poly(vinyl fluoride) have flow points of 116 and 198°C respectively.

Although poly(vinyl fluoride) has relatively good adhesive properties among fluorinated polymers, and can be dyed and processed comparatively readily, further improvement in these properties is of great practical interest. For this purpose styrene [343–346], methyl meth-

acrylate [344,346,347], vinyl acetate [346,347], and vinylidene chloride [344] have been grafted on a poly(vinyl fluoride) film, both under the influence of cobalt-60 $\gamma$-rays and by the use of an electron accelerator, and methyl methacrylate has been grafted on a copolymer of trifluoroethylene and vinyl fluoride under the influence of ultrasound [345]. Among these monomers methyl methacrylate gave the best graft [346], because of its high radiation sensitivity: almost all the methyl methacrylate was grafted during the first hour of irradiation. In the case of styrene the rate of grafting passes through a maximum with increasing time of exposure [343], which is attributed to the shielding effect of the more radiation-resistant grafted polystyrene.

These monomers form the sequence

vinyl acetate < styrene < methyl methacrylate

of increasing rate of grafting to poly(vinyl fluoride), which correlates with their sorption on the polymer [346]. The graft layer formed initially has a significant influence on the subsequent course of the process. Grafting obviously loosens the film surface, which facilitates diffusion of the monomers into the interior. Loosening of the structure of poly(vinyl fluoride) by grafting has been confirmed by X-ray diffraction and by a study of the density of graft copolymers [346,348].

The thermomechanical curves of graft copolymers containing up to 30% of methyl methacrylate or styrene are analogous to those of the original poly(vinyl fluoride) [346,347]. With further increase in the content of the grafted component segments appear in the curve corresponding to a vitreous state, rubberlike elasticity, and viscous flow.

Grafting the above monomers improves the wettability and dyeing properties of a poly(vinyl fluoride) film [346-348]. This effect is due firstly to the appearance on the film surface of functional groups that increase its affinity for liquids and secondly to diminished crystallinity of the polymer. With the same content of the grafted polymer the wettability by water increases in the sequence

poly(methyl methacrylate) < polystyrene < poly(vinyl acetate).

The increased adhesive power of modified poly(vinyl fluoride) is due [346] to the presence of the grafted side-chains, not to any other factor, in particular not to the influence of the $\gamma$-rays. The dyeability of the graft copolymers of poly(vinyl fluoride) increases in the sequence [348]

polystyrene < poly(methyl methacrylate) < poly(vinyl acetate).

This rule is due to the nature of the grafted polymers, since under identical conditions the dyeability of the polymers themselves also increases in the same sequence.

## VI. PROCESSING AND APPLICATION OF VINYL FLUORIDE POLYMERS

Poly(vinyl fluoride) can be processed into appropriate articles by all the methods that have been developed for and applied to other thermoplastic polymers, although its characteristic features must be taken into account. Injection moulding of poly(vinyl fluoride) above 200°C was suggested [12] for the production of films or monolithic articles possessing good impact strength. The possibility of film formation from solution was also examined [12]. A dimethylformamide solution containing 8% of the polymers was quite adequate for this purpose, and film formation was hindered from higher solution concentrations. However, the only method that found wide application for the production of poly(vinyl fluoride) films was extrusion. Various stabilisers must then be used to prevent thermal degradation [218,349].

The most convenient method has proved to be moulding in the presence of so called latent solvents, which tend to lower the melting point and diminish orientational stretching of the polymers, thereby preventing degradation [350]. Latent solvents, by causing partial dissolution and good swelling, promote high dispersion of the polymer. Homogeneous films containing up to 50% of poly(vinyl fluoride) have been prepared from such fine dispersions [81,93,351-357]. The latent solvent most often employed is dimethyl sulphoxide, either alone [350,358-360] or in the presence of an electroluminescent substance. Various lactones [351,353,361], tetramethylurea, triethyl phosphate [78], pyrrolidones [93], and piperidines [362,363] have also been proposed as latent solvents.

A method has been suggested for the production of both films and fibres from aqueous dispersions of poly(vinyl fluoride) in the presence of small quantities of a latent solvent [78,364,365]. Mixtures of water and sulpholan have also been proposed as dispersion medium [356]. The role of the latent solvent is aggregation of particles; although aggregates are formed from the accumulation of a few particles, they are separated from one another by a thin layer of solvent.

The processing of poly(vinyl fluoride) into films can be facilitated by preparing dispersions during the actual synthesis of the polymer in the presence of latent solvents. This avoids isolation and redissolution or redispersion of the polymer. Thus a film prepared from a 22% dispersion of poly(vinyl fluoride) synthesised in a medium containing 71% of dimethyl sulphoxide and 7% of water has good mechanical properties [366]. Opaque films devoid of lustre can be obtained by introducing into the dispersion an opalescent substance such as titania [367] or silica [368]. Various pigments, stabilisers, and plasticisers are also used in the preparation of poly(vinyl fluoride) films [152,369-377].

Several difficulties are involved in orienting the films at low temperatures: in all cases local stretching occurs, leading to non-uniformity of thickness over the area of the film [152]. These difficulties can be avoided by orienting films containing at least 35% of a latent solvent [377]. In this way a film 1.04 mm thick has been obtained from a sheet of poly(vinyl fluoride) 13.9 mm thick. At the present time films of this polymer are produced only in the USA, under the name Tedlar [378]. Several brands are available, differing in tensile strength—from the high value of 1265 kgf cm$^{-2}$ with great bending strength to the low value of 492 kgf cm$^{-2}$.

During recent years the possibility of obtaining fibres from poly(vinyl fluoride) has also been studied. Thus Knunyants et al. [379] developed methods for obtaining a technical fibre from the bulk polymer. A fibre can be prepared from the paste obtained by drying an emulsion of the polymer stabilised with partly hydrolysed adiponitrile [380], which acts also as a plasticiser. Monofilaments of tenacity 5 g denier$^{-1}$ can be formed from the polymer of reduced viscosity 1.25, by extruding a coalescing dispersion into a latent solvent [381].

The use of poly(vinyl fluoride) in coatings has proved especially fertile. They are distinguished by high adhesion, resistance to chemical reagents, abrasion, and weathering, and a wide range of working temperatures. The polymer composition for their production is prepared

by methods that are widely employed in the paint and varnish industry [350,382,383]. It contains not only the polymer and solvents but also pigments, stabilisers, fillers, and modifiers [180,350,384,385]. Pigments are selected on the basis of their thermal stability during baking and their behaviour in the final coating [350]. Various fillers, e.g. calcium silicate, magnesium silicate, and silicon dioxide, are also used [350].

Various viscosity modifiers are necessary ingredients in obtaining polymer coatings [350]. They should be soluble in an inert solvent and thermostable, and should neither prevent adhesion nor exert an adverse influence on the properties of the coating. Various acrylate polymers and poly(vinyl acetate) are generally used as modifiers [385]. In isolated cases the dispersion obtained during emulsion polymerisation can be used directly to obtain coatings [386]. A properly prepared and applied dispersion of poly(vinyl fluoride displays excellent adhesion to metals, without the need to use an organic primer. The dispersions are applied with spraying equipment, by means of reversing rollers, by dipping, and by centrifugal casting [350]. Procedures have been suggested for applying the powdered polymers in a stream of gas flowing at 100 m $s^{-1}$. [387]

Various compositions have now been developed for definite fields of application—to obtain transparent protective coatings, chemically stable and corrosion-resistant pigmented coatings and linings, pigmented architectural claddings [350]. In agriculture poly(vinyl fluoride) films can successfully replace those of the chloride and polyethylene for covering hotbeds and for protecting plantings from early spring frosts [388].

Poly(vinyl fluoride) can be widely applied in the building industry [165,168,350]. Panels coated with the polymer are used as external and internal facings in residential and industrial buildings [389,390]. Films of the polymer are used also for coating ornamental laminated plastics [391-399], asbestos goods [400], rolls of aluminium foil [401], charts, dials, signs and other decorative items, window and door fittings, and furniture upholstery. The useful life of such a coating functioning in the open air exceeds 25 years.

A film of poly(vinyl fluoride) in combination with polystyrene is used in the construction of luminous panels [402]. If a poly(vinyl fluoride) film 0.025 mm thick is attached to the inner surface of luminous polystyrene panels, they will function for at least 20 years.

A new brand of poly(vinyl fluoride) Delvar is also widely used for coating various articles, including those used in the building industry [403]. It is a component of the chemically resistant coating Delbon, which is unlike Tedlar film in being applied to a surface without a priming or an adhesive. Veneers having coloured poly(vinyl fluoride) coatings are manufactured under the name Welwood PF-L, [404-406] and asbestos-cement panels under the names Colorbest and Ternol [407]. Because of its great chemical resistance this polymer is used also to protect various cement structures from leaching, marine salts, and water vapour [408].

The good dielectric properties and retention of flexibility at low temperatures are recommendations for the use of poly(vinyl fluoride) film in the manufacture of electric batteries intended to function at low temperatures [409]. A more thermostable polymer, partly dehydrofluorinated and containing 26–38 wt.% of fluorine, is used as an insulator to separate two electrodes, acting as a capacitor [410]. Copolymers of vinyl fluoride with alkyl vinyl ethers have also proved suitable for this purpose [411]. Poly(vinyl fluoride) has been used in making the diphragms of electrolytic cells for the manufacture of chlorine [412].

Poly(vinyl fluoride) is used in the automobile and shipbuilding industries for coating various copper, brass, steel, and aluminium articles [166,350,413-418]. It provides excellent protection from corrosion and does not affect the decorative effect of the main material. During recent years coatings based on the polymer and on various copolymers of vinyl fluoride have come to be widely used in the container industry, instrument-making [350], and solar energy equipment [419], as well as for infrared detectors [420].

Among various fluorinated polymers poly(vinyl fluoride) exhibits relatively high radiation resistance [421]. It has therefore found application in nuclear technology [422,423] and is used as a coating for the protection of spacecraft [350,382,424]. Another reason for its use in space technology is that its loss in weight is only 0.5% under a residual pressure of around $10^{-6}$ mmHg at ~150°C, while articles made of it retain their appearance and shape [425,426].

The small water adsorption and high elasticity have made possible the use of vinyl fluoride polymers and copolymers for the production of photographic films [427,428]. Chemical industry is a promising field for application of the polymer, which can be used to cover and line tubes, extractor fans, reservoirs for fresh and salt water, reaction vessels, drying units, etc. [429-431] Poly(vinyl fluoride) also provides a coating for external and internal surfaces of chemical plant to prevent corrosion by chlorine, hydrochloric acid, caustic soda, acetone, petrol, tetrachloromethane, and butan-2-one [350,432].

Poly(vinyl fluoride) and various copolymers especially modified with ultraviolet absorbers are widely used for coating polyethylene [148] and poly(ethylene terephthalate) [433] films, polychloroprene felt [282,377,434], wood, and textiles [49]; they are used also as lubricants and impregnants [435].

It is thus obvious that vinyl fluoride polymers are worthy of comprehensive examination as materials having an extremely wide range of application.

# Structural Chemistry of Substituted Benzene Derivatives

Z.V.Zvonkova

Structural data for substituted benzene derivatives (bond lengths and angles) are summarised. A structural scheme of the deformation of $\sigma$ bonds in the benzene ring under the influence of electron-donating and electron-accepting substituents is based on X-ray diffraction results. The general rule is revealed that the valence angle of a substituted carbon atom in the benzene ring increases with the nuclear potential of the substituents. A correlation is established between such angles and the Taft inductive constants. The structural characteristics of substituted benzenes are compared with those of metal complexes. A list of 258 references is included.

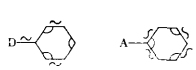
## I. INTRODUCTION

The present Review is based on X-ray diffraction data for crystals of substituted benzene derivatives, and is confined to a discussion of the nature of the intramolecular interaction between atoms. Questions of the packing of molecules in a crystal and the interaction of non-bonded atoms are not considered. Special monographs[1] and reviews have been devoted to the latter problem.

The modern theory of organic chemistry interprets the properties of molecules in terms of the displacement of valency electrons by inductive and conjugative mechanisms[2,3]. The electronic nature of chemical substituents was first characterised quantitatively by Hammett's $\sigma_p$ and $\sigma_m$ constants[4]. These constants were subsequently separated by Taft and Lewis[5] into components representing inductive $\sigma_I$ and conjugative $\sigma_R$ effects. Dewar and Grisdale[6] have since suggested that five mechanisms should be distinguished--the field $\sigma$-induction, $\pi$-induction, mesomeric, and electromeric effects--but Hammett[4] considers that there is no need to introduce more than two structural variables.

It is of great importance to place the qualitative electronic theory of organic chemistry on a quantitative basis by establishing correlations[7] between the structure and the physicochemical properties of a molecule. The chemical shifts $\delta_H$ and $\delta_{^{19}F}$ of the nuclear magnetic resonance spectra are adopted as sensitive measures of the effects of substituents on the distribution of electron density in the benzene ring. A correlation has been found between the chemical shifts and the Hammett constants.



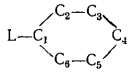
X-Ray structural investigations of the nature of the donor–acceptor interaction in organic molecules provide the most direct information for establishing a correlation between structure and physicochemical properties.

## II. STRUCTURAL SCHEME OF SUBSTITUTED BENZENES

The benzene molecule is a regular hexagon in which the angles between the bonds are 120° and the carbon–carbon bond lengths are 1.392(4) and 1.398 Å according to X-ray[8] and neutron[9] diffraction respectively. The mean carbon–carbon bond lengths in aromatic compounds are 1.398(5)–1.395(3) Å.[10,11]

The influence of an acceptor substituent A on the geometry of a substituted benzene molecule was first established for nitro-derivatives by Trotter[12], Bailey and Prout[13], Carter, McPhail, and Sim[14], and many later investigators. The valence angle of the substituted carbon atom C($NO_2$) in the ring has increased to a value that is independent of the angle of deflection of the nitro-group from the plane of the benzene ring, while the ($NO_2$)C–C bond length is shorter than in unsubstituted benzene. In a paper at the Ninth International Congress of Crystallography Hamilton[15] pointed out that donor substituents D—nitrogen, phosphorus, and antimony—diminish the C(D) bond angles and increase the (D)C–C bond lengths in the benzene ring. Papers both at the First All-Union Conference on Organic Crystal Chemistry[16] and at the Tenth International Congress of Crystallography[17] reported that the C(D,A) angles increase with the electronegativity of the elements along a period on passing from $\sigma$ donors to $\sigma$ acceptors, and also that they correlate with the Taft $\sigma_I$ inductive constants.

A scheme of deformation of $\sigma$ bonds in the benzene ring under the influence of electron-donating and electron-accepting substituents D and A was based[18] on X-ray diffraction data. According to the scheme the structure of such substituted benzenes can be represented as



where a tilde represents a shortened carbon-carbon bond length, and an arc an increased valence angle at a carbon atom, in the ring. A consequence of the rehybridisation of $\sigma$ bonds is an increased proportion of the $p$ state of the hybrid $sp^2$ orbital of the carbon atom in an exocyclic A–C bond, with a resultant increase in the proportion of the $s$ state in the adjacent (A)C–C bonds forming an angle exceeding 120° in the benzene ring. The increased proportion of the $s$ state of the carbon atom leads to contraction of the bond. In an exocyclic D–C bond the proportion of the $s$ state of the hybrid orbital of the carbon atom is increased, and also the proportion of the $p$ state in the (D)C–C cyclic bonds, so that the angle they form is $< 120°$, while the (D)C–C bond becomes longer.

Such a view of the nature of atomic interaction in substituted benzenes reflects the general character of the structure of molecular compounds and is consistent with several published communications. As Bent showed[19], the *s* component of a hybrid orbital has a tendency to concentrate in those orbitals that are directed towards electropositive atoms. This conclusion is based on the results of a microwave spectral analysis of molecules of general formula HCO.R (where R = H, $CH_3$, OH, $OCH_3$, F), in which increase in the electronegativity of the substituent R is accompanied by contraction of the C–H and C=O bonds and increase in the H–C=O angle. A similar conclusion can be reached by quantum-chemical calculation[20]: formation of a D–A σ bond leads to decrease in the proportions of the *s* state of the electropositive atom D and of the *p* state of the electronegative atom A in comparison with the D–D and A–A σ bonds. Hence the populations of σ bonds can be written D(*p*)–(*s*)C and A(*s*)–(*p*)C. Since *p* electrons are more weakly bound to the atomic nucleus than are *s* electrons, an acceptor A acquires a *p* electron preferentially from the carbon atom, but a donor D donates a *p* electron preferentially to the carbon atom.

## III. STRUCTURAL CHARACTERISTICS (BOND LENGTHS AND ANGLES)

In the most exact modern X-ray structural work the accuracy of the determination of interatomic distances and bond angles is respectively ±0.001–0.003 Å and ±0.1–0.3 deg. More detailed information on the accuracy of individual data can be found in the references cited. Systematic information on the crystal structures of organic molecules is given in works of reference[21-24]. The above structural scheme of the deformation of σ bonds in the benzene ring enables conclusions on the σ donor–acceptor character of a substituent L in any structure to be reached directly from the angle at the substituted carbon atom C(L) in the benzene ring.

### 1. Monosubstituted Benzene Derivatives

Experimental values are averages for the chemically equivalent valence angles at $C_{(2)}$ ($C_{(6)}$) and $C_{(3)}$ ($C_{(5)}$) and bond lengths $C_{(1)}$–$C_{(2)}$ ($C_{(1)}$–$C_{(6)}$), $C_{(2)}$–$C_{(3)}$ ($C_{(5)}$–$C_{(6)}$), and $C_{(3)}$–$C_{(4)}$ ($C_{(4)}$–$C_{(5)}$). It is difficult to judge from experimental results the extent to which the alternation of bond lengths and angles is transmitted to all atoms in the benzene ring. One difficulty is the thermal oscillation of the atoms, which becomes stronger on passing from the centre of gravity of the molecule to the terminal atoms, producing a tendency for their bonds to contract. In any case, changes in bond angles and lengths are more clearly defined for the three carbon atoms nearest the substituent. The changes in the angle at the substituted atom C(L) provide a considerably more sensitive criterion for regarding the substituent L as a donor D or an acceptor A than do the changes in bond lengths.

Alkyl substituents produce a sharp decrease below 120° in the cyclic angle at the carbon atom, and are thus strong σ donors. In tetraphenylmethane[25], triphenylmethane[26], diphenylaminotriphenylmethane[27], *N*-1′-phenylcyclohexylpiperidinium chloride[28], 3-diphenylacetoxy-1-ethylpiperidinium chloride[29], (+)-benzylmethyl-1-methyl-2-*N*′-phenylpropionamidoethylammonium bromide[30], and tribenzylamine[31] this angle is respectively 117.5°, 117.8°, 117.9°, 117.6°, 117.4°, 116.8°, and 117.4°.

Although hyperconjugation of methyl groups has been discussed in the literature, structurally the need for this hypothesis does not arise. In several cases it is advisable to use instead a mechanism of σ rehybridisation, since with donor substituents D the two mechanisms—σ rehybridisation and π conjugation—have the same effect on the structural characteristics of the benzene ring: the D–$C_{(1)}$ and $C_{(2)}$–$C_{(3)}$ bonds contract, the (D)$C_{(1)}$–$C_{(2)}$ bond becomes longer, and the cyclic $C_{(1)}$(D) angle becomes smaller.

Substituents containing multiple bonds C=C and C≡C also have a well defined σ-donor character. In structures possessing a substituent vinyl group—tetraphenylethylene[27], 1,2-diphenylcyclopentene[32], tetraphenylcyclopenta-1,3-diene[33], *trans*-stilbene[34], 2,3-diphenylindole[35], 2,5-distyrylpyrazine[36], *cis*-1,*cis*-3-distyrylazulene[37], anthr-9-yl styryl ketone[38], β-*p*-tolylthio-*trans*-cinnamic acid[39], chalcone[40], 1,6-diphenylocta-1,2,4,5-tetraene[41], and dicinnamyl disulphide[42]—the C(C :C) angles are respectively 118.7°, 117.6°, 118.3°, 118.1°, 118.9°, 117.7°, 118.2°, 118.5°, 118.6°, 118.2°, 117.5°, and 118.4°. The substituted carbon atoms in biphenyl[43], terphenyl[44], and quaterphenyl[45] have bond angles of 117.9°. In 1,8-bisphenylethynylnaphthalene[46] C(C :C) angle is 119.2°. Thus the vinyl group is a stronger σ donor than the ethynyl group, a result that is consistent with the chemical properties of these molecules.

The σ-acceptor power increases on passing from the vinyl to the carbonyl group. The C(C :O) angle in benzamide[47], acetyl benzoyl peroxide[48], ethylene dibenzoate[49], hippuric acid[50], and 2-hydroxy-4-methoxybenzophenone[51] is respectively 120.1°, 119.7°, 119.9°, 120.1°, and 119.8°. In *N*-diphenylmethyleneaniline[52] the C(C :N) and C(N :C) angles are respectively 119.2° and 119.9°; and in αα-*N*-triphenylnitrone[53] the C(C=N→O) and C(O←N=C) angles are 118.2° and 122.0°: the angle in the benzene ring is larger when the substituents bind through a nitrogen atom than through a carbon atom. Clearly, the nitrone group can act both as a strong σ donor and as a strong σ acceptor.

Table 1. Bond angles C(D,A) and nuclear potentials $z^*/r$ of elements in monosubstituted benzene derivatives.

| D, A | C(D, A), ° | $z^*/r$ | D, A | C(D, A), ° | $z^*/r$ |
|---|---|---|---|---|---|
| B | 116.7 | 3.13 | Al | 116.4 (113.7) | 2.78 |
| C | 117.5 | 4.21 | Si | 116.1 | 3.55 |
| N | 119.4 | 5.27 | P | 118.9 (117.6) | 4.36 |
| O | 120.5 | 6.23 | S | 120.2 | 5.24 |
| F | 123.4 | 7.32 | Cl | 122.4 | 6.14 |
| Ga | 116.9 | 3.97 | | | |
| Ge | 118.3 | 4.62 | | | |

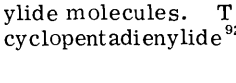
With respect to the donor–acceptor characteristics of heteroatoms differing in their electronic nature, Table 1 summarises the C(D,A) bond angles with donor D and acceptor A substituents, and compares them with the nuclear potentials of the elements $z^*/r$ (where $z^*$ is the effective charge on the nucleus and $r$ the covalent radius

of the atom). Values of the angle are given for triphenylborane[54], tetraphenylmethane[25], aniline[55], phenol[56], fluorobenzene[57], di-μ-phenylbisdiphenylaluminium[58], tetraphenylsilane[59], pentaphenylphosphorane[60], diphenyl disulphide[61], chlorobenzene[62], triphenylgallane[63], and tetraphenylgermane[64,65].

The general rule is that the cyclic angle at the substituted carbon atom C(D,A) increases with the nuclear potentials of the substituents along a series in the Periodic System:

$$C(B)<C(C)<C(N)<C(O)<C(F)$$

$$C(Al)<C(Si)<C(P)<C(S)<C(Cl).$$



The C(D,A) angles of elements in the third and fourth periods are smaller than those in the second and fourth periods. The reason for such behaviour is that $z^*/r$ increases monotonically along a period, and changes abruptly within a group[66,67].

In the main, Table 1 correctly reflects the trends in the variation of the bond angles of the elements. These tendencies can be revealed by analysing the experimental results for complicated structures. As examples the C(Si) angles in phenyl-triphenylsilyldiazomethane[68], chlorobis-π-cyclopentadienyl-triphenylsilylzirconium(IV)[69], 2,2-diphenyl-2-silaindane[70], and acetyltriphenylsilane[71] are respectively 117.1°, 117.0°, 117.6°, and 117.5°; the C(P) angles in *p*-dimethylaminophenyldiphenylphosphine[72], bisdiphenylphosphinoacetylene[73], and dimethylphenylphosphine[74] are 118.1°, 118.8°, and 117.7°; the C(Ge) angles in acetyltriphenylgermanium[75] and triphenylgermanium *p*-t-butylphenyl sulphide[76] are 118.3° and 118.9°; and the C(N.N) angles in tetraphenylhydrazine[27] and 1-phenyl-thiosemicarbazide[77] are 119.1° and 119.2°. The number of known structures containing elements of the fifth series as substituents is still small.

The formation of double bonds with carbon, oxygen, and sulphur atoms increases the σ-acceptor power of heteroatoms. This is observed in the structures of methylenetriphenylphosphorane[78] (in which the C(P:C) angle is 119.1°), bistriphenylphosphoranylidenemethane[79] C(P:C:P) 119.2°, triphenylphosphine oxide[80] C(P:O) 118.9°, *p*-chloro- and *p*-bromo-phenyldiphenylphosphine oxides[81,82] and the corresponding phosphine sulphides[83,84]—C(P:O) 119.1° and 119.7°; and C(P:S) 119.5° and 119.2°—phenylsulphinylacetamide[85] C(S:O) 121.6°, diphenyl disulphone[86] C($SO_2$.$SO_2$) 122.5°, and 3-methyl-3-phenylsulphinylbutan-2-ol[87] C(S:O) 120.3°.

A significant increase in σ-acceptor power occurs with increase in the positive charge on the heteroatom. In the case of the nitrogen atom, however, the same effect may be produced by loss of π conjugation with the benzene ring due to steric hindrance. We note increases in the C(N.C:O) angle in *N*-phenylacetanilide[88], (+)-benzylmethyl-1-methyl-2-*N'*-phenylpropionamidoethylammonium bromide[30], *N*-methylacetanilide[89], and isonitrosoacetanilide[90] (120.2°, 120.2°, 122.8°, and 120.2°); and the C(N.C:S) angle in 4-phenyl-thiosemicarbazide[91] is larger than the C(N.N) angle in 1-phenyl-thiosemicarbazide[77] (121.1° and 119.2°).

The fact that the charges on substituents influence the deformation of the benzene ring has been established in ylide molecules. The structure of triphenylphosphonium cyclopentadienylide[92] shows an increase in the

angle 119.6° in conformity with the charge on the phosphorus atom of +0.69 e, found by phostoelectronic spectroscopy. Still larger increases in angles have been established in triphenyl-*N*-toluene-*p*-sulphonyliminophosphorane[93] C($P^+$.$N^-$) 120.1° and *SS*-diphenyl-*N*-toluene-*p*-sulphonylsulphidimine[94] C($S^+$.$N^-$) 121.1°.

The C($As^+$) angle of 121.7° in tetraphenylarsonium triiodide[95] and the C($P^+$) angles of 119.9° and 120.0° in tetraphenylphosphonium[96] and methyltriphenylphosphonium bistetracyanoquinodimethanes[97] suggest that positively charged arsenic and phosphorus atoms lose their σ-donor properties. The positively charged iodine atom in diphenyliodonium nitrate[98] remains a strong σ acceptor with C($I^+$) 122.4°, but negatively charged boron and indium atoms remain strong σ donors, as is indicated by C($B^-$) angles of 114.1° and 116.3° in π-cyclopentadienyl-η-ruthenium(II) tetraphenylborate[99] and bis(trimethyl phosphito)-rhodium(I) tetraphenylborate[100] and by a C($In^-$) angle of 118.2° in sodium tetraphenylindate[101]. The dependence of the C(P) angles on the partial charges on the phosphorus atoms in substituted benzenes has been reported[102].

The accurate experimental data that have now accumulated are still insufficient as a basis for quantitative conclusions on the σ bonds of all metals in the Periodic System. Evidence that the atoms of transition metals are among the strongest σ donors is provided e.g. by the angles C(Zn) 115.8°, C(Ni) 115.9°, and C(Cr) 115.2° in bis[phenyl(acetylacetonato)zinc]-bis(acetylacetonato)zinc[103], phenyl-(π-cyclopentadienyl)(triphenylphosphine)nickel[104], and *cis*-diphenylbis-2,2'-bipyridylchromium iodide[105].

## 2. Disubstituted Benzene Derivatives

It is of interest to trace the changes in structural characteristics as the number of substituents is successively increased. The donor–acceptor characteristics of disubstituted benzenes differ according to the orientation of the substituents. The structures of *para*-substituted benzenes have been the most thoroughly studied.

### *para*-Disubstituted derivatives

As in monosubstituted benzene derivatives the angles at the carbon atoms in *para*-disubstituted derivatives indicate that alkyl substituents are strong σ donors. Thus the C($CH_3$) and C($CH_2$) angles in di-*p*-tolyl disulphide[106], *p*-bitolyl[107], toluic acid[108], nitrotoluene[109], cresol[110], 1,1-di-*p*-tolylethylene[111], di-*p*-tolylcarbodi-imide[112], the enolic form of ω-*p*-tolylacetophenone[113], β-*p*-tolylthio-*trans*-cinnamic acid[39], ethyl *N*-methyl-*N*-*p*-tolylsulphonylmethylcarbamate[114], (+)-methyl *p*-tolyl sulphoxide[115], propenyl *p*-tolyl sulphone[116], triphenyl-*N*-toluene-*p*-sulphonyliminophosphorane[93], [8]paracyclophane-4-carboxylic acid[117], trisdiphenylmethane-*pp'*-diamine[118], and acetotoluidine[119] are respectively 117.3°, 117.8°, 118.5°, 117.5°, 117.8°, 118.0°, 117.7°, 118.2°, 117.8°, 118.8°, 118.2°, 118.6°, 117.5°, 117.6°, 118.6°, and 117.5°. Similarly to monosubstituted benzene derivatives, the C(C≡C) angle of 119.4° in *p*-diethynylbenzene[120] is larger than the C(C:C) angle in the presence of a vinyl group in 1,1-di-*p*-tolylethylene[111], diethylstilboestrol[121], [2.2](2,6)pyridinoparacyclophane-1,9-diene[122], and 1,6-di-*p*-chlorophenyl-3,4-dimethylhexatriene[123]—117.9°, 118.2°, 117.5°, and 118.0°.

An advantage of X-ray structural analysis in comparison with other methods—both physical and chemical—is that comparison of the angles at the carbon atoms in the benzene

ring provides an exceptional opportunity for determining the relative σ donor–acceptor characteristics of different substituents in the same molecule. Thus in tetra-*p*-tolyltin[124] the σ-donor power of the tin atom exceeds that of the methyl group: C(Sn) 116.4° and C($CH_3$) 117.3°. The structure of trisdiphenylmethane-*pp'*-diamine-sodium chloride[118], with angles C($CH_2$) 118.6° and C($NH_2$) 119.2°, shows that methylene is a stronger σ donor than is the amino-group. Examination of the structures of *p*-dimethylaminophenyldiphenylphosphine[72] and *p*-dimethylaminophenyl phenyl sulphide[125] reveals that in the former the phosphorus atom is a stronger σ donor than is the dimethylamino-group, for C(P) 116.9° and C[$N(CH_3)_2$] 117.5°, and that in the latter structure the dimethylamino-group is a stronger σ donor than is the sulphur atom, since C[$N(CH_3)_2$] 117.8° and C(S) 118.4°.

**Table 2.** Bond angles C(D) and C(A) in *para*-substituted hydroxy- and alkoxy-benzenes.

| Compound | D | A | C (D), ° | C (A), ° |
|---|---|---|---|---|
| Cresol[110] | $CH_3$ | OH | 117,8 | 120,4 |
| Anisidine[128] | $NH_2$ | $OCH_3$ | 118,4 | 120, 2 |
| Diethylstilboestrol[121] | C=C | OH | 118,2 | 120, 2 |
| *trans-pp'*-Diethoxyazobenzene[129] | N=N | $OC_2H_5$ | 119,5 | 120,5 |
| Hydroxyacetanilide[130] | N—$COCH_3$ | OH | 119,8 | 120,2 |
| Hydroxyacetanilide[131] | COOH | OH | 117,7 | 120,3 |
| Methoxybenzoic acid[132] | COOH | $OCH_3$ | 119,7 | 120,4 |
| Ethoxybenzoic acid[133] | COOH | $OC_2H_5$ | 118,7 | 120,4 |
| n-Butoxybenzoic acid[134] | COOH | $OC_4H_7$ | 118,9 | 120,2 |
| Potassium hydrogen bis-*p*-hydroxybenzoate monohydrate[135] | COOH | OH | 119,6 | 120,7 |
| Pyridinium hydroxybenzoate[136] | $COO^-$ | OH | 118,2 | 119,5 |

Further, comparison of the angles in terephthalic acid[126] and γ-quinol[127]—C(COOH) 120.4° and C(OH) 121.0°—shows that hydroxyl is a stronger σ acceptor than is carboxyl. This is confirmed by Table 2, which indicates that hydroxyl, methoxyl, ethoxyl, and butoxyl are weak σ acceptors in comparison with such σ donors as methyl, amino, ethylenic, azo, acetylimino, and carboxyl groups.

**Table 3.** Bond angles C(D) and C($NO_2$) in *para*-substituted nitrobenzenes.

| Compound | D | C (D), ° | C ($NO_2$), ° |
|---|---|---|---|
| Nitrotoluene[109] | $CH_3$ | 117,5 | 122,7 |
| Nitrobenzoic acid[141] | COOH | 119,8 | 122,6 |
| α-Nitrophenol[142] | OH | 120,9 | 122,3 |
| β-Nitrophenol[143] | OH | 120,5 | 122,0 |
| α-Di-*p*-nitrophenyl disulphide[144] | S | 119,0 | 122,7 |
| 1,1-Di-*p*-nitrophenylethylene[145] | C=C | 118,3 | 122,2 |
| Nitrobiphenyl[146] | $C_6H_4$—$C_6H_4$ | 118,6 | 122,2 |
| *syn-p*-Nitrobenzaldehyde oxime[147] | C=N—OH | 119,2 | 122,7 |
| Nitroacetophenone[148] | $COCH_3$ | 118,4 | 121,7 |
| Nitrophenyl acetate[149] | $COOCH_3$ | 120,7 | 121,5 |
| D-*p*-nitrophenylcarbodi-imide[150] | N=C=N | 120,4 | 122,1 |
| *N*-Ethyl-*N*-*p*-nitrophenylcarbamoyl chloride[151] | N($C_2H_5$)COCl | 120,5 | 123,8 |

As in monosubstituted benzene derivatives, the silicon atom is one of the strongest σ donors. Therefore the C(Si) angle in *p*-bistrimethylsilylbenzene[137] is 115.8°. The azoxy-group in *p*-azoxyanisole[138] has a dual role: it acts both as a σ donor with C(N :NO) 119.1° and C($OCH_3$) 119.6°, and as a σ acceptor, with C(NO :N) 121.1° and C($OCH_3$) 119.9°. The σ-acceptor properties of the azo-group are exhibited in *S*-methyldithiazone[139], with C(N :N) 120.2° and C(N.N) 119.1°, and especially in benzenediazonium-*p*-sulphonate[140], with C($N^+$≡N) 125.4° and C($SO_3^-$) 121.0°. Data on the C($NO_2$) angles in *para*-substituted nitrobenzenes are listed in Table 3.

Sulphonyloxy, sulphonyl, and sulphinyl groups act as σ acceptors: in *cis*-4-t-butylcyclohexyl toluene-*p*-sulphonate[152] C($SO_3$) 120.6° and C($CH_3$) 117.7°, ethyl *N*-methyl-*N*-*p*-tolylsulphonylmethylcarbamate[114] C($SO_2$) 121.1° and C($CH_3$) 118.8°, propenyl *p*-tolyl sulphone[116] C($SO_2$) 120.7° and C($CH_3$) 118.6°, β-sulphanilamide[153] C($SO_2NH_2$) 120.5° and C($NH_2$) 118.7°, and in (+)-methyl *p*-tolyl sulphoxide[115] C(SO) 120.3° and C($CH_3$) 118.2°. However, in *N*-dimethylsulphoniotoluene-*p*-sulphonamide[154] C($SO_2.N^-.S^+$) 119.7° and C($CH_3$) 118.9°, and in triphenyl-*N*-toluene-*p*-sulphonyliminophosphorane[93] C($SO_2.N^-.P^+$) 119.7°, so that the sulphonyl group has lost its σ-acceptor properties in structures of the ylide type.

The C($SOCH_3$) angle of 120.3° in (+)-methyl *p*-tolyl sulphoxide, indicating that the sulphinyl group is not a strong σ acceptor, was inconsistent[115] with the Hammett $\sigma_p$ constants, according to which the acceptor power of the methylsulphinyl group exceeds that of the chlorine atom. This discrepancy remains even with the Taft constants: $\sigma_I(Cl) = +0.40$ and $\sigma_I(SO.CH_3) = +0.49$. The C(Cl) angle of 122.1° in γ-*p*-chlorobenzene[155] shows that the chlorine atom is a strong σ acceptor. Closely similar C(Cl) angles were obtained in *p*-chlorobenzoic acid[156] C(Cl) 122.1° and C(COOH) 119.9° and in α-chlorophenol[157] C(Cl) 122.4° and C(OH) 121.1°. The C(Cl) angle in the latter compound coincides with C(Br) in 1-*p*-bromophenylbutane-1,3-dione[158]: C(Br) 122.4° and C(C :O) 119.3°.

**Table 4.** Mean bond angles C(D,A) for elements in the second period.

| D, A | C (D, A), ° | D, A | C (D, A), ° | D, A | C (D, A), ° |
|---|---|---|---|---|---|
| $B^-(C_6H_5)_3$ | 114.1 | $COCH_3$ | 118.8 | $N^+H_3$ | 121.6 |
| $N(CH_3)_2$ | 117.2 | $CONH_2$ | 119.8 | CN | 121.8 |
| $C_6H_5$ | 117.6 | COOH | 119.8 | $NO_2$ | 122.1 |
| $CH=CH_2$ | 118.0 | $OCH_3$ | 119.9 | F | 123.4 |
| $CH_3$ | 118.1 | N=N—$C_6H_5$ | 120.0 | $N^+\equiv N$ | 124.9 |
| $NH_2$ | 118.4 | OH | 120.2 | | |

It is worth noting the mean angles C(D,A) for elements of the second period in the structures of monosubstituted and *para*-disubstituted benzene derivatives (Table 4) given in a paper[17] and in a review[159]. The standard deviations of the angles are 0.1–0.2 deg. However, there are certain discrepancies. In particular, the σ-donor power of the methyl group exceeds that of the vinyl group[7]—$\sigma_I(CH_3) = -0.08$ and $\sigma_I(CH :CH_2) = +0.01$—so that the C($CH_3$) angle should be smaller than the C($CH :CH_2$) angle.

A linear relation has been reported in a review[160] between the mean C–D and C–A bond lengths and the C(D) and C(A) angles for elements in the third period: silicon (1.8683 Å, 116.98°), phosphorus (1.8276–1.7908 Å, 118.50–119.78°), sulphur (1.708–1.7534 Å, 119.73–121.19°), and chlorine (1.7404 Å, 121.37°). Table 1 shows that the

correlation between C–(D,A) and C(D,A) is due to the increase in the nuclear potential $z^*/r$ caused by the decrease in the radius $r$ and the increase in the effective charge on the nucleus $z^*$ for the atoms along the period.

*meta*-Disubstituted derivatives

Available data on the structures of *meta*-disubstituted benzene derivatives confirms the σ-donor nature of the methyl group in cresol[161] C($CH_3$) 118.7°, the amino-group in nitroaniline[162] C($NH_2$) 119.6°, the dimethylamino-group in nitro-*NN*-dimethylaniline[163] C[$N(CH_3)_2$] 117.7°, the carboxy-group in isophthalic acid[164] C(COOH) 119.8°, and the amino-group in *o*-*m'*-trifluoromethylanilinobenzoic acid[165] C(NH) 118.8°. In contrast to this, a σ-acceptor nature has been found for the amino-group in aminophenol[166] C($NH_2$) 120.9°, the hydroxy-group in resorcinol[167], cresol, aminophenol, and hydroxybenzamide[168] C(OH) 121.1°, 121.7°, 121.5°, and 120.5°, the chlorine atom in potassium hydrogen bis-*m*-chlorobenzoate[169] C(Cl) 122.4°, the iodine atom in *p*-*m'*-iodophenylbenzoic acid[170] C(I) 121.3° and C($C_6H_4$) 117.6°, the ammonio-group in *m*-carboxyanilinium chloride[171] C($NH_3^+$) 121.7°, the nitro-group in dinitrobenzene[172], *m*-nitroperchlorylbenzene[173], nitroaniline, and nitro-*NN*-dimethylaniline C($NO_2$) 123.6°, 124.1°, 122.3°, and 124.4°, the trifluoromethyl group in *o*-*m'*-trifluoromethylanilinobenzoic acid[165] C($CF_3$) 121.8°, and the sulphamoyl group in *m*-sulphamoylanilinium chloride[174] C($SO_2NH_2$) 121.7°.

*ortho*-Disubstituted derivatives

Significant steric hindrance is present between *ortho*-substituents. The σ donor–acceptor characteristics of donor D and acceptor A substituents differ more markedly when their mutual orientation is *ortho* than in the *para*- and *meta*-derivatives. The close proximity of the D and A substituents is responsible for an increase in the C(A) angle and a related decrease in the C(D) angle. Thus among the cresols the difference between these angles diminishes on passing from the *ortho*- to the *meta*- and the *para*-isomers: C(OH) 121.7°, 121.7° and 120.4° respectively; and C($CH_3$) 117.0°, 118.7°, and 117.8°.[175] In *o*- and *p*-nitrobenzoic acids[176] the C($NO_2$) angle is respectively 123.7° and 122.8°, while C(COOH) is 116.2° and 121.2°: i.e. the difference between corresponding angles C(A) and C(D) increases on passing from the *para*- to the *ortho*-derivative, although the angle $\varphi$ of rotation of the plane of the nitro-group relative to that of the benzene ring is larger in the *ortho*- than in the *para*-isomer (54.3° and 24.1°).

Data on the structure of *o*-ethoxybenzoic acid[177] — C($OC_2H_5$) 120.8° and C(COOH) 118.0° — are consistent with results for the *para*-derivatives: i.e. the ethoxy-group surpasses the carboxy-group in σ-acceptor power. This is observed also in salicylic acid[167,178] — C(OH) 119.5° and C(COOH) 119.1° — though the difference is less marked. As was to be expected, a still larger difference between the angles C(OH), C($OCH_3$), C(COOH) and the angles C($CH_3$), C(CH), C($CH_2$) has been established in cresol[175], 1,1,2,2-tetrakis-*o*-methoxyphenylethane[179] C($OCH_3$) 120.5° and C(CH) 117.4°, and in toluene-α,2-dicarboxylic acid[180] C(COOH) 120.3° and C($CH_2$COOH) 116.1°. In salicylaldehyde oxime[181] the angles are C(OH) 119.6° and C(C :N.OH) 118.0°, since the hydroxyimino-group occupies a position intermediate between the carboxyl and methyl groups. It is noteworthy that, despite the difference between the angles of rotation of the carboxylate groups around carbon-carbon bonds (32° and 71°), both the C($COO^-$) angles in diammonium phthalate[182] are 119.3°.

The identity of the cyclic angles at the substituted carbon atoms in *o*-hydroxymethanesulphonanilide[183] — C(OH) 120.6° and C($NHSO_2$) 120.8° — suggests approximate equality of the σ-acceptor powers of the substituents. There are examples of variation in the angles of nitrogen-containing substituents: thus in *trans*-*oo'*-dichloroazobenzene[184] C(N.N) 118.6° and C(Cl) 121.3°, *o*-chlorohydroxyiminoacetanilide[185] C(N.C :O) 118.6° and C(Cl) 121.0°, *o*-ethoxyhydroxyiminoacetanilide[186] C(N.C :O) 120.3° and C($OC_2H_5$) 119.8°, *o*-phenylenediamine hydrochloride[187] C($NH_3^+$) 122.3° and C($NH_2$) 117.1°, *NN*-dimethylanthranilic acid[188] C[$N^+H(CH_3)_2$] 122.5° and C($COO^-$) 117.0°, potassium *o*-nitrophenoxide hemihydrate[189] C($NO_2$) 122.5° and C($O^-$) 115.2°, nitrobenzamide[190] C($NO_2$) 122.1° and C($CONH_2$) 118.8°, and 4-acetyl-2'-nitrobiphenyl[191] C($NO_2$) 123.3° and C($C_6H_4$) 115.6°. Since the iodine atom is a weaker σ acceptor than is the nitro-group, a smaller difference between the angles C(A) and C(D) is observed in *p*-*o'*-iodophenylbenzoic acid[192] — C(I) 122.6° and C($C_6H_4$) 117.9° — than in the corresponding nitro-derivative.

The structures of the racemate[193] and an optically active form of (–)-*o*-methylsulphinylbenzoic acid[194], with C(S :O) 119.8°, 119.5° and C(COOH) 118.0°, 118.4°, orthanilic acid[195] C($SO_3^-$) 119.2° and C($NH_3^+$) 120.6°, and sulphobenzoic acid trihydrate[196] C($SO_3^-$) 119.6° and C(COOH) 118.4° clearly show that the sulpho and sulphinyl groups are σ donors.

It is significant that the introduction of two acceptors in the *ortho*-position leads to a mutual weakening of their σ-acceptor power. Thus in *o*-phenylenediammonium dichloride[197] and dibromide[198] the C($NH_3^+$) angles are respectively 120.1° and 119.4°. The hydroxyls in catechol[199] are weaker σ acceptors than are those in resorcinol and quinol: C(OH) 119.9°, 121.1°, and 121.0°.

3. Trisubstituted Benzene Derivatives

Trisubstituted benzenes retain the characteristic features of the variation in bond angles inherent in *meta*- and *ortho*-derivatives. Closely similar C($NO_2$) angles (123.4° and 123.6°) have been found in 1,3,5-trinitrobenzene[200] and in *m*-dinitrobenzene[172]. The acetyl group remains a weak σ donor in 1,3,5-triacetylbenzene[201] C($COCH_3$) 119.8°. As was to be expected, the σ-acceptor power of nitro- and hydroxy-groups and of fluorine and chlorine atoms is increased by the introduction of σ donors into the *ortho*-position. This is readily seen from a comparison of the C(A) and C(D) angles in *N*-methyl-*m*-nitro-*p*-toluidine[202] with C($CH_3$) 114.3°, C($NO_2$) 124.1°, and C($NHCH_3$) 117.3°, 2,5-dimethylphenol[203] C(OH) 121.5° and C($CH_3$) 116.6° and 117.3°, (±)-2-(2-fluorobiphenyl-4-yl)propionic acid[204] C($CC_6H_5$) 117.1°, C(F) 123.9°, and C(C) 119.6°, and 3-chloro-*NN*-dimethyl-4-nitrovinylaniline[205] C(C :C) 113.0°, C(Cl) 125.7°, and C[$N(CH_3)_2$] 116.6°. Another striking fact is that the σ-acceptor power of the bromine atom is diminished by the introduction of an *o*-nitro-group and an *o*-sulpho-group respectively in 4-bromo-*N*-methyl-3-nitroaniline[202], with C(Br) 116.1°, C($NO_2$) 122.4°, and C($NHCH_3$) 118.0°, and in the trihydrate of 2,5-dibromobenzenesulphonic acid[206] C(Br) 120.2° and 122.8° and C($SO_3^-$) 119.9°, since the C(Br) angle *ortho* to C($SO_3^-$) is smaller than the *meta*-C(Br) angle.

Among 1,2,3-derivatives pyrogallol[207]—C(OH) 120.7°, 119.8°, and 121.2°—has C(OH) angles at positions 1 and 3 that are closely similar to those (121.0° and 121.1°) in γ-quinol and resorcinol, whereas the C(OH) angle at position 2 is close to those in catechol (119.9°). In hemimellitic acid dihydrate[208], despite the marked difference in angles of rotation of the planes of the carboxyls relative to that of the benzene ring (the angles φ at positions 1–3 are respectively 9.6°, 87.2°, and 4.1°), the C(COOH) angles are also larger at positions 1 and 3 (119.7° and 120.0°) than at position 2 (118.9°).

Hydroxyl, ethylenic, and methyl groups undergo greater increase in σ-donor power when located between two σ acceptors: in 2,6-dinitrophenol[209] C(OH) 116.0° and C($NO_2$) 122.3° and 121.9°; in 1-(2,6-dichlorophenyl)-4-phenylbuta-*trans*-1,*trans*-3-diene[210] C(C :C) 114.6° and C(Cl) 122.8° and 123.9°; and in 3-bromo-2-methylphenol[211] C($CH_3$) 114.4°, C(OH) 124.9°, and C(Br) 124.5°.

Comparison of the structures of 2,3-dimethylphenol[211, 202]—C(OH) 122.4° and C($CH_3$) 118.1° and 119.7°—and of 2,3-dimethylbenzoic acid[212]—C(COOH) 121.3° and C($CH_3$) 117.4° and 120.3°—clearly shows, as a consequence of the location of hydroxy- and carboxy-groups *ortho* to the methyl groups, the sequence OH > COOH > $CH_3$ according to their σ-acceptor power, which is consistent with conclusions reached from mono- and di-substituted derivatives.

The difference between the C(O) angles is especially clearly developed in the oxygen bridge in 1-t-butyl-2-(2,6-dinitrophenoxy)benzene[213]: *ortho* to the t-butyl group as σ donor C(O) 123.9°, but *ortho* to two σ-acceptor nitro-groups C(O) 116.2°.

## 4. Tetrasubstituted Benzene Derivatives

Among 1,2,4,5-tetrasubstituted benzene derivatives—tetra-t-butylbenzene[214], durene[215], pyromellitic acid dihydrate[216], and tetracyanobenzene[217]—the σ-acceptor power increases in the sequence

C($C(CH_3)_3$) 115.1°<C($CH_3$) 118.2°<C(COOH) 119.7°<C(CN) 121.3°.

In 3,4,5-trimethylbenzoic acid[218], of course, the C(COOH) angle is 119.7°, but when the hydroxyl is located *ortho* to two t-butyl groups in 2,6-t-butyl-4-methylphenol[211], and a carboxyl is *ortho* to two methyl groups in mesitoic acid[219], the C(OH) angle increases to 122.6°, and C(COOH) to 120.7°. Similarly, the arrangement of a nitro-group *ortho* to two methyl groups in 3,5-dimethyl-4-nitrobenzoic acid[220] has increased the C($NO_2$) angle to 124.8°, and diminished the C($CH_3$) angles to 116.6°. The introduction of two nitro-groups or two chlorine atoms yields the respective angles—in 4-methyl-3,5-dinitrobenzoic acid[221] C($CH_3$) 114.1° and C($NO_2$) 124.3°, in 2,6-dichloro-4-nitroaniline[222] C($NH_2$) 115.2° and C(Cl) 123.0°, and in 2,4,6-trichlorobenzonitrile[223] C(C≡N) 117.6° and C(Cl) 123.6°.

In 1,2,3,5-tetrasubstituted benzenes containing three nitro-groups the presence of such strong σ acceptors at positions 1 and 3 leads to smaller angles at position 2 substituted by a σ-donor or a weaker σ-acceptor substituent. Therefore in picryl chloride[224], *NN*-difluoro-2,4,6-trinitroaniline[225], 2,4,6-trinitrophenetole[226], *N*-methyl-2,4,6-trinitroacetanilide[227], and in the anion of 2,4,6-trinitrobenzenesulphonic acid tetrahydrate[228] $H_5O_2^+C_6H_2(NO_2)_3SO_3^-$. $2H_2O$, as the angle at position 1 decreases—C(Cl) 117.0°, C($NF_2$) 116.8°, C(OR) 116.4°, C(N.C :O) 115.4°, and C($SO_3^-$) 115.1°—the angles at positions 2 and 6 correspondingly increase: C($NO_2$) 122.4°, 122.6°, 122.8°, 123.5°, and 123.7°.

Variation in σ donor–acceptor characteristics is clearly exhibited in a series of structures containing bridging substituents[229–233]. Thus in methyl 3-nitro-4-(2,4,6-trimethylbenzyl)benzoate, 3-nitro-4-(2,4,6-trimethylbenzoyl)benzoate, 4-mesitylthio-3-nitrobenzoate, 4-mesitylsulphinyl-3-nitrobenzoate, and 4-mesitylsulphonyl-3-nitrobenzoate the C($CH_2$), C(C :O), C(S), C(S :O), and C($SO_2$) angles are respectively 119.5°, 120.6°, 121.5°, 121.6°, and 121.5° with these groups *ortho* to two methyl groups, but 114.8°, 116.7°, 115.5°, 117.9°, and 117.7° when *ortho* to the nitro-group.

A comparison[227] of structures differing in the angle of rotation of the N–C=O group relative to the plane of the benzene ring—acetanilide[234] (N–$C_{Ar}$ 1.413 Å, C(N.C :O) 119.6°, and φ = 17.6°), *N*-methyl-2,4,6-trinitroacetanilide (1.417 Å, 115.4°, and 61°), and *N*-methylacetanilide (1.481 Å, 122.8°, and 90°)—has shown that the $N^{\delta+}$–C=$O^{\delta-}$ group develops strong σ-acceptor power in the third structure as a consequence of the absence of π conjugation, but in the second structure the overlap of the π orbitals of the nitrogen atom and the ring carbon atom is less than one-quarter of the maximum value (cos 60° = 0.25), so that the decreases in the C(N.C : O) angle and the N–$C_{Ar}$ bond length must be attributed to the σ-acceptor power of the nitro-groups. A similar effect is observed in 2-chloro-4,6-dinitrophenol[235], since the O–C bond is shorter than in phenol (1.333 and 1.383 Å) owing to the decrease in the C(OH) angle from 120.5° to 116.7°. A linear relation has been established between the acid strength p$K_a$ and the C–OH bond length in substituted benzenes[235]. For example, the dissociation constant increases by a factor of $10^8$ on passing from phenol to 2-chloro-4,6-dinitrophenol. It may be supposed that an increase in the contribution by the *s* state of the hybrid orbital of the carbon atom in the C–OH bond leads to an increase in the acid strength.

## 5. Penta- and Hexa-substituted Benzene Derivatives

On passing further sterically overcrowded molecules having five or six substituents in the benzene ring, we again see mainly a trend to preservation of the cyclic angles characteristic of the σ nature of electron-donating and electron-accepting substituents. The typical features of *ortho*-substituents noted in preceding subsections are also maintained.

In 2,4,6-trinitro-1,3-xylene[236] the angles are C($CH_3$) 114.2° in the 1 and 3 positions, with C($NO_2$) 127.2° (φ = 75.2°) at the 2 position and 122.4° (35.7°) at the 4 and 6 positions; in 4-bromo-*N*-methyl-2,6-dinitro-3-toluidine[237] C($NHCH_3$) 112.0°, C($CH_3$) 115.0°, C(Br) 123.5°, and C($NO_2$) 127.0° (φ = 73°) and 122.5° at positions 2 and 6. Hence the ring angles at nitro-substituted carbon atoms differ from those at atoms substituted by methyl and by a methylamino-group by 13° and 15° respectively, in agreement with their tendency to maintain the σ-bond angles of D and A substituents. An analogous phenomenon is observed in the structure of 2,4,6-trimethyl-3-pivaloylbenzoic acid[238]: C($CH_3$) 117.6°, 117.3°, and 116.7°, C(COOH) 121.7°, and C(CO) 121.8°.

In hexasubstituted benzenes steric hindrance also has a significantly weaker effect than has σ rehybridisation. Thus in pentafluorobenzoic acid[219] the C(COOH) angle of 116.7° has diminished, and the C(F) angles of 121.7° at

positions 2 and 6 are larger than the C(F) angles of 119.9–120.0° at positions 3, 4, and 5; in tetrakispentafluorophenylgermanium[239] C(Ge) 115.6° and C(F) 122.7° and 119.0–120.3°; and in decafluorobiphenyl[240] C($CF_5$) 116.3° and C(F) 122.1° and 119.7–120.1°. In 3-amino-6-ethylpyromellitonitrile[241] the angles increase in the sequence C($NH_2$) 116.2°, C($C_2H_5$) 116.3°, and C(CN) 121.3° and 122.4°.

Further refinement of the structure of hexachlorobenzene[242] has established that the carbon–carbon bond lengths (1.393 ± 0.002 Å, with temperature correction 1.401 Å) differ insignificantly from those in the unsubstituted benzene molecule. The carbon–chlorine bond lengths in substituted aromatic and quinonoid rings[243] are significantly shorter (mean distance 1.709 Å) when in the *ortho*-position and when more distantly separated or when isolated (mean 1.737 Å). The carbon–chlorine bond length in the overloaded hexachlorobenzene molecule (1.715 ± 0.002 Å, with temperature correction 1.722 Å) is shorter than an isolated bond. The steric effect should have increased the bond lengths in the overloaded molecules owing to mutual repulsion of the chlorine atoms. It is more correct to suppose that the possibility of σ rehybridisation is greater for well separated or isolated bonds, since the increase in the proportion of the *p* state of the carbon atom in the bonds is balanced, as a consequence of the strong σ-acceptor power of the chlorine atom, by an increase in the proportion of the *s* state of the carbon atom in the benzene ring. In hexachlorobenzene such a possibility of σ rehybridisation is excluded because all the carbon bonds in the ring are 120.0°, so that the carbon–chlorine bonds remain shortened owing to the excess content of the *s* component of the carbon atom in them. For the same reason the carbon–chlorine bond length should be increased by increase in the C(Cl) angle, as is observed on comparing the structure of picryl chloride C(Cl) 117.0° and C–Cl 1.709 Å with that of 2,6-dichloro-4-nitroaniline 123.0° and 1.743 Å. In decachlorobiphenyl[244], in which the dihedral angle between the phenyl rings is 86.7°, and the bond angles are C($C_6H_5Cl_5$) 118.7° and C(Cl) 121.0°, 118.9°, and 121.7°, the mean carbon–chlorine bond length somewhat exceeds the bond length in hexachlorobenzene (1.718 and 1.715 Å).

**Table 5.** Bond lengths (Å) and angles (°) in *para*-substituted anilines with the Hammett $\sigma_p$ constants of the substituents.

| Substituent | N–$C_1$ | $C_1$–$C_2$ | $C_2$–$C_3$ | $C_3$–$C_4$ | $C_5$–$C_1$–$C_6$ | $C_1$–$C_2$–$C_3$ | $C_2$–$C_3$–$C_4$ | $C_3$–$C_4$–$C_5$ | $\sigma_p$ |
|---|---|---|---|---|---|---|---|---|---|
| $NH_2$ | 1.408 | 1.389 | 1.377 | 1.389 | 117.1 | 121.4 | 121.4 | 117.1 | −0.47 |
| COOH | 1.380 | 1.399 | 1.375 | 1.398 | 119.3 | 120.8 | 121.1 | 118.3 | +0.38 |
| SCN | 1.376 | 1.393 | 1.373 | 1.385 | 118.1 | 121.1 | 119.8 | 119.6 | +0.52 |
| $SO_2NH_2$ | 1.385 | 1.402 | 1.381 | 1.393 | 118.7 | 120.8 | 119.7 | 120.5 | +0.55 |
| $NO_2$ | 1.371 | 1.412 | 1.375 | 1.390 | 118.9 | 120.5 | 119.5 | 121.2 | +0.76 |

## IV. X-RAY σ CONSTANTS

It appears reasonable to adopt the structural characteristics of molecules as the basis for constants representing their reactivity. We shall apply the special term "X-ray σ constants" to the C(D) and C(A) bond angles, the problem of which requires special discussion.

A linear dependence exists between the mean bond angles C(D,A)[17,160] and the Taft induction constants $\sigma_I$ (Fig. 1), values of which have been taken from a monograph[7]. Comparison of these angles in various structures has established relative series of σ-acceptor and σ-donor substituents.

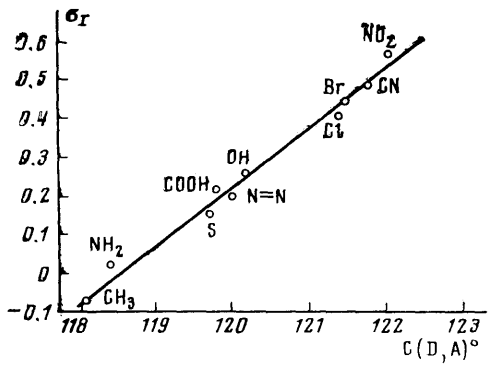


Figure 1. Dependence of induction constants $\sigma_I$ on bond angles C(D,A).

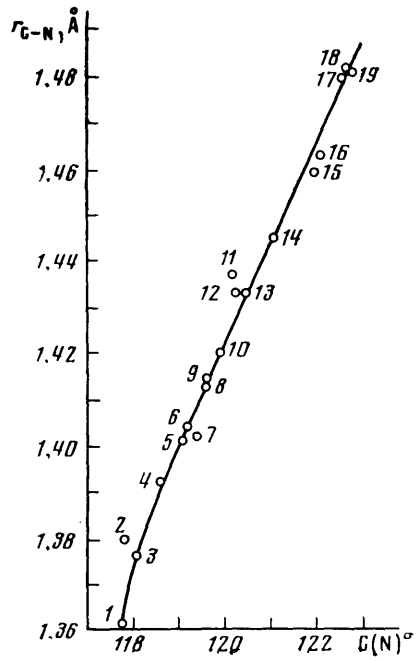
Insignificant π conjugation of the nitro-group with the benzene ring can be assumed in *p*-nitrotoluene and *p*-nitrobenzoic acid (C–$NO_2$ 1.482 and 1.491 Å). However, the data in Table 5[245–249] are consistent with the view that D and A substituents influence the distribution of C(A) bond angles in *para*-substituted anilines (C–$NH_2$ 1.408–1.371 Å) even when π interaction is superimposed on σ interaction.

When π conjugation of D and A substituents with the benzene ring is insignificant, the bond angles C(D,A) will obviously determine directly the induction effect $\sigma_I$ of the substituent. Such π conjugation is most strongly developed among elements in the second period, especially by the nitrogen atom. The plot of carbon–nitrogen bond length against the C(N) angle (Fig. 2) has a straight segment indicating a linear relation between σ rehybridisation and π conjugation. Hammett's equation $\lg(K/K_0) = \rho\sigma$ (where $K$ and $K_0$ are equilibrium constants of the chemical reaction) is based[252] on the linear relation between changes in free energy. The hypothesis[253] of a linear dependence between σ rehybridisation and π conjugation enables the bond angles C(D,A) to be used instead of Hammett σ constants. The correctness of this approach is supported by the linear correlation of the C(D,A) angles[160] with the nuclear potentials $z^*/r$ for elements in the second, third, and fourth periods (Fig. 3). Hence these angles obey a periodic law. The C(N) and C(O) angles plotted in Fig. 3 relate to compounds in which the contribution of π conjugation is insignificant.

A change of 0.5 deg in the C(N) angle is accompanied by a change in the Hammett $\sigma_p$ constant[3,7] by ~ 0.2 (Fig. 4). Modern X-ray techniques enable C(D,A) angles to be determined to 0.1–0.3 deg, and C–D,A bond lengths to 0.001–0.003 Å. X-Ray diffraction thus provides the most accurate method for determining constants characterising the reactivities of molecules.

Fig. 2 shows that the linear relation between the carbon–nitrogen bond length and the C(N) angle breaks down in *p*-thiocyanatoaniline and in 2-*p*-dimethylaminobenzylidenindane-1,3-dione, where strong direct polar $\pi$ conjugation is present, as well as in the presence of the saturation effect in *p*-phenylenediamine. For this reason the Hammett $\sigma$ constants should be replaced by other parameters.



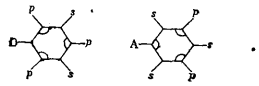


**Figure 2.** Correlation between C–N bond lengths and C(N) angles for: 1) 2-*p*-dimethylaminobenzylidenindane-1,3-dione; 2) *p*-dimethylaminophenyl phenyl sulphide; 3) *p*-thiocyanatoaniline; 4), 5), 13) anilinophenylphthalimide; 6) 1-phenyl-thiosemicarbazide; 7) aniline; 8) acetanilide; 9) *NN'*-diphenyl-*p*-phenylenediamine[250]; 10) *N*-diphenylmethylenaniline; 11) *N*-phenylacetanilide; 12) azobenzene[251]; 14) 4-phenyl-thiosemicarbazide; 15) $\alpha\alpha N$-triphenylnitrone; 16) mean values for *p*-nitrobenzenes[159]; 17) *p*-nitrobenzoic acid; 18) *p*-nitrotoluene; 19) *N*-methylacetanilide.

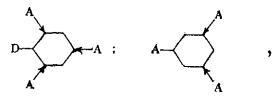
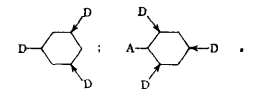


A review[160] has shown that the C(D, A) bond angles (denoted $\alpha$ by the reviewers) of elements in the third period are related to the Pauling[254] electronegativities $\chi$ by the linear formula $\alpha = 3.33\,\chi + 111.4$. On Pauling's thermochemical scale, however, the electronegativity sequence of the elements C > Si = Ge = Sn = Pb and N > P > As > Sb = Bi does not correspond to the bond angles and nuclear potentials of the elements.

Considering the structural aspect of the reactivity of the benzene molecule, we note that, according to the scheme of $\sigma$ rehybridisation of bonds in Section II, increase in the bond angle of a carbon atom in the benzene ring implies an increase in the proportion of the *s* state of this atom in the cyclic carbon–carbon bonds and hence an increase in the proportion of the *p* state of this atom in the exocyclic carbon–hydrogen bond. The distribution of predominant *s* and *p* components of $\sigma$-hybrid bonds of carbon atoms in the exocyclic bonds of monosubstituted derivatives can be represented



As a result, electrophilic-acceptor substituents will be oriented in conformity with the excess of *p* electrons, and nucleophilic-donor substituents according to the excess of *s* electrons:

electrophilic substitution

nucleophilic substitution

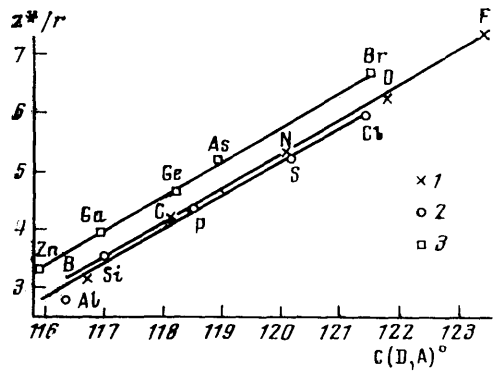


**Figure 3.** Dependence of bond angles C(D, A) on nuclear potentials $z^*/r$ of elements in different periods: 1) second; 2) third; 3) fourth.

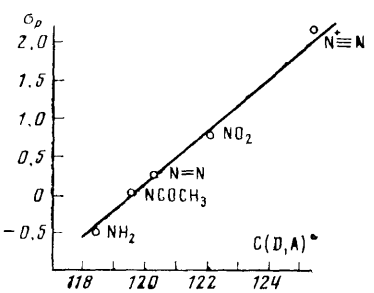

**Figure 4.** Dependence of the constants $\sigma_p = \sigma_I + \sigma_R$ on the bond angles C(D, A).

Thus the structural scheme of substituted benzenes is fully consistent with experiment: a donor D orients electrophilic substituents to *ortho* and *para*-positions, and nucleophilic substituents to the *meta*-position; but an

acceptor A orients electrophilic substituents to the *meta*-position, and nucleophilic substituents to *ortho*- and *para*-positions. Since σ bonds with excess of the *p* state are less stable than those with excess of the *s* state, electrophilic substitution should occur more readily than nucleophilic substitution. Thus the structural scheme of σ rehybridisation explains the main features of the reactivity of substituted benzenes, and hence σ bonds are of decisive significance for establishing the orienting effect of substituents.

## V. COMPARISON OF STRUCTURAL CHARACTERISTICS OF SUBSTITUTED BENZENES AND OF METAL COMPLEXES

It is of interest to compare the structural characteristics found for substituted benzenes with X-ray results obtained for metal complexes containing the same substituents as ligands in the coordination sphere. In the modern theory of the *trans*-effect in complex compounds of metals widespread use is made of the concept of the σ rehybridisation of orbitals of the central metal atom, according to which an increase in the proportion of a given component (*s*, *p*, or *d*) in the hybrid bond of the metal atom implies a decrease in an adjacent bond of the metal[255].

The scheme of population of σ bonds suggested for substituted benzenes D(*p*)–(*s*)A(*p*)– operates also in metal complexes. The *trans*-effect of ligands L, which has been most thoroughly studied in complex platinum compounds, is evident in the lability of the platinum–chlorine bond along the L–Pt–Cl axis: D(*p*)–(*s*,*d*)Pt(*p*)–Cl. Thus the platinum–chlorine bond length should increase on passing from acceptor ligands A to donor ligands D because of the increased fraction of the *p* state of the platinum atom in the platinum–chlorine σ bonds. Table 6 shows that decrease in the C(D,A) bond angle[160] is accompanied by an increase in the platinum–chlorine bond length[256].

Table 6.

| L | O | Cl | $PR_3$ | $CR_3$ | $SiR_3$ |
|---|---|---|---|---|---|
| Pt—Cl, Å | 2.28 | 2.30 | 2.37 | 2.415 | 2.45 |
| C(D, A)° | 121.8 | 121.4 | 118.5 | 118.1 | 117.0 |

Several deductions can be made from the above structural characteristics. According to the platinum–chlorine bond lengths the Taft induction constant $\sigma_I$ for the methyl group should exceed that for a trialkylsilyl group. This is supported by a comparison of the C(C) bond angle in triphenylmethane with C(Si) in tetraphenylsilane (117.8° and 116.1°). These results suggest that the sequence of the $\sigma_I$ constants of methyl and silyl groups (–0.08 and +0.01)[3] should evidently be refined.

The X-ray spectra of platinum complexes indicate[257] that the polarity of the platinum–chlorine bond is enhanced by the *trans*-effect of a ligand L. This is quite consistent with the concept of σ rehybridisation. The polarity of the platinum–chlorine bond would increase because *p* electrons are more weakly bound to the nucleus than are *s* electrons. Hence the ultimate cause of the enhanced bond polarity is an increase in the proportion of the *p* component of the platinum atom in this bond.

Similar ideas enable us to understand the relative stabilities of bonds involving other metals. For example, more substantial changes in bond lengths involving metal atoms are observed in tin than in platinum complexes[258].

We note in conclusion that the variation of the effect of substituents in benzene derivatives is paralleled by that of the *trans*-effect of the corresponding ligands in metal complexes. This is due to the important role of σ bonds in both classes of chemical compounds, resulting from the influence of donor–acceptor substituents (ligands) on the σ rehybridisation of (D,A)–C and (D,A)–M bonds. As a result, the influence of such donors D or acceptors A is apparent in the thermodynamic lability or stability of the C–H and M–L bonds involved in substitution. The reason for such behaviour of substituents (ligands) lies in the general rule that the length of a D–A bond decreases with fall in the nuclear potential $z^*/r$ of the donor atom D and rise in that of the acceptor atom A.[66,67]

# Gas Chromatography with Organic Eluents

A.V.Garusov and M.S.Vigdergauz

The characteristics of the use of organic gases and vapours as the mobile phases in the elution gas chromatography as well as additives to the usual carrier gases are considered. Methods are described for the preparation of the eluents and detection, and the role of the eluent as the factor permitting the regulation of the retention of the sorbate and the shape of the chromatographic band is discussed. The considerable advantages of organic gases and the vapours of organic compounds as eluents in preparative chromatography are demonstrated.
The bibliography includes 100 references.

## I. INTRODUCTION

In the elution version of gas chromatography, the mobile phase (carrier gas) plays as a rule merely the role of a transporting agent; the concentration of the sorbate analysed in this phase is determined by the vapour pressure of the sorbate at the working temperature and the nature of the sorbent. The first studies on gas chromatography with organic eluents and with organic additives to the usual carrier gases were published as early as 1956–1959.[1-10] It was shown that the use of organic and mixed eluents makes it possible to change significantly the pattern of the chromatographic separation of substances; thus the nature of the mobile phase becomes a factor which determines to a large extent both the retention of the chromatographic band and the shape of the recorded peak.

Together with their role as transporting agents, organic eluents and additives can perform the following "active" functions: (1) the blocking of the active centres of solid carriers (polar eluents) with formation of symmetrical bands of polar sorbates; (2) adsorption on the surface of the adsorbent and formation of a liquid layer which alters the partition coefficient of the sorbate in the mobile phase—sorbing medium system and hence the retention (the latter is usually decreased); (3) dissolution in the stationary liquid and formation of a binary stationary phase whose composition determines the retention of the sorbates; (4) the shift of the phase equilibrium of the sorbate in the mobile phase (it is manifested to the greatest extent with increase of the pressure)†; (5) the formation of volatile derivatives of involatile substances (particularly metals), which can be transported along the column; (6) the increase in some cases of the sensitivity of the detectors in relation to the substances analysed.

The above characteristics of organic eluents make it possible to extend the scope of gas chromatography as a method for the analysis of polar and high-boiling compounds.

† The above phenomena are observed also when a vapour eluent is used. The relevant studies have been reviewed[11].

Other advantages of organic eluents are noteworthy: (1) the ease of condensation (which enables them to be used in preparative chromatography without the need for low-temperature cooling of the traps); (2) the availability of hydrocarbon gases in petrochemical undertakings (this facilitates the employment of these gases as eluents in industrial control). The vapour of the stationary liquid which is volatile under the selected working conditions can be used as the eluent or its component and the analysis can be carried out both under the conditions of circulation chromatography[7,8] and with continuous saturation (before the column) of the carrier gas by the vapour[9]. Thus the range of the stationary phases employed is extended to include more volatile substances.

Table 1 presents data for the conditions in the chromatographic process with organic or mixed eluents. Methane and its mixture with hydrogen were used for the first time as carrier gases in 1956 by Taramasso[1,2]. In many instances, this proved to be convenient and economical in industrial monitoring (naturally, provided that safety precautions are taken), which was subsequently confirmed[12]. Furthermore the use of methane as the carrier gas instead of nitrogen increases the sensitivity of the katharometer because of the greater thermal conductivity of methane.

In 1959 Dumazert and Ghiglione[5] suggested that the chromatographic process be carried out in ethanol vapour, which influenced significantly the nature of the sorption of the substances analysed in the column and hence also the retention and shape of the concentration bands. Thus the eluent ceased to be merely a transporting agent; its nature became a factor influencing the phase equilibrium. A year earlier, Knight[6] showed that the introduction of small amounts of polar organic additives into the usual carrier gases ensures symmetrical peaks of polar sorbates and thus reduces the requirement for the inertness of solid carriers with respect to adsorption, since polar additives block their active centres. Subsequent studies on these lines were performed by Ackman and coworkers[14-16]. Organic additives were used in 1960 to increase the sensitivity of ionisation detectors with respect to inorganic gases[39] and in 1971 in order to form volatile adducts with metals[40].

**Table 1.** Conditions in the separation of substances in a stream of organic eluents or their mixtures with ordinary carrier gases.

| Substance | Eluent | Sorbent | Column Temp., °C | Detector | Ref. |
|---|---|---|---|---|---|
| Natural gas ($C_1$-$C_4$) | methane, methane with an admixture of hydrogen | n-hexadecane, dinonyl phthalate on Celite | 25 | katharometer | 1,2 |
| Methane | acetylene | wood charcoal | 25 | katharometer | 3 |
| Lower alcohols, water, allylamines | helium saturated by a mixture of water and n-hexylamine | di-isodecyl phthalate, tricresyl phosphate, triethylene glycol, $\beta\beta'$-oxydipropionitrile, poly(propylene glycol), DC-550 silicone on refractory brick | 25-60 | katharometer | 4 |
| $C_2$-$C_5$ acids | ethanol | liquid paraffin and stearic acid on refractory brick | 100-110 | katharometer | 5 |
| Nitrogen, ethylene, propane | methane | silica gel, dibutyl phthalate on silica gel | 75 | katharometer | 6 |
| Acetone, n-heptane, toluene, n-hexane, n-octane, benzene, cyclohexane, methylcyclohexane | helium with added solvent vapour | methanol, aniline on C-22 refractory brick | 20-150 | katharometer | 7,8 |
| $C_4$-$C_8$ hydrocarbons, oxygen compounds | helium with added solvent vapour | n-octane, n-decane on C-22 refractory brick | 30,60 | katharometer | 9 |
| $C_5$-$C_7$ hydrocarbons, $C_1$-$C_5$ alcohols | methane, ethane, ethylene, n-pentane | $\beta\beta'$-oxydipropionitrile, Paraplex, UCON-LB-550-X, Apiezon L, di-iso-decyl phthalate on Chromosorb W | 100 | katharometer | 12 |
| Isoalkenes | hydrogen, nitrogen with added solvent vapour | methanol, ethanol, acetone, ethyl methyl ketone, dioxan on a solid carrier | 28-45 | katharometer | 13 |
| Volatile $C_2$-$C_6$ aliphatic acids | helium with added formic acid vapour | ethyl formate, ethyl acetate, n-hexane, cyclohexane, ethylene glycol sebacate on Chromosorb W, Porapak QS, Chromosorb-101 | 160-200 | FID | 14-16 |
| Oxygen, argon, neon, helium | nitrogen with added iso-$C_5$ vapour | 5 Å molecular sieves | – | FID | 17 |
| Methane, propane, n-decane, n-heptane | methane, methane-propane mixture | n-decane, n-heptane on a solid carrier | – | katharometer | 18 |
| n-Pentane, isopentane, hexane, 2-methylpentane, 2,2-dimethylbutane | methane, ethane | squalane on Celite | 25,50 | katharometer | 19 |
| Toluene, 1-propanol, 1,2-dichloroethane, benzene, carbon tetrachloride | nitrogen, hydrogen with added benzene and 1,2-dichloroethane vapours | toluene, 1-propanol, 1,2-dichloroethane, benzene, carbon tetrachloride on Fluon, Haloport, Teflon-6 | 30-65 | FID | 20 |
| Barbiturates | nitrogen with added formic acid vapour | Apiezon L on Chromosorb | 185 | FID | 21 |
| Pentane, hexane, heptane benzene, toluene, ethanol, propanol, isobutyl alcohol, acetone, water | nitrogen with added n-octane, n-nonane, n-decane, hexanol, and dibutyl phthalate vapours | ethanol, propanol, isobutyl alcohol, heptane, octane, benzene, *p*-xylene on Chromosorb and INZ-600 | | katharometer | 22,23 |
| Isopropylbenzene | inorganic carrier gas with added solvent vapour | dioctyl phthalate on a solid carrier | – | – | 24 |
| $C_1$-$C_7$ hydrocarbons, oxygen compounds | methanol, ethanol, isopropyl alcohol, heptane, hexane, ethyl acetate, n-butyl chloride, chloroform, and dichloroethane vapours<br>mixtures of ethanol with methanol, heptane, benzene, hexane, and iso-octane | dioctyl phthalate on Chromosorb W A W, Porapak S and Q, activated alumina, silica gel, diethylene sebacate, silicone oil, poly(ethylene glycol) on C-22 refractory brick | 80, 140-230 | katharometer, u.v.cell | 25-30 |
| $C_9$-$C_1$ hydrocarbons, $C_4$-$C_6$ aliphatic alcohols | ethanol and heptane vapours | Apiezon L on INZ-600 | 135, 160 | katharometer | 31 |
| Free $C_2$-$C_{18}$ aliphatic acids, $C_3$-$C_{18}$ aliphatic amines, ethylenediamine, ethanolamine | water vapour with added formic acid or hydrazine hydrate vapour | Chromosorb GAW, Corning GLC-100 porous glass beads | 125-200 | FID | 32 |
| $C_6$-$C_1$ hydrocarbons, amines, isomeric geranate esters, halogenoalkenes, free aliphatic acids | Freon, formic acid, and methanol vapours | poly(ethylene glycol), SKTV polydimethylpolysiloxane on Chromosorb A and Chromaton | 120-175 | FID, densitometer, electron capture detector | 33,34 |
| Acetone, methanol, ethanol, diethyl ether | inorganic carrier gas with added isopentyl and hexyl alcohol vapours | isopentyl alcohol, high-vacuum grease on Celite-545 | 50,70 | katharometer | 35 |
| Nitrogen, argon, carbon dioxide, sulphur dioxide | Freon-116 vapour | silica gel | – | FID | 36 |
| Aromatic hydrocarbons | water vapour with added organic vapour (ethanol, pentane-ethylene fraction) | poly(ethylene glycol adipate), n-butylamine on Spherochrome | 130 | katharometer | 37 |
| Nitrogen compounds | nitrogen with added ammonia, polyethylene-amine, tetraethylene-pentamine, tetra(hydroxyethyl)-ethylene-diamine | OV-1 silicone on Chromosorb | 235 | FID | 38 |

This review considers the possibility of employing organic eluents and organic additives to carrier gases in analytical and preparative chromatography and also in physicochemical measurements. Attention has been concentrated on experiments under the usual pressures. As regards fluid chromatography[41-56], which constitutes a very powerful means of increasing the mobility of involatile sorbates, only some of its aspects are discussed below, because a number of reviews have been devoted to this method[40-42,45,47]. Since the review is restricted to the discussion of elution gas chromatography, frontal and displacement versions, where the mobile phase usually consists of organic gases and vapours, and particularly chromatography without a carrier gas[57] (with the exception of the problem of the preparation of a fixed mobile phase which has a bearing on the subject of the review) remain outside its scope.

## II. PREPARATION OF THE ELUENT

The organic additives are introduced into the carrier gas in the following ways: (1) by passing the stream of carrier gas through a tube or vessel with an adsorbent or

solid carrier impregnated with the volatile organic liquid; (2) by bubbling a layer of the liquid with the carrier gas; (3) by passing the carrier gas over a layer of the liquid; (4) by injecting a portion of the volatile solvent into the metering device of the chromatograph.

Thus the carrier gas has been passed[9] through a vessel with Sil-o-cel impregnated with the corresponding volatile solvent, and, in order to ensure the complete saturation of the gas, the temperature of the vessel exceeded by several degrees the working temperature of the column; after coming into contact with the solvent, the gas was cooled to the working temperature and was introduced into the chromatographic column.

In order to evaporate a mixture of water and formic acid, Nonaka[32] used a modified evaporator in the chromatograph. The carrier gas is usually saturated with formic acid vapour by passing it over a layer of concentrated formic acid[14-16].

Virtually complete saturation of the carrier gas by the organic vapour takes place when the gas is bubbled through a layer of the liquid[37,58]. An apparatus has been described[58] for a vacancy-chromatographic study of the phase equilibrium constants in which a saturator is used to saturate the carrier gas with the organic sorbate by bubbling. A device described by Benedek and Ratkovics[59] was used as the saturator.

In order to create a mobile band of the volatile liquid phase in the column, a number of workers[23,24,35] introduced the solvent directly into the column through a metering device. Evaporators of different designs have been used to obtain individual eluent vapours. Thus the generation system in one investigation[31] incorporated two steel cylindrical containers heated to 200°C. The liquid was evaporated in the first container and the resulting vapour passed to the second container, which served as a damping device and which was provided with a manometer and a fine control valve. The vapour then passed to the column through a heated capillary.

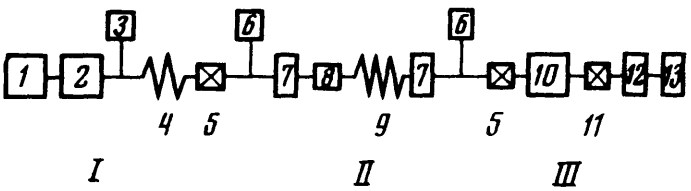

**Figure 1.** Schematic representation of the chromatographic apparatus with an organic vapour-phase eluent: I) gas-generating section; II) separating column; III) condenser for organic vapour-phase carrier; 1) vapour generator; 2) buffer reservoir; 3) manometer; 4) hydraulic resistance; 5) needle valve; 6) manometer; 7) detector; 8) evaporator; 9) column; 10) cooled trap; 11) cut-off valve; 12) trap with $CaCl_2$; 13) vacuum pump.

Fig. 1 illustrates schematically an apparatus where the vapour of an organic substance was used as the eluent (carbon tetrachloride, benzene, and ethanol)[26]. It consists of three parts: the gas generator, the column, and the condenser for the organic eluent. After the system had been evacuated, the reservoir *1*, containing the organic solvent, was heated to the required temperature (80° to 110°C); the vapour pressure reached 1–2 kgf $cm^{-2}$ at this temperature and the vapour was supplied to the separating column. The flow rate of the organic eluent was controlled by the inlet and outlet pressures in the column by means of a needle valve. The pressure in the column and the gas generator temperature were limited by the level of errors in the zero line. Before connection to the rest of the apparatus, the chromatographic system was conditioned for several hours in order to ensure equilibration. Because of its prior evacuation, the system usually operated at a reduced pressure. The flow rate of the organic eluent was calculated by dividing the dead volume of the saturating column by the retention time of the non-sorbed component.

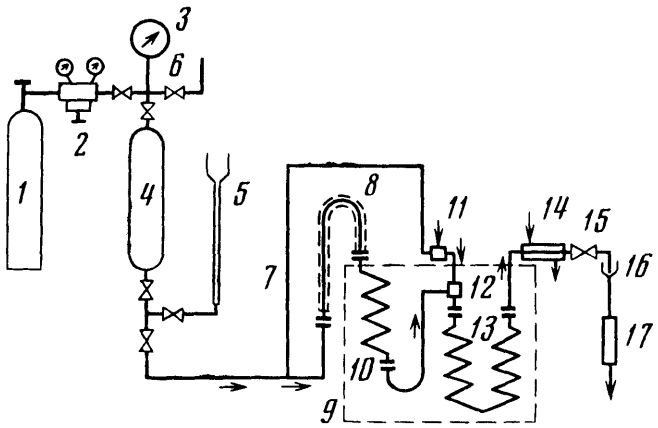

**Figure 2.** Schematic illustration of the apparatus for chromatography with hypercritical liquids: 1) gas cylinder; 2) reduction valve; 3) Bourdon manometer; 4) reservoir; 5) funnel; 6) valve; 7) side line; 8) heater; 9) air thermostat; 10) conditioning tube; 11) pneumatic injector; 12) three-way connector; 13) chromatographic column; 14) capillary tube; 15) needle valve; 16) degassing unit; 17) detector.

The apparatus usually employed to generate the vapours of organic eluents in fluid chromatography[45,47,48] is illustrated schematically in Fig. 2.[47] The mobile liquid phase is under nitrogen pressure in a stainless steel reservoir *4*, whence it passes to a heater *8*, where its temperature is adjusted to a value close to the critical temperature. The eluent is heated to the working temperature in the conditioning tube *10*, assembled, together with the chromatographic column *13*, in an air thermostat *9*. The pressure in the apparatus is regulated by the nitrogen pressure in the reservoir *4* and by the needle valve *15*. In later studies by the same workers[47], the pressure was generated by means of a pump.

## III. DETECTION

With some exceptions[1,2,36], organic eluents greatly reduce the sensitivity of the katharometer (K) and rule out the possibility of the application of a flame-ionisation detector (FID) for analysis; the above detectors are the

most widely used in traditional gas chromatography. In chromatography with organic eluents, the FID can be used only after the introduction into the usual carrier gas of small amounts of organic additives [38], which generate a small background current, or under conditions such that the detector does not record the organic substance (for example, when pure formic acid vapour is used as the eluent [34] and also when it is added to a usual carrier gas [14-16,21]), or under special conditions, for example as the carrier gas in the analysis of inorganic gases [17,60].

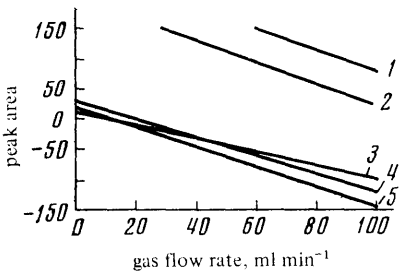

Figure 3. The influence of the flow rate of different carrier gases on the sensitivity of the katharometer to n-pentane ($t_c$ = 100°C): 1) hydrogen; 2) helium; 3) ethane; 4) methane; 5) nitrogen.

Despite the above limitations, the katharometer is widely used in this version of chromatography, both because a sufficient difference between the thermal conductivities of the eluent and the sorbate is achieved and because of the lack of an alternative. Fig. 3 [12] illustrates the influence of the nature of the carrier gas and of its flow rate on the sensitivity of the katharometer.

In order to improve the sensitivity of the usual katharometer, it is necessary to increase the current passed through the detector, which is impossible when the thermal conductivity of the organic vapour is low. In recent years studies have been published [61-63] in which an improved version of the katharometer with a constant filament temperature is proposed. The suggested version is free from the above disadvantages and the use of eluents with a low thermal conductivity actually increases its sensitivity [61].

An ultraviolet cell, which is selectively sensitive to aromatic compounds, has been used in studies by Tsuda and coworkers [25,27-30], whose work has been most productive in chromatography employing organic eluents. The ultraviolet cell is also widely used in fluid chromatography. The possibility of its successful employment up to 290 atm without reducing the pressure before its inlet has been demonstrated [53]. However, as stated above, its application is limited owing to its selectivity.

Despite the fact that examples of the use of the densitometer [33] and the electron capture detector [34] have been described in the literature, the katharometer and the ultraviolet cell will probably remain in the immediate future the most convenient detectors for this version of gas chromatography.

A comparative analysis of the results obtained with the aid of the ultraviolet cell and the katharometer in experiments where they were incorporated in the system in succession has been published [27]. The detectors operated in the linear range; the widths of the recorded peaks at the level of half their heights for a specific flow rate of the eluent vapour (ethanol) were approximately the same. The sensitivities of the detectors to substances containing one benzene ring are likewise approximately identical; the ultraviolet cell is more sensitive (approximately by a factor ten) to polycyclic aromatic compounds. The minimum amount of substance detected by the ultraviolet cell is 10–100 ng. A two-channel scheme with two detectors, one universal and the other selective with respect to the class of compounds investigated, is available and is suitable also for eluents in the vapour phase. Fig. 4 [27] presents chromatograms for the same mixture of substances obtained with the aid of these two detectors. The ratios of the peak heights of the same substance on the u.v. and K chromatograms are 1.4, 0.1, and 15 for derivatives of benzene, olefins or ketones, and naphthalenes respectively. The *b*, *d*, and *f* peaks correspond to olefins or ketones, the *c*, *e*, *g*, *h*, *i*, and *j* peaks correspond to benzene derivatives, and the *a* peak corresponds to a saturated hydrocarbon.

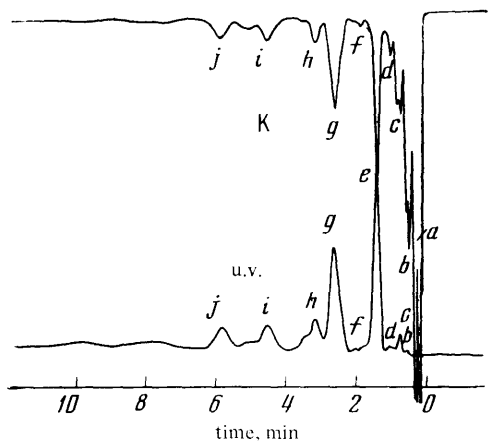

Figure 4. Combination of two detectors: sorbate—0.2 ml of petrol; column with 20 wt.% of dioctyl phthalate; $t_c$ = 120°C.

Ionisation detectors are relatively insensitive to inorganic gases. When an organic substance is introduced into the stream of carrier gas and an inorganic gas is then injected into the detector, the ionisation current is reduced to a greater extent than after the introduction of single gas into the stream of pure carrier [39]. Methods have been developed on this basis for the chromatographic determination of inorganic gases by ionisation detectors [17,36,39,60,64-67] (with a sensitivity of $0.5 \times 10^{-4}$% to $H_2$, $O_2$, and $CH_4$ and of $1 \times 10^{-4}$% to nitrogen [39]).

A universal detector meeting the requirements of fluid chromatography has not yet been devised. When traditional chromatographic detectors are used, it is necessary to reduce the pressure to atmospheric before the detector, which leads to the condensation of the mobile phase or to its degassing. As already stated, the majority of workers use the ultraviolet cell. Detectors which do not require the reduction of pressure beyond the chromatographic column have been proposed [44,54].

## IV. SORBENTS

In experiments with organic and mixed eluents, it is possible to use all the liquid phases and adsorbents which are employed in ordinary chromatography with inorganic carrier gases. Furthermore, in the presence of polar organic eluents and additives, requirements for the inertness of solid carriers become less stringent, and the set of possible liquid phases is extended by the inclusion of volatile solvents. Data concerning the application of liquid phases and adsorbents are presented in Table 1.

Having noted that organic eluents and additives affect the retention times of the substances analysed and the shape of the peaks, a number of workers [14-16,21,25,30,31,38,68-74] expressed different views concerning their influence on the mechanism of the interaction of the sorbate with the sorbent. The view that a thin liquid film is formed from the eluent vapour on the adsorbent surface, altering its sorption properties, is generally accepted. On the other hand, in the gas–liquid version, four factors, believed to be responsible for the change in the mechanism of the interaction of the liquid phase with the sorbate, have been isolated: (1) the formation of a liquid film on the surface of the liquid phase; (2) the formation of binary liquid phases; (3) temporary modification of the solid carrier by the molecules of the vapour phase; (4) the interaction between the sorbate and the eluent in the gas phase.

When organic eluents are used, all the above factors operate, but the role of each can be estimated only when account is taken of the specific experimental conditions: temperature, pressure, and the nature of the liquid phase or adsorbent and the eluent.

Berezkin et al. [31] analysed mixtures of alcohols and hydrocarbons in a stream of ethanol and heptane vapours and in nitrogen using Apiezon L as the liquid phase. At a high column temperature (160°C), nitrogen and ethanol vapour yielded virtually identical retention characteristics, because at an elevated temperature an eluent film is not formed on the surface of the liquid phase and a binary liquid phase is not produced, since ethanol is almost insoluble in Apiezon L. This also shows that, under the given conditions, the interaction in the gas phase does not have a significant influence on the retention. On the other hand, in the presence of heptane the retention volumes are altered, as a result of the dissolution of heptane in Apiezon L and the formation of a binary liquid phase with modified sorption properties.

An increase or decrease of the retention of propanol, octane, and toluene in ethanol and benzene vapours at a lower temperature (125°C) and using poly(ethylene glycol), dioctyl phthalate, and silicone as the stationary phases, relative to the retention of the same sorbates in a stream of nitrogen, has been explained [26] by the formation of a surface layer of condensed eluent, which prevents the mass transfer process and also by the dissolution of a small amount of the eluent in the stationary liquid. It is noteworthy that these explanations are in many respects contradictory, and the observed phenomena require a more detailed study. The retention volumes obtained in a number of studies [26,31] are listed in Table 2.

The process occurring in the column is in many respects determined by the temperature. When volatile solvents are used as the stationary phase by their partial condensation on an inert carrier in the column, a change in column temperature alters not only the partition coefficient of the sorbate in the gas–liquid system but also the thickness of the surface layer of the eluent, i.e. the amount of the stationary phase [7,8,22,23,35].

When the liquid phase and the eluent are only slightly miscible, a thick liquid film is formed on the surface of the liquid phase (according to Tsuda et al. [30], the thickness of the film corresponds to approximately 2–10 molecules when ethanol and alumina are used as the carrier vapour and adsorbent respectively at a column temperature of 100–150°C); on the other hand, when the liquid phase and the eluent are miscible, a binary phase is formed. Since the thickness of the film is determined by the sorption capacity of the support, the film is naturally thicker on an adsorbent than on a solid carrier; on the other hand, the adsorbent influences significantly the retention and the shape of the peaks.

Table 2. The ratios of the retention volumes of the sorbates for different carrier gases and liquid phases to the retention volumes for the nitrogen carrier gas [26,31].

| Liquid phase | Poly(ethylene glycol) | | Dioctyl phthalate | | Silicone | | Apiezon L | |
|---|---|---|---|---|---|---|---|---|
| Carrier gas | $C_2H_5OH$ | $C_6H_6$ | $C_2H_5OH$ | $C_6H_6$ | $C_2H_5OH$ | $C_6H_6$ | $C_2H_5OH$ | $n\text{-}C_7H_{16}$ |
| Ethanol | — | — | — | 1.7 | — | 1.9 | — | — |
| 1-Propanol | 0.9 | 1.0 | 0.8 | 1.2 | 0.7 | 1.4 | — | — |
| 1-Butanol | — | — | — | — | — | — | 0.9 | 1.7 |
| 1-Pentanol | — | — | — | — | — | — | 1.0 | 1.5 |
| 1-Hexanol | — | — | — | — | — | — | 1.0 | 1.3 |
| n-Octane | 0.7 | 0.8 | 0.8 | 1.0 | 0.5 | 1.3 | 0.9 | 1.1 |
| Toluene | 0.7 | 0.9 | 0.7 | 1.0 | 0.6 | 1.1 | — | — |
| n-Nonane | — | — | — | — | — | — | 1.0 | 1.2 |
| n-Decane | — | — | — | — | — | — | 1.0 | 1.3 |

Pressure has a significant influence on the chromatographic process only when it is greatly increased, although there is some change in the retention characteristics when the pressure is altered, but not to an extent sufficient to affect the chromatographic separation pattern. Thus Tsuda et al. [26] showed that, when the pressure is increased by a factor of seven (from 100 to 700 mmHg), the retention of octane and toluene increases by a factor of 1.3, while that of propanol remains unchanged. A different situation is observed with increase of pressure during the condensation of the eluent vapour on the adsorbent surface. According to Rakhmankulov and Vigdergauz [75] (they used water vapour as the eluent, alumina as the adsorbent, and a column temperature of 170°C), an increase of pressure from 1.6 to 7.2 atm entails a sharp decrease of retention—by a factor of several tens for high-boiling paraffins, and significantly smaller for polar sorbates soluble in water. An analogous effect obtains also in the presence of an organic-vapour eluent [12,28,30].

In fluid chromatography, the fluid has a very strong influence on the retention, displacing the phase equilibrium in the direction of the mobile phase. In fluid–liquid chromatography, stationary liquids such as Apiezon M and UCON-50-HB-2000 are eluted from the column in several minutes [49], which necessitates the use of high-molecular-weight liquids as stationary phases. One can instead saturate the mobile phase with the vapour of the stationary liquid, or the liquid phase can be grafted onto a solid carrier [44,50,51,53].

The formation of a liquid film with a simultaneous increase of partition coefficients is also observed in fluid-adsorption chromatography under certain conditions [45].

## V. THE SHAPE OF THE PEAKS AND RETENTION

The use of vapour-phase eluents permits in many instances a significant improvement of the separation as a result of the improvement in the shape of the peaks of the components to be separated and in view of the possibility of regulating the selectivity of the chromatographic column. In ordinary chromatography, the shape of the peaks is determined mainly by two factors: the influence of active adsorption centres of the carrier leading to the spreading of the rear sections of the peaks, and diffusion in the mobile phase, influencing the overall spreading. The use of vapour-phase eluents makes the peaks narrower and more symmetrical as a result of the suppression of the adsorption centres and decrease of the diffusion-induced spreading, since the extent of diffusion in vapour–vapour systems is smaller than in vapour–gas systems.

Table 3. Ratios of the retention volumes of the sorbates for different carrier gases to the retention volumes for the nitrogen or helium carrier gas [28].

| Liquid phase | Carrier gas | Sorbate | Ratio of retention volumes |
|---|---|---|---|
| Dioctyl phthalate, 20 wt.% Silicone, 25 wt.% | $CCl_4$, He | ethylbenzene, n-decane | 1.7–1.6 |
| | $CCl_4$, $N_2$ | 1-propanol, n-octane, toluene | 1.2–0.9 |
| | $C_2H_5OH$, $N_2$ | ditto | 0.7–0.5* |
| | $C_6H_6$, $N_2$ | " | 1.4–1.1* |
| Porapak S | $CCl_4$, He | n-hexane, cyclohexane, benzene | 0.18–0.15 |
| Porapak Q | $CCl_4$, $N_2$ | benzene | 0.4 |
| Alumina | $C_2H_5OH$, $N_2$ | benzene | 0.01 |

*Data of Tsuda et al. [30]

Table 4. The influence of the carrier gas (and the liquid phase) on the absolute specific retention volumes [12].

| Sorbate | Liquid phase—15% UCON-LB-550-X oil on Chromosorb W (60–80 mesh) | | | Liquid phase—15% Apiezon on Chromosorb W (50–80 mesh) | | |
|---|---|---|---|---|---|---|
| | He | $N_2$ | $CH_4$ | He | $N_2$ | $CH_4$ |
| n-Pentane | 5.9 | 5.8 | 4.8 | 6.0 | 5.2 | 3.9 |
| n-Hexane | 10.6 | 10.0 | 9.6 | 11.2 | 10.0 | 9.2 |
| n-Heptane | 19.2 | 18.2 | 18.0 | 22.0 | 18.7 | 19.7 |
| Hex-1-ene | 7.8 | 9.1 | 10.0 | 9.9 | 9.5 | 8.7 |
| Cyclohexane | 20.3 | 17.8 | 17.5 | 20.7 | 20.0 | 19.7 |
| Ethylcyclohexane | 52.4 | 51.1 | 50.8 | 67.7 | 64.5 | 64.5 |
| Cyclohexene | 19.9 | 20.6 | 24.1 | 23.2 | 22.2 | 21.2 |
| Benzene | 22.3 | 21.4 | 20.6 | 19.8 | 18.7 | 17.8 |
| Toluene | 42.6 | 38.8 | 39.8 | 41.0 | 39.2 | 31.8 |
| *p*-Xylene | 75.1 | 74.1 | 72.7 | 81.9 | 78.0 | 78.0 |
| *o*-Xylene | 91.1 | 88.0 | 87.6 | 96.6 | 92.4 | 92.0 |
| Isopropylbenzene | 102.5 | 101.4 | 99.8 | 103.9 | 102.6 | 100.7 |
| Methanol | 3.5 | 3.6 | 2.6 | 1.7 | 1.2 | 0.8 |
| Ethanol | 5.9 | 5.9 | 5.3 | 3.5 | 2.6 | 1.9 |
| 1-Propanol | 10.9 | 10.3 | 10.1 | 6.9 | 6.1 | 4.8 |
| 1-Butanol | 18.8 | 17.8 | 19.7 | 14.2 | 13.1 | 12.0 |
| 1-Pentanol | 38.7 | 36.5 | 38.5 | 30.6 | 30.9 | 28.4 |
| Isopropyl alcohol | 5.9 | 5.2 | 5.7 | 5.6 | 3.9 | 2.9 |
| Isobutyl alcohol | 15.6 | 15.1 | 13.6 | 12.5 | 9.6 | 9.6 |
| Isopentyl alcohol | 30.9 | 29.7 | 28.5 | 25.4 | 23.1 | 22.2 |
| t-Butyl alcohol | 6.6 | 6.7 | 6.1 | 6.0 | 5.2 | 4.8 |
| s-Butyl alcohol | 13.3 | 12.7 | 12.3 | 12.1 | 8.3 | 7.7 |

The change in the retention of substances when vapour-phase eluents are used is caused by the formation of binary stationary phases or surface films of the eluent and also by the formation of compounds more volatile than the initial sorbates (particularly in the analysis of metals) [40,76–81]. For example, the addition of aluminium chloride vapour to helium (carrier gas) made it possible to analyse metal chlorides having boiling points up to 2000°C (for $t_c$ = 150 to 500°C), which had not been analysed previously by gas chromatography [76].

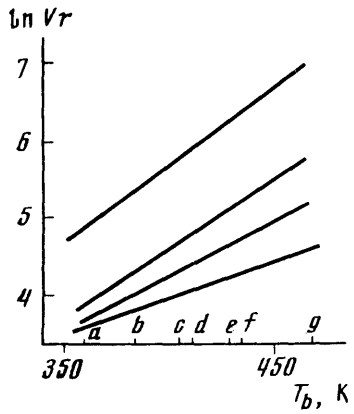

Figure 5. The influence of the nature of the carrier gas on the retention volumes in a column with activated alumina; vapour phase carrier: 1) n-hexane; 2) n-butyl chloride; 3) ethyl acetate; 4) ethanol; sorbates: *b*) toluene; *c*) chlorobenzene; *d*) ethylbenzene; *e*) bromobenzene; *f*) n-propylbenzene; *g*) iodobenzene; $t_c$ = 150°C; vapour flow rate 200 μl $min^{-1}$; sensitivity of u.v. detector 0.32 or 0.16 OD. The retention volumes are quoted with allowance for the pressure drop in the column; 75 cm column with activated alumina.

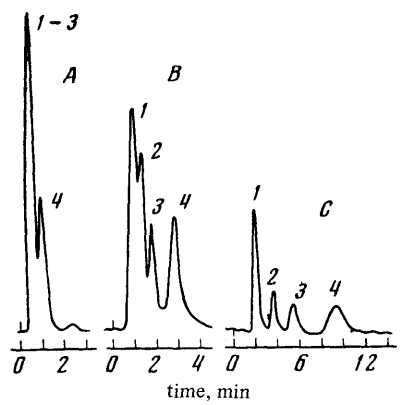

Figure 6. Chromatogram obtained using ethanol (*A*), ethyl acetate (*B*), and n-hexane (*C*) vapours as eluents. 75 cm column with activated alumina (100–300 mesh); column temperature 150°C; sample size 1–3 μl of ethanol containing 1% of different additives: 1) benzene; 2) toluene; 3) ethylbenzene; 4) n-propylbenzene.

Tables 3 and 4 and Figs. 5 and 6 [30] present data demonstrating the influence of the nature of the carrier gas on the retention volumes and chromatographic separation. When ethanol vapour and alumina are used as the carrier gas and adsorbent respectively, the retention volume of

benzene is 1/100 of the retention volume when nitrogen is used as the carrier gas in the presence of the same adsorbent.

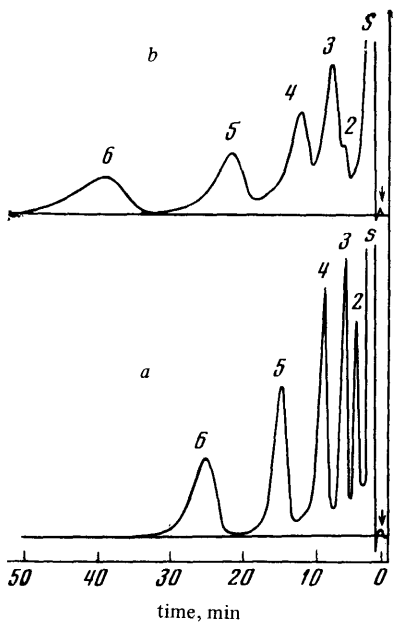

**Figure 7.** Chromatograms of a mixture of $C_2-C_6$ acids with (*a*) and without (*b*) addition of formic acid to the carrier gas; column with silicone; $t_c = 138°C$; helium flow rate 8 $cm^3\ min^{-1}$; *s*—acetone peak; the numerals against the peaks denote the number of carbon atoms.

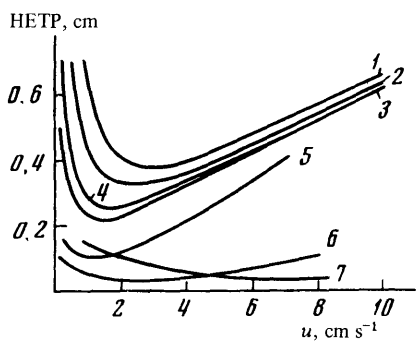

**Figure 8.** Variation of column efficiency (HETP) with the linear flow rate *u* and the nature of the carrier gas: 1) hydrogen; 2) helium; 3) methane; 4) nitrogen, ethane, ethylene ($t_c = 100°C$);[12] 5) carbon tetrachloride ($t_c = 90°C$);[28] 6) nitrogen; 7) helium[81].

As an illustration of the influence of the polar organic additive (formic acid) on the shape of the peaks and the degree of separation, Fig. 5 [15] presents chromatograms for the separation of volatile $C_2-C_6$ aliphatic acids on a column with silicone. Fig. 8 [12,28,82] illustrates the variation of HETP with the flow rate of eluents of different types. With increase of the molecular weight of the eluent, i.e. with decrease of the diffusion coefficient of the sorbate–eluent mixture (the diffusion coefficients of the hydrocarbons ethane, butane, and benzene are 0.6–0.8 $cm^2\ s^{-1}$ at 120–190°C in helium, or approximately 0.1 $cm^2\ s^{-1}$ in chloroform, carbon tetrachloride, and dichloroethane vapours at the same temperatures[28]), the HETP minimum is displaced towards lower linear flow rates of the eluent.

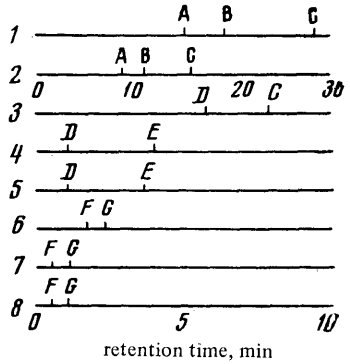

**Figure 9.** The influence of the nature of the carrier gas on the retention time; vapour-phase carrier: 1) benzene; 2) mixture of 10% of benzene and ethanol; 3) and 6) mixture of 1% of ethanol and iso-octane; 4) and 7) ethanol; 5) and 8) mixture of 1% of water and ethanol; flow rate 200 $\mu l\ min^{-1}$; A) phenol; B) *o*-cresol; C) *m*-cresol; D) *p*-di-isopropylbenzene; E) admixture of *p*-di-isopropylbenzene; G) cumene; F) admixture of cumene; 1) and 2) adsorbent—K-923 silica gel, column length 50 cm, internal diameter 3 mm, $t_c = 140°C$; 3)–8) adsorbent—HS-Pellumina, column length 1 m, internal diameter 2 mm, $t_c = 150°C$.

It is also possible to use multicomponent vapour-phase eluents and the components of such mixtures may be not only the vapours of organic substances but also permanent gases, water vapour, ammonia, etc. This approach makes it possible to regulate the selectivity of the chromatographic system (the stationary liquid–vapour-phase eluent system) by selecting the composition of the eluent. Thus, when the eluent was a mixture of ethanol and water vapours [30] (this method was first proposed by Mar'yakhin and Vigdergauz [37]) in the analysis of a mixture of $\alpha$- and $\beta$-naphthols on a column with silica gel, the retention time of the naphthols increased by 5–8 min compared with the experiment where the carrier gas was the vapour of pure ethanol. Similar effects have also been observed when the vapours of mixtures of ethanol with methanol, iso-octane, benzene [30], and hexane [25] were used.

The influence of the nature and composition of the eluent on the retention of sorbates is illustrated by the data in Fig. 9. [30]

## VI. DETERMINATION OF PHYSICOCHEMICAL PROPERTIES

Organic eluents may be used widely in the determination of the physicochemical properties of substances. The gas-chromatographic methods for the determination of physicochemical constants are based on the interaction between the sorbate, the liquid phase, and the carrier gas, so that an increase of the number of substances used as carrier gases greatly extends the range of interactions investigated.

The use of organic eluents in the corresponding systems does not affect the existing methods for the determination of diffusion coefficients [26,83-85], virial coefficients, and activity coefficients [9,18-20,22,86-93]. Thus Kobayashi and coworkers [18,89-93] investigated the gas–liquid equilibria in multicomponent systems, including gaseous and liquid hydrocarbons, and determined the diffusion coefficients [85] up to 136 atm. The employment of organic eluents makes it possible to simplify or modify some of the physicochemical methods (for example the determination of molecular weights [94-96] or of heats of desorption [30]) and to devise new ones, for example the procedure for the determination of complex-formation constants [87].

In particular, when a liquid film is formed on the surface of the adsorbent, the determination of the heat of desorption in chromatography with an organic eluent requires a modification of the method used in traditional chromatography [97]. Tsuda et al. [30] suggested that there is a relation in this case between the heats of desorption and the boiling point of the individual component analogous to Trouton's rule and obtained on this basis an approximate formula for the heat of desorption

$$\Delta H = K_2 T_b,$$

where $K_2 = K_1 T_c$, $T_b$ is the boiling point of the individual substance (in degrees Kelvin), $T_c$ the column temperature (in degrees Kelvin), and $K_1$ is determined from the slope of the linear plot based on the equation

$$\ln V_R = K_1 T_b + A_1 \quad (V_R \text{— is the retention volume}).$$

Using the equation obtained, the authors confirmed the presence of a liquid film on the adsorbent and concluded that the use of ethanol vapour is to be preferred in the analysis of high-boiling mixtures.

## VII. PREPARATIVE CHROMATOGRAPHY

Only a few studies have been made on the use of organic eluents in preparative gas chromatography [33,37,98-100], although the advantages of their employment (as well as water vapour [11]) are quite evident, since, apart from the possibility of modifying the sorption properties of the stationary phase, vapour-phase eluents ensure the virtually complete recovery of the products separated.

In order to increase the degree of recovery of benzene, Tsuda and Ishii [98] added to the carrier gas (nitrogen) a stream of toluene vapour, which condensed in a cooled trap together with the benzene issuing from the column. The degree of recovery of benzene depended on the ratio of the nitrogen and toluene streams and on the rate at which they passed through the column, exceeding 90% under optimum conditions.

Vigalok and coworkers [99,100] achieved a preparative separation of *m*- and *p*-xylenes on a column with a modified synthetic zeolite at 200°C in a stream of benzene vapour. Virtually complete recovery of the high-purity products was achieved (up to 99% after the removal of benzene). Naturally, the recovery did not require low temperatures.

Vigdergauz and Mar'yakhin [37] used, together with water vapour, its mixtures with various organic vapours in preparative chromatography. After their emergence from the column (3.2 m long and with an internal diameter of 20 mm), the mixed eluents were fully condensed (together with the substances isolated in traps cooled by tap water). The version where the eluent is a mixture of water and hydrocarbon vapours is of interest [37]. By varying the composition of this eluent, it is possible to regulate the selectivity and separating capacity of the preparative column. Furthermore, aqueous and hydrocarbon layers are formed in the traps and the substances isolated may concentrate in one of them (depending on their solubility).

Freons have been used in preparative chromatography [33] on a 15 m column having an internal diameter of 10 mm with poly(ethylene glycol) on Chromosorb A, where isomers of geranate ester were separated. Another version [33] involves the use of nitrogen as the carrier gas and the injection of small amounts of Freon into the gas stream directly before entering the trap.

In connection with the considerable progress in the improvement of the productivity of preparative chromatographic apparatus and the transition from preparative chromatography to semi-industrial and industrial chromatographic processes, the use of organic vapour-phase eluents, mainly readily available pure hydrocarbons and petroleum fractions, may serve as a basis for further advances in this field.

# The Electron Affinities of Organic Electron Acceptors

V.Kampars and O.Neilands

The principal methods used to determine the electron affinities of organic molecules are examined and the published data in this field are analysed. Briegleb's series, used in the majority of instances, yields absolute values which are too low. The most probable absolute electron affinities are quoted for the majority of organic electron acceptors investigated and their dependence on substituents and structural features is analysed.
The bibliography includes 121 references.

## I. INTRODUCTION

The electron affinities of organic molecules and ions are nowadays essential for the interpretation of the results in a very wide variety of research fields, associated mainly with the study of the properties of charge-transfer complexes and their role in organic, catalytic, and biological processes [1-7] as well as the study of one-electron transfer reactions [6,8], organic semiconductors [9-11], and organic materials with metallic conduction [12,13]. The publication of the handbook of Gurvich et al. [14] made available a large number of experimental electron affinities of organic acceptors but did not in any way solve the problem of their utilisation, since the results obtained by various workers for the same acceptors frequently differ by more than 1 eV.

The aim of the present review is to select from the available experimental data the most reliable electron affinities of organic acceptors. We also hope that the review will draw the attention of new investigators to the problem of the determination of electron affinities, which will directly assist in its final solution.

Since this review deals with compounds having fairly distinct electron-accepting properties, aromatic hydrocarbons, heterocyclic compounds, and other compounds with a negative or small positive electron affinity are excluded.

Among the methods for the determination of electron affinities, quantum-mechanical calculations are not considered, since we believe that they should be the subject of a separate review.

## II. FUNDAMENTAL CONCEPTS

Electron capture in the gas phase can be most conveniently treated in relation to a neutral diatomic molecule AB. This process can be regarded as a transition between two vibronic levels [15], one of which characterises the neutral molecule AB and the other the corresponding

radical-anion $AB^{\cdot-}$. Case *a* (Fig. 1) represents dissociative electron capture. Electrons whose kinetic energy varies from $E_1$ to $E_2$ are captured, while those having other kinetic energies are scattered. In case *b* (Fig. 1), the capture of electrons with a kinetic energy in the range $E_4 < E_{kin} < E_3$ leads to vibrational excitation of the radical-anion $AB^{\cdot-}$, which is stabilised in collisions with other species. The potential energy curve for the radical ion has a minimum. In case *c*, the molecule can capture an electron only in a vibrationally excited state and the radical-ion is stabilised in subsequent collisions between molecules.

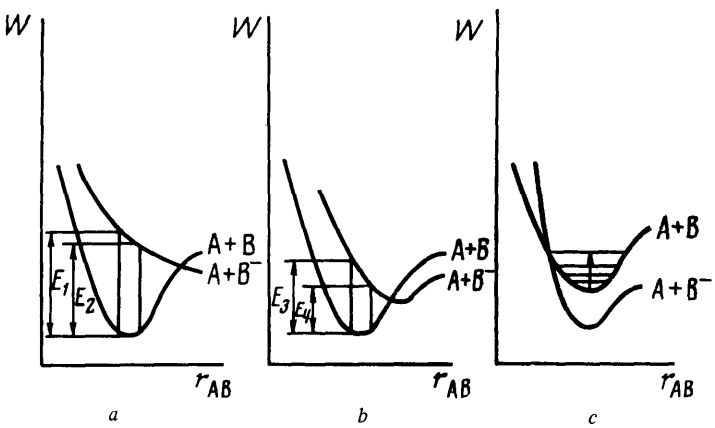

Figure 1. Electron capture by a diatomic molecule AB.

It is noteworthy that only in the last case does the molecule AB have a positive electron affinity ($EA$). Electron affinity is an energetic characteristic of electron capture processes and is equal to the amount of energy consumed or evolved when an electron is added to a gas-phase molecule in the state with minimum energy. Depending on whether the electron adds to a radical-ion in the ground (equilibrium) or vibrationally excited state, adiabatic (thermodynamic) and vertical electron affinities are distinguished. All the foregoing considerations may be expressed by the following equations:

$$AB + e \rightleftarrows AB^{\cdot-},$$
$$EA\ (\text{adiabatic}) = E(AB^{\cdot-}, r_{AB^{\cdot-}}) - E[(AB, r_{AB}) + e],$$
$$EA\ (\text{vertical}) = E(AB^{\cdot-}, r_{AB}) - E[(AB, r_{AB}) + e],$$

where $E$ is the total energy of the $AB^{\cdot-}$ and AB species in the equilibrium ($AB^{\cdot-}$, $r_{AB^{\cdot-}}$ and AB, $r_{AB}$) and vibrationally excited ($AB^{-}$, $r_{AB^{-}}$) states.

By definition, the adiabatic ionisation potential ($IP$) of the radical-anion $AB^{\cdot-}$ is expressed as follows:

$$-IP_{ad}(AB^{\cdot-}) = E[(AB, r_{AB}) + e] - E(AB^{\cdot-}, r_{AB^{\cdot-}})$$

and

$$EA_{ad}(AB) = IP_{ad}(AB^{\cdot-}).$$

The above relation is invalid for vertical processes.

Examination of processes of this kind for polyatomic molecules does not entail fundamental difficulties, although it is much more complex owing to the larger number of degrees of freedom. In principle, a molecule can combine not only with the first electron to form a radical-anion, but also with a second electron to form a dianion. In the latter case, one is dealing with the second electron affinity. In the gas phase, such processes are extremely improbable, but they are known in the condensed phase, where their occurrence is promoted by the strong solvation of charged species.

Electron affinities in the gas and condensed phases are also distinguished. In the condensed phase, the electron affinity does not characterise an individual molecule but a molecule in a crystal lattice or a solvation shell and is correspondingly increased by the polarisation ($P$) or solvation[9] ($E_{solv}$) energy:

$$EA_{cr} = EA + P$$
$$EA_{solv} = EA + EA^{\cdot-}_{solv} - E^{A}_{solv}.$$

## III. METHODS FOR THE DETERMINATION OF ELECTRON AFFINITY

The fundamental methods for the determination of electron affinity have been examined in a number of monographs and reviews[15-23]. Most of them are indirect, permitting the calculation of electron affinity from the general energetics of the given process. Some of them are related to the study of the given electron-accepting molecule in a condensed medium.

### Photochemical Elimination of Electrons from Negative Ions (The Photoabstraction Method)

This is a direct and most accurate method for the determination of electron affinities[20,21,24,25]. After their generation, capture, and detection, negative ions are irradiated with monochromatic light having a smoothly varying frequency. When the threshold photon energy is reached, the photoabstraction of electrons from the negative ions $A^{\cdot-}$ begins:

$$A^{\cdot-} + h\nu \rightarrow A + e.$$

The efficiency curves or the curves of the relative cross-sections for the photoabstraction of electrons plotted as a function of the energy of photons make it possible to determine the threshold photon energies from which the electron affinities of the acceptors A are determined. Considerable progress has been achieved in the development of apparatus for the method and increasingly more complex ions[26-28], including aromatic ions[29], are being investigated.

### Mass Spectrometry of Negative Ions

This procedure has been recently used with increasing frequency. Measurements of the appearance potentials ($AP$) of negative fragments under electron or photon impact permit the calculation of the electron affinities of radicals coupled with the negative ions formed[23,30,31]. The principle of this method can be described by the following equations:

(1) dissociative electron capture:

$$R_1{-}R_2 + e \rightarrow R_1^{-} + R_2^{\cdot},$$
$$EA(R_1^{\cdot}) = D(R_1 - R_2) - AP(R_1^{-}) + KE + IE;$$

(2) the formation of an ion pair:

$$R_1 - R_2 \xrightarrow{e,h\nu} (R_1{-}R_2)^{*} \rightarrow R_1^{+} + R_2^{-},$$
$$EA(R_2) = AP(R_2^{-}) - D(R_1{-}R_2) - IP(R_1^{\cdot}) - KE - IE,$$

where $D(R_1 - R_2)$ is the homolytic bond dissociation energy and $KE$ and $IE$ are the kinetic and internal energies of the species involved. The necessity for the determination of $D$, $KE$, $IE$, and $IP$ complicates the application of this method.

A method involving the mass spectrometric investigation of the equilibria in proton transfer reactions has also been used to determine the electron affinities of organic free radicals [32].

### The Method of Collision Ionisation of Alkali Metal Atoms

This procedure is promising. The electron affinities are calculated from the threshold value for the reaction

$$M + A \rightarrow M^+ + A^-,$$

where M is an alkali metal, usually caesium. The threshold value is determined by studying the dependence of the relative reaction cross-section on the translational energy of the reactants [33]. It is equal to the difference between the ionisation potential of the alkali metal and the electron affinity of the acceptor A. The method yields reliable results and has no fundamental limitations except that the process must lead to the formation of the molecular ion $A^-$ and not its decomposition products. The accuracy of the method [34-36] does not usually exceed ±0.1 eV. Electron transfer to the acceptor can be achieved also with the aid of other electron donors with known ionisation potentials [36,37].

### The Electron Capture or Thermal Equilibrium Method [15,19]

The method reduces to the investigation of the equilibria in reactions involving the capture of thermalised electrons by the acceptor in the gas phasa:

$$e + A \xrightarrow{K} A^- .$$

The steady-state concentration of electrons varies exponentially with the acceptor concentration in the system:

$$[e] = [e_0]e^{-\varkappa[A]},$$

where $\varkappa$ is the electron capture coefficient. The method is based on the determination of the electron capture coefficients. When $[e] \gg [A]$, we have $\varkappa = K$. At fairly high temperatures, $\ln \varkappa T^{3/2}$ varies linearly with $1/T$ and the slope of the straight line is $EA/K$. The intercept which the plot makes on the ordinate axis is not constant. It is believed that the temperature variation of $\varkappa$ is required for the correct determination of $EA$. At low temperatures, $\varkappa$ becomes approximately constant. Many $EA$ values for organic compounds have also been determined using the relative [19] electron capture constant $\varkappa'$.

Thermalised electrons are obtained in the form of secondary electrons when a mixture of gases, usually of methane and argon, is irradiated. Apart from thermalised electrons, radicals and positively charged ions, whose concentration does not vary under standard conditions even when the amounts of the acceptor investigated are small, are generated. The presence of the test gas influences only the concentration of the thermalised electrons. The experimentally determined quantities are [e] and [A]. Their separate determination is based either on the different mobilities of the electron and the acceptor molecule or on the magnetron effect. The latter requires special consideration, since the method based on this effect has come to be called the "magnetron method". The method, introduced for the first time by Sutton and Mayer [38,39], has been used particularly successfully by Page and coworkers [17,40]. The experimental apparatus consists of a cathode, a grid, and an anode mounted within a solenoid. The test substance is introduced in the gaseous state (vapour pressure $10^{-4}$–$10^{-2}$ mmHg). Thermalised electrons are generated by the heated cathode. In the absence of a magnetic field, both the electrons and the radical-anions $A^-$ reach the anode. The magnetic field forces the electrons to move along a circular orbit and they are captured by the grid. The magnetic field has little effect on the motion of $A^-$. Thus it is possible to measure separately the currents generated by the streams of electrons ($i_e$) and radical-anions ($i_i$). Since

$$i_e/i_i = K \cdot \exp(-EA/RT) \quad \text{and}$$

$$-\frac{R\, d\ln(i_e/i_i)}{d(1/T)} = EA(\bar{T}),$$

the slope of the straight line defined by the equation $Rd\ln(i_e/i_i) = cd(1/T)$ is equal to the electron affinity at a temperature $T$. The latter is determined as the average temperature of the cathode in the range where the measurements are made. The electron affinity at 0 K is obtained from the relation $EA_0 = EA(\bar{T}) - {}^3/_2 R\bar{T}$.

The method is unreliable, because the negative ion corresponding to the given species for which $EA$ is to be determined is not identified, which may lead to erroneous results [41]. Small amounts of impurities and products of thermal reactions can also bind electrons and can lead to considerable errors.

### The Method of Charge-Transfer Complexes (CTC)

It is based on the determination of the charge-transfer (CT) energy for complexes of a series of donors with the electron acceptor investigated [19]. The CT energy is usually determined from the CT band maximum. According to Mulliken's theory [5], the CT energy for a weak interaction between the donor and the acceptor can be expressed by the following equation:

$$h\nu_{CT} = IP - EA + G_0 - C + X_1 + X_0 \quad , \qquad (1)$$

where $G_0$ is the energy of all types of interactions between the donor and the acceptor in the ground CTC state, with the exception of the donor–acceptor interaction, $C$ is the energy of the Coulombic interaction between the components in the excited CTC state, and $X_0$ and $X_1$ are the energies of the resonance interaction between $\psi(D, A)$ and $\psi(D^+, A^-)$ in the ground and excited CTC states.

Using the expressions for $X_0$ and $X_1$, it is possible to obtain the following equation:

$$h\nu_{CT} = IP - EA - C - G_0 + \frac{\beta_0^2 + \beta_1^2}{IP - EA - C - G_0},$$

where $\beta_0 = H_0 + S_{01}W_0$ and $\beta_1 = H_{01} - S_{01}W_1$. The latter equation may be simplified because $C$ and $G_0$ can be assumed to be constant for CTCs of the same type with a fairly satisfactory degree of approximation. For a weak interaction between the donor and the acceptor, the overlap integral $S_{01}$ is small, so that $\beta_0$ and $\beta_1$ can also be regarded as approximately constant. Thus we obtain [1]

$$h\nu_{CT} = IP - (EA + E) + \frac{C_1}{IP - (EA + E)}.$$

For small values of $C_1$ and fairly high ionisation potentials, this equation acquires an even simpler form, which is frequently used in investigations [1-4,42-45]:

$$h\nu_{CT} = IP - EA - W, \qquad (2)$$

where $W$ is an approximately constant quantity for the given class of CTC.

In principle, Eqn. (2) can be used directly to calculate the electron affinities of acceptors, provided that $W$ is known. Since its exact value is not known, one usually starts with Eqn. (2), obtaining in this way the following expression for complexes of a common donor with a series of acceptors [19]:

$$h\nu_{CT}^{x} - h\nu_{CT}^{0} = \overset{0}{EA} - EA^{x} + W^{0} - W^{x}, \quad (3)$$

where $EA^0$ and $EA^X$ are the electron affinities of the reference acceptor and the test acceptor respectively.

It is frequently assumed [1-4,19] that $W^0 - W^X = 0$ and Eqn. (3) is simplified in this way is used to calculate $EA^X$. This is apparently justified only for acceptors having a similar structure and when, instead of a single donor, a series of donors are used in order to eliminate specific interactions of the components, since it has been shown [46] that the error resulting from the introduction of the last approximation can reach as much as 0.4 eV. Aromatic hydrocarbons, whose first and second ionisation potentials differ little in terms of energy, are most suitable as donors. *p*-Chloranil is most often employed as the reference acceptor [3,19,47].

## The Method Based on the Study of the Equilibrium Between the Radical-Ion and the Neutral Molecule

It is based on the determination of the equilibrium constant for the reaction

$$A^{\bar{\cdot}} + B \overset{K}{\rightleftarrows} B^{\bar{\cdot}} + A, \quad (4)$$

using spectroscopic analytical methods for this purpose. If the medium is insufficiently polar and ion pairs are present, another equilibrium actually obtains:

$$(A^{\bar{\cdot}}, K^{+}) + B \overset{K'}{\rightleftarrows} (B^{\bar{\cdot}}, K^{+}) + A$$

$$K' = K\frac{K_{diss}(A^{\bar{\cdot}}, K^{+})}{K_{diss}(B^{\bar{\cdot}}, K^{+})},$$

where $K_{diss}$ are the dissociation constants of the ion pairs. In solutions of radical-ions, more complex equilibria can also occur [48]. The enthalpy of reaction (4) is correlated with the difference between the values of $EA$ for the acceptors A and B. The less well-founded equation

$$-RT \ln K' = EA(A) - EA(B).$$

is usually employed [49].

## The Potentiometric Method [15]

The method is based on the measurement of the potential arising in the $A/A^{\bar{\cdot}}$ redox system. A modified method, resembling potentiometric titration, has found the most extensive applications. Measurements are made of the potential between two platinum electrodes, one of which is immersed in a standard redox system $A_0/A_0^{\bar{\cdot}}$ and the other in a solution containing the test redox system $A_X/A_X^{\bar{\cdot}}$. The redox system investigated is obtained by titrating a solution of $A_X$ with a standard solution of $A_0/A_0^{\bar{\cdot}}$. The half-wave potential $\epsilon$ is determined from the titration curve. According to Jagur-Grodzinski et al. [50], it is given by the expression

$$\varepsilon = \varepsilon_0 + 0.03 \ln (K_{A_0}/K_{A_x}) + 0.03 \ln \frac{[A_x, K^{+}]_t}{[A_0, K^{+}]_t}$$

where $\epsilon_0$ is the standard potential of the reaction $A_0^{\bar{\cdot}} + A_X \rightleftharpoons A_X^{\bar{\cdot}} + A_0$, $K_{A_0}$ and $K_{A_X}$ are the dissociation constants of the corresponding ion pairs, and $[A^{\bar{\cdot}}, K^{+}]_t$ is the sum of $(A_0^{\bar{\cdot}}, K^{+})$ and $(A_X^{\bar{\cdot}}, K^{+})$.

The standard potential $\epsilon_0$ is equal to the difference between the electron affinities of $A_X$ and $A_0$, i.e. the method yields the relative electron affinities. The relative electron affinities thus obtained are satisfactorily correlated with the corresponding absolute values for the gas phase, the slope of the straight line being close to unity [15].

## The Polarographic Method

The reversible one-electron reduction of the acceptor A is determined by the following process:

$$A_{solv} + e \rightleftharpoons A_{solv}^{\bar{\cdot}} \quad .$$

The half-wave potential is given by the expression [51]

$$E_{1/2} = E_0 - \frac{RT}{F} \ln \frac{D_1}{D_2},$$

where $E_0$ is the formal or standard potential, $R$ the gas constant, $F$ the Faraday, and $D_1$ and $D_2$ are the diffusion coefficients of the oxidised and reduced forms in the layer near the electrode.

$E_0$ is determined by the energetic characteristics of many processes [19], including the electron affinity of the acceptor A:

$$EA = E_{1/2} - \Delta E_{solv} - 5.07 + \frac{RT}{F} \ln D_1/D_2,$$

where $\Delta E_{solv}$ is the difference between the solvation energies of $A^{\bar{\cdot}}$ and A.

Since the diffusion coefficients $D_1$ and $D_2$ cannot differ by more than 1-2 orders of magnitude, the last term of this equation is negligibly small and can be rejected. Consequently the relation between the electron affinity in the gas phase and the half-wave potential of the reversible one-electron reduction is given by the equation

$$EA = E_{1/2} - \Delta E_{solv} + 5.07 \text{ (eV)} \quad . \quad (5)$$

Since the solvation energies of neutral molecules are small, the quantity $\Delta E_{solv}$ is determined mainly by the solvation energy of the corresponding radical-anion, i.e. $\Delta E_{solv} \simeq E_{solv}^{A^{\bar{\cdot}}}$. The study of the radical-anions of aromatic hydrocarbons [19,51,52] and of other electron acceptors [19] has shown that the solvation energies of radical-anions do not vary significantly with the structure of the delocalised radical-ion. According to Briegleb [19], the differences between the values of $\Delta E_{solv}$ for a series of different electron acceptors in acetonitrile do not exceed ±0.15 eV. A change of solvent can alter the solvation energy to a greater extent and hence also the values of $E_{1/2}$. Thus, when acetone is replaced by dichloromethane [53], the values of $E_{1/2}$ for a series of different acceptors change by 0.31 ± 0.05 V, i.e. the changes in the solvation energies for different radical-ions are approximately the same on passing from one solvent to another. The following equation can therefore be used with an adequate degree of approximation to calculate the electron affinities of acceptors forming delocalised radical-ions:

$$EA \simeq E_{1/2} + C \quad ,$$

$$\Delta EA \simeq \Delta E_{1/2},$$

where $C$ is a constant and $E_{1/2}$ the half-wave potential for polarographic reduction under the same condition.

Apart from the methods described above, other procedures are also available for the determination of electron affinities[21,54], but are not considered here.

## IV. ELECTRON AFFINITIES OF NEUTRAL ELECTRON ACCEPTORS

The vast majority of experimental data have been obtained by methods which do not yield directly the absolute electron affinities, but permit their calculation, provided that one can estimate in some way the remaining unknowns in the equations used to determine $EA$. It is therefore not surprising that the polarographic and CTC methods lead to very different estimates of absolute electron affinities (Table 1) in studies by different investigators. If one considers relative electron affinities obtained for the same estimates of other unknowns, instead of their absolute values, the situation changes radically (Table 1) and the majority of values for a particular acceptor agree to within 0.15 eV. It is also found that the relative electron affinities are satisfactorily correlated (Figs. 2 and 3) with the absolute electron affinities obtained by independent methods (electron capture, magnetron, and mass-spectrometric methods), the slope of the straight lines being close to unity.

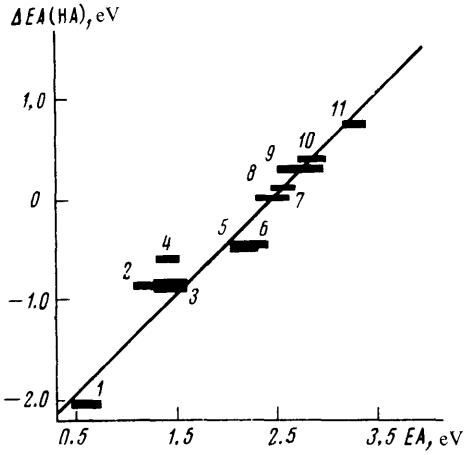

**Figure 2.** Relation between the relative (CTC method, reference acceptor–$p$-chloranil) and absolute electron affinities: 1) acceptor 45, electron capture method; 2) acceptor 144, magnetron method; 3) acceptor 11, mass spectrometric method; 4) acceptor 100, magnetron method; 5) acceptor 104, magnetron method; 6) acceptor 40, magnetron method; 7) acceptor 129, magnetron method; 8) acceptor 44, magnetron method; 9) acceptor 8, magnetron method; 10) acceptor 168, magnetron method; 11) acceptor 10, magnetron method (the acceptors are numbered in accordance with Table 1).

Consequently the problem of determining the absolute electron affinities can be solved by determining the relative electron affinities of different acceptors and by selecting the most probable absolute electron affinity of the reference acceptor–$p$-chloranil (HA). The absolute electron affinities of $p$-chloranil, obtained by the magnetron method, are also listed in Table 1. The validity of the latter results can be assessed in several ways. One of these involves the comparison of the results obtained by different methods using the relative electron affinities; the required data are presented in Table 2.

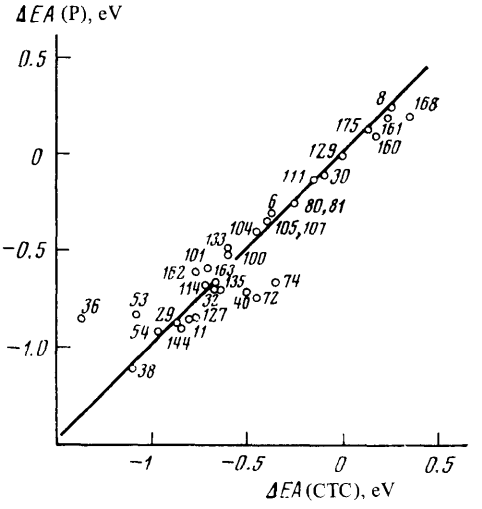

**Figure 3.** Comparison of the results obtained by the CTC and polarographic methods (the acceptors are numbered in accordance with Table 1).

Tbe absolute electron affinity of $p$-chloranil can also be inferred from a more detailed analysis of the results obtained by the polarographic method. Here the principal difficulty consists in the estimation of the solvation energies of the radical-anions arising in the one-electron reduction of the acceptor. Although much attention has been devoted to the determination of the solvation energies of charged species, their exact values are unknown[23,110,111]. This is particularly true of organic radical-anions and is the reason why the polarographic method has yielded two series[14] of electron affinities, differing by 1 eV.

One can assume with a satisfactory degree of approximation that the lower limit to the solvation energies of organic ions in polar solvents is given by the polarisation energies[9] in crystals of non-polar aromatic hydrocarbons, which are of the order[9,112] of 1.5 eV. Since the polarisation energy of negative ions is approximately 0.2 eV higher than that of positive ions and the negative charge of the radical-anions of acceptors is largely localised on the heteroatoms, one can assume that the lower limit to the solvation energies of the radical-anions of organic electron acceptors is approximately 2 eV. Since the solvation energy depends markedly on the charge density, the solvation energy of the iodide ion should probably be regarded as the upper limit, assuming that the charge is more delocalised in any organic radical-anion with a fairly well developed $\pi$-electron system. In aprotic polar solvents, incapable of specific solvation of anions, the solvation energy of the iodide ion[110,113] is approximately 2.5–3 eV. Since $\Delta E_{solv}$ is somewhat smaller than $E_{solv}$, it follows that, in conformity with Eqn. (5), the most probable electron affinity of $p$-chloranil exceeds 2.2 eV.

**Table 1.**

*$\Delta EA$ = EA(X) - EA(HA), where EA(X) and EA(HA) are the electron affinities of the test acceptor and *p*-chloranil respectively, determined by the same method.

**QC = quantum-mechanical calculation; EC = electron capture; MM = magnetron method; CTC = charge-transfer complex method; P = polarography; MS = mass spectrometry.

***For acceptors 169–176, the values of $EA$(abs.) were estimated from the $E_{1/2}$ using tetracyanoquinodimethane as the reference acceptor.

The CTC method constitutes yet another possibility for an approximate estimation of the absolute electron affinity of *p*-chloranil. It is assumed[5] that Eqn. (1) can be simplified to the following expression with a satisfactory degree of approximation for weak $\pi-\pi$ complexes:

$$EA = IP - h\nu_{CT} + g_1 + x_1. \qquad (6)$$

Table 2. Estimation of the electron affinities of *p*-chloranil relative to the absolute electron affinities of other electron acceptors.

| Acceptor | $EA$, eV | Method of determination of $EA$ | $\Delta EA = EA$ (X) $- EA$ (HA), eV | $EA$ (HA), eV |
|---|---|---|---|---|
| Hexachlorobenzene | 0.55 | EC | −2.05 | 2.6 |
| Benzaldehyde | 0.43 | EC | −1.85 | 2.3 |

| Anthracene | 0.57 | EC | −1.95 | 2.5 |
| Maleic anhydride | 1.4±0.2 | MS | 0.85 | 2.25±0.2 |
| 7,7',8,8'-Tetracyano-quinodimethane | 2.88±0.2 | MM | 0.37 | 2.50±0.2 |
| | 2.80±0.1 | MS | 0.37 | 2.43±0.1 |

*CT and CTC methods of determination.
**$EA_{av}$(HA) = 2.45 eV.

The first of the two unknowns $g_1$ and $x_1$ makes the greatest contribution, which in the case of $\pi-\pi$ complexes consist entirely of the Coulombic interaction energies ($C$) between the oppositely charged radical-ions in the excited CTC state. The latter can be estimated and then, using Eqn. (6) in the form

$$EA \geqslant IP - h\nu_{CT} - C, \qquad (7)$$

the absolute electron affinities of the acceptors can be inferred. Several models have been used to estimate $C$.[3,19,114] The model of point charges at the centres of the donor and acceptor molecules must be regarded as the least satisfactory approximation. The use of localised charge models[5,114] showed that the average values of $C$ for $\pi-\pi$ complexes are of the order of 3.3 eV. It follows from Eqn. (6) that $EA$(HA) ≥ 2.3 eV.

Another method for the determination of the absolute electron affinities of $\pi$-electron acceptors may be used on a comparison of the CT energies of their complexes with the CT energies of CTC acceptors of halogen atoms. Comparison of the results of the study of CTC of acceptors differing so greatly may appear incorrect at first sight. However, the characteristics of the complexes belonging to these groups are extremely similar. Thus the enthalpies of formation of the benzene–iodine[114,115] and *o*-xylene–iodine[116] complexes are 0.09 and −0.19 eV respectively. The distances between the components in the CTC of $\pi$-electron donors[115,116] are as follows: 3.36 Å for $Br^-$ complexes[61] and 3.7 Å for $I^-$ complexes[117]. All these characteristics are within the limits of the corresponding characteristics of the $\pi-\pi$ complexes[3]. Consequently the stabilisation energies of the excited CTC states of the $\pi-\pi$ and $\pi$-halogen atom complexes should not differ greatly and the differences between the CT energies (in the presence of a common donor) are approximately equal to the differences between the electron affinities. The electron affinities of the $Br^-$ and $I^-$ acceptors are known fairly well, although the data quoted by different workers[118] vary somewhat: 3.38–3.55 eV for $Br^-$ and 3.08–3.25 eV for $I^-$. According to Buchel'nikova[21], higher values should be used: 3.66 and 3.29 eV. The relevant data are presented in Table 3.

Table 3. Estimation of the electron affinity of *p*-chloranil.

| Donor | Acceptor | | | | $h\nu_{CT}$(X) − $h\nu_{CT}$(HA), eV | $EA$(HA), eV** |
|---|---|---|---|---|---|---|
| | $Br^-$ | | HA (3) | | | |
| | $h\nu_{CT}$, eV | solvent | $h\nu_{CT}$, eV | solvent | | |
| Benzene | 2.21–2.32 | Benzene (Ref.119) | 3.71 | $CCl_4$ | −1.39 – −1.50 | 2.2–2.3 |
| Toluene | 2.15 | Toluene (Ref.119) | 3.25 | $CCl_4$ | −1.10 | 2.56 |
| Naphthalene | 1.82 | | 2.61 | $CCl_4$ | −0.80 | 2.86 |
| | $I^-$ | | | | | |
| Benzene | 2.48–2.67 | Benzene (Ref.119) | 3.71 | $CCl_4$ | −1.03 – −1.23 | 2.2–2.3 |
| Benzene | 2.88 | In gas phase (Ref.12) | 3.90* | In gas phase | −1.0 | 2.3 |
| Toluene | 2.39–2.41 | Toluene (Ref.119) | 3.25 | $CCl_4$ | 0.85 | 2.44 |
| *o*-Xylene | 2.18 | *o*-Xylene (Ref.119) | 3.06 | $CH_2Cl_2$ | 0.88 | 2.41 |
| Mesitylene | 2.10 | Mesitylene (Ref.119) | 2.89 | $CH_2Cl_2$ | 0.79 | 2.50 |

*The polarisation energy was used[121].
**$EA_{av}$(HA) = 2.45 eV.

The data in Tables 1–3 show that the most probable value of the absolute electron affinity of *p*-chloranil is 2.45 ± 0.15 eV. It has been used to calculate the electron affinities of the acceptors for the determination of which there are no data obtained by absolute methods and to refine the electron affinities of the acceptors for which such data are available [Table 1, the values of $EA$(abs.)].

Comparison of the results obtained by different methods (Figs. 2 and 3) makes it possible in its turn to infer the errors; they do not appear to exceed 0.2 eV and in those cases where reliable results found by several methods are available, the error is much smaller.

It is well known that the introduction of substituents can alter greatly the electron affinity. The amino-, methoxy-, and alkyl groups reduce electron affinities, while the nitro-, cyano-, acyl, and alkoxycarbonyl groups as well as halogens increase them. The problem of the possible utilisation of the increments due to various substituents has remained unresolved due to the inaccuracy of the $EA$ values themselves [19]. Nevertheless the employment of empirical increments for substituents would provide the easiest and possibly the most accurate method at the present time for the estimation of the electron affinity of a compound, since quantum-mechanical calculations for large systems with heteroatoms by the Hückel and PPP methods using the Koopmans theorem do not yield reliable results.

The increments due to substituents may be determined by comparing the affinities of the monosubstituted and unsubstituted compounds. We adopted *p*-benzoquinone as the standard system, since a fairly large number of monosubstituted *p*-benzoquinones have been investigated (Table 1, acceptors Nos. 100–113) and the following increments were obtained: −0.15 eV ($CH_3O$); −0.05 eV ($CH_3$); +0.13 eV (F); +0.18 eV (Cl); + 0.19 eV (Br); +0.17 eV (I); +0.20 ($CH_3OCO$); +0.25 eV ($CH_3CO$); +0.30 eV ($CF_3$); +0.43 eV (CN); +0.70 eV ($NO_2$).

The electron affinities of polysubstituted acceptors can be calculated from the general equation

$$EA = EA_0 + C_1 \sum_n I_n - C_2 C_1 \sum_n I_n,$$

where $EA_0$ is the electron affinity of the initial unsubstituted acceptor, $C_1$ a coefficient characterising the sensitivity of the given system to the introduction of substituents, which is determined from measurements for monosubstituted compounds and is unity for *p*-benzoquinones, $I$ are the increments of the substituents, and $C_2$ is a coefficient taking into account the effects of the interaction of the substituents, i.e. the non-additivity in the case of polysubstituted compounds; for monosubstituted compounds, $C_2 = 0$.

It was found that $C_2 = 0.1$ for polysubstituted *p*-benzoquinones and remains constant for a series of other compounds, i.e. the equation for the calculation of the electron affinities of polysubstituted acceptors can be formulated as follows:

$$EA = EA_0 + 0.9C \sum_n I_n \,. \qquad (8)$$

Eqn. (8) and the above series of increments can be used without modification to estimate the electron affinities only in those systems where the effects of the substituents in different positions are approximately the same and the introduction of a new substituent does not alter appreciably the steric structure of the acceptor molecule (the substituent has a small steric effect). Such systems proved to be the derivatives of fluorenone (Table 1, Nos. 76–79) and dicyanomethylenefluorene (Nos. 80–86 with $C_1 = 0.25$), 1,4-naphthoquinone ($C_1 = 0.29$ for substituents in the 5-, 6-, 7-, and 8-positions, and $C_1 = 1.08$ for substituents in the 2- and 3-positions; Nos. 135–143), 7,7′,8,8′-tetracyanoquinodimethane ($C_1 = 0.63$; Nos. 168–174), the anhydride of phthalic acid ($C_1 = 0.75$; Nos. 11–13), *o*-benzoquinone ($C_1 = 0.7$; Nos. 159–161), diphenoquinone ($C_1 = 0.92$; Nos. 150–152), trinitrobenzene with electron-accepting substituents (with small steric effects; $C_1 = 1.1$; Nos. 52, 55, and 56), and ethylene ($C_1 = 1.9$; Nos. 3, 4, 5, 7, and 8).

Among the 45 compounds for which tests were made, the discrepancy between the experimental and calculated electron affinities did not exceed ±0.05 eV for 34 compounds and ±0.1 eV for 8 compounds, exceeding 0.1 eV for only three compounds. This shows that equations of this kind are very promising for the specific synthesis of new electron acceptors. Eqn. (8) also makes it possible to estimate the electron affinities of the unsubstituted initial compounds. A fairly unexpected result is obtained for ethylene: $EA = 0.2$ eV.

An increase of the π-electron system of the acceptor leads to a decrease of the electron affinity, despite the fact that in systems without heteroatoms the opposite behaviour is observed. This shows that, in systems with heteroatoms (they are all powerful electron acceptors), the lowest vacant molecular orbital is to a large extent localised in the part of the molecule which is directly linked to the heteroatom and its additional delocalisation leads to an increase of its energy. Thus the changes observed on passing from maleic anhydride (Table 1, No. 11) to phthalic anhydride (No. 58) and from 7,7′,8,8′-tetracyanoquinodimethane (No. 168) to 11,11′,12,12′-tetracyano-1,4-naphthoquinodimethane (No. 175) are associated with a decrease of the electron affinity by 0.25 and 0.2 eV respectively. In the series of *ortho*-quinones (No. 159, 162, and 163), an increase of the system by one benzene ring reduces the electron affinity on average by 0.2 eV. The linear condensation of benzene rings in *p*-benzoquinone derivatives (Nos. 100, 135, 144, 147, 148, 149) leads to a decrease of the electron affinity on average by 0.1–0.15 eV (per benzene ring) and this behaviour holds satisfactorily throughout the series. On the other hand, an increase of the conjugated π-electron system between the electron-accepting groups leads to an increase of electron affinity (see Nos. 168 and 176).

The replacement of the carbonyl group by the dicyanomethylene group increases electron affinity by 0.25–0.45 eV (Table 1, Nos. 68, 69, 70, 76, 83, 77, 84, 78, 85; 79, 86; 100, 168, 135, 175). In quinonoid systems, the increase is a maximum and is close to 0.45 eV for each dicyanomethylene group (Nos. 100, 168; 135, 175).

# Compounds of Two-coordinated Phosphorus

N.I.Shvetsov-Shilovskii, R.G.Bobkova, N.P.Ignatova, and N.N.Mel'nikov

A systematic account is given of the available literature data on phosphorus(III) compounds with multiple bonds. The methods of synthesis, the physicochemical properties, and the chemical properties of phosphamethinecyanines, phosphorins, (phosphabenzenes), 1,2,3-diazaphospholes (phosphadiazoles), and other compounds of two-coordinated compounds are considered. The bibliography includes 100 references

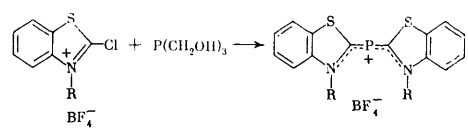
## I. INTRODUCTION

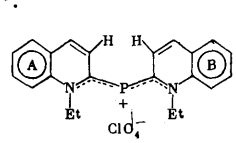
Compounds containing two-coordinated phosphorus were virtually unknown until 1964. It was believed that structures with multiple bonds involving a tervalent phosphorus atom are unstable. The diatomic molecules with one-coordinated phosphorus described previously, namely $P_2$, PN, and PO, were detected only by spectroscopic methods at high temperatures [1-3]. Methinophosphide (phospha-acetylene, carbophosphil) HC≡P could be isolated in the form of a white solid stable at the temperature of liquid nitrogen, but polymerising above −120°C, [4-6] Apart from methinophosphide, its halogeno-, amino-, and hydroxy-derivatives were described [7]. The author demonstrated the monomeric nature of these derivatives by the fact that the phosphorus signals in the $^{31}P$ NMR spectra consist of narrow singlets. Evidence confirming the molecular weight adopted is not quoted in the relevant paper.



Kirby and Warren [8] compared phosphorus with carbon and nitrogen and adduced a number of causes which explain the greater difficulty of the formation of multiple bonds involving phosphorus(III). The conditions for sufficient overlapping of the orbitals and the formation of $\pi$-bonds are apparently more favourable for the $2p$ orbitals of the atoms of Second Period elements, separated by $2p_\sigma$-bonds, than for the more diffuse $3p$ orbitals of the atoms separated by the longer $3p_\sigma$-bonds. Furthermore the repulsion of the filled inner electron shells of the atoms of the Third Period elements constitute an additional obstacle, hindering the decrease of the bond length required for the formation of strong $p_\pi$-bonds [9]. Hudson [10] and Mulliken [11] suggest that the relative instability of the $\pi$-bonds involving Third Period elements is also caused by the greater energy of their $\sigma$-bonds, in particular by the contribution of the $d\sigma$-orbitals.

Nevertheless, a number of acyclic and cyclic compounds containing two-coordinated phosphorus in CPC (phosphamethinecyanines and phosphorins), CPN (diazaphospholes), and NPN [bis(trimethylsilyl)aminotrimethylsilyliminophosphine and triazaphospholes)] fragments have been synthesised recently.

## II. ACYCLIC COMPOUNDS

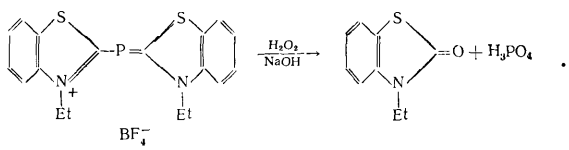


### 1. PHOSPHAMETHINECYANINES

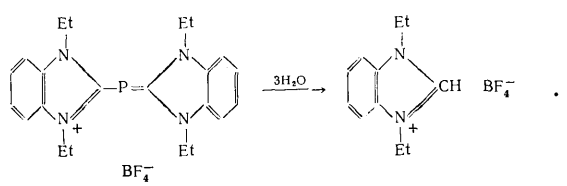
The first compounds of two-coordinated phosphorus–phosphamethinecyanines–were obtained from *N*-alkylated benzothiazolyl fluoroborates and tris(hydroxymethyl)phosphine in the presence of ethyldi-isopropylamine in dimethylformamide [12]:

Symmetrical and asymmetric phosphamethinecyanines were synthesised analogously from benzothiazolium and quinolinium fluoroborates and perchlorates [12-14]. Instead of tris(hydroxymethyl)phosphine, tris(trimethylsilyl)-phosphine may be used to obtain phosphamethinecyanines.[15] The stability of structures with two-coordinated phosphorus is apparently due to the involvement of the phosphorus atom in conjugation. An X-ray diffraction study of the structure of bis-(*N*-ethyl-2-benzothiazolyl)phosphamethinecyanine showed that the planes of both benzothiazole rings are in the *cis*-positions relative to the phosphorus atom and are rotated relative to one another only by 6°. The C–P–C angle is 104.6°. Both C–P bonds have the same length, amounting to 1.76 Å, i.e. they are longer than the P=C bonds in phosphinylides (1.65–1.68 Å) and shorter than the P–C bonds in triphenylphosphine (1.83 Å).[13]

The replacement of benzothiazole by quinoline in phosphamethinecyanines leads to an appreciable change of molecular geometry, as was to be expected from steric considerations [the close proximity of the hydrogen atoms attached to $C_{(3)}$] [16]:



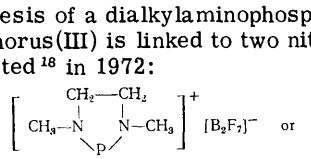
Thus the planes of the quinoline rings A and B are inclined at angles of 40° and 24° relative to the C–P bonds of the cyanine plane. As a result of this, conjugation in the cyanine cation is hindered, which leads to some increase in the length of the C–P bonds, to 1.81 and 1.77 Å, The C–P–C angle in bis-(1-ethyl-2-quinolinyl)-phosphamethinecyanine is 100.4°.



The chemical shift of phosphorus in the $^{31}P$ NMR spectra is −24.9 p.p.m. for bis-(*N*-ethylbenzothiazolyl)-phosphamethinecyanine and −48.8 p.p.m. for the bis-quinolinyl derivative (relative to 85% $H_3PO_4$).

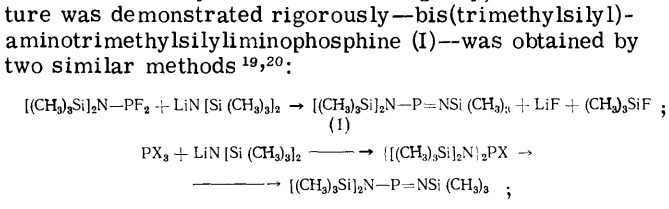
The electronic spectra of phosphamethinecyanines resemble those of monomethine- and monoazamethine-cyanines, the position of $\lambda_{max}$ corresponding to the lower electronegativity of phosphorus compared with carbon and nitrogen [13,14].

The majority of reactions of two-coordinated phosphorus are associated with oxidations involving the phosphorus atom. Phosphamethinecyanines are decomposed by oxidising agents. When treated with 30% hydrogen peroxide in an alkaline solution, the salts of bis-(*N*-alkyl-2-benzothiazolyl)- and bis-(*N*-alkyl-2-quinolinyl)-2-phosphamethinecyanines are smoothly oxidised to 2-benzothiazolone and 2-quinolone derivatives and phosphates. A large number of unidentified radicals are formed at intermediate stages [16]:



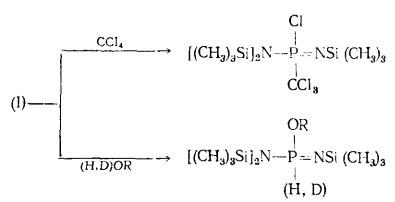
Like methinecyanines, phosphamethinecyanines are protonated by strong acids with formation of colourless dications, which can be reconverted into phosphamethinecyanines by treatment with weak bases [17]. When benzimidazolylphosphamethinecyanine was treated with silver tetrafluoroborate in methanol, colourless crystalline silver complexes, decomposed by an excess of methanol, were isolated. Mercury chloride forms similar complexes with phosphamethinecyanines. Water decomposes phosphamethinecyanines [17]:

## 2. BIS(TRIMETHYLSILYL)AMINOTRIMETHYLSILYLIMINOPHOSPHINE



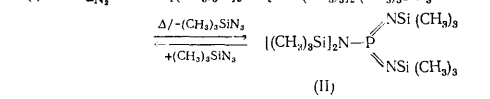
Compounds of two-coordinated phosphorus(III) with a phosphorus–nitrogen multiple bond were unknown until 1972. The reasons for the difficulty of the formation of $p\pi-p\pi$ bonds involving phosphorus(III) were noted above. One need only point out that, whereas the difference between the energies of the σ- and π-bonds for the phosphorus–carbon linkage amounts to 18 kcal mole$^{-1}$, the difference for the P–N linkage is 23 kcal mole$^{-1}$.

The synthesis of a dialkylaminophosphonium cation, in which phosphorus(III) is linked to two nitrogen atoms, was briefly reported [18] in 1972:



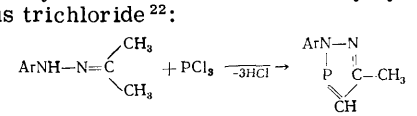
A downfield shift of the $^{31}P$ signal, which is unusual for organophosphorus compounds was noted in the $^{31}P$ NMR spectrum of this cation: $\delta_{^{31}P}$ = −274 p.p.m. (in toluene) and −264 p.p.m. (in 1,2-dichloroethane). The magnitude of this shift constituted the only argument justifying the structure adopted.

The first compound with a –P=N group, whose structure was demonstrated rigorously—bis(trimethylsilyl)-aminotrimethylsilyliminophosphine (I)—was obtained by two similar methods [19,20]:



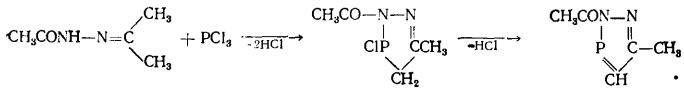
Compound (I) is a yellow-green liquid sensitive to hydrolysis, which is fairly stable in a pure form at temperatures below 0°C and in the absence of light. The composition and structure of the aminoiminophosphine (I) were demonstrated by elemental analysis, mass-spectrometry, and infrared and NMR spectroscopy. The chemical shift of phosphorus is −325.5 p.p.m. This range of chemical shifts had not been reached by any of the phosphorus compounds known hitherto.

The phosphorus atom in bis(trimethylsilyl)aminotrimethylsilyliminophosphine is highly electrophilic, which is manifested in a number of exothermic 1,1-addition reactions [19]:



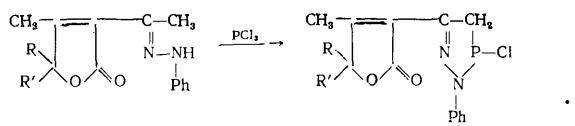
The interaction of bis(trimethylsilyl)aminotrimethylsilyliminophosphine with trimethylsilyl azide leads to phosphine di-imide(II), the first representative of compounds with a three-coordinated phosphorus(V) atom [21]:

## III. FIVE-MEMBERED HETEROCYCLES

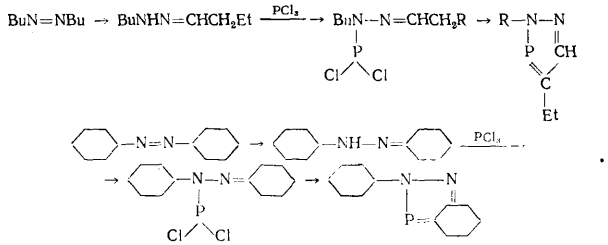


### 1. DIAZAPHOSPHOLES

The first derivatives of 1,2,3-diazaphospholes were synthesised by the reaction of acetone arylhydrazones with phosphorus trichloride [22]:

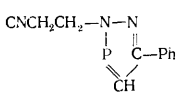


The excess initial phenylhydrazone or triethylamine serves as the hydrogen chloride acceptor. The phenylhydrazones of alkyl methyl ketones and acetaldehyde, β-cyanoethyl-, benzoyl-, and butoxycarbonyl-hydrazones of acetone, and β-cyanoethylhydrazones of acetophenone and *p*-bromoacetophenone react similarly with phosphorus trichloride[22-28].

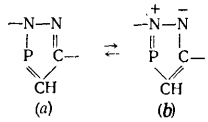


The reaction of phosphorus trichloride with acetone acetylhydrazone under the same conditions leads to 2-acetyl-3-chloro-5-methyl-1,2,3-diazaphospholine, which is converted into 1,2,3-diazaphosphole by additional treatment with triethylamine[24,26-29]:

The formation of 3-chlorodiazaphospholines was also observed when the phenylhydrazones of 2-acetyl-2-but-4-enolides reacted with phosphorus trichloride[30]:



A new method of synthesis of diazophospholes from azo-compounds and phosphorus trichloride was published in 1974. The reaction mechanism involves the isomerisation of the azo-compound to hydrazones[31]:

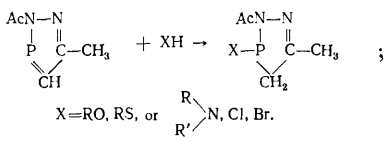


It is interesting to note that, having replaced phosphorus trichloride by arsenic trichloride in the reaction with hydrazones, Märkl obtained a series of arsadiazoles[32,33].

## (a) Physicochemical Properties

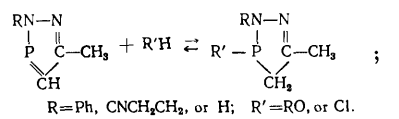
An X-ray diffraction study of 2-(β-cyanoethyl)-5-phenyldiazaphosphole[34]

showed that the five-membered heterocycle and the benzene ring are planar (the maximum deviation of the atoms from their average planes does not exceed 0.01 Å), the mutual rotation of the planes of the rings is by an angle of only 16.1°, and the $C_{(2)}-C_{(3)}$ bond is coplanar with the planes of both rings, so that the conjugation between the two fragments is unaffected. The P–N and P=C bond lengths are respectively 1.676 and 1.702 Å, i.e. corespond to partial double bond character. The C=N bond length (1.34 Å) is comparable to the value (1.32 Å) found for the diazomethane molecule and the N–N bond length (1.34 Å), although appreciably smaller than the value corresponding to a single bond, is nevertheless characteristic of the bonds between nitrogen atoms of the type =N–N=. Finally, $C_{(1)}-C_{(2)}$ (with a length of 1.41 Å) is a typical linkage with a bond order of 1.5. The observed distribution of bond lengths in the diazaphosphole ring corresponds to partial delocalisation of electrons with structure *a* predominating to some extent:



X-Ray diffraction analysis confirmed that 2-(β-cyanoethyl)-5-phenyldiazaphosphole is not dimeric, since the atoms of the closest molecules in the unit cell are separated by a distance greater than the van der Waals radius. The results of the X-ray diffraction study of 2-(β-cyanoethyl)-5-phenyldiazaphosphole are consistent with earlier electron-diffraction data[23,29] for 2-acetyl-5-methyldiazaphosphole and 5-methyl-2-phenyldiazaphosphole.

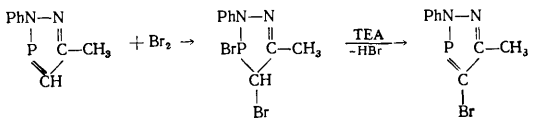
The ultraviolet spectra of diazaphosphole are similar to those of the corresponding triazoles. There is a bathochromic shift due to the lower electronegativity of phosphorus compared with nitrogen. The wavenumber of the most intense band (1295 $cm^{-1}$) in the infrared spectra of diazaphospholes was assigned to the pulsating (puckering?) vibration of the ring. The lower value of this wavenumber compared with those of the pulsating vibrations of pyrazoles, triazoles, and oxadiazoles can be explained by the greater mass of the phosphorus atom in the ring[22].



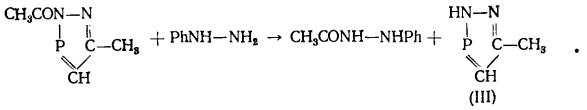
The chemical shift of phosphorus, determined by the method of double phosphorus–proton resonance, is −225 p.p.m. for 2-phenyldiazaphosphole and −238 p.p.m. for 2-acetyldiazaphosphole.

## (b) Chemical Properties

A wide variety of compounds with an active hydrogen atom readily add to the multiple bonds of diazaphospholes, which has been investigated in greater detail for 2-acetyl-4-methyldiazaphosphole. The latter reacts readily with alcohols, amines, phenols, mercaptans, nitrogen-containing heterocycles, and hydrogen halides[28]:



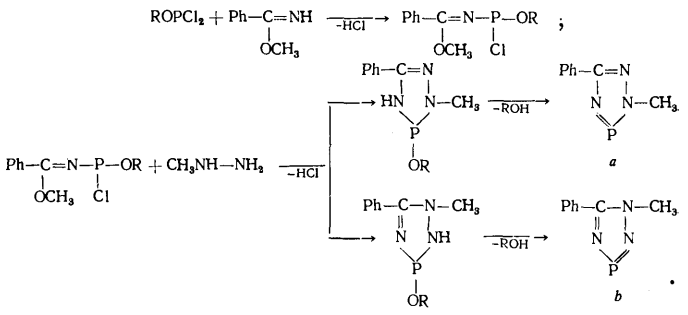
When alcohols and hydrogen chloride add to 2-phenyldiazaphosphole and when alcohols add to 2-(β-cyanoethyl)-diazaphosphole and diazaphospholes unsubstituted in the 2-position, the products are diazaphospholines, which are thermally unstable and are readily reconverted into the initial compounds[35]:



On treatment with an excess of alcohol or alkali, diazaphospholes decompose to hydrazones and phosphites.

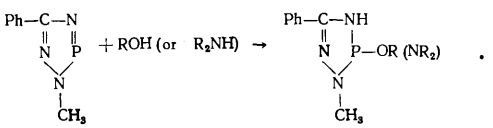
Bromine also adds to the C=P bond of 2-phenyldiazaphosphole, giving rise to the unstable 3,4-dibromo-5-methyl-2-phenyldiazaphosphole, the formation of which was confirmed by the PMR method. On treatment of the

reaction mixture containing the above compound with triethylamine (TEA), 4-bromo-5-methyl-2-phenyldiazaphosphole was obtained[35]:



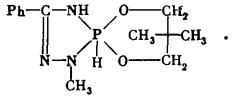
The reaction of 2-acetyl-5-methyldiazaphosphole with phenylhydrazine leads to β-acetylphenylhydrazine and a diazaphosphole unsubstituted in the 2-position: 5-methyldiazaphosphole(III):

The structure of compound (III) was demonstrated by infrared spectroscopy, NMR, and mass spectrometry[35].



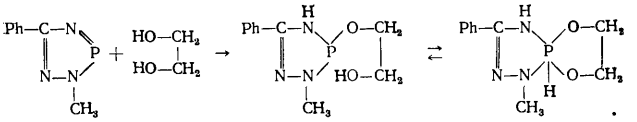
## 2. TRIAZAPHOSPHOLES

Triazaphospholes were synthesised from *O*-methyl iminobenzoate, phosphorodichloridite, and methylhydrazine[36]:



Structure *a* and *b* were attributed on the basis of NMR spectra to the isomeric substances obtained, the ratio of the isomers being 6 : 1. The chemical shifts of the triazaphospholes are −256.1 and −261 p.p.m. respectively.

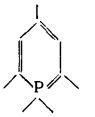
One of the isomeric triazaphospholes (isomer *a*) is involved in the 3,4-addition reaction with certain alcohols and amines:



The occurrence of this reaction was inferred[36] from the change in the signals in the $^{31}P$ NMR spectra. When an attempt is made to vacuum-distill them, the addition products are reconverted into the initial triazaphosphole.

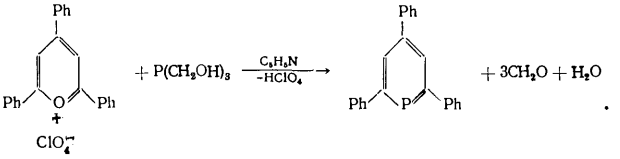
The reaction of triazaphospholes with catechol and pinacone leads to spirophosphoranes:

The reaction with ethylene glycol results in the formation of an equilibrium mixture[36]:



## IV. SIX-MEMBERED HETEROCYCLES

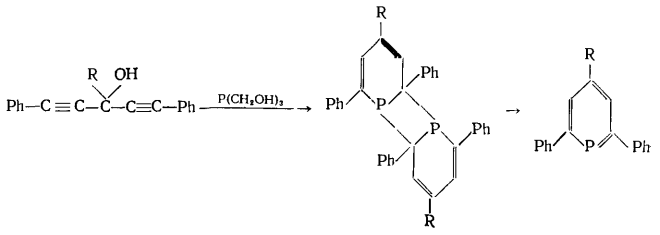
### 1. PHOSPHORINS



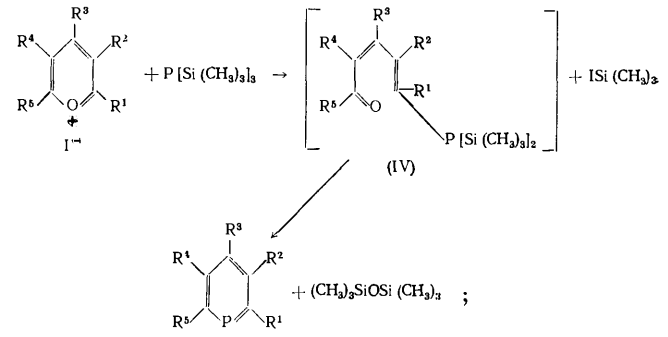
#### (a) Methods of Preparation

The majority of phosphorin derivatives have been obtained by the reaction of pyrylium salts with phosphines. The general methods for the synthesis of phosphorins also includes the thermolysis of 1-substituted dihydrophosphorins and 1,1-disubstituted phosphorins, the rearrangement of methylenephosphacyclohexadienes, and the reaction of 1,1-dibutyl-1,4-dihydrostannanes with phosphorus tribromide.

Phosphorin derivatives with a phosphorus(V) atom have been synthesised by Märkl[37,38] from cyclic phosphonium salts and by Price[39] from pyrylium fluoroborates by reaction with phenylphosphine:



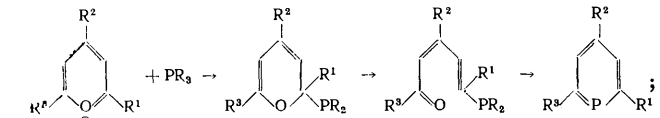
Using tris(hydroxymethyl)phosphine instead of phenylphosphine in the reaction with pyrylium fluoroborate and pyridine as the base and solvent, Märkl synthesised 2,4,6-triphenylphosphorin:



2,4,6-Triphenylphosphorin is a pale-yellow crystalline substance with a melting point of 172–173°, which is readily soluble in organic solvents[40,41]. Tolmachev and Kozlov[42] obtained by the same procedure, involving the reaction of 2,4,6-triarylpyrylium perchlorate with tris-(hydroxymethyl)phosphine, and almost simultaneously with Märkl, a series of arylphosphorins. 4-Indolyl- and 4-pyrrolylpyrylium salts react similarly with tris(hydroxymethyl)phosphine[42,44].

The first phosphorin derivative containing only aliphatic substituents was obtained from 2,4,6-tri-t-butylpyrylium tetrafluoroborate and tris(hydroxymethyl)phosphine[45]. The reaction of tris(hydroxymethyl)phosphine with 1,5-diphenylpenta-1,4-diyn-3-ol gave a phosphorin

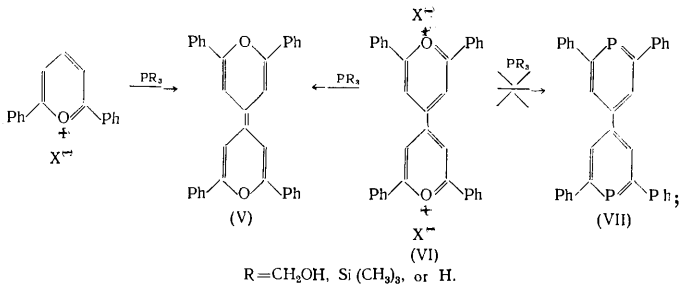
dimer, which can be cleaved to the monomeric phosphorin by thermal and photochemical reactions[46]:



Märkl et al.[15] suggested that tris(trimethylsilyl)phosphine be used to obtain phosphorin derivatives instead of tris(hydroxymethyl)phosphine. In this case there is no need for solvents with basic properties and the yield of substituted phosphorins increases:

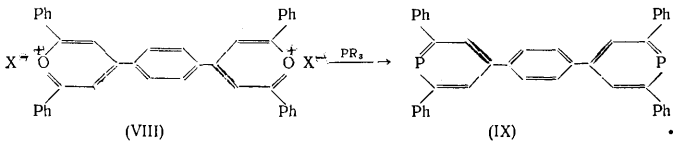
$R^1=R^5=$Ph, $p$-$CH_3C_6H_4$, $p$-$CH_3OC_6O_4$; $R^2=R^4=$H,Ph; $R^3=$Ph, or $p$-$CH_3OC_6H_4$ .

However, when tris(trimethylsilyl)phosphine is used to synthesise phosphorin derivatives, the second reactants can be only pyrylium iodides. The fluoroborates and perchlorates are unsuitable in view of the weak nucleophilic properties of the anions. The intermediate compound (IV) was not isolated, since spontaneous elimination of hexamethyldisiloxane leads to ring closure with formation of a substituted phosphorin.



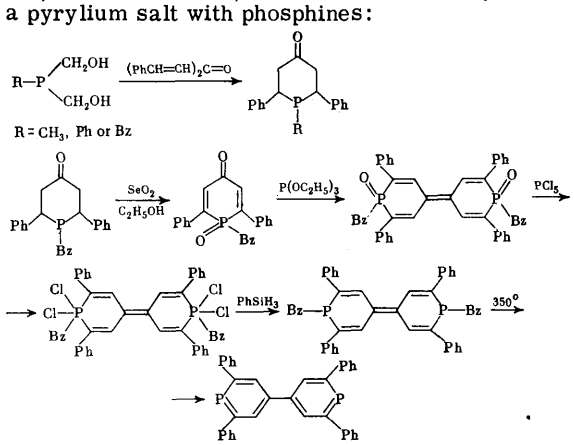
Together with tris(hydroxymethyl)- and tris(trimethylsilyl)-phosphines, unsubstituted phosphine can also be used to synthesise substituted phosphorins. 2,4,6-Trialkylphosphorins, the synthesis of which is hindered by steric factors, have been obtained with the aid of unsubstituted phosphine. The greater the difference between the dimensions of the substituents in the pyrylium salt and of the phosphine molecule, the easier the nucleophilic attack by phosphine on the carbon atom in the 2-position of the pyrylium salt. Subsequently the reaction leads to the formation of a substituted phosphorin:

R=$CH_2OH$, Si $(CH_3)_3$, or H; $R^1$, $R^2$, $R^3$=$CH_3$, or Ph.



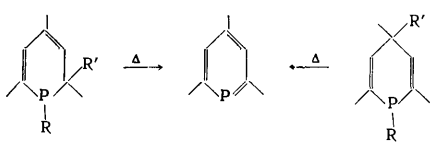
The use of unsubstituted phosphine, whose molecule is much smaller than those of tris(hydroxymethyl)- and tris(trimethylsilyl)-phosphines, extended the scope of the method for the synthesis of phosphorin derivatives. The reaction with unsubstituted phosphine is carried out under the conditions of acid catalysis at 120–130°C.[47]

The method of synthesis of phosphorin derivatives by the reaction of pyrylium salts with phosphines is unsuitable for salts without a substituent in the 4-position. In this case the $C_{(4)}$ atom is involved in the reaction and 2,2′,6,6′-tetraphenyldipyrylene (V) is formed[48,49]:

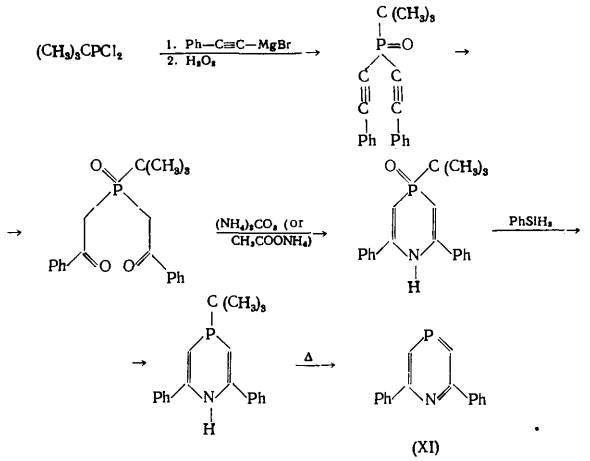


R=$CH_2OH$, Si $(CH_3)_3$, or H.

On reaction with tris(hydroxymethyl)phosphine, tris-(trimethylsilyl)phosphine, and unsubstituted phosphine, the bispyrylium salt (VI) is reduced to the dipyrylene (V) and does not give rise to the diphosphapyrylene (VII). On the other hand, the pyrylium salt (VIII) reacts under analogous conditions to form the phosphorin derivatives (IX) in a low yield (up to 15%):

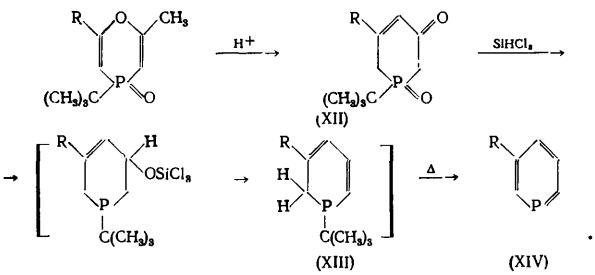


The authors[48,49] attribute this finding to the difference between the redox potentials of compounds (VI) and (VIII).



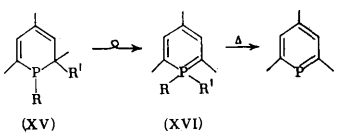
**Thermolysis of 1-substituted dihydrophosphorins and 1,1-disubstituted phosphorins.** Märkl et al.[49] proposed the following cycle of reactions for the synthesis of diphosphapyrylene (VII), which, as stated above, cannot be obtained by the reaction of a pyrylium salt with phosphines:

The thermolysis of 1,1′-dibenzyl-1,1′-diphospha-4,4′-pyrylene (X) is the first example of the synthesis of phosphorins with a two-coordinated phosphorus atom from 1-substituted dihydrophosphorins[45]. The reaction is general, which Märkl and coworkers showed in relation to the thermolysis of a series of 1-substituted 1,4- and 1,2-dihydrophosphorins:



This procedure made it possible to synthesise a wide variety of substituted phosphorins, many of which had been unknown previously[49-52]. Thus a heterocyclic compound containing a nitrogen atom in the six-membered ring together with a two-coordinated phosphorus atom—2,6-diphenyl-1,4-azaphosphorin or phosphapyridine (XI)—was obtained by Märkl and Matthes[50] by means of a scheme based on the thermolysis of 1-substituted 1,4-dihydrophosphorins:

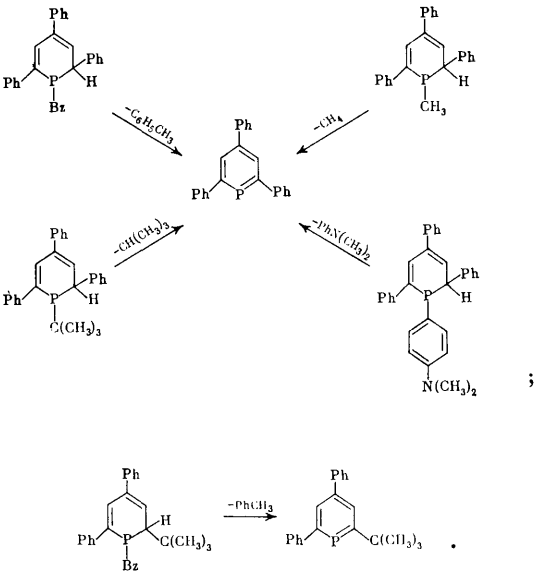
(XI)



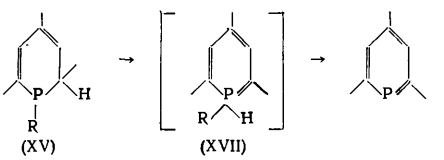
3-Arylphosphorins (XIV), which cannot be synthesised by the reaction of pyrylium salts with phosphines, can be obtained[53] from the readily available 1-t-butyl-3-R-phosphacyclohex-3-ene-1,5-diones (XII) [54]:

(XII) (XIII) (XIV)

The resulting 1-t-butyl-3-R-1,2-dihydrophosphorin (XIII) apparently undergoes thermolysis in the last stage of the reaction.



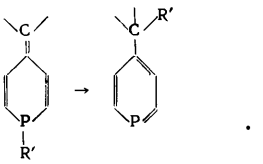
Märkl and Merz[51] showed that the thermolysis of 1-substituted 1,2-dihydrophosphorins involves the migration of the substituent from the 2-position and the formation of 1,1-disubstituted phosphorins in the first stage:



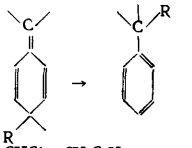
(XV) (XVI)

A similar rearrangement of 1-substituted 1,2-dihydrophosphorins (XV) to 1,1-disubstituted phosphorins (XVI) is the first example of the transformation of tertiary phosphines into phosphinoalkylenes and can be accounted for solely by the stabilisation of the phosphorin system as a result of conjugation. The conditions for the rearrangement depend on the substituents R and R′. Thus the temperature of the rearrangement is 220° for R = $C_6H_5$ and R′ = $CH_2C_6H_5$, 180°C for R = R′ = $CH_2C_6H_5$, 220°C for R = $C_6H_5$ and R′ = $CH_2CH{=}CH_2$, and 25°C for R = $CH_2C_6H_5$ and R′ = $C(C_6H_5)_3$.

1-Alkyl- and 1-aryl(2*H*)-dihydrophosphorins are cleaved similarly to phosphorins:



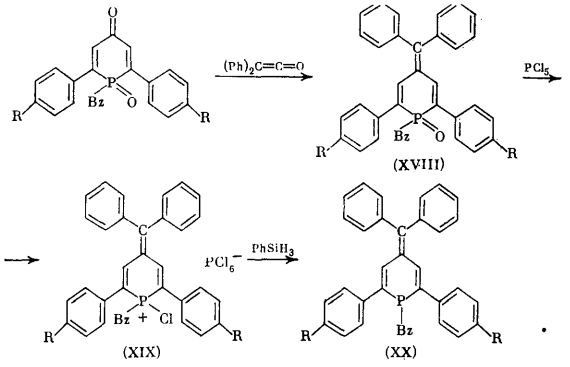
According to the authors[51], the mechanism of this reaction when the latter involves compounds (XV, R′ = H) also consists of the conversion of 1-alkyl(aryl)-2*H*-dihydrophosphorins into 1-alkyl(aryl)-1*H*-phosphorins with subsequent synchronous 1,1-elimination:



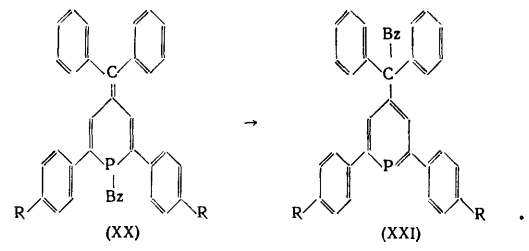
(XV) (XVII)

The authors draw an analogy between this process and the spontaneous N–H → P–H isomerisation of cyclophosphazadienes to cyclotriphosphazenes[55]. Since the formation of 1-R-1*H*-phosphorins (XVII) has not been demonstrated unambiguously hitherto, one cannot rule out the possibility of 1,2-elimination.

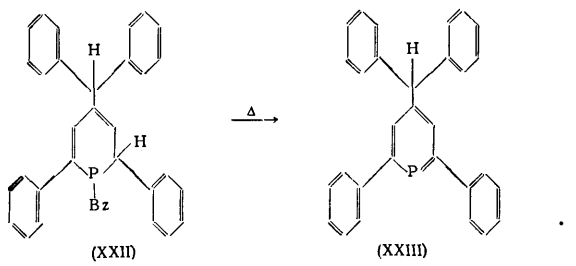
Rearrangement of methylenephosphacyclohexadienes to phosphorins. Continuing the investigation of the thermal behaviour of phosphorus-containing heterocycles, Märkl and Fischer[56] found yet another method for the synthesis of phosphorin derivatives substituted in the 4-position. This involves the rearrangement of methylenephosphacyclohexadienes to phosphorins:



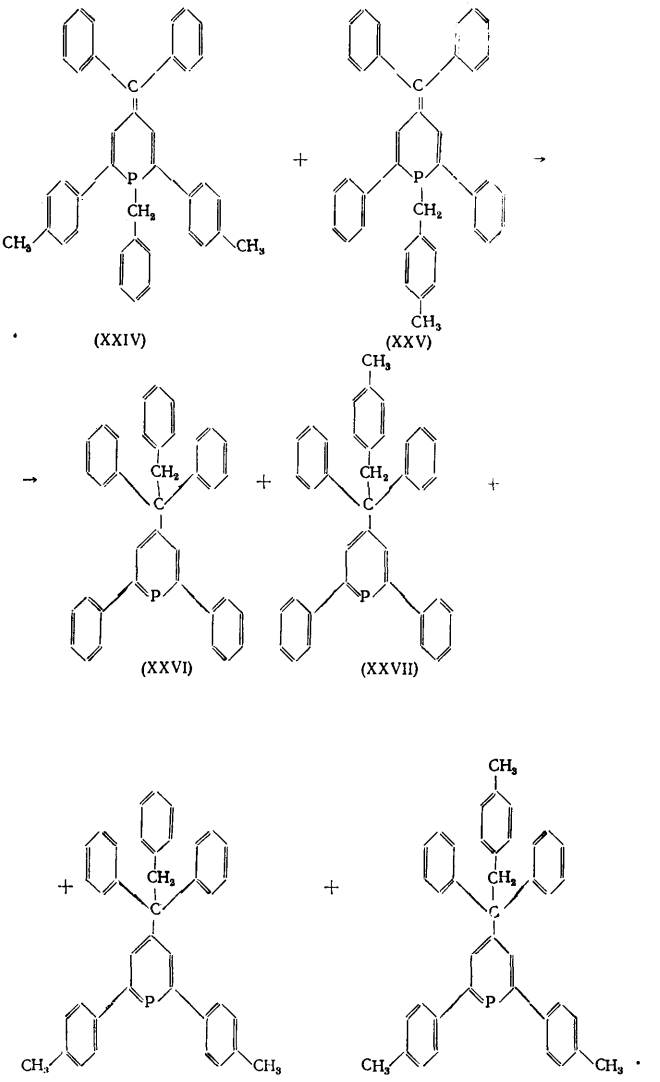
A similar rearrangement of carbocyclic compounds has been known for a long time[57]:



R=$CCl_3$, $CHCl_2$, $CH_2C_6H_5$, or $CH_2CH{=}CH_2$.

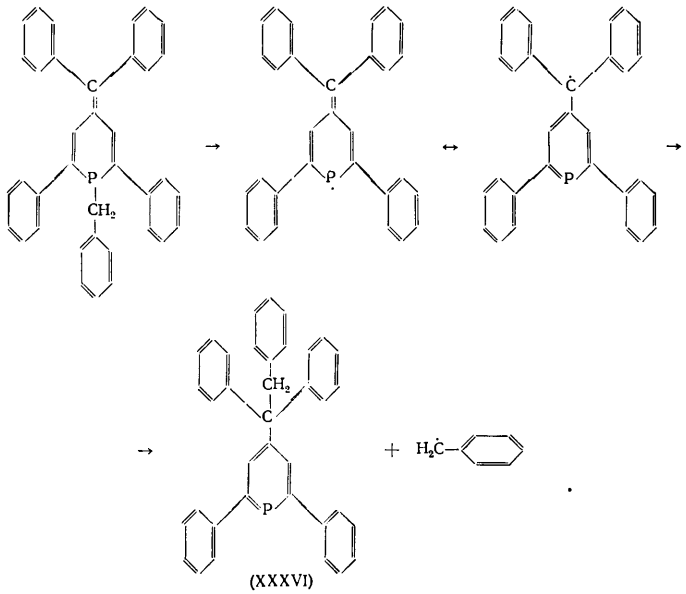


Märkl and Fischer[56] studied the thermolysis of 1-benzyl-4-methylene-1-phosphacyclohexa-2,5-diene (XX), synthesised via the following scheme:



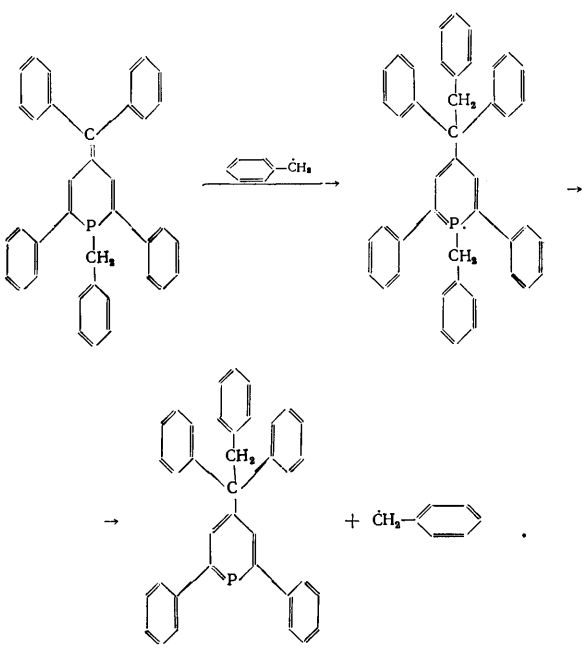
At the melting point (250°C), the resulting methylenephosphacyclohexadiene (XX) undergoes the above rearrangement. This leads to the quantitative formation of a phosphorin derivative (XXI) with a two-coordinated phosphorus atom:

It is interesting to note that the reaction of the oxide (XVIII) in which R = H with phosphorus pentachloride unexpectedly does not lead to the dark-red hexachlorophosphate (XIX) and gives rise instead to yellow hygroscopic salt of unknown structure, whose reduction with phenylsilane gives the 1,2-dihydrophosphorin derivative (XXII). The latter undergoes thermolysis, like the dihydrophosphorin described above, with elimination of toluene and the formation of the phosphorin (XXIII)[56]:



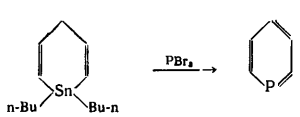
A mass-spectrometric study[58] of the thermolysis products of a mixture of 1-benzyl-4-diphenylmethylene-2,6-di-*p*-tolyl-1-phosphacyclohexa-2,5-diene (XXIV) and 2,6-diphenyl-4-diphenylmethylene-1-*p*-xylylphosphacyclohexa-2,5-diene (XXV) revealed the presence of four reaction products, which supports an intermolecular mechanism of the rearrangement:

The rearrangement probably has a radical mechanism. This hypothesis is based on the analogies, in the first place, with tertiary phosphines, for which thermal heterolytic dissociation of the P–C bond is unknown, and, in the second place, with 1,1-dibenzylphosphorins, the thermolysis of which results in the formation of bibenzyl, which demonstrates the formation of benzyl radicals. The radical mechanism of the rearrangement has been confirmed by experimental data.



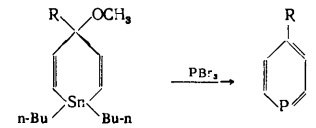
The benzyl radicals formed from Hg $(CH_2C_6H_5)_2$ are capable of becoming involved in the rearrangement of methylene phosphacyclohexadiene. Thus the rearrangement of 1-*p*-xylyl-1-phosphacyclohexadiene (XXV) in the presence of $Hg(CH_2C_6H_5)_2$ entails the formation of the benzylphosphorin (XXVI) together with the xylylphosphorin

(XXVII). The probable mechanism of this rearrangement is as follows[58]:

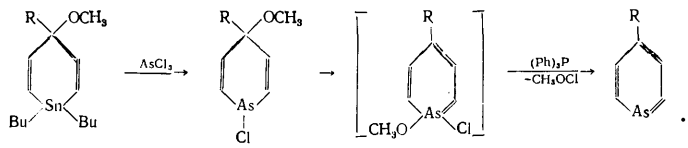


(XXXVI)

According to the authors, the benzyl radical formed reacts immediately with 1-benzyl-1-phosphacyclohexadiene, by analogy with the carbocyclic "semibenzene–benzene" rearrangement, which has been thoroughly investigated:



The reaction of phosphorus tribromide with 1,1-dibutyl-1,4-dihydrostannanes. The hitherto unknown unsubstituted phosphorin was synthesised by the reaction of phosphorus tribromide with 1,1-dibutyl-1,4-dihydrostannane[59]:



Unsubstituted phosphorin is a colourless liquid, unstable in air, with the characteristic smell of phosphine[59]. In this compound, the properties of the ring are not masked by the effect of substituents, which were to some extent responsible for the interest in its synthesis.

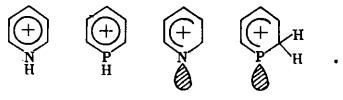
The above method was used by Märkl and Kneidl[60] to obtain previously unknown 4-monosubstituted phosphorins from 4-substituted 4-methoxy-1,4-dihydrostannanes:

The mechanism of the reaction was examined in relation to the synthesis of arsenic compounds–arsenines, obtained when phosphorus tribromide is replaced by arsenic trichloride:

(b) Physicochemical Properties

The ultraviolet, infrared, and PMR spectra of unsubstituted phosphorin are similar to those of pyridine[59]. The magnetic anisotropy of the heteroatom is manifested by a downfield shift of the signals of $\alpha$-protons in the PMR spectrum and an upfield shift of the signals of the protons attached to $C_{(3)}$ and $C_{(4)}$. The 1515 and 1395 $cm^{-1}$ lines in the infrared spectrum of phosphorin have been assigned to the ring vibrations. $\lambda_{max}$ = 213 $\mu$m ($\epsilon$ = 19 000) and 246 $\mu$m ($\epsilon$ = 8500) as well as a shoulder at 290 $\mu$m ($\epsilon$ = 250) have been noted in the ultraviolet spectrum of phosphorin, i.e. there is a bathochromic shift relative to pyridine and benzene, which is associated with the fact that phosphorus is less electronegative than nitrogen and carbon.

An X-ray diffraction study of 2,6-dimethyl-4-phenylphosphorin showed that the molecule has 2($C_2$) symmetry, the symmetry axis passing through the phosphorus atom and the most remote carbon atom of the phenyl substituent. Both six-membered rings are planar within the limits of the accuracy of the X-ray diffraction analysis. The dihedral angle between the rings is 38.8°C, i.e. approaches the angle of 42° found for biphenyl. The C–P–C angle is 103° and may be compared with the values found for triphenylphosphine (103°) and phosphamethinecyanines. Since the phosphorin ring is planar, the remaining P–C–C and C–C–C angles are greater than 120°. A similar increase of the angles occurs also in the pyridine molecule. The P–C bond length is 1.75 Å, i.e. is comparable to the 1.76 Å bond length found for bis-(*N*-ethyl-2-benzothiazolyl)phosphamethinecyanine. The C–C bond lengths are virtually the same as in benzene[61,62].



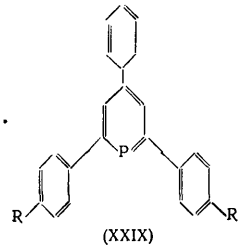
In the ultraviolet spectra of substituted phosphorins, $\lambda_{max}$ is in the range 258–299 $\mu$m and there is also a bathochromic shift relative to the analogous pyridines and aromatic hydrocarbons. The chemical shift $\delta_{^{31}P}$ in the NMR spectra is −178.2 p.p.m. for 2,4,6-triphenylphosphorin and −178.5 p.p.m. for 2,4,6-tri-t-butylphosphorin

(relative to 85% $H_3PO_4$).[40,63] Such a large downfield displacement of the signal is explained by the effect of the magnetic anisotropy of the $-P=C\langle$ multiple bond.

The introduction of nitrogen into a system containing a two-coordinated phosphorus atom leads, as expected, to a downfield shift of the $^{31}P$ signals. Thus $\delta_{31P} = -245.4$ p.p.m. for 2,6-diphenyl-1,4-azaphosphorin (XI).[50]

NMR, ultraviolet spectroscopic, and X-ray diffraction data led to the conclusion that phosphorins are aromatic. This has bene confirmed by calculations of the electronic structures of phosphorins by the CNDO/2 method, which showed that the main contribution to $\pi$-bonding comes from the $3p_z$ orbital of phosphorus together with an appreciable contribution of the $d_\pi$ orbitals[64-66].

The CNDO/2 method also made it possible to estimate the basicity of phosphorin[65]. By analogy with pyridine, basic properties might have been expected for phosphorin, but calculations disproved this hypothesis. The calculated proton affinities of pyridine and phosphorin are 328 and 232 kcal mole$^{-1}$ respectively. Since the true experimental proton affinities of these molecules are unknown, Oehling and Schweig[65] obtained "experimental" values of 213 kcal mole$^{-1}$ for pyridine and 192 kcal mole$^{-1}$ for phosphorin by comparing the experimental and theoretical proton affinities of $NH_3$ and $PH_3$. The difference between the proton affinities of 21 kcal mole$^{-1}$ corresponds to a difference of 15 units between the $pK_a$ values. Thus it is found that the basicity of two-coordinated phosphorus(III) in phosphorin is just as low as that of the perchlorate and iodide anions ($pK_a = -9$ for $HClO_4$ and $pK_a = -8$ for HI). However, the low $pK_a$ predicted for the phosphorinium ion protonated at the phosphorus atom [the ion (XXVII)] does not imply that phosphorin cannot be more easily protonated at other atomic centres. Indeed primary [preliminary] calculations have shown that protonation in the 2-position is much more preferable for phosphorin [the ion (XXVIII)]:



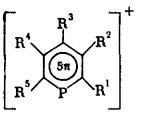
(XXVII) (XXVIII)

Data obtained from the photoelectronic spectra of substituted phosphorins permitted certain conclusions[89]. As was to be expected, phosphorins ionise more readily than the corresponding pyridines, but, the energies of the molecular orbitals of pyridines and phosphorins differ little. The authors suggest that the difference between the energies of molecular orbitals in the pyridine and phosphorin series is probably associated with the contribution of the atomic orbitals of the heteroatom and the neighbouring carbon atoms. The highest occupied molecular orbital (HOMO) of phosphorin is a molecular $\pi$-orbital, while in pyridine it is the orbital of the free electron pair of the nitrogen atom. The free electron pair of the phosphorus atom has a greater amount of *s* character than that of the nitrogen atom in pyridine. The electron pair of phosphorus occupies a more diffuse orbital than that of nitrogen. The sequence of $\pi$-orbitals in the phosphorin system differs from that in pyridine.

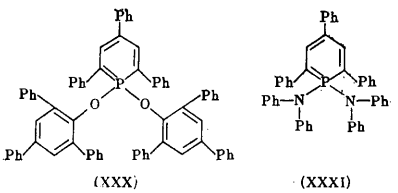
Molecular $\pi$-orbitals with a non-zero coefficient at the heteroatom have a higher energy than the molecular $\pi$-orbitals with a node at the heteroatom[64-66].

(c) Chemical Properties

Oxidation. The oxidation of 2,4,6-triphenylphosphorin (XXIXa) by various phenoxy-radicals proceeds via a radical mechanism[69], which is confirmed by the ESR spectrum where the constant for the hyperfine interaction of the unpaired electron with the nucleus of the phosphorus atom $a_p = 23.2$ G.



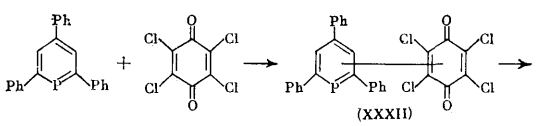
(*a*) R=H; (*b*) R=$OCH_3$



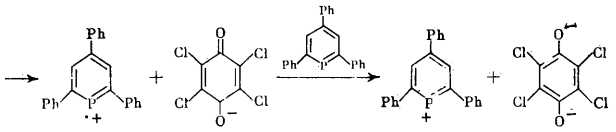
(XXIX)

The spectrum is independent of the structure of the oxidant, which leads to the conclusion that there is no linkage between the phenoxy-group and the phosphorus-containing group.

2,4,6-Tri-t-butylphenoxy-a and 2,6-di-t-butyl-4-phenylphenoxy-radicals do not oxidise 2,4,6-triphenylphosphorin. Probably either the t-butyl group causes steric hindrance to the reaction or the oxidation-reduction potential of the phenoxy-radical is insufficient. The decrease of the oxidation-reduction potential of compound (XXIX) as a result of the introduction of two *p*-methoxy-groups into the phenyl substituents [compounds (XXIXb)] makes it possible to carry out the oxidation even with lead dioxide. This leads to the formation of the analogous phosphorus-containing radical. According to Dimroth et al.[70], this species has the structure of a radical-cation:

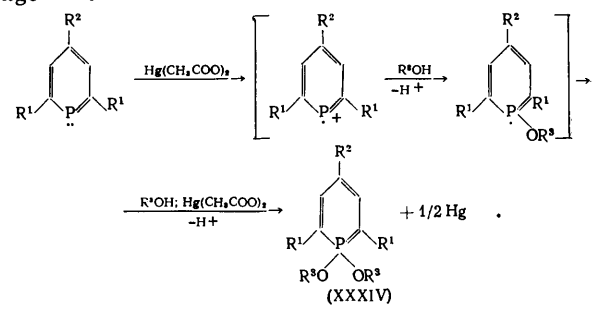


When 2,4,6-triphenylphosphorin reacts with two moles of 2,4,6-triphenylphenoxy-radicals, the product is 2,4,6-triphenyl-1,1-bis-(2,4,6-triphenylphenoxy)phosphorin (XXX). The reaction of tetraphenylhydrazine with 2,4,6-triphenylphosphorin yields 2,4,6-triphenyl-1,1-bis-(diphenylamino)phosphorin (XXXI)[71]:

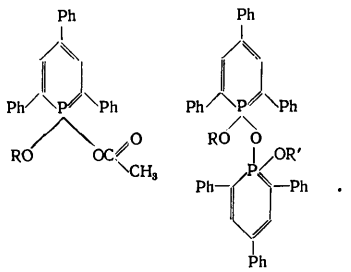


(XXX) (XXXI)

Dimroth and Stade[71,72] investigated the oxidation of triphenylphosphorin by tetrachloro-*p*-benzoquinone. The complex (XXXII) without electron transfer is apparently formed initially, but, when a polar solvent, for example acetonitrile, is added, a doublet with $a_p = 23.2$ G due to the radical-cation (XXXIII) appears in the ESR spectrum:

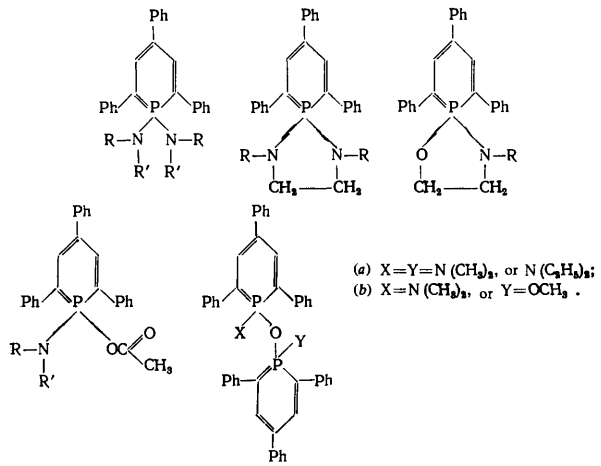


(XXXII)



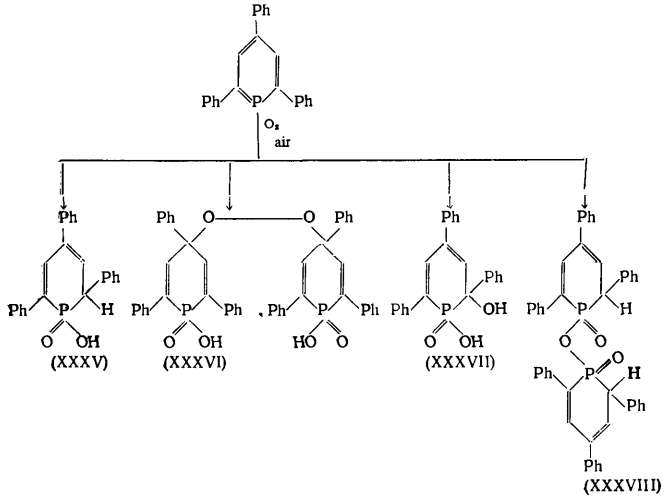
(XXXIII)

When 2,4,6-trisubstituted phosphorins are oxidised by mercury (II) acetate in the presence of an excess of an alcohol of phenol, mercury is liberated and 1,1-dialkoxy- or 1,1-diaryloxy-phosphorins (XXXIV) are formed. The process also probably proceeds via a radical-cation stage [72,73]:

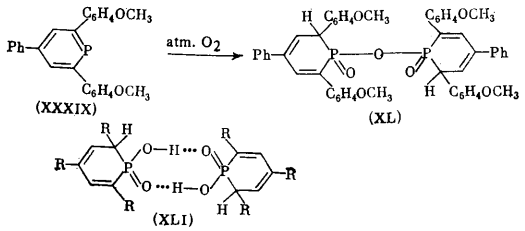


(XXXIV)

A change in the conditions of this reaction leads to the formation of phosphorins belonging to new classes: 1-acetoxy-1-alkoxyphosphorins and substituted bis-(1-alkoxy)hydroxyphosphorins [74]:



Compounds of the first type described above are formed from trisubstituted phosphorins on oxidation with mercury(II) acetate in dry benzene with one equivalent of alcohol. Those of the second type have been obtained in the presence of 1.5 equivalents of alcohol and one equivalent of water. Depending on the reaction conditions, the following types of compounds have been obtained on oxidation with mercury(II) acetate in the presence of amines [74]:

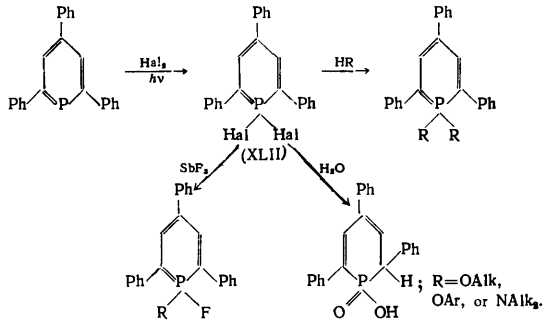


(a) X=Y=N(CH$_3$)$_2$, or N(C$_2$H$_5$)$_2$;
(b) X=N(CH$_3$)$_2$, or Y=OCH$_3$.

Several 2,4,6-trisubstituted phosphorins have been oxidised by atmospheric oxygen [75,76]. The oxidation of 2,4,6-triphenylphosphorin in benzene solution has been examined in greatest detail [76]; it led to the isolation of compounds (XXXV), (XXXVI), and a substance of unknown structure having the composition $C_{46}H_{36}O_3P_2$. In an earlier investigation [75], the structures of the 2-hydroxyphosphinic acid (XXXVII) and the phosphinic acid anhydride (XXXVIII) were attributed to the products of the oxidation of 2,4,6-triphenylphosphorin by atmospheric oxygen:

(XXXV) (XXXVI) (XXXVII) (XXXVIII).

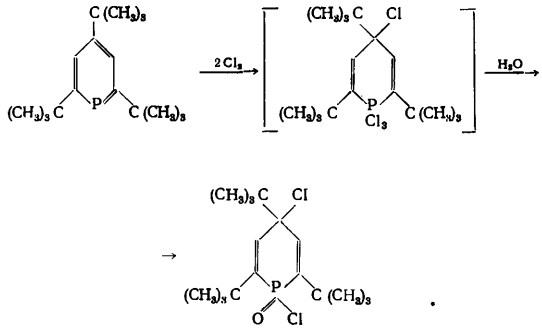
Compound (XL) is formed from 2,6-bis-(4-methoxyphenyl)-4-phenylphosphorin (XXXIX) on oxidation with atmospheric oxygen, while 2,4,6-triphenyl- and 2,4,6-tri-t-butylphosphorins give rise to the dimer (XLI) under the same conditions:



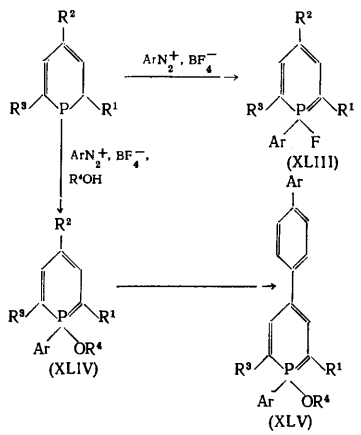
(XXXIX) (XL)

(XLI)

Compounds (XLI) were obtained also on oxidation of 2,4,6-tri-t-butyl- and 2,4,6-triphenyl-phosphorins with hydrogen peroxide in acetone [75,76]. Hydrogen peroxide in ethanol cleaves 2,4,6-tri-t-butylphosphorin, which entails the formation of tri-t-butyl 3,5-di-t-butyl-2-furyl ketone in 30% yield [45].



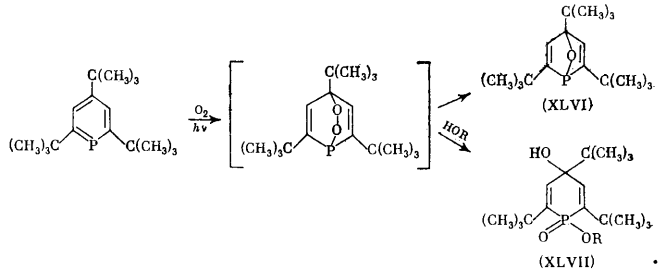
Kanter and Dimroth [77] oxidised 2,4,6-triphenylphosphorin with bromine and chlorine in the light and obtained 1,1-dihalogenophosphorins (XLII), which readily undergo nucleophilic substitution reactions with water, alcohols, amines, and antimony trifluoride:



(XLII)

R=OAlk, OAr, or NAlk$_2$.

It was shown earlier that 2,4,6-tri-t-butylphosphorin may combine with two moles of chlorine [77]. This involves the formation of 2,4,6-tri-t-butyl-1,1,1,4-tetrachlorophosphorin, which readily hydrolysss and gives rise to a 4-chlorophosphinyl chloride:



The interaction of trisubstituted phosphorins with aryldiazonium tetrafluoroborates results in the evolution of nitrogen and the formation of 1-aryl-1-fluorophosphorins (XLIII).[78] If the reaction is carried out in the presence of an alcohol, the products are 2,4,6-trisubstituted 1-alkoxy-1-arylphosphorins (XLIV):

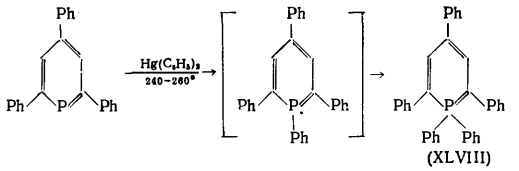
The authors [78] suggest that the phosphorin is oxidised initially by the aryldiazonium ion. The oxidation product (a radical cation) then reacts with the aryl radical and the nucleophile (alcohol or $F^-$ ion derived from $BF_4^-$) to form a 1,1-addition product. In alcohol in the presence of an excess of aryldiazonium tetrafluoroborate, the doubly arylated phosphorin (XLV) is formed together with compound (XLIV). The former can also be obtained directly from compound (XLIV) and the diazonium salt.

When 2,4,6-tri-t-butylphosphorin was oxidised in dry cyclohexane using a mercury lamp in the presence of eosin as the sensitiser, two crystalline compounds were obtained in 15% yield. The structures (XLVI) and (XLVII) were attributed to them on the basis of the results of elemental analysis and infrared and ultraviolet spectroscopic, NMR, and mass-spectrometric measurements [79].

Compound (XLVII) is also obtained when 2,4,6-tri-t-butylphosphorin is oxidised with a mixture of nitric and phosphoric acids. Photochemical oxidation of 2,4,6-triphenylphosphorin leads to a large number of products which are difficult to separate.

Attempts to use concentrated perchloric and sulphuric acid solutions as oxidants for triphenylphosphorin have been described in the literature. Oxidation did occur under these conditions, but the reaction products could not be isolated [75].

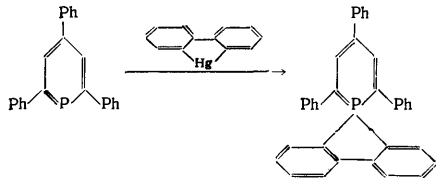
Thus the mode of oxidation of phosphorins depends on the oxidant employed, the reaction conditions, and the nature of the substituents in the phosphorin ring. Depending on these factors, the oxidation either involves the phosphorus atom with formation of 1,1-disubstituted phosphorins, or it involves the 1,2- or 1,4-positions with formation of oxidised derivatives of 1,2- or 1,4-dihydrophosphorins, or the phosphorin ring is disrupted.



Reduction of phosphorin. Phosphorin derivatives are capable of being reduced to radical-ions [80]. ESR has shown that, when 2,4,6-triphenylphosphorin is reduced with a potassium mirror or a sodium–potassium alloy in tetrahydrofuran, stable radical-anions are formed with a constant for hyperfine interaction of the unpaired electron with the phosphorus nucleus $a_P = 32.4$ G. When a benzene solution of the radical-cation (with $a_P = 23.2$ G),[69] obtained by oxidising triphenylphosphorin, is added to a solution of the radical-anion, the signals of both radicals in the ESR spectra vanish and triphenylphosphorin is reformed.

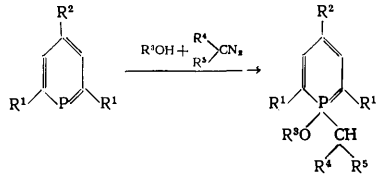
On being reduced, 2,4,6-triphenylphosphorin can combine with three electrons in succession and the reaction products can likewise give up three electrons in succession. In the absence of air, all three reduction products (radical monoanions, non-radical dianions, and radical-trianions) persist for a long time.

Electrophilic properties of the phosphorin system. As noted above, theoretical calculations by the CNDO/2 method established the presence of weak basic properties in phosphorins. Märkl and coworkers [40] demonstrated experimentally that phosphorins do not exhibit nucleophilic properties. Thus 2,4,6-triphenylphosphorin is not alkylated by methyl iodide or triethyloxonium fluoroborate, reacting instead with nucleophiles and radical reagents.

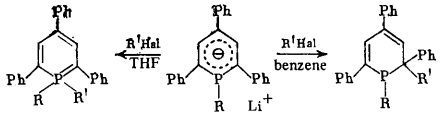


The reaction of triphenylphosphorin with diphenylmercury, involving the formation of 1,1-diarylphosphorins (XLVIII), probably proceeds via a radical mechanism.

Such oxidative arylation probably takes place via the formation of the 1,2,4,6-tetraphenylphosphorinyl radical:

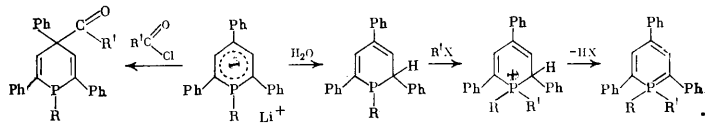


(XLVIII)



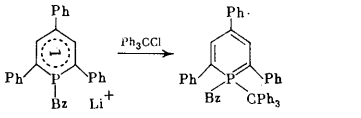
The reaction of diphenylenemercury with 2,4,6-triphenylphosphorin gives a 20% yield of spiro-1,1-diphenylene-2,4,6-triphenylphosphorin[81]:

Trisubstituted phosphorins readily react with diazoalkanes[82] to form 1-alkoxy-1-alkylphosphorins in the presence of alcohols and phenols. It is suggested that the reaction begins with nucleophilic attack by diazoalkanes on the phosphorus atom:



Powerful nucleophiles such as alkyl- and aryl-lithium and organomagnesium compounds react with 2,4,6-triphenylphosphorin even at room temperature[15,83]. The base adds directly to the phosphorus atom with formation of the anion (XLIX), which has ambident properties and has reaction centres in the 1-, 2-, 4-, and 6-positions[84]. In complex-forming solvents such as tetrahydrofuran and 1,2-dimethoxyethane, electrophilic substitution by reaction with alkyl halides takes place preferentially in the 1-position with formation of a 1,1-disubstituted phosphorin (L). In non-polar solvents, for example in benzene, a 2-alkyl-1,2-dihydrophosphorin (LI) is formed:

(L) (XLIX) (LI)

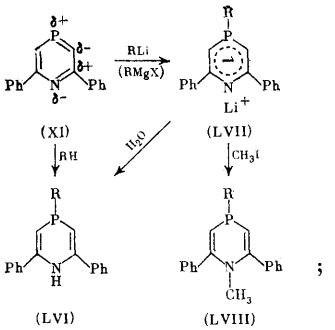


Electrophilic substitution as a result of reaction with acid chlorides takes place in the 4-position and the products are 4-acyl-1,4-dihydrophosphorins (LII). Hydrolysis of the anion (XLIX) leads to 1,2-dihydrophosphorins (LIII):

(LII) (XLIX) (LIII)

The alkylation of the anion (XLIX) by alkyl halides apparently proceeds both via an $S_E1$ and an $S_E2$ mechanism. The reaction involving the $S_E2$ mechanism proceeds via the more nucleophilic centre—the phosphorus atom; when the $S_E1$ mechanism operates, centres with a higher electron density react, i.e. the carbon atoms in the 2-, 4-, and 6-positions. The reaction mechanism depends not only on the solvent used but also on the nature of the alkyl halide. The reaction with alkyl halides via the $S_E2$ mechanism leads to the formation of 1,1-disubstituted phosphorins (L, R′ = $CH_3$ or $C_2H_5$). In the reactions with alkyl halides forming a stabilised carbonium ion, alkylation takes place in the 2-position and leads to the dihydrophosphorins (LI, R′ = $CH_2C_6H_5$ or $CH_2$–CH=$CH_2$).[84]

As noted above[49], 1-substituted 1,2-dihydrophosphorins (LI) are capable of rearranging to 1,1-disubstituted phosphorins (L), while the reverse rearrangement of compounds (L) to (LI) is impossible. This probably accounts for the, at first sight, unexpected formation of the 1,1-disubstituted phosphorin (LV) in the reaction of the anion (LIV) with chlorotriphenylmethane. The structure of the alkyl halide suggested that in this case the reaction should proceed via the $S_E1$ mechanism with formation of a 1,2-disubstituted 1,2-dihydrophosphorin[84]:

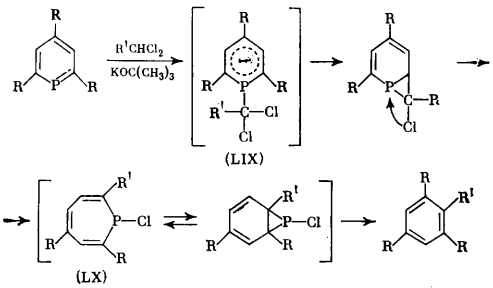


(LIV) (LV)

Presumably the 1,2-dihydrophosphorin formed immediately rearranges to a 1,1-disubstituted phosphorin (LV).

The replacement of carbon by nitrogen in the phosphorin enhances the electrophilic properties of the system[50]. Thus 2,6-diphenyl-1,4-azaphosphorin (XI) reacts readily not only with organometallic compounds but also, in contrast to phosphorins, with weaker nucleophiles such as phenols, alcohols, amines, and mercaptans. In the latter case, addition in the 1,4-positions takes place with formation of the corresponding 1,4-dihydro-derivatives (LVI).

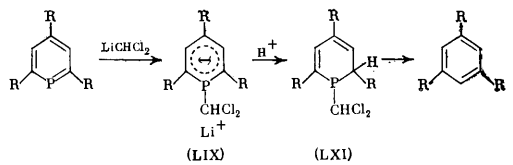
The azaphosphorin (XI) reacts with organometallic compounds to form initially the mesomeric anion (LVII), which then interacts with water and is alkylated, also with formation of the 1,4-dihydro-derivatives (LVI) and (LVIII):



(XI) (LVII) (LVI) (LVIII)

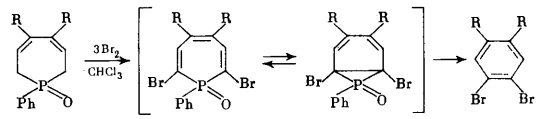
R = R′O, R′S, or $R'_2N$ .

The reactions of phosphorins with carbenes. When 2,4,6-triphenyl-, and 2,4,6-tri-t-butyl-phosphorins react with the halogenomethanes $CH_2Cl_2$, $CHCl_3$, and $C_6H_5CHCl_2$ in the presence of potassium



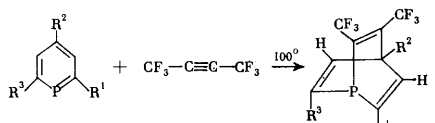
t-butoxide, phosphorus is eliminated and benzene derivatives are formed[85]. On the basis of a series of analogies, the authors suggest the following reaction mechanism:

(LIX)



(LX)

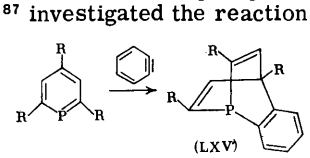
The intermediate anion (LIX) is probably formed via a process resembling the reaction of 2,4,6-triphenylphosphorin with dichloromethyl-lithium. The dark-red 1-dichloromethylphosphorin anion (LIX) is formed in tetrahydrofuran at −80°C. Its protonation by glacial acetic acid gives 1-dichloromethyl-2,4,6-triphenyl-1,2-dihydrophosphorin (LXI), which was identified by PMR.[85] This compound is unstable and is readily converted into an aromatic hydrocarbon:



(LIX) (LXI)

As for the reaction of the intermediate phosphepin (LX), the authors found that the reaction of 4,5-dimethoxycarbonyl-1-oxo-1-phenyldihydrophosphepin (LXII) with bromine results in the formation of a 4,5-dibromophthalate ester (LXIII):

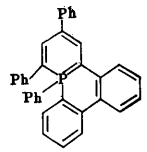
(LXII) (LXIII)



The Diels–Alder reaction in the series of phosphorin derivatives. 2,4,6-Trisubstituted phosphorins are involved in diene synthesis only with highly reactive dienophiles but under milder conditions than aromatic hydrocarbons. For example, hexafluorobutyne reacts[86] with substituted phosphorins at 100°C, while the reactions with benzene and durene take place only at 200°C:

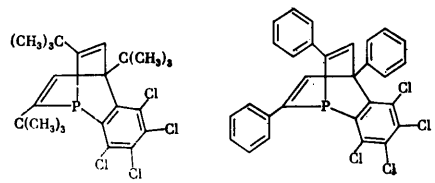
(LXIV)

Apart from hexafluorobutyne, the Diels–Alder reactions of dicyanoacetylene, diethyl acetylenedicarboxylate, and maleic anhydride with phosphorins were investigated[86]. In all cases cycloaddition takes place exclusively in 1,4-positions with formation of 1-phosphabarrelenes (LXIV).



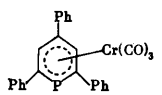
Märkl et al.[87] investigated the reaction of phosphorin with arynes:

(LXV)



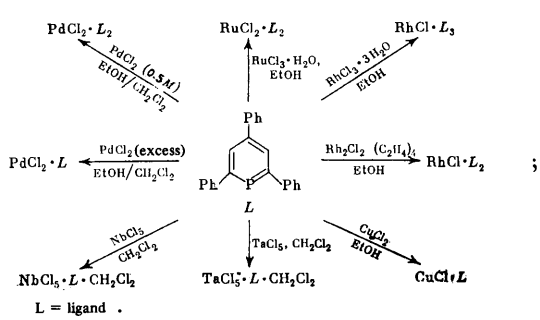
They suggest that the reaction may proceed via the intermediate formation of ambident phosphorin anions.

The reaction of 2,4,6-triphenylphosphorin with dehydrobenzene yields, in addition to the phosphabarrelene (LXV), a 1 : 2 adduct to which the structure (LXVI) was attributed on the basis of spectroscopic data:



(LXVI)

Pentachlorophenyl-lithium reacts with 2,4,6-tri-t-butyl- and 2,4,6-triphenyl-phosphorins, again forming benzophosphabarrelenes [compounds (LXVII) and (LXVIII)]:

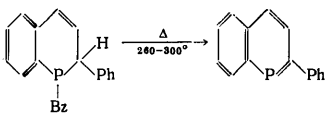


(LXVII) (LXVIII)

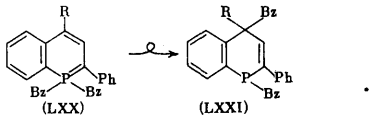
Electron-donating properties of phosphorins. In contrast to pyridine derivatives, aryl- and alkyl-phosphorins cannot be protonated by strong acids which are not oxidants, such as, for example, trifluoroacetic acid. However, trisubstituted phosphorins are capable of forming complexes with transition metal salts. For example, 2,4,6-triphenyl- and 2,4,6-tri-t-butylphosphorins react with chromium hexacarbonyl, forming π-complexes. The structure of the π-complex (LXIX) obtained from 2,4,6-triphenylphosphorin was confirmed by X-ray diffratcion analysis[88]:

(LXIX)

In an inert atmosphere, 2,4,6-triphenylphosphorin also forms complexes with transition metal chlorides[89]:

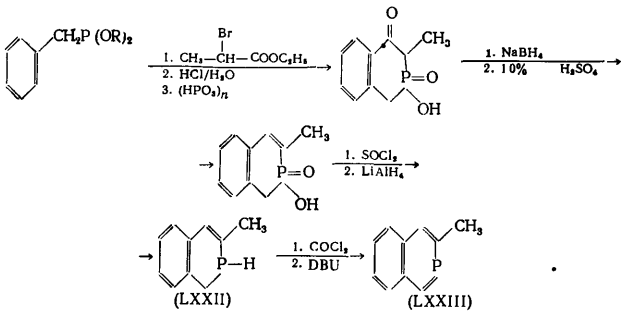


L = ligand .

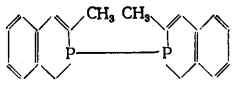


## 2. COMPOUNDS WITH CONDENSED RINGS

### (a) Phosphanaphthalenes



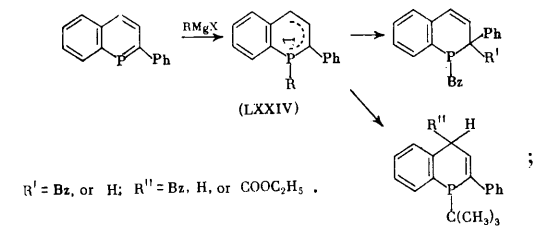
Three phosphanaphthalene derivatives have now been obtained, namely: 2-phenyl-1-phospha- and 3-methyl-2-phospha-naphthalenes as well as unsubstituted 2-phosphanaphthalene. 2-Phenylphosphanaphthalene is obtained similarly to phosphorin, by the thermolysis of 1-substituted dihydro-derivatives [90]:



In contrast to phosphorin derivatives, phosphanaphthalenes cannot be obtained by the thermolysis of 1,1-disubstituted phosphanaphthalenes. Thus 1,1-dibenzylphosphanaphthalene (LXX) rearranges at 230–250°C to 1,4-dibenzyl-1,4-dihydrophosphanaphthalene (LXXI) [91]:

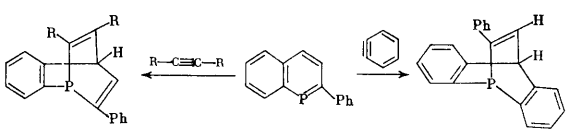
3-Methyl-2-phosphanaphthalene (LXXIII) is synthesised by the dehydrochlorination of the appropriate chlorodihydro-derivatives with the aid of 1,5-diazabicyclo[5,4,0]-undec-5-ene (DBU) [92]:

The chlorophosphine formed in the reaction of the secondary phosphine (LXXII) with phosgene is treated with DBU without being isolated. After the separation of the DBU hydrochloride and the vacuum sublimation of the residue, white crystals of compound (LXXIII) are obtained in a low yield. Apart from this product, the dimer



is also formed in the reaction.

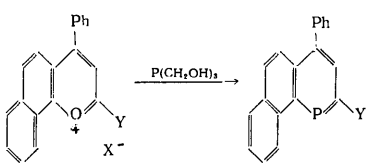
The attempt to obtain by this procedure the unsubstituted 2-phosphanaphthalene was not altogether successful, since it could not be isolated in a pure form [92]. The presence of 2-phosphanaphthalene in the reaction mixture was only inferred from ultraviolet spectroscopic data. In another paper [93] devoted to this compound, the method of preparation is not described.



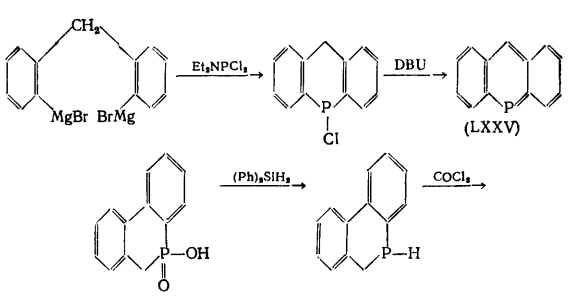
The structure of phosphanaphthalene derivatives has been demonstrated by ultraviolet spectroscopy and NMR. The chemical shift and the spin–spin interaction constants are consistent with the values for phosphorins. A bathochromic shift is observed in the ultraviolet spectra of phosphanaphthalenes relative to the corresponding aromatic hydrocarbons, for example $\lambda_{max}$ = 332 nm for 2-phenyl-1-phosphanaphthalene compared with 322 nm for 2-phenylquinoline. [92]

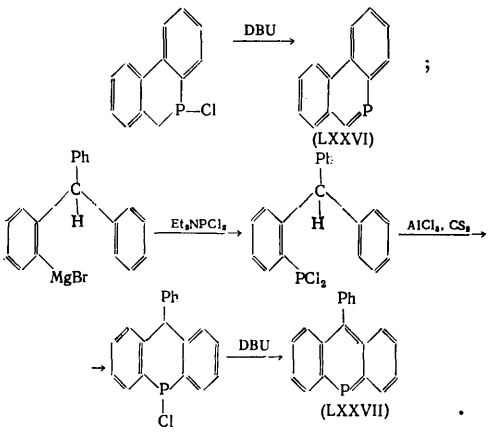
The chemical properties of phosphanaphthalenes have been studied comparatively little. When 2-phosphanaphthalene is reduced with metallic potassium in tetrahydrofuran, a radical-anion similar to that obtained in the reduction of phosphorin is formed [93].

2-Phenyl-1-phosphanaphthalene reacts with organomagnesium compounds and gives rise to the anion (LXXIV), which is capable of reacting with dialkyl halides [94]:



2-Phenyl-1-phosphanaphthalene combines with arynes and alkynes, forming benzo- and dibenzo-phosphabarrelenes [95]:





### (b) Phospha-anthracenes and Phosphaphenanthrenes

The above derivatives of phosphorin with condensed rings are synthesised, like phosphorin, from substituted pyrylium salts [96,97]:

Dibenzo[*b*, *e*]phosphorin (LXXV), dibenzo[*c*, *e*]phosphorin (LXXVI), and 10-phenyldibenzo[*b*, *e*]phosphorin (LXXVII) can be obtained similarly to 3-methyl-2-phosphanaphthalene [92], by the dehydrochlorination of chlorodihydro-derivatives with the aid of DBU [98–100]:

Compounds (LXXV) and (LXXVI) are unstable and their formation has been demonstrated mainly by spectroscopic methods. Compound (LXXVII) is stable and can be sublimed at 160°C and $10^{-3}$ mmHg. The PMR and ultraviolet spectra of condensed phosphorins are consistent with those observed for the non-condensed systems [100]. An X-ray diffraction study of 4-aryl-2-t-butyl-5,6-dihydro-1-phosphaphenanthrene showed that the phosphorus-containing ring in this compound is also planar and has the same bond lengths and angles as in substituted phosphorins [97].

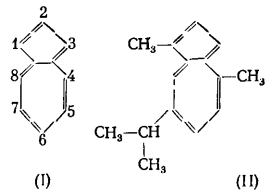
# Advances in the Chemistry of Azulene

V.B.Mochalin and Yu.N.Porshnev



The chief methods of preparation and the chemical properties of azulene hydrocarbons are described. Attention is paid mainly to the most recent papers, not covered in previous reviews. Certain aspects of the application of azulene compounds are also considered. A list of 315 references is included.

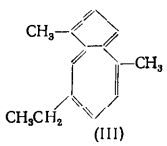
## I. INTRODUCTION



Forty years have passed since Pfau and Plattner finally established the structure of azulene hydrocarbons[1]. The parent of this class of non-benzenoid aromatic compounds is bicyclo[5,3,0]decapentaene, azulene (I). Azulene hydrocarbons are present in various natural oils, where they are formed by the dehydrogenation and dehydration of bicyclic sesquiterpenoid alcohols. Specific names have been retained for many azulene hydrocarbons isolated from natural sources: guaiazulene (II) is 7-isopropyl-1,4-dimethylazulene, obtained by dehydrogenating the oil from the wood of *Guaiacum officinale* L., patchouli oil from *Pogostemon patchouli*, and eucalyptus oil from *Eucalyptus globulus*; chamazulene (III) is present in camomile oil from *Matricaria camimilla* L., oil of yarrow *Achillea millejolun* L., oil of wormwood *Artemisia absinthium* L., and certain other oils; lactaroviolin (IV) is an aldehyde contained in edible fungi; and vetivazulene (V) and zierazulene (VI) are dehydrogenation products of the sesquiterpenoid ketones vetivone and zierone[2]. Azulene hydrocarbons are also present in many other plant species, but in extremely small amounts.

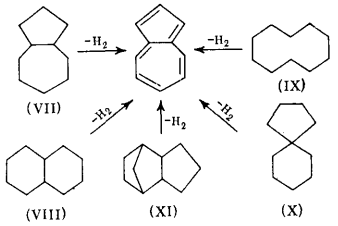
(VI)

Azulene and its simple homologues are deeply coloured compounds of high boiling point, volatile in steam, which dissolve in hydrocarbon solvents and crystallise well. The simplest azulene hydrocarbons absorb light in the range 550–650 nm.[2,4] They are stable in air up to 300–350°C, and only above this temperature do they begin to be converted into valence isomers of benzenoid structure, naphthalene and its homologues[2]. Azulene compounds can also undergo photoisomerisation[5].



The unusual physical and chemical properties of azulene hydrocarbons have long attracted the attention of many investigators, but until the end of the 1950s these compounds were extremely inaccessible, and only after the development by Hafner and by Nozoe of effective methods for the synthesis of azulenes did their widespread study become possible. The most complete survey of the literature on the structure and the chemistry of azulenes appeared in 1959 [3] (translated into Russian in 1963 [2]). Subsequent reviews[6,7] contained data only on individual problems of the synthesis or the reactivity of azulenes. Therefore the present Review, devoted to methods of preparation, chemical properties, and prospects for the application of azulene derivatives, covers mainly the literature from 1959 to 1975. The large number of publications that appeared during this period prevent the inclusion of several aspects—(i) methods for the isolation, purification, and identification of azulene compounds, (ii) the physical and physicochemical characteristics of azulenes, and (iii) the chemical properties and methods of preparation of heteroazulene compounds, in which one or more methine groups have been replaced by heteroatoms[8]—which all, without doubt, deserve special discussion.

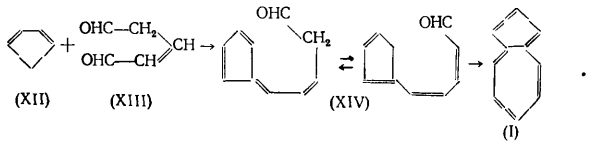
## II. METHODS OF PREPARATION OF AZULENE COMPOUNDS

### 1. Methods involving Dehydrogenation

Dehydrogenation of bicyclic precursors of azulene having the bicyclo[5,3,0]decane structure (VII) or of the corresponding partly unsaturated compounds was historically the first (and for a long time the only) method for obtaining azulene and its alkyl homologues. Both natural oils containing sesquiterpenoid precursors and synthetic bicyclic derivatives were used. Although guaiazulene,

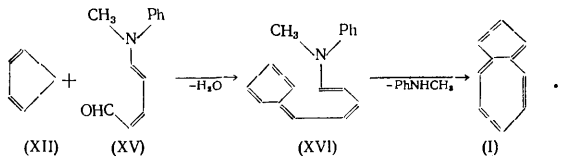
chamazulene, and vetivazulene have hitherto been obtained mainly by the dehydrogenation of natural oils, substituted bicyclo[5,3,0]decanes have rarely been used for preparing other azulene derivatives owing to the complexity and the multistage character of the process[2]. Azulenes have been obtained by dehydrogenation not only of bicyclo[5,3,0]-decane (VII) derivatives[9] but also of compounds of the cyclodecane (IX),[2,10,11] decahydronaphthalene (VIII),[12] tetrahydrodicyclopentadiene (XI),[12] and spiro[4,5]decane (X)[13] series.

However, the complexity of the preparation of most such compounds, the formation of mixtures of isomeric azulenes from substituted derivatives of (VIII)–(X), and—the most important—the low yields (1–10%) at the dehydrogenation stage have resulted in the extremely rare use of these methods also. Such yields are greatly increased when highly unsaturated hydrocarbons such as dihydroazulenes are used, so that "partial" dehydrogenation remains an important method of preparation in the chemistry of azulenes. Dehydrogenation is sometimes employed also to prove the structure of a sesquiterpene hydrocarbon.



Sulphur, selenium, 5–10% palladium on carbon, chloranil, and diphenyl disulphide are widely employed as dehydrogenating agents. Dehydrogenation with sulphur is accomplished on heating (200°C), with yields usually not exceeding 10%[14,15] and only in isolated cases reaching 30–50%.[16,17] Acyl- and alkyl-azulenes may form thienoazulenes on dehydrogenation with sulphur[17–19]. The use of selenium[20–22] or palladium[23–25] for liquid-phase dehydrogenation requires higher temperatures (280–300°C), which often leads to migration of hydrocarbon substituents or even partial isomerisation of the azulene into the naphthalene system[26]. Yields of azulenes are 1–10%. Catalytic dehydrogenation in the gas phase over palladium on carbon, molybdenum sulphide, or other catalysts frequently gives higher yields, but requires careful selection of optimum conditions in each specific case[9,12,27]. Little information is available on the dehydrogenating action of diphenyl disulphide; it has been successfully used for the preparation of guaiazulene[28].

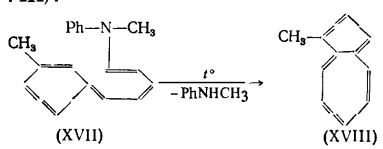
Recently chloranil has been the hydrogenating agent used most often[29–33]. Dehydrogenation occurs under very mild conditions, but a high degree of unsaturation is required in the compounds to be dehydrogenated.



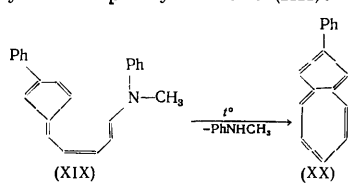
The complexity of the directed preparation of hydrogenated precursors of azulene and the low yields obtained in their dehydrogenation have led to the development of fundamentally new ways of obtaining azulene that avoid dehydrogenation.

## 2. Cyclisation of Polymethinium Salts and Fulvenes

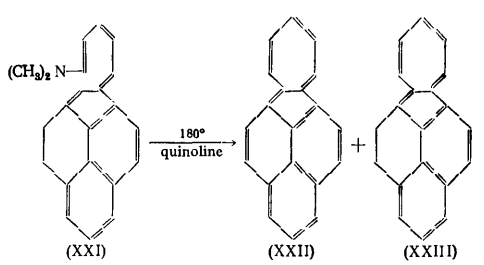
In 1955 Ziegler and Hafner[34], and almost simultaneously Rösler and König[35], reported a new synthesis of azulene systems that eliminated the dehydrogenation stage. The general principle consisted in obtaining fulvene (XIV) from cyclopentadiene (XII) and glutaconaldehyde (XIII) and cyclising the product to azulene (I):



However, this form of the process has not yet been accomplished: in practice the relatively unstable glutaconaldehyde is replaced by a derivative, Zincke's aldehyde (XV), which is converted into the fulvene (XVI). In the presence of a base such as benzidine or trishydroxyethylamine at 200–300°C this fulvene is cyclised to azulene, which sublimes as it is formed:

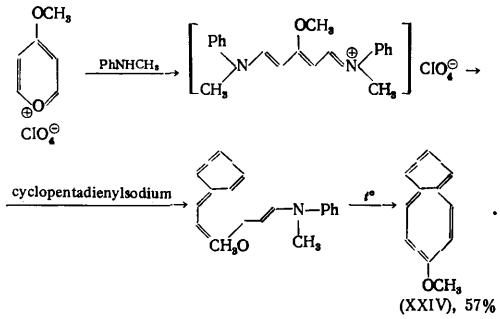


The high yield of azulene (up to 70%) makes this method most promising for industrial application[34].

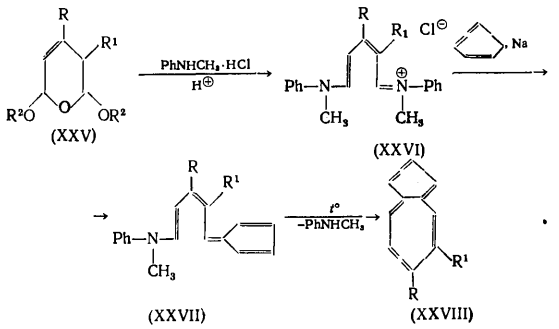


Azulenes substituted in the five-membered ring can be obtained by the same method. Cyclisation of the fulvene (XVII) obtained from methylcyclopentadiene gives 1-methylazulene (XVIII):[36]

However, the corresponding cyclisation of the phenylated fulvene (XIX) yields 2-phenylazulene (XX):[37]

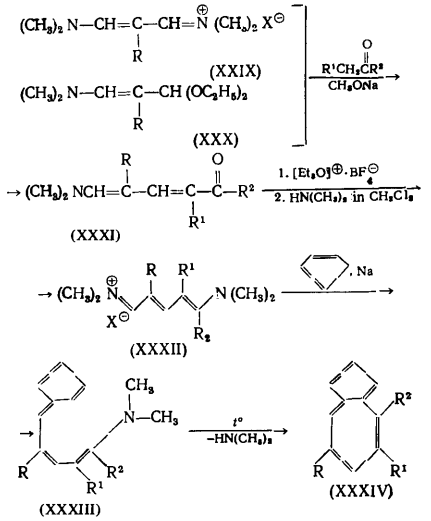


Such a difference in the course of cyclisation is probably due to both electronic and steric factors. A 62% yield of azuleno[1,2,3-*cd*]phenalene (XXII) has recently been obtained[38] by cyclisation of the corresponding fulvene (XXI), with separation of the dihydro-derivative (XXIII) as a byproduct:

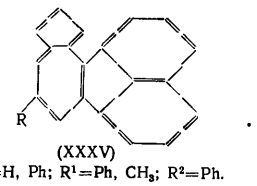


Azulenes substituted in the seven-membered ring can be obtained by reaction between cyclopentadiene and substituted Zincke aldehydes, but the cleavage of mono- and poly-alkylated pyridines to the desired glutaconaldehyde derivatives presents certain difficulties[39]. Since pyrylium salts are cleaved considerably more readily by amines, they may serve as convenient starting materials

for obtaining several difficultly accessible azulenes, e.g. 6-methoxyazulene (XXIV):[39]



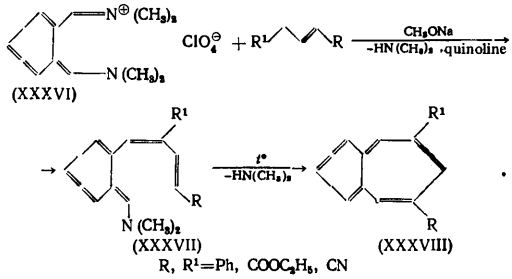
(XXIV), 57%



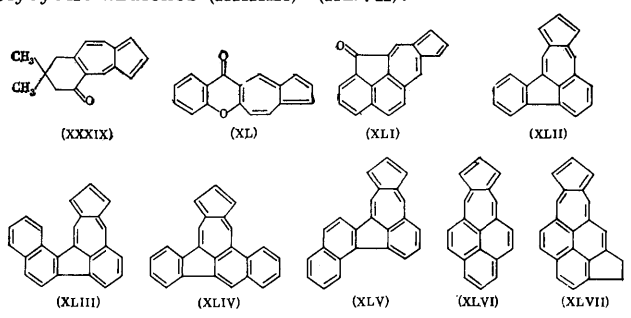
6(5)-Arylated azulenes (XXVIII) can be obtained from 2,6-dialkoxy-4(5)-aryl-$\Delta^3$-dihydropyrans (XXV)[40] via the *N*-methyl chlorides (XXVI) and fulvenes (XXVII):

This method has been used to obtain 6-phenyl-,[41] 6-thien-2′-yl-,[42] and 5-phenyl-azulenes[43].

Another method of obtaining substituted pentamethinammonium salts—derivatives of glutaconaldehyde—is based on condensation of a malonaldehyde derivative (XXIX) or (XXX) with a carbonyl compound containing an active methylene group[44]. The resulting amino-dienone (XXXI) is converted into the pentamethinammonium salt (XXXII) by treatment with triethyloxonium tetrafluoroborate followed by dimethylamine. The subsequent action of cyclopentadienylsodium forms the fulvene (XXXIII), which when heated to 180–190°C is converted into the azulene (XXXIV) substituted in the seven-membered ring (yield 15–35%):

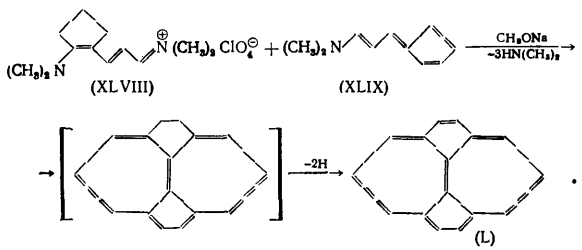


(XXXV)
R=H, Ph; $R^1$=Ph, $CH_3$; $R^2$=Ph.



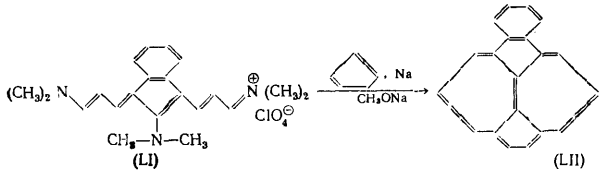
The presence of bulky substituents $R^1$ and $R^2$ in the fulvene (XXXIII) prevents formation of an azulene, probably owing to hindrance to establishment of the *cis*-configuration necessary for cyclisation. Application of this method to acenaphthenone yields fused pentacyclic compounds of the azuleno[4,5-*a*]acenaphthylene series (XXXV).[44]

The salt (XXXVI), containing a dimethylaminofulvene group, became very valuable as initial compound for the synthesis of polycyclic azulene hydrocarbons[45-50]. It reacts with derivatives of glutaconic or 4-phenylbut-3-enoic acid in the presence of sodium methoxide to give fulvenes (XXXVII) capable of cyclisation with high yields into 5,7-disubstituted azulenes (XXXVIII):[44]

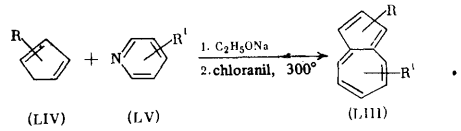


R, $R^1$=Ph, $COOC_2H_5$, CN

Replacement in this reaction of derivatives of glutaconic acid by isophorone, 2-methylchromone, acenaphthenone, fluorene, benzofluorenes[44], phenalene[51], and 1,2-dihydro-5*H*-cyclopenta[*c*, *d*]phenalene[52] gave the corresponding polycyclic azulenes (XXXIX)–(XLVII).

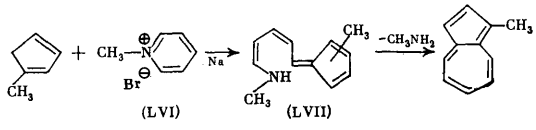


Jutz and Schweiger[53] suggested a method of double cyclisation of the pentamethinammonium salt (XLVIII)[54] with the fulvene (XLIX) in the presence of sodium methoxide to give an approximately 5% yield of the extremely difficultly accessible pyraceheptylene (L):



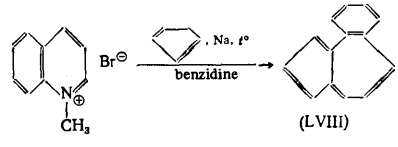
Condensation of cyclopentadiene with the salt (LI) obviously involves both formation of a fulvene and its subsequent

double cyclisation with the further elimination of two molecules of dimethylamine to give a 2.5% yield of benzo[*a*]-pyraceheptylene (LII):[53]

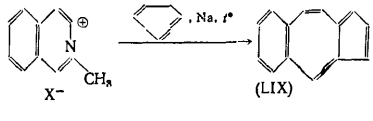


3. Syntheses from Pyridinium and Pyrylium Salts

The relationship between glutaconaldehyde and pyridine enabled Hafner[55] to synthesise azulene (LIII) by the condensation of substituted cyclopentadienes (LIV) with substituted pyridines (LV) followed by cyclisation and dehydrogenation at an elevated temperature:

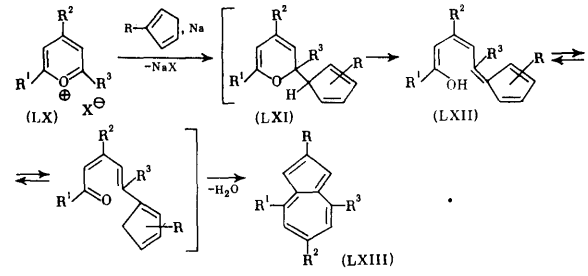


This method was used to obtain 1-, 4-, and 5-methylazulenes, 4,8-dimethylazulene, 1-isopropylazulene, 1-diphenylmethylazulene, and also 1,2-benzazulene,

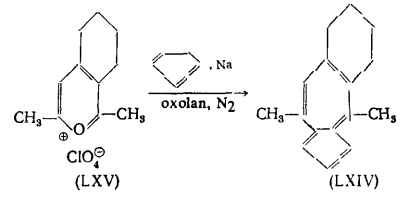


However, quaternary pyridinium and homologous salts have been more widely used. For example, reaction between *N*-methylpyridinium bromide (LVI) and methylcyclopentadienylsodium in liquid ammonia enabled Ziegler and Hafner to obtain the fulvene (LVII), which cyclised thermally into 1-methylazulene in 55% yield[56]:

1,2,3-Triphenylazulene was obtained similarly from 1,2,3-triphenylcyclopentadiene[57].

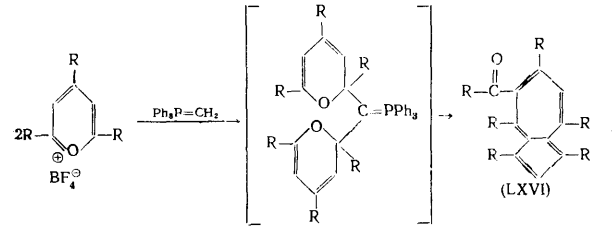


Cyclopentadienylsodium reacts with quinolinium[58] and isoquinolinium[59] salts to give low yields of respectively 4,5-benzazulene (LVIII) and 5,6-benzazulene (LIX):



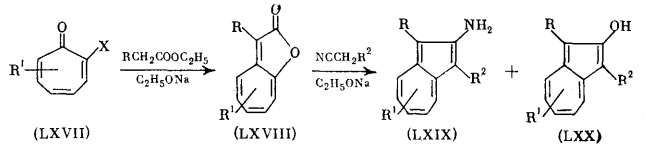
The syntheses are fairly complicated when used as methods of preparation, and published yields are not always reproducible.

Considerably better results are obtained by replacing pyridinium by pyrylium salts. Hafner showed[60] that several salts (LX) form with cyclopentadienylsodium even at room temperature azulenes substituted in the seven-membered ring, in yields that in individual cases are nearly theoretical. The hypothetical intermediate products (LXI) and (LXII) could not be isolated. The alkyl group in the cyclopentadiene appears at position 2 in the azulene (e.g. 2,4,6,8-tetramethylazulene (LXIII: R = $R^1$ = $R^2$ = $R^3$ = $CH_3$) is formed):



Various substituted azulenes—4,6,8-trimethyl, 4,8-dimethyl-6-t-butyl, 4-methyl-6,8-diphenyl, 4,8-dimethyl-6-phenyl, 6-methoxy-4,8-dimethyl, and several other analogues—have been obtained by this reaction[61], but it is not universally applicable to the synthesis of substituted azulenes. Thus 5,6,7,8-tetrahydro-4,10-dimethylbenz-[*f*]azulene (LXIV) was obtained from the salt (LXV) in only 3.3% yield[59]:

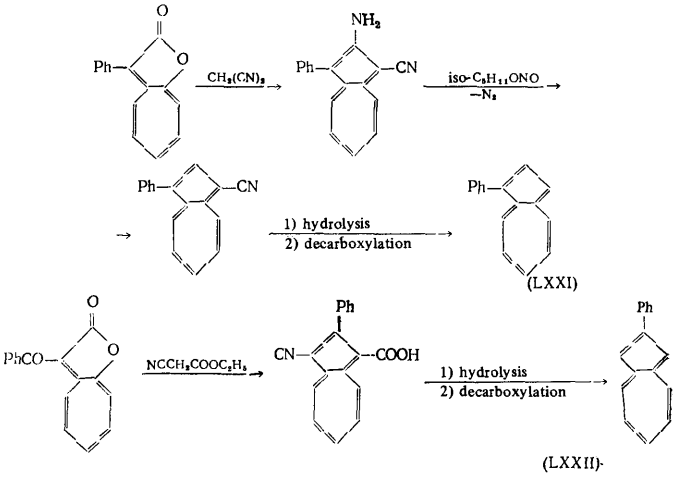
Unsubstituted pyrylium perchlorate[62] and 4-unsubstituted 2,6-dialkylpyrylium salts do not form azulenes when treated with cyclopentadienylsodium. Nor can 2,4,6-triphenylpyrylium and 4-phenyl-2,6-distyrylpyrylium perchlorates, as well as several other pyrylium salts, serve as sources of azulenes. Clearly, unsubstituted pyrylium salts on reaction with the cyclopentadienyl anion readily undergo condensation involving the carbon atoms at positions 2, 4, and 6, with the formation of a large number of unstable side-products. 2,4,6-Triarylated pyrylium salts do not undergo cleavage by the cyclopentadienyl anion under mild conditions, because of their stability due to conjugation[61].



Another interesting route to azulene compounds was suggested in 1963 by Dimroth et al.[63] In this synthesis both azulene rings are formed from a pyrylium salt. The action of excess of methylenetriphenylphosphorane on a pyrylium salt produces in a single stage a substituted 5-acylazulene (LXVI) in ~30% yield:

Thus, despite certain limitations, the use of pyrylium salts provides a most effective method for synthesising azulenes, because of the acceptability of the initial compounds, the mild reaction conditions, and the high yields.

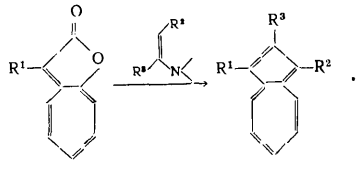
### 4. Tropones, Tropolones, and Heptafulvenes in the Synthesis of Azulenes



Another method of forming azulene compounds that has been studied in detail[64] involves closure of a five-membered ring in compounds that already contain a cycloheptatriene system. One such process is the action of esters containing an active methylene group on tropones substituted at the 2 position by halogen[64-68], arenesulphonyloxyl[69], or alkoxyl[70] (LXVII):

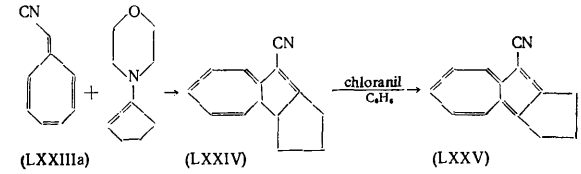
(LXVII) (LXVIII) (LXIX) (LXX)

X = Cl, Br, $OSO_2Ar$, $OCH_3$, $OC_2H_5$; R = CN, $COOC_2H_5$, $C_6H_5$, $C_6H_5CO$;
$R^1$ = Alk, Ar; $R^2$ = CN, $COOC_2H_5$



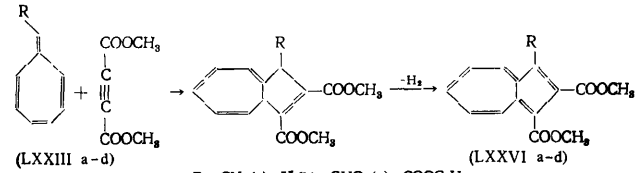
In the presence of sodium ethoxide substituted cycloheptafuranones (LXVIII) are readily formed, and are then converted into azulenamines (LXIX). Application of a twofold excess of cyanoacetic ester enables good yields of diethyl 2-aminoazulene-1,3-dicarboxylates (LXIX: R = $R^2$ = $COOC_2H_5$) to be obtained; the use of malononitrile gives the 1,3-dicyanoazulen-2-amine (LXIX: R = $R^2$ = CN). Low yields of the 2-hydroxy-derivatives (LXX: R = CN; $R^2$ = $COOC_2H_5$ or CN) are formed as secondary products. The nitrile and ester groups can be removed by hydrolysis followed by decarboxylation[66], and the amino-group replaced by hydrogen by diazotisation with isopentyl nitrite in alcohol in the presence of sulphuric acid[68]. These reactions can be illustrated by the preparation of 1- and 2-phenylazulenes (LXXI) and (LXXII):

(LXXI)



(LXXII)

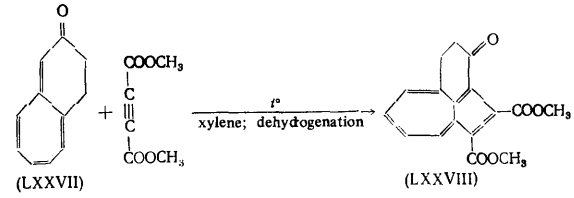
Cycloheptafuranones (LXVIII) can be converted into azulenes by a different route—by cycloaddition with vinylamines[71,72]:



1,2-Propano-, 1,2,butano-, and 1,2-pentano-azulenes, 1- and 2-phenylazulenes[71], indeno[2,1-*a*]azulene, indeno-[1,2-*a*]azulene, and their 3-cyano-derivatives[72] have been obtained in this way.

Cycloheptafuranones (LXVIII) are heptafulvene derivatives. Heptafulvenes themselves are also able to undergo cycloaddition with enamines. For example, the condensation of 8-cyanoheptafulvene (LXXIIIa) with N-cyclopentenylmorpholine leads to formation of the dihydroazulene derivative (LXXIV), whose dehydrogenation by chloranil gives 3-cyano-1,2-propanoazulene (LXXV):[73]

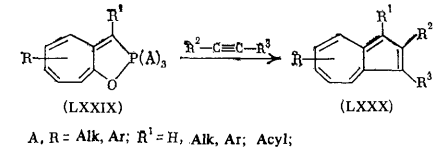
(LXXIIIa) (LXXIV) (LXXV)



The 1,3-cycloaddition† of acetylenedicarboxylic esters to heptafulvene and its derivatives leads to formation of the five-membered ring of the dihydroazulene system, whose dehydrogenation readily gives azulene derivatives. Thus the heptafulvenes (LXXIIIa–d) have given the azulene-1,2-dicarboxylic ester (LXXVIb),[24] as well as the corresponding 3-aldehyde (LXXVIc), the tricarboxylic ester (LXXVId),[74] and the 3-cyano-derivative (LXXVIa):[73]

(LXXIII a–d) (LXXVI a–d)

R=CN (a), H(b), CHO (c), $COOC_2H_5$ (d)



Similarly, the heptafulvene derivative (LXXVII) yields dimethyl 11-oxo-1,8-propanoazulene-2,3-dicarboxylate (LXVIII)

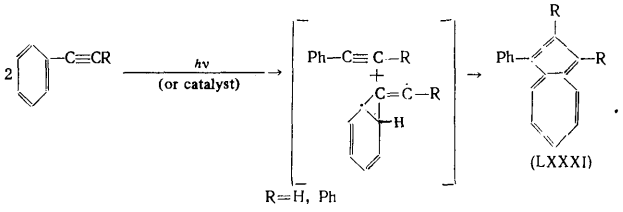
(LXXVII) (LXXVIII)

which is then converted into the fully conjugated tricyclic 3-benz[*c*, *d*]azulenone system[75].

The phosphoranes (LXXIX) are also able to undergo a similar reaction with acetylenes containing electron-accepting substituents, to form substituted azulenes (LXXX) with simultaneous elimination of trialkyl- or triarylphosphine oxides[76]:

(LXXIX) (LXXX)

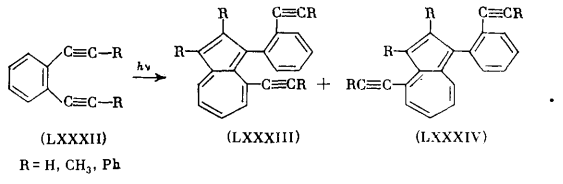
A, R = Alk, Ar; $R^1$ = H, Alk, Ar; Acyl;
$R^2$, $R^3$ = CN, COOR .



Methods based on the use of troponoid compounds readily yield azulene derivatives functionally substituted in the five-membered ring, and thus a useful supplement to preparations based on pyridinium, pyrylium, and Zincke salts. Many 2-substituted azulene derivatives—with chloro, iodo, amino, cyano, carboxy, methoxy,

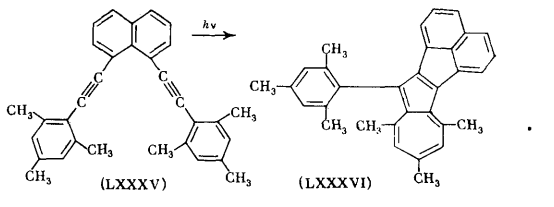
† It would have been more correct to term this reaction *1,8-cycloaddition*, since it takes place at the ends of the conjugated chain (in heptafulvene this chain comprises eight atoms).

hydrazino, or other functional group—completely inaccessible by other routes, have been obtained from troponoid compounds[77]. Tri- and tetra-cyclic azulenoid systems, containing fused pyridine, pyridazine, pyrazole[78-80], and thophen[81] rings, have been obtained similarly.

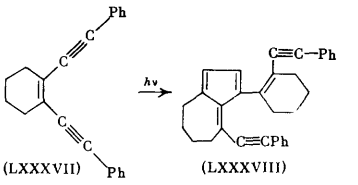


## 5. Cyclisation of Acetylenic Compounds and Other Methods

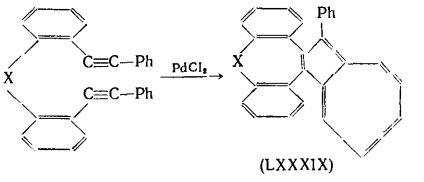
Formation of the azulene system from acetylenic compounds was observed as early as 1948 by Reppe and his coworkers[82], who reported the appearance of small quantities of azulene in the preparation of cyclo-octatetraene from acetylene. Such processes usually involve active species formed e.g. on cleavage of the benzene ring in phenylacetylene and similar in structure to heptafulvene; cycloaddition of such a species at the triple bond entails closure of the five-membered ring of the azulene system. The reactions are initiated photochemically, and sometimes can be accomplished also by means of certain catalysts. An illustration is the conversion of phenylacetylene into 1-phenylazulene (LXXXI: R = H):[83]



Diphenylacetylene undergoes a similar reaction also in the presence of 2,4-dinitrophenylsulphenyl chloride and anhydrous aluminium chloride or bromide, to give an approximately 25% yield of 1,2,3-triphenylazulene (LXXXI: R = $C_6H_5$).[84,85] The same reaction is effected also by palladium chloride, with which diphenylacetylene forms the complex compound $2C_6H_5C{:}CC_6H_5 \cdot PdCl_2 \cdot C_2H_5OH \cdot HCl$.[86] Cyclisation of acetylenes into azulenes can probably occur by both radical and ionic mechanisms.

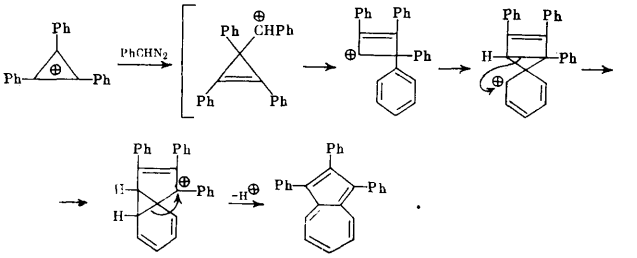


Diacetylenes (LXXXII) undergo an analogous reaction to form mixtures of the structurally isomeric azulene hydrocarbons (LXXXIII) and (LXXXIV):[87,88]

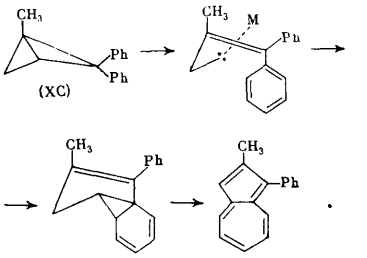


Intramolecular cyclisation of 1,8-dimesitylethynylnaphthalene (LXXXV) on ultraviolet irradiation gives the polycyclic azulene hydrocarbon (LXXXVI):[89]

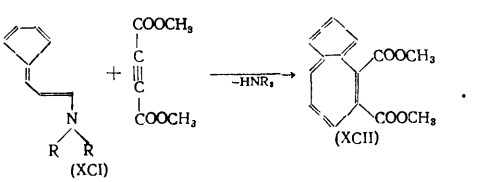
In connection with the mechanism of such reactions it is interesting that 1,2-diphenylethynylcyclohexene (LXXXVII) is converted by radiation into a hydrogenated azulene derivative (LXXXVIII)[88]



dehydrogenation of which by chloranil yields the corresponding azulene. Intramolecular cyclisation has been employed to obtain polycyclic azulene derivatives (LXXXIX) containing a silicon or sulphur atom in one of the fused rings[90,91]:

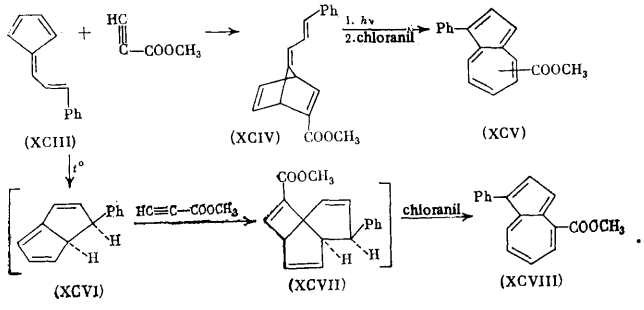


X=SO, Si $(CH_3)_2$ .

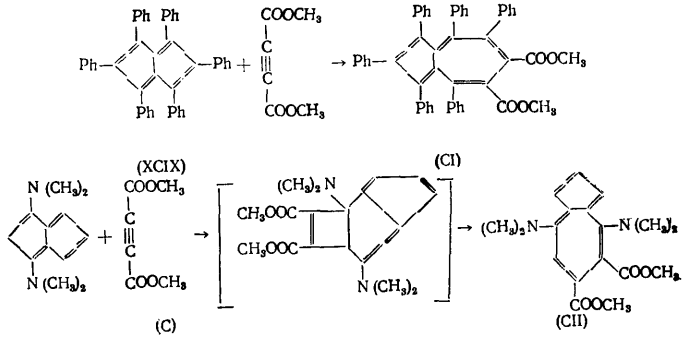


Another method of obtaining azulene derivatives—from arylcyclopropenylium salts[92-94]—also involves expanding the ring of a phenyl substituent:

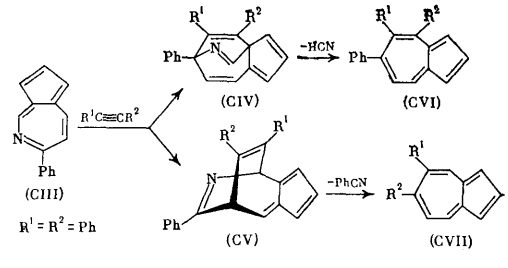
A further synthetic approach to azulenes involving intramolecular cycloaddition is based on rearrangement of a phenylated bicyclo[1,1,0]butane (XC) initiated by a transition-metal carbonyl[95]:



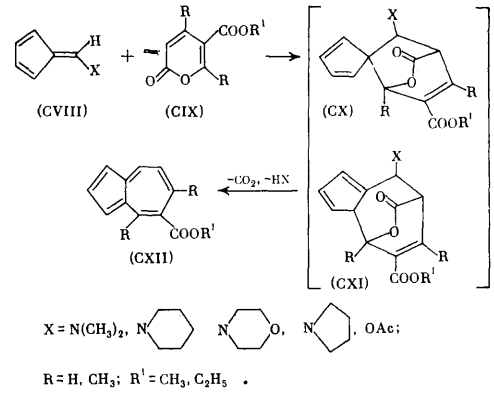
Like heptafulvenes (§II, 4) aminovinylfulvenes (XCI) are able to undergo cycloaddition with acetylenedicarboxylic esters, to give azulene-4,5-dicarboxylic esters (XCII):[96]



6-Styrylfulvene (XCIII) undergoes diene synthesis with methyl propiolate to form an adduct (XCIV) that rearranges into a mixture of phenyldihydroazulenecarboxylic esters;

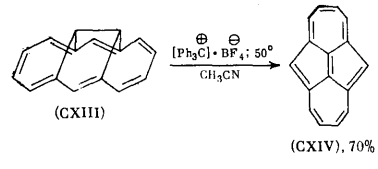


the latter are readily dehydrogenated by chloranil, forming a mixture of methyl 1-phenylazulene-4(8)-carboxylates (XCV). When heated the fulvene (XCIII) isomerises into phenyldihydropentalene (XCVI); cycloaddition of the propiolic ester produces the cyclobutene derivative (XCVII), which on dehydrogenation is converted into the individual methyl 1-phenylazulene-4-carboxylate (XCVIII).[29]

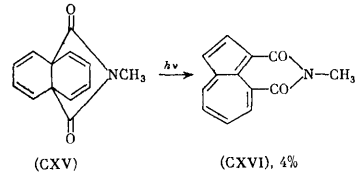


This mechanism is supported by the well known methods of converting the substituted pentalenes (XCIX) [97] and (C) [98] into the corresponding azulenes (CI) and (CII) by the action of acetylenedicarboxylic ester:

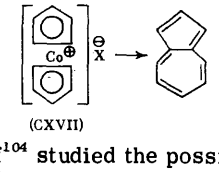
The cyclic analogue of styrylfulvene, 6-phenyl-5-aza-azulene (CIII), also undergoes cycloaddition with acetylenic compounds[99], when both possible adducts (CIV) and (CV) are formed; these eliminate hydrocyanic acid or benzonitrile to give a mixture of the corresponding azulene derivatives (CVI) and (CVII):



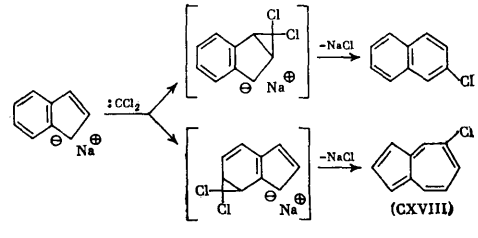
Cycloaddition of dialkylaminofulvenes (CVIII) to coumalic esters (CIX) gives the adducts (CX) and (CXI), which are aromatised into azulenes (CXII) with elimination of carbon dioxide and the dialkylamine[100]:



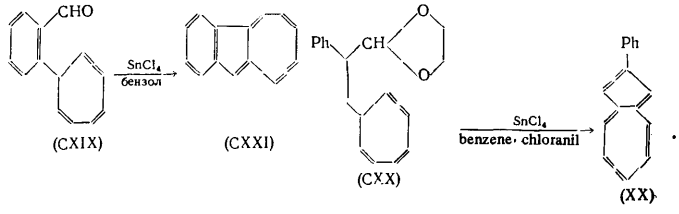
Syntheses of azulene compounds based on cycloaddition have been actively studied during recent years, and their possibilities are probably far from exhausted.



A few other methods of obtaining azulene compounds have been described which, although of no great synthetic value, provide a good illustration of the stability of the aromatic azulene system. Thus 1,6:8,13-ethanediylidene-[14]annulene (CXIII) is converted in high yield into dicyclohepta[*c*,*d*:*g*,*h*]pentalene (CXIV), a novel non-benzenoid isomer of pyrene[101]:

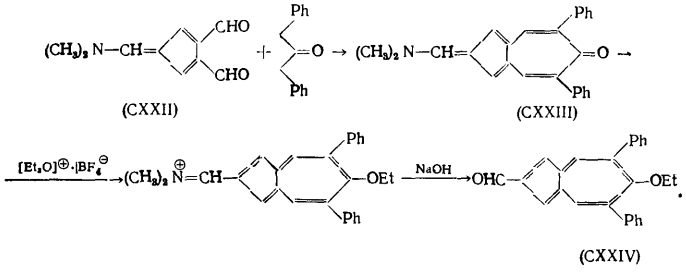


When the propellane (CXV) is exposed to ultraviolet radiation, *N*-methylazulene-1,8-dicarboximide (CXVI) is formed in 4% yield together with other compounds[102]:



Cobalticinium hexafluorophosphate (CXVII) forms azulene in low yields when treated with bases[103]:

Parham and Reiff[104] studied the possibility of obtaining azulene compounds from indenylsodium by the addition of dichlorocarbene; they found the course of the reaction to be ambiguous, giving 5-chloroazulene (CXVIII) in only about 0.5% yield:



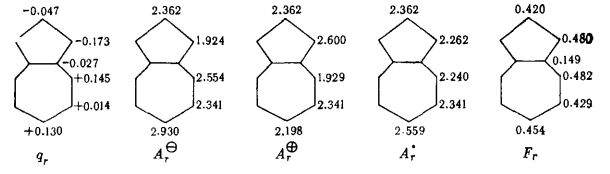
Syntheses of azulene compounds by closure of a five-membered ring in aldehydes or acetals of the cycloheptatriene series (CXIX) and (CXX) have also been reported[105]. Low yields of 1,2-benzazulene (CXXI) and 2-phenylazulene (XX) have been obtained by this method; in the latter case the intermediate dihydro-derivative was dehydrogenated by means of chloranil:

(CXIX) (CXXI) (CXX) (XX)

Another method of condensation of aldehydes involves closure of the seven-membered ring of the azulene system[48]. Borrowed from the chemistry of tropones, it converts the substituted cyclopentadiene dialdehyde (CXXII) into the azulenequinonemethide (CXXIII), which can then be transformed into the azulene derivative (CXXIV):

(CXXII) (CXXIII) (CXXIV)

The methods described in this Section have been used to synthesise various azulenoid polycyclic compounds containing 3–7 fused rings, not only carboxylic azulenoid systems[106–127] but also fused heterocyclic azulene compounds containing nitrogen[128–134], sulphur[135–140], or oxygen[141] as heteroatom.



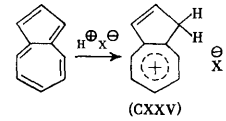
It must be noted in conclusion that no universal method is yet available for the synthesis of substituted azulene hydrocarbons. Many of the above processes cannot be used to prepare azulene and its homologues, both because of the inaccessibility of the initial compounds and because of the low yields. The search for effective new syntheses of azulenes is therefore still continuing at the present time.

## III. CHEMICAL PROPERTIES OF AZULENE COMPOUNDS

### 1. Structure and Reactivity of Azulene

The chemistry of azulene compounds has been intensively developed mainly during the past two decades; certain theoretical views on the reactivity of the azulene system have been elaborated in parallel with or even preceding the synthetic investigations. In spite of the difficulties involved in assessing the contribution of polar structures, even the simplest LCAO-MO calculations[142–152] showed high electronegativity of the five-membered ring and a deficiency of electrons on the atoms of the seven-membered ring.

The charges $q_r$, localisation energies $A_r$, and free valency indices $F_r$ calculated by the Hückel method are



The calculated results lead to several conclusions: (i) the liability to electrophilic attack should decrease either in the sequence of carbon atoms 1(3) > 2 > 5(7) > 6 > 4(8) according to the charges, or in the sequence 1(3) > 5(7) > 2 > 4(8) > 6 according to the localisation energies; (ii) the reactivity towards nucleophilic attack should diminish in the sequence of carbon atoms 4(8) > 6 > 5(7) > 2 > 1(3); and (iii) homolytic reactions should take place at carbon atoms 4(8) [142] or 1(3).[153] As will be shown later, the results of synthetic investigations exhibit in the main good agreement with these theoretical ideas.

### 2. Electrophilic Substitution

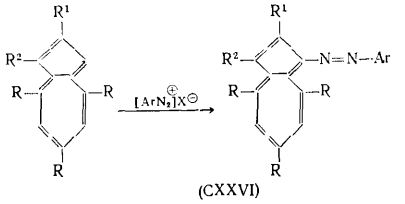
A consequence of the high electron density on the carbon atoms forming the five-membered ring is that the aromatic azulene system is highly reactive towards various electrophilic reagents. Azulene and its derivatives readily form $\pi$ complexes with various electron-deficient compounds—trinitrobenzene, trinitrotoluene, picric acid[4,154], tetracyanoquinodimethane[155], tetracyanoethylene[156,157], and several other similar compounds[158]—and trinitrobenzene complexes are often used for the isolation, purification, and identification of azulenes, since they readily break down into their components when chromatographed on aluminium oxide. Complexes of azulenes with metal carbonyls have also been described[159–162].

#### (*a*) Reactions of azulenes with acids

The strongly basic character of azulenes leads to the formation of azulenium salts (CXXV) on treatment with mineral acids[163–165]:

(CXXV)

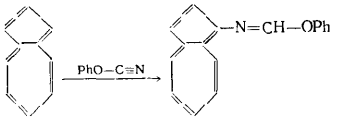
The ability of azulene and its derivatives to dissolve with salt formation in 60% sulphuric and 85% phosphoric acids[15] is used in several cases to isolate azulene compounds, since dilution of the acid solution with water leads to hydrolysis of the salt with separation of the initial azulene. Salts can be formed by azulenes also with aprotic acids[166], which leads in several cases to the appearance of secondary products when Friedel–Crafts catalysts are used.



The active hydrogen atoms at positions 1 and 3 exchange readily for deuterium[167,168], whereas the remaining hydrogen atoms exchange only under severe conditions[169].

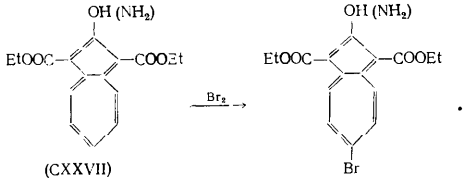
(*b*) Nitration, nitrosation, and azo-coupling

Because of the sensitivity of the ring system to strong acids, azulene and its homologues cannot be nitrated with a nitrating mixture. However, the nitration of unsubstituted azulene can be easily accomplished by means of acetyl[170], copper[171], or urea[172] nitrate. The use of tetranitromethane in pyridine is especially convenient[173]. With urea nitrate azulene gives both 1-mono-.and 1,3-di-nitroderivatives, whereas with tetranitromethane only 5-nitroazulene is formed. Azulene derivatives containing isopropyl and t-butyl substituents at positions 1 and 3 are nitrated at position 5 in ~25% yield[32].



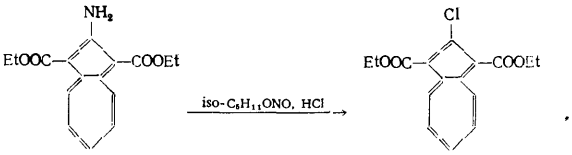
Azulene is nitrosated at position 1 by nitrosyl perchlorate to give the unstable 1-nitrosoazulene[174]. The corresponding nitroso-derivative of 4,6,8-trimethylazulene, obtainable in high yield, is considerably more stable. Nozoe et al.[175] effected the nitrosation of ethyl 2-aminoazulene-1-carboxylate with isopentyl nitrite with formation of ethyl 2-amino-3-nitrosoazulene-1-carboxylate.

1(3)-Unsubstituted azulene derivatives are able to undergo azo-coupling with such weak electrophiles as diazonium salts to give high yields of azo-dyes (CXXVI):[171,176-179]



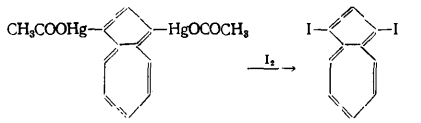
(CXXVI)

These dyes are readily reduced to azulenamines[179,180]. Azulene reacts also with phenyl cyanate[181]:



(*c*) Halogenation

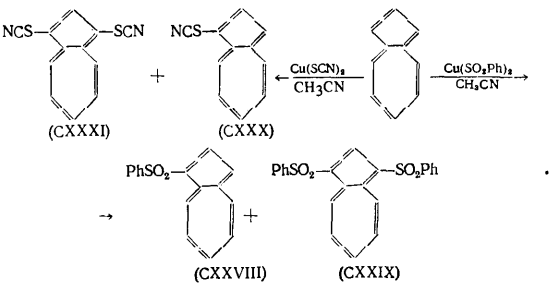
The best halogenating agents for obtaining 1(3)-mono- and 1,3-di-halogenated azulenes are *N*-chlorosuccinimide[182-184], *N*-bromosuccinimide[183-185], and *N*-iodosuccinimide[184], which give high yields. Chlorinating agents producing good results are t-butyl hypochlorite[183], phosphorus pentachloride[183,186], phosphoryl chloride[183], and copper(II) chloride[187]; sulphur monochloride in the presence of aluminium chloride also has a chlorinating action[178]. Azulene compounds can be brominated also by means of dioxan dibromide[183], phosphorus pentabromide[183], phosphoryl bromide, pyridinium bromide–perbromide, cyanogen bromide[185], and copper(II) bromide[187]. 1,3-Dibromoazulene can be obtained also by the hypobromination of 1,3-diacetylazulene[170]. Unusually, dialkyl 2-hydroxy- and 2-amino-azulene-1,3-dicarboxylates (CXXVII) are brominated at the 6 position[188,189]:



(CXXVII)

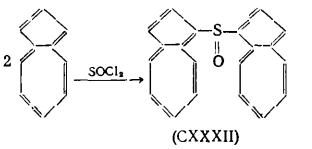
1,3-Dichloroazulene can be chlorinated by *N*-chlorosuccinimide at position 5 to give a 17% yield of 1,3,5-trichloroazulene[243]. 2-Chlorinated azulenes have been obtained by diazotising diethyl 2-aminoazulene-1,3-dicarboxylates in the presence of hydrochloric acid[190]:

6-Chloro-derivatives have been obtained from the corresponding azulen-6-ols[183].



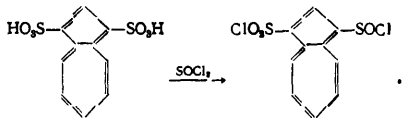
A complex of iodine chloride in dioxan[183] and iodine in the presence of copper acetate[187] have been used to obtain 1(3)-mono- and 1,3-di-iodoazulenes. Another method is exchange substitution of acetoxymercuric groups by treatment with iodine[46]:

1(3)-Halogenoazulenes form normal organomagnesium derivatives[4] and are able to exchange their halogen for the thiocyanato- or cyano-group when heated with the copper or silver salts[183]. Nucleophilic exchange of the halogen has been studied in 6-chloroazulenes[183] and 2-chloroazulenes[191].



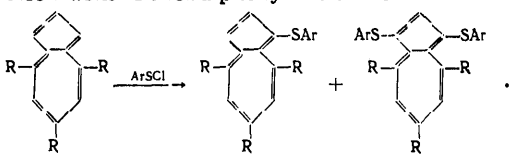
(*d*) Sulphonation, thiocyanation, and other reactions

Azulene is sulphonated by a solution of sulphuric acid in acetic anhydride or by dioxan–sulphur trioxide to the 1,3-disulphonic acid[185,192]. 1-Monosulpho-derivatives of azulene and its homologues have been obtained by sulphonation with copper sulphate in acetic anhydride[193] and with dioxan–sulphur trioxide[194]. The action of copper benzenesulphinate on azulene gives the azulenyl phenyl sulphone (CXXVIII) and the corresponding 1,3-disulphone (CXXIX);[193] methanesulphonyl chloride reacts with azulene to form azulenyl methyl sulphone[195]; and copper thiocyanate gives good yields of 1-cyanatoazulene (CXXX) and 1,3-dithiocyanatoazulene (CXXXI),[193] which had been obtained earlier from azulene and thiocyanogen[178]:



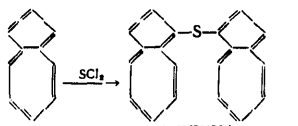
(CXXXI) (CXXX) (CXXVIII) (CXXIX)

At low temperatures azulene reacts with thionyl chloride to form diazulenyl sulphoxide (CXXXII), which on oxidation with sodium periodate is converted into diazulenyl sulphone[196]:



(CXXXII)

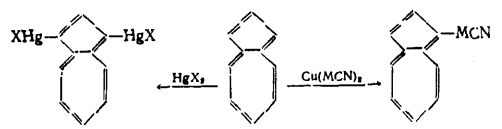
An unusual reaction takes place when the 1,3-disulphonic acid is treated with excess of thionyl chloride, for 3-chlorosulphinylazulene-1-sulphonyl chloride (CXXXIII) is formed[192]:



(CXXXIII)

Azulene and its derivatives readily give the 1-sulphides (CXXXIV) and the corresponding 1,3-bis-sulphides (CXXXV) on interaction with arenesulphenyl chlorides[174,178,195,197]:

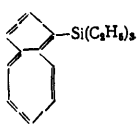
(CXXXIV) (CXXXV)



At −78°C sulphur dichloride acts on azulene to give diazulenyl sulphide (CXXXVI):[196]

(CXXXVI)

(*e*) Organoelementary azulene derivatives

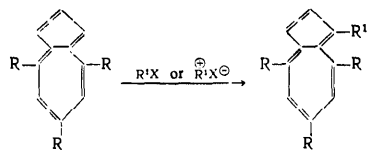


Azulene is readily mercurated by mercury(II) chloride to form azulene-1,3-dimercuric dichloride (CXXXVII):[198]

(CXXXVII) (CXXXVIII)

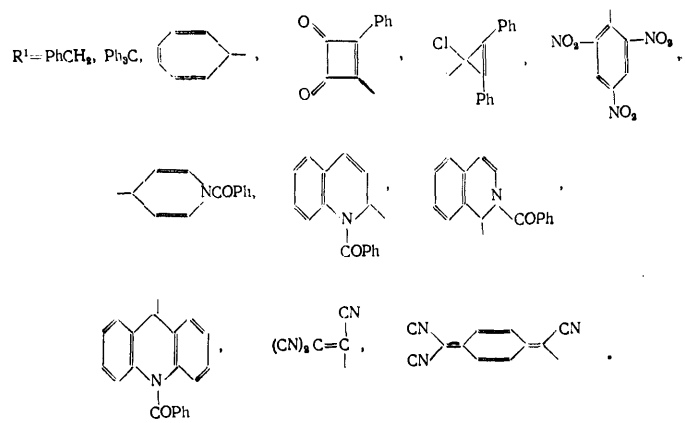
X=Cl, $OCOCH_3$; M=Se, Te

Mercury acetate is equally effective[192]. Monomercurated derivatives can also be obtained by varying the proportions of the reactants. The chloromercuri-derivatives are converted quantitatively into halogeno- or thiocyanato-derivatives by the action of copper(II) chloride, bromide, or thiocyanate[193]. Copper selenocyanate and tellurocyanate give good yields of the corresponding seleno- and telluro-cyanatoazulenes (CXXXVIII).[199] The organosilicon azulene derivative



(CXXXIX)

was synthesised indirectly, not by direct substitution[200].

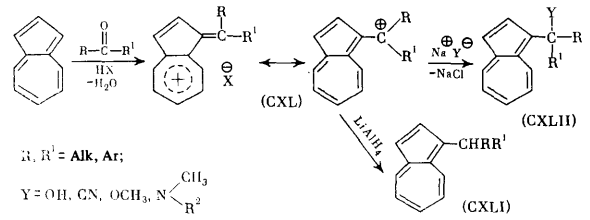


(*f*) Alkylation

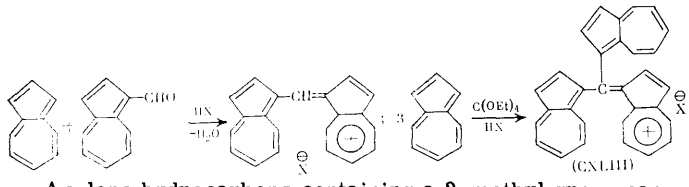
Alkylation of azulene and its homologues under the conditions of Friedel–Crafts reaction takes place at positions 1 and 3, but such reactions give by no means high yields owing to the great sensitivity of azulenes to catalysts[166,198]: for example, benzyl chloride forms 1-benzylazulene in only 5.6% yield[198]. Alkyl halides give still poorer results[201,202]. However, compounds capable of forming stable carbonium ions—such as triphenyl chloromethane[203], tropylium bromide[204], 3-bromo-4-phenylcyclobutene-1,2-dione[205], and 3,3-dichloro-1,2-diphenylcyclopropene[206]—readily alkylate azulene at positions 1 and 3. Good results have been obtained by the action of picryl chloride and *p*-chloronitrobenzene on azulene hydrocarbons[166]; the condensation of azulene with pentaacetylbromoglucose has been described[207].

X=Cl, Br, CN;

R=H, $CH_3$;

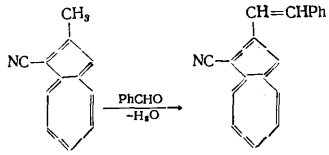


Di- and tri-phenylmethanols, their ethers or esters, or arylated ethylenes capable of forming stable carbonium ions have been used as alkylating agents[203,208] instead of alkyl halides. Tropylium and triphenylmethyl perchlorates are also effective alkylating agents[174,209]. 1-Ethyl-4,6,8-trimethylazulene has been obtained by alkylating 4,6,8-trimethylazulene with triethyloxonium tetrafluoroborate[174], but such a reaction could not be accomplished with unsubstituted azulene[198]. Yields of 40–60% have recently been obtained in the heteroarylation of azulene and its homologues with *N*-acylated pyridinium, quinolinium, isoquinolinium, and acridinium salts[210,211]. The $\pi$ complexes of azulene hydrocarbons with tetracyanoethylene and tetracyanoquinodimethane are converted into the 1-tricyanovinyl derivatives with the elimination of hydrogen cyanide[155–157].

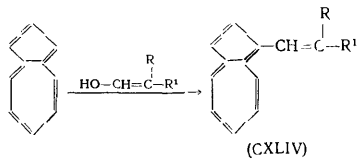


(*g*) Reactions with carbonyl compounds

In the presence of various mineral and organic acids azulene hydrocarbons condense with aromatic[165,212–219], heterocyclic[217,218,220,221], aliphatic[222,223], polyene[222,224], and azulene[212,214,222] aldehydes, ketones[206,225], and several dicarbonyl compounds[222]. The resulting mesomeric cations (CXL) can easily be reduced to the corresponding



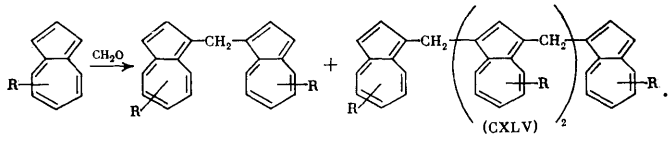
1-alkylazulenes (CXLI),[219,223] and are converted by bases into compounds of type (CXLII):[223]



This reaction has been used to obtain azulenoid polymethine dyes[220,221]. Saltlike dyes of the diazulenylmethane series have been obtained by the interaction of azulene and 1-formylazulene[214,215,218,222]; and a triazulenylmethane dye (CXLIII) is produced by condensing azulene with orthocarbonic ester in acid medium[214]:

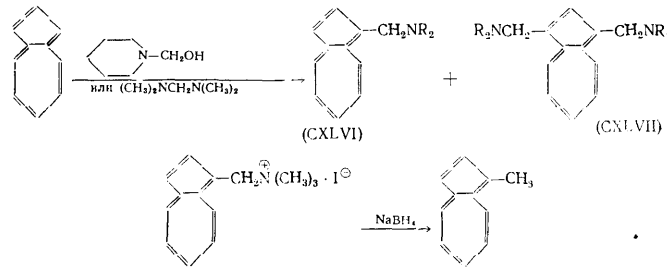
Azulene hydrocarbons containing a 2-methyl group can be condensed with benzaldehyde to form 2-styrylazulenes[226].

Enols alkylate azulene and its homologues in acid media with the elimination of water and the formation of vinyl derivatives (CXLIV):[222]



(CXLIV)

R=H, CN, $NO_2$, Ph, CHO; $R^1$=$COCH_3$, COPh

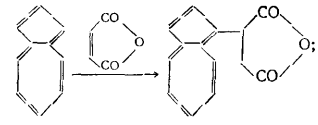


## (*h*) Aminomethylation

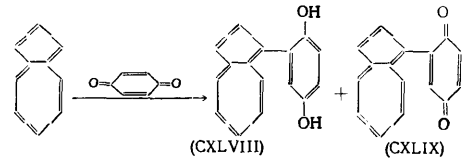
Chloromethylation and hydroxymethylation of azulene and guaiazulene by means of formaldehyde yield only products of diazulenylmethane structure[216] or of further condensation (CXLV),[227] not the corresponding chloromethyl or hydroxymethyl derivatives:

(CXLV)

However, the use of mild aminomethylating agents, such as aminomethanols[227,228] and methylenebisdialkylamines[229], made it possible to accomplish the Mannich reaction. Azulene is aminomethylated at positions 1 and 3 to give the unstable dialkylaminomethyl derivatives (CXLVI) and (CXLVII); with methyl iodide these form the more stable quaternary salts, which can be reduced by sodium tetrahydroborate to methylazulenes:



(CXLVI) (CXLVII)

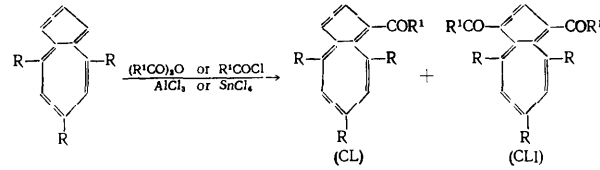


Reactions of these salts with alkali-metal phenoxides and cyanides have been described, as well as several other transformations of aminomethyl derivatives[137,228,230-232].

## (*i*) 1,2-Addition

Azulenes do not undergo diene condensation, but are able to add to active dienophiles—acetylenecarboxylic and azo-dicarboxylic esters[233], maleic anhydride[233,234], benzoquinone[233,234], 1,2-naphthaquinone[181]—with the formation of 1,2-addition products: e.g.

The product (CXLVIII) formed initially by the addition of benzoquinone to azulene may be oxidised by excess of the former reactant to the substituted quinone (CXLIX):[235]

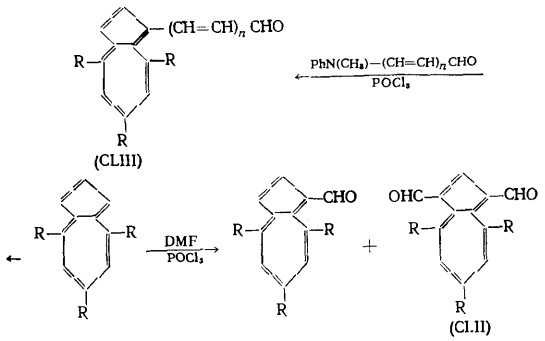


(CXLVIII) (CXLIX)

Azulene adds also to phenyl isocyanate to form azulene-1-carboxyanilide[181].

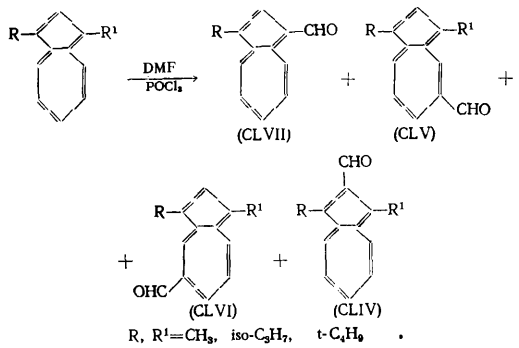
## (*j*) Acylation

Azulene is acylated by chlorides and anhydrides of carboxylic acids in the presence of aluminium chloride[171,201], perchloric acid[225], or tin tetrachloride[170] with the formation of 1-mono- and 1,3-di-acyl derivatives (CL) and (CLI):



(CL) (CLI)

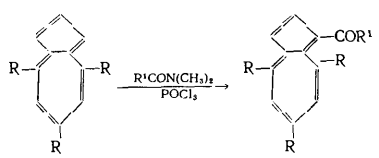
With trifluoroacetic anhydride the reaction goes almost quantitatively in the absence of a catalyst[236,237]. Acylation has been achieved with oxalyl[238-240], malonyl[241,242], and phenylacetyl[244] chlorides or bromides. Under the conditions of the Friedel–Crafts reaction carbonyl chloride forms diazulenyl ketones[212]. Guaiazulene may be formylated under the conditions of the Gattermann reaction[239]. In all the above cases acylation occurs at positions 1 and/or 3, at which the greatest electron density is concentrated; when these are occupied, position 5 becomes acylated.



Substituents already present at the former positions—chloro[182,243], isopropyl[173], t-butyl[174]—often exchange simultaneously for an acyl group. 1- and 3-Acetyl groups may in turn be displaced by other electrophilic reagents[174], e.g. when heated with alcohols in acid media[225].

The Vilsmeier–Haack reaction is mostly used at the present time to obtain acyl and especially formyl derivatives of azulene hydrocarbons. Many diverse 1(3)-formyl derivatives of azulene have been prepared by this method[4,203,245-250]. The corresponding 1,3-dialdehydes (CLII) have also been obtained in good yields, and application of the reaction to unsaturated amino-aldehydes yields vinylogues of 1-formylazulene (CLIII):[117,224]

R=H, $CH_3$; n=1, 2 .

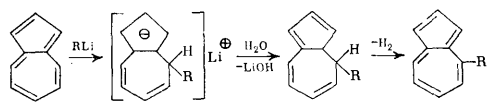


Treatment of 1,3-dialkylated azulenes with a complex of dimethylformamide and phosphoryl chloride gives a mixture of the 2-, 5-, and 7-formyl derivatives (CLIV)–(CLVI) together with the product (CLVII) of replacement of an alkyl by a formyl group[173]:

R, $R^1$=$CH_3$, iso-$C_3H_7$, t-$C_4H_9$ .

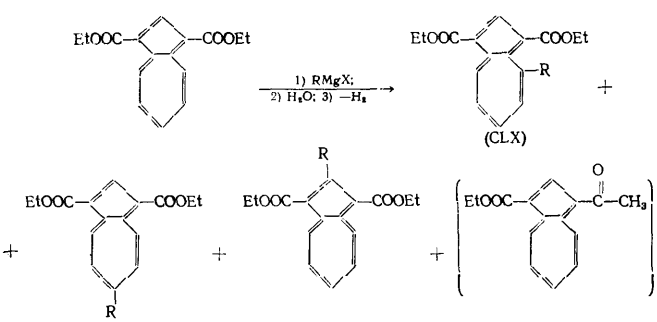
At a high temperature the formylating complex is able to displace the bromine atoms in 1,3-dibromoazulene[251] (see below).

Azulene can be formylated also by means of orthoformic ester in acid media[214]. Aldehydes have been obtained also by oxidising 1-dialkylaminomethylazulenes[228] and 1-methylazulene[260] with potassium permanganate. Treatment of azulene hydrocarbons with acylating complexes obtained from dimethylamides of acetic[18,127,248], chloroacetic[254], oxalic[253], benzoic[127,248], and several other acids have been used to prepare the corresponding 1(3)-acylazulenes (CL):



R=H, $CH_3$; $R^1$=$CH_3$, $CH_2Cl$, $CON(CH_3)_2$, $C_6H_5$ .

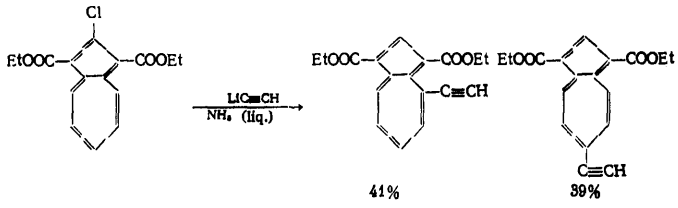
Azulene aldehydes and ketones are used as initial compounds for obtaining various classes of derivatives containing the azulene ring system[81,107,110,116-118,120,127,131,132,254-259].



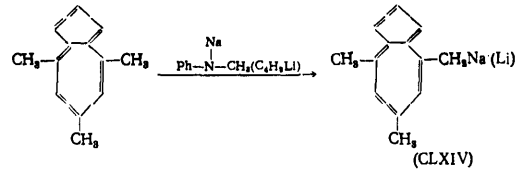
Displacement of substituents at positions 1 and 3 in the ring system is met quite often in the chemistry of azulene compounds and occurs readily under conditions of electrophilic attack. This phenomenon especially often accompanies formylation[173,251] and acylation[173,174,243], although it has been observed also during halogenation[186], nitrosation[175], and azo-coupling[174]. Groups that give stable carbonium cations are very easily replaced. Thus the ease of substitution of alkyl groups increases on passing from methyl to isopropyl, t-butyl, and then to triphenylmethyl and cycloheptatrienyl. Either one or both groups at positions 1 and 3 may undergo substitution. Not only alkyl groups but also the acetyl group[174] and halogens[243,251] may be replaced.

## 3. Nucleophilic Substitution

Considerably less study has been made of nucleophilic than of electrophilic substitution in azulene compounds. As LCAO-MO calculations have predicted, nucleophilic attack takes place at carbon atoms 4(8) and 6. Thus azulene reacts with organolithium compounds to give addition products (CLVIII), which on hydrolysis yield colourless dihydroazulene derivatives (CLIX), whose dehydrogenation by chloranil produces 4-substituted azulenes[30,32]:



in which R = $CH_3$, $(CH_3)_3C$, $C_6H_5$, 1-$C_{10}H_7$, $C_6H_5CH_2$, 2-$C_4H_3S$, 2-$C_5H_4N$, or 2-$C_5H_4NCH_2$. 4,8-Disubstituted azulenes can be obtained similarly. It is interesting that diethyl azulene-1,3-dicarboxylate reacts with aliphatic and aromatic organomagnesium compounds without involvement of the ester groups, to form after hydrolysis and dehydrogenation a mixture of 4-, 6-, and 2-substituted azulenes (CLX)–(CLXII),[31,262] and in only one case has the product of interaction between an organomagnesium compound and an ethoxycarbonyl group (CLXIII) been detected:

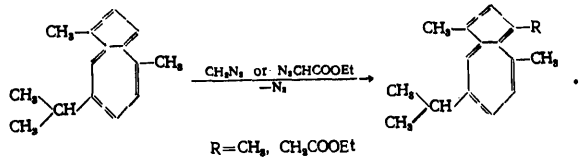


R=Alk, Ar .

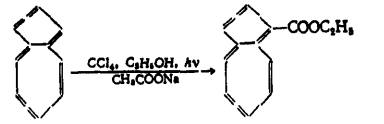
An ethynyl group is readily introduced into the azulene ring system by the action of lithium acetylenide in liquid ammonia on 2-chloroazulenecarboxylic esters[261]:

Here, too, ethoxycarbonyl groups are unaffected, though their electron-accepting effect activates the azulene system to nucleophilic attack: unsubstituted azulene does not undergo such a reaction with acetylenides. The presence of halogen at position 2 makes it possible to eliminate the dehydrogenation stage, since the aromatic azulene structure is regenerated, by dehydrochlorination under the influence of ammonia, from the intermediate dihydro-derivatives formed by addition.

Metal derivatives of alkylated azulenes have been obtained by the action of the sodium derivative of *N*-methylaniline or of butyl-lithium on 4- or 6-methylated azulenes[244,262]:

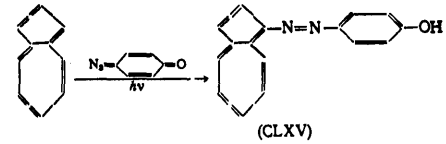


(CLXIV)



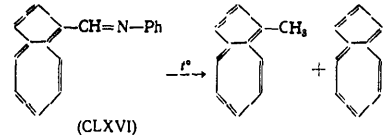
The organometallic derivatives (CLXIV) undergo the usual reactions with alkyl halides, carbon dioxide, and carbonyl compounds, forming various 4-substituted azulene derivatives[116,120,244,262–265]. Azulene is aminated at position 4 in low yield by sodamide[185]. Various nucleophilic reactions involving exchange of halogen in halogenated azulenes have been studied[183,266–268].

## 4. Radical Substitution

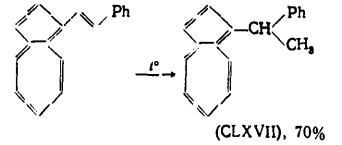


Calculated localisation energies suggest that radical reactions should occur at position 4 in azulene compounds[269], but the difference in energy of localisation at positions 1 and 4 is insignificant, and almost all known radical reactions take place at the 1-carbon atom. Such reactions, which have been studied with the alkylation of guaiazulene by diazomethane and diazoacetic ester as example[270], yield the corresponding substitution products:

A 15% yield of 1-phenylazulene has been obtained[216] by the action of nitrosoacetanilide on azulene. The radical benzylation of azulene[271] gives a mixture of the 1- and 2-isomers, the latter probably formed by secondary migration of the benzyl group under the severe reaction conditions (see below). Of preparative interest is the photoalkyoxycarbonylation of azulene[272] to give a 52% yield of ethyl azulene-1-carboxylate:

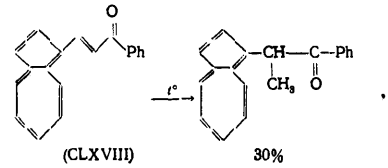


A high yield of the azo-dye (CLXV) is obtained by the action of *p*-diazoquinone on azulene during exposure to ultraviolet radiation[273]:



(CLXV)

Several thermal reactions of azulene derivatives resulting in modification of 1-substituents are probably also radical in character. Thus the Schiff base (CLXVI) when heated is converted into a mixture of 1-methylazulene and azulene in 36% and 24% yield respectively[274]:



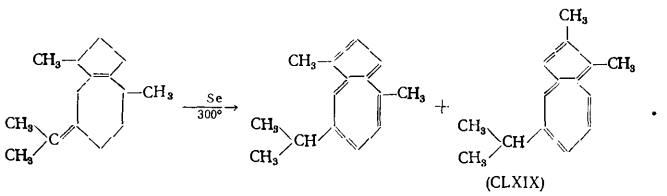
(CLXVI)

1-Styrylazulene is transformed in high yield into 1-α-methylbenzylazulene (CLXVII):[275]

(CLXVII), 70%

Azulenylvinyl phenyl ketone (CLXVIII) undergoes analogous rearrangement[276]:

(CLXVIII) 30%

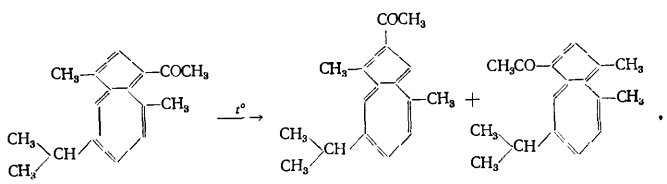


Reduction of the rearranged products is a consequence of partial decomposition of the azulene compounds. Although the yields in these processes are not always high, such reactions enable several difficultly accessible azulene derivatives to be obtained.

On irradiation 1-nitroazulene exchanges its nitro-group for a cyano- or a methoxy-group[277,278], a reaction of especial interest for obtaining the difficultly accessible 1-methoxyazulene. It is quite likely that the migration of various groups from 1 to the 2 position in the azulene ring system has a radical mechanism.

## 5. Migration of Substituents

The most common specific migration of groups is the conversion of 1- into 2-substituted azulenes, first observed by Plattner[279]; it has now been studied on several examples, and provides a route to 2-substituted azulenes, which are



extremely difficult to obtain by other methods, although the yield is often diminished by secondary processes due to the high temperature of conversion. Dehydrogenation of guaiene with selenium at 300°C yields not only guaiazulene (II) but also the isomeric (CLXIX):[279,280]

(CLXIX)

Isopropyl[282], t-butyl[283], phenyl[281], acetyl[19,285,286], benzoyl[284], and formyl[252] groups migrate in this way. Ease of migration increases on passing from methyl to t-butyl[283].

This isomerisation is promoted by substituents at positions 4 and 8. Thus 1-formylazulene does not isomerise into the 2-aldehyde, whereas 1-formyl-4,6,8-trimethylazulene is converted into the 2-formyl derivative in 16% yield[252,287]. The reaction may be accompanied by exchange of the migrating group for hydrogen[283] and by intermolecular alkylation. A case of the simultaneous migration of two substituents is known[286]:

## IV. PRACTICAL APPLICATIONS OF AZULENE COMPOUNDS

Two main trends in the practical application of azulene derivatives have developed during recent years: the first is based on the broad spectrum of biological activity exhibited by azulenes and has led to the production of various medicinal preparations; the second exploits the peculiar electronic structure of azulene hydrocarbons, which enables these compounds to be used as dyes, optical sensitisers, and perhaps photosemiconductors. Many plants that are natural sources of azulene compounds have long been employed in folk and official medicine. A broad study of natural and synthetic azulenes has established that many of them possess high bacteriostatic[288,289], anti-inflammatory[290-295], antipyretic[70,129,133], sedative[134,296-298], antiallergic, antasthmatic[299-302], and several other types of activity. During recent years preparations possessing antineoplastic activity have been based on azulene compounds[141,179,204,303,304], although no statistical data on their application have appeared. The high anti-inflammatory activity of several azulene compounds has led to their widespread introduction as components of toothpastes, creams, and several other cosmetic materials[306]. For this purpose methods have been developed for producing stable emulsions and water-soluble formulations[295]. Azulene analogues of known medicinal preparations have been synthesised[307,308]. The influence of azulene compounds on several enzyme systems was studied[309] in order to elucidate the mechanism of their biological action. The carcinogenic effect of several fused polycyclic azulenes has been examined[310,311].

The ability of azulene derivatives to absorb in the visible led to an intensive study of azulene analogues of triphenylmethane[107] and polymethine[221,255,312] dyes, including those based on azulenylthiazole[254]. Photoconduction by azulene crystals has been studied[313]. Certain substituted heterocyclic azulenes are used as stabilisers for polymers[314]. The use of azulene in analytical chemistry has been reported[315].

In assessing the practical utilisation of azulenes we must emphasise that research on their application was held back for a long time by the absence of effective methods of synthesis, which have been developed only during the past two decades[305]. However, the results already available suggest that great prospects lie before this class of non-benzenoid aromatic compounds.

# The Addition of Sulphenyl Chlorides to Unsaturated Compounds

L.Rasteikiene, D.Greiciute, M.G.Lin'kova, and I.L.Knunyants

One of the aspects of the chemistry of sulphenyl chlorides, which is vigorously developing at the present time, is examined. It involves their interaction with unsaturated compounds. The application of modern physical research techniques has made it possible to investigate the addition of sulphenyl chlorides to asymmetric olefins, which results as a rule in the formation of a mixture of isomeric β-halogenoalkyl sulphides. The interconversions of the β-halogenoalkyl sulphides, associated with the vicinal positions of the halogen and sulphur atoms in the molecule, are considered. The high reactivity of the halogen and sulphur atoms in the molecule, are considered. The high reactivity of the halogen permits its ready nucleophilic substitution with formation of a series of new interesting compounds.
The bibliography includes 210 references.

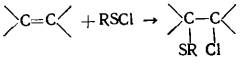
## I. INTRODUCTION



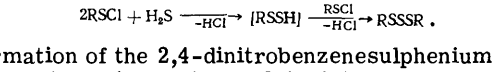
Reactive sulphenyl chlorides add readily and quantitatively to unsaturated compounds. The reaction constitutes a convenient method of synthesising various β-chloroalkyl sulphides, which are used as insecticides, fungicides, and bactericides or serve as the starting materials for the synthesis of aminomercaptans, monomers, etc. Certain β-chloroalkyl sulphides exhibit antitumour or mutagenic activities. The addition of sulphenyl chlorides to unsaturated compounds such as olefins, acetylenes, and steroids is also used for their characterisation and quantitative determination.

Certain reactions involving the addition of sulphenyl chlorides to unsaturated compounds are briefly reviewed in Kharasch's monograph[1], but many new data have been published in recent years, which necessitated significant modifications of the earlier ideas. Gundermann's review[2] deals with the involvement of the sulphur atom in nucleophilic substitution of the halogen in β-halogenoalkyl sulphides. Mueller[3] analysed the influence of steric and electronic factors, confirming the formation of the episulphonium ion as an intermediate in the addition of sulphenyl chlorides to unsaturated compounds and in the cleavage of thiirans by electrophiles. Kuhle[4] described methods for the preparation of sulphenyl chlorides and a wide variety of their reactions.

This review includes new studies on the addition of alkyl, aryl, acetylthio-, dialkoxyphosphoryl, alkoxyalkylphosphinyl, and alkylamino-derivatives of sulphenyl chlorides to olefins, dienes, allenes, acetylenes, and derivatives of αβ-unsaturated acids.

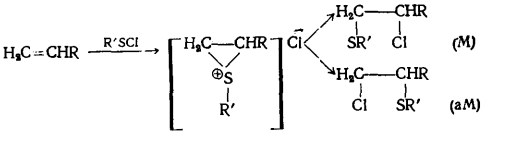
## II. ADDITION TO OLEFINS

The first data on the addition of sulphenyl chlorides to olefins were published by Lecher et al.[5] in 1925:



R = $C_6H_5$; *p*-$CH_3C_6H_4$; or *o*-$NO_2C_6H_4$.

The reaction drew attention, since, owing to their high reactivity, sulphenyl chlorides add easily and quantitatively to double bonds with formation of the corresponding β-chloroalkyl sulphides. According to modern ideas, the sulphenyl chloride molecule is polarised in such a way that the partial positive charge is localised at the sulphur atom. This structure is confirmed also by the interaction of sulphenyl chlorides with compounds containing a mobile hydrogen atom, such as malonic ester, acetoacetic ester, nitromethane, hydrogen cyanide, etc. The reaction leads to the formation of sulphides[6-8]:



Sulphenyl chlorides react with hydrogen sulphide to form trisulphides[9,10]:

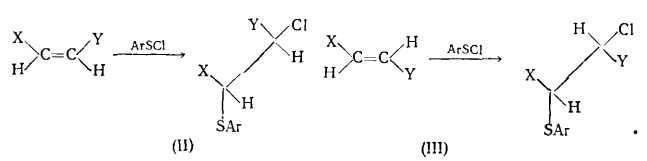
The formation of the 2,4-dinitrobenzenesulphenium cation $(NO_2)_2C_6H_3S^+$ on dissolution of 2,4-dinitrobenzenesulphenyl chloride in concentrated sulphuric acid has also been described[11,12].

Kharasch contributed much to the study of the mechanism of the addition of sulphenyl chlorides to unsaturated compounds. He was the first to suggest the formation in this reaction of the intermediate cyclic episulphonium ion (I). The subsequent opening of the ring by the chloride anion leads to the formation of β-chloroalkyl sulphides. With asymmetric olefins, adducts can be formed both in accordance with (designated subsequently by M) and contrary to (designated subsequently by aM) the Markovnikov rule[13]:

(I)

The study of the kinetics of the addition of sulphenyl chlorides to olefins showed that this is an electrophilic reaction [14,15]. The rate of addition of 2,4-dinitrobenzenesulphenyl chloride (DNBS) to *p*-substituted styrenes is influenced by those *p*-substituents which increase the electron density in the double bond of styrene [16]. The addition to cyclohexene is ten times faster than to styrene and three times faster than to *p*-methylstyrene [17-20]. The rate of addition of DNBS to 4,5-disubstituted cyclohexenes and to norbornene derivatives decreases with enhancement of the electron-accepting properties of the substituents [21]. Methanesulphenyl chloride adds faster to olefins containing methyl groups attached to the double bond. The influence of the nucleophilic properties of the double bond and steric factors on the relative rates on addition of sulphenyl chlorides has been demonstrated for olefin homologues and *cis*- and *trans*-isomers. Comparison of the reactivities of sulphenyl chlorides and chlorine in addition to olefins under analogous conditions showed that the formation of the intermediate sulphonium ion is less sensitive to changes in the nucleophilic properties of the olefins than in the case of chlorine and is extremely sensitive to steric factors. The relative reactivities of olefins with respect to electrophilic attack in non-polar solvents are given below:

| Olefin | $Cl_2$ | $CH_3SCl$ | Olefin | $Cl_2$ | $CH_3SCl$ |
|---|---|---|---|---|---|
| But-1-ene | 1.6 | 1.0 | Isobutene | 50 | 0.75 |
| *cis*-But-2-ene | 63 | 13.0 | Trimethylethylene | 11.000 | 8.26 |
| *trans*-But-2-ene | 58 | 0.72 | Tetramethylethylene | 430.000 | 12.90 |



The rate of addition is also influenced by the geometry of the olefins; for example, *cis*-but-2-ene combines with methanesulphenyl chloride faster than its *trans*-isomer [22].

The nature of the substituent in the benzene ring of benzenesulphenyl chloride also affects the rate of addition. *p*-Methyl- and 2,4-dichloro-benzenesulphenyl chlorides add to but-2-ene faster than DNBS. [23] The study of the relative rates of addition of *p*-substituted *o*-nitrobenzenesulphenyl chlorides to cyclohexene led to analogous conclusions [24-26].

It is believed that the formation of the episulphonium ion is the rate-determining stage in the addition of DNBS to styrene [27], *p*-substituted styrenes [16], and cyclohexene [17]. The ionic reaction mechanism is also confirmed by data obtained in the study of the influence of the polarity of the solvent on the rate of addition of DNBS to cyclohexene. The reaction in nitrobenzene is 3000 times faster and in acetic acid 1400 times faster than in carbon tetrachloride [17].

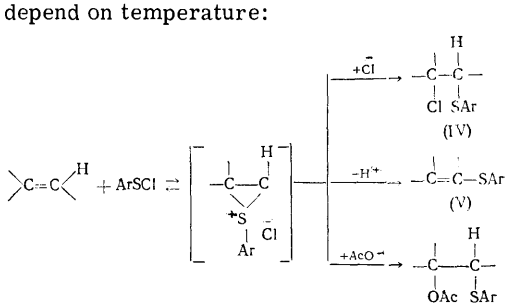
The Hammett and Taft constants calculated for the addition of arenesulphenyl chlorides to olefins also point to the existence of an intermediate episulphonium ion rather than a carbonium ion [25,28].

The addition of sulphenyl chlorides to unsaturated compounds is strictly stereospecific [29]. Different arenesulphenyl chlorides yield respectively the racemic *threo*- and *erythro*-adducts (II) and (III) on interaction with the *cis*- and *trans*-isomers of 2-phenylbut-2-ene, [30] but-2-ene [23,31], stilbene [32-34], and 1-phenylprop-1-ene [35]:

(II) (III)

*cis*-Stilbene reacts more slowly than its *trans*-isomer. The two adjacent phenyl groups apparently prevent the formation of the intermediate episulphonium ion [32].

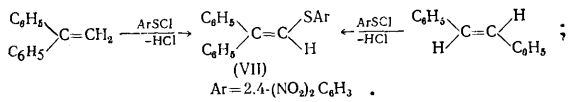
Kinetic studies on the addition of 2,4-dinitrobenzenesulphenyl chloride to the vapours of various 1-arylpropenes and the corresponding olefins also showed that all the *trans*-isomers of 1-arylalkenes are more reactive than the *cis*-isomers. On the other hand, the rate of addition of sulphenyl chlorides to *cis*-alkenes is approximately ten times higher than the rate of addition to the *trans*-isomers [36].



Data indicating the high stereospecificity of the addition of *p*-chlorobenzenesulphenyl chloride to *cis*- and *trans*-but-2-enes over a wide temperature range (from −34° to +180°C) also confirm the formation of an intermediate cyclic episulphonium ion. If an intermediate carbonium ion, which has presumably a planar configuration with free rotation about the central C=C bond, had been formed, the ratio of the *erythro*- and *threo*-adducts would have been identical for both *cis*- and *trans*-but-2-enes [37]. The addition of RSCl to cyclohexenes resulted in the formation of *trans*-adducts [31,38,40]. In some investigations, the configuration of the cyclohexene adducts was not determined [41-48]. *trans*-Adducts were also obtained with other cyclic compounds: norbornene [49,50], norbornadiene [51-54], and sulpholene [55].

Following the addition of benzenesulphenyl chloride to 7-chlorodibenzobicyclo[2,2,2]octatriene [54] and of 2,4-dinitrobenzenesulphenyl chloride to norbornene [56], the Wagner–Meerwein rearrangement was observed.

The *trans*-addition of methanesulphenyl chloride to acenaphthylene, of benzenesulphenyl chloride to 7,7-dimethylnorbornene [57-61], and of various alkanesulphenyl chlorides to dihydropyran [62,63] was confirmed by NMR spectra.

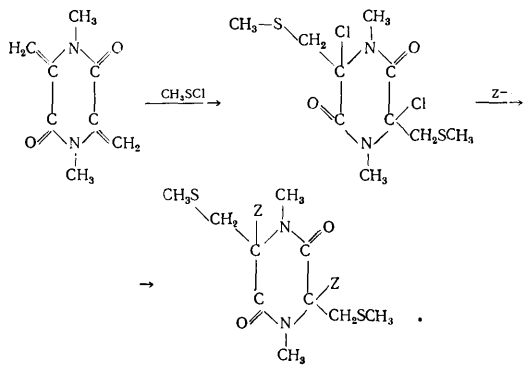


A single non-stereospecific example, involving the addition of 2,4-dinitrobenzenesulphenyl chloride to *cis*- and *trans*-anetholes in tetrachloroethane, has been described. *cis*-Anethole yields 70% of the *threo*-adduct and 30% of the *erythro*-adduct, while the *trans*-isomer gives rise to 5 and 95% of the two adducts respectively. A slow rearrangement was observed until the attainment of equilibrium with approximately equal proportions of the isomers (51.8% of the *erythro*-adduct and 48.2% of the *threo*-adduct) [64].

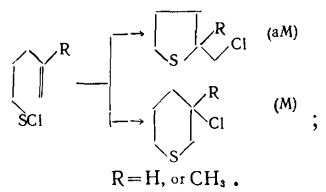
When arenesulphenyl chlorides react with anethole [13], *p*-methoxystyrene [16], and 3,3-dimethylbutene [65] in glacial acetic acid, several compounds are obtained, whose formation can be explained solely by the transformation of an intermediate episulphonium ion. The addition of the chloride anion to the intermediate episulphonium ion gives rise to a β-chloroalkyl sulphide, while the abstraction of a proton from the latter results in the formation of a vinyl sulphide and solvolysis with glacial acetic acid gives a β-acetoxyalkyl sulphide. The proportions of the compounds depend on temperature:

In the reaction involving *p*-methoxystyrene, the vinyl sulphide (V) and the β-acetoxyalkyl sulphide (VI) are formed from β-chloroethyl sulphide (IV) much more

slowly than in the direct addition of the arenesulphenyl chloride to the olefin [16]. In the addition of ArSCl to 1,1-diphenylethylene, HCl is evolved and the unsaturated sulphide (VII) is formed [13]; it was also obtained from *trans*-stilbene in boiling acetic acid [66]:



(VII)

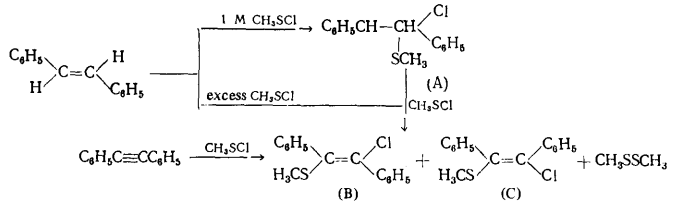


Ar = 2,4-$(NO_2)_2C_6H_3$ .

It has been shown that, when 2,3,5,6-tetrachloropyridine-4-sulphenyl chloride adds to asymmetric alkenes, the ratio of the M and the aM adducts is greatly influenced by steric factors and the solvent [67].

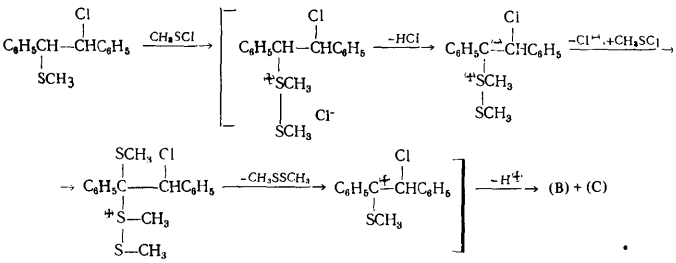
The addition of methanesulphenyl chloride to 1,4-dimethyl-3,6-dimethylenepiperazine-2,5-dione results in an adduct which loses HCl on prolonged storage with formation of three isomeric compounds. On treatment with nucleophiles, chlorine is readily substituted [68]:

The intramolecular addition of a sulphenyl chloride with formation of a mixture of aM and M compounds has been achieved:

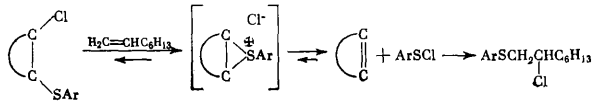


R = H, or $CH_3$ .

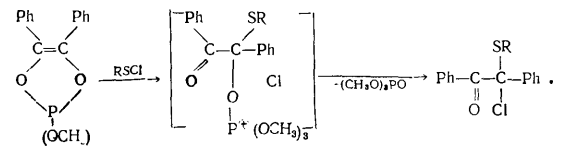
The aM adduct is first formed preferentially and then gradually isomerises to the M adduct. The structures were confirmed by NMR and by oxidation to sulphones [69].



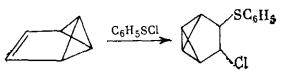
The addition of arenethiosulphinyl chlorides leads to the corresponding mixed β-halogenodisulphides [70]:



Interesting results were obtained in a study of the addition of methanesulphenyl chloride to *trans*-stilbene [71]. On treatment of *trans*-stilbene with one mole of methanesulphenyl chloride, the adduct (A) is formed, while on treatment with an excess of the reagent the product consists of a mixture of compounds (B) and (C). The same mixture was obtained following the addition of methanesulphenyl chloride to tolane:

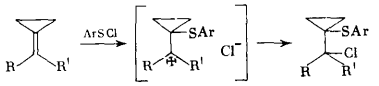


with *cis* : *trans* = 4 : 1. The authors suggested the following mechanism for the formation of compounds (B) and (C):

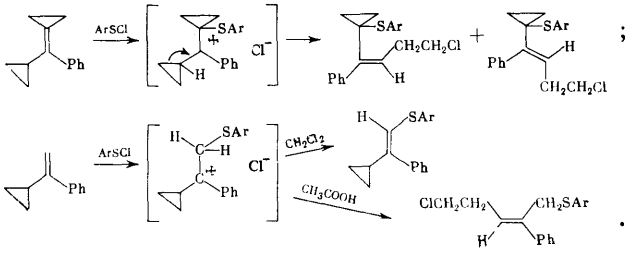


The exchange of sulphenyl chloride between olefins has been achieved [72]. It has been shown that the adducts obtained by the addition of 4-chlorobenzenesulphenyl chloride to cyclic or acyclic olefins exchange it with oct-1-ene on heating in tetrachloroethane:

The addition of sulphenyl chlorides to 1,3,2-dioxaphospholen leads to the elimination of phosphate and the formation of α-chloro-α-thioketones [73]:



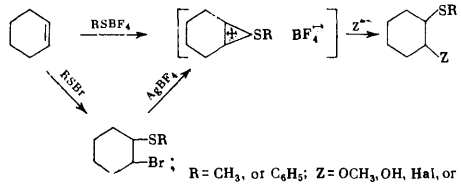
The addition of benzenesulphenyl chloride to benzvalene has been achieved [74]:



The effect of the cyclopropyl substituents on the rate of electrophilic addition has been investigated [75] and it has been shown that the rate of addition of β-chlorobenzenesulphenyl chloride to cyclopropylethylene is an order of magnitude higher than the rate of addition to n-butylethylene:

The addition of 2,3-dinitrobenzenesulphenyl chloride to phenylmethylenecyclopropanes and α-cyclopropylstyrene [76] has been studied. Phenylmethylenecyclopropanes with R = R′ = Ph and R = Ph, R′ = H normally combine with sulphenyl chlorides via the mechanism

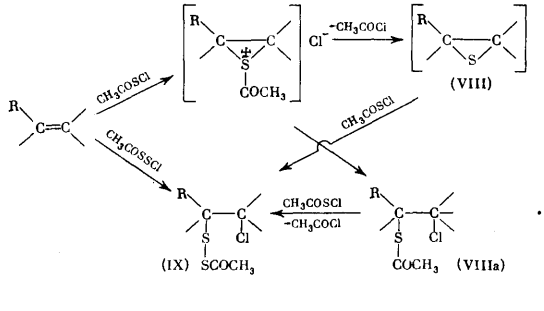
In the reaction of phenylcyclopropylmethylenecyclopropane and α-cyclopropylstyrene, the unsubstituted cyclopropane ring rearranges to homoallyl adducts:



The tendency by the intermediate to lose a proton diminishes with increase of the acidity of the solution in the following sequence:

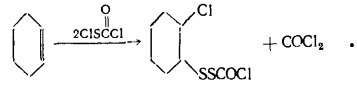
$$CH_3COOH \gg CH_3NO_2 > CH_2Cl_2 .$$

When sulphenyl chloride adds in acetic acid solution, chlorine is partly substituted by the acetoxy-group [76].



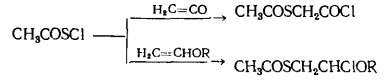
The possibility of addition to the multiple bonds of the more highly polarised sulphenyl fluoroborates has also been demonstrated [77,78]:

R = $CH_3$, or $C_6H_5$; Z = $OCH_3$, OH, Hal, or $NHCOCH_3$ .

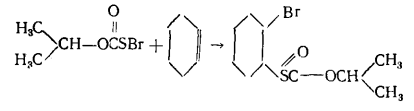


However, the authors were unable to isolate the intermediate in the form of a stable episulphonium salt; only the products of the subsequent nucleophilic substitution were isolated. Under these conditions, there was *trans*-addition to tetradeuterocyclohexene [79].

The addition of acetylsulphenyl chloride to olefins takes place in an unusual manner. It is suggested that here too an episulphonium ion is formed as an intermediate and is stabilised by ejecting acetyl chloride with formation of the thiiran (VIII). The latter is immediately cleaved by a second molecule of acetylsulphenyl chloride with formation of the β-chloroalkyl acetyl disulphide (IX), which is also obtained by the addition of acetylthiosulphenyl chloride to an olefin [80-82]. However it has been shown recently [83] that the *S*-acetyl-β-chloromercaptan (VIIIa) likewise readily reacts with acetylsulphenyl chloride to form compound (IX). Thus another mechanism is also possible in this instance:



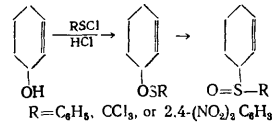
If the rate of addition of acetylsulphenyl chloride to olefins with the reactants taken in equimolar amounts is much higher than the rate of cleavage, only the normal adducts are formed—*S*-acetyl-β-chloromercaptans (VIIIa); on the other hand, if the rate of addition of acetylsulphenyl chloride is lower than the rate of cleavage of compound (VIIIa) by the sulphenyl chloride, only the disulphides (IX) are formed.



Chlorocarbonylsulphenyl chloride adds similarly to a cyclic olefin [84]:

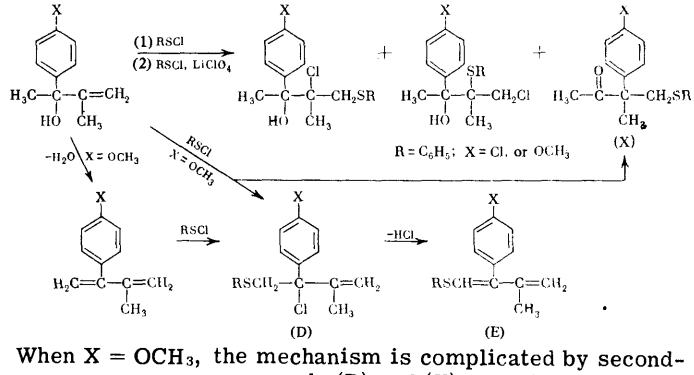
Like other sulphenyl chlorides [85], acetylsulphenyl chloride reacts normally with ketones [81,86] and vinyl ethers [81] to form monoadducts:

Isopropoxycarbonylsulphenyl bromide likewise reacts with cyclohexene to form a monoadduct [87]:



The addition of sulphenyl chlorides to enolic esters [88], allyl chloride [89,90], vinyl chloride [91] and the phthalimide derivative of allylamine [92] has been achieved.

Allyl alcohol reacts with sulphenyl chlorides preferentially via the hydroxy-group, forming unstable allyl sulphenates. The latter readily rearrange to the isomeric sulphoxide [93-95]:



Analogous reactions have been carried out with cyclohexen-2-ol [96]:

R = $C_6H_5$, $CCl_3$, or 2.4-$(NO_2)_2C_6H_3$ .

However, sulphenyl chlorides normally add to the double bond of 3-methyl-2-(4-X-phenyl)but-3-en-2-ols. The subsequent rearrangement of the adduct gives the ketone (X), whose amount is much larger in the presence of $LiClO_4$ (51%):

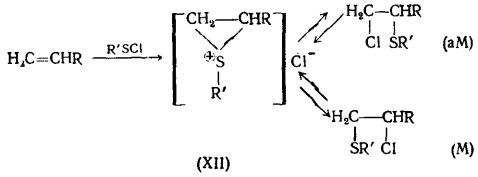
When X = $OCH_3$, the mechanism is complicated by secondary processes; compounds (D) and (E) were isolated in addition to the ketone [97,98].

Kharasch was the first to note that the asymmetric olefins propene and pent-2-ene react with DNBS to form simultaneously two adducts, M and aM, the M adduct predominating (65%). The authors demonstrated the

structure of these isomeric β-chloroalkyl sulphides by converting them into alkyl aryl sulphones (XI):[13]

$$2,4\text{-}(NO_2)_2C_6H_3SCH_2CHClCH_3 \xrightarrow[(3)\ H_2/Ni]{\substack{(1)\ KMnO_4/CH_3COOH \\ (2)\ (C_2H_5)_3N \\ (4)\ C_6H_5COCl}} \rightarrow 2,4\text{-}(C_6H_5CONH)_2C_6H_3SO_2CH_2CH_2CH_3 .$$

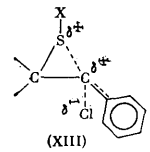
(XI)



In a number of studies on the addition of sulphenyl chlorides to unsaturated compounds, the structures of the adducts were also determined solely by chemical methods: by converting them into sulphones[23,43,99], lactones, and thiolactones[100,101], by dehydrohalogenation[47,102], and by specific synthesis[48,49]. Some workers adopted the M structure solely on the basis of the Markovnikov rule[93-99].

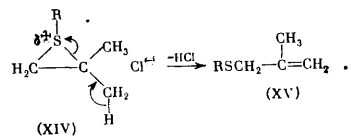
**Table 1.** Dependence of the initial isomer ratio on the structure of the initial reactants.

| Initial olefin | Substituent R in RSCl | Adducts, % $CH_2-C(Cl)-SR$ (aM) | Adducts, % $CH_2-C(SR)-Cl$ (M) | References |
|---|---|---|---|---|
| $H_2C=CHCH_3$ | $CH_3$ | 82 | 18 | 59 |
| $H_2C=C(CH_3)_2$ | $CH_3$ | 80 | 20 | |
| $H_2C=CHCH(CH_3)_2$ | $CH_3$ | 94 | 6 | |
| $H_2C=CHC(CH_3)_3$ | $CH_3$ | 95 | 5 | |
| $H_2C=CHCH_3$ | $(CH_3)_2N$ | 78 | 22 | 110 |
| $H_2C=C(CH_3)_2$ | $(CH_3)_2N$ | 71 | 29 | |
| $H_2C=CHCH(CH_3)_2$ | $(CH_3)_2N$ | 90 | 10 | |
| $H_2C=CHC(CH_3)_3$ | $(CH_3)_2N$ | 95 | 5 | |
| $H_2C=CHCH_3$ | $C_6H_5$ | 68 | 32 | 59 |
| $H_2C=CHCH(CH_3)_2$ | $C_6H_5$ | 87 | 13 | |
| $H_2C=CHCH_3$ | $CH_3C(O)S$ | 60 | 40 | 82 |
| $H_2C=C(CH_3)_2$ | $CH_3C(O)S$ | 32 | 68 | |
| $H_2C=CHC(CH_3)_3$ | $CH_3C(O)S$ | 82 | 18 | |
| $H_2C=CHCH_3$ | $(CH_3O)_2P(O)$ | 50 | 50 | 59 |
| $H_2C=C(CH_3)_2$ | $(CH_3O)_2PO$ | 19 | 57* | |
| $H_2C=C(C_6H_5)_2$ | $CH_3$ | 10 | 90 | 59,82 |
| $H_2C=CHC_6H_5$ | $CH_3$ | 2 | 98 | |
| $H_2C=CHC_6H_5$ | $CH_3C(O)S$ | — | 100 | |
| $H_2C=CHCH_2CH(CH_3)_2$ | $2\text{-}NO_2\text{-}4\text{-}CH_3O\text{-}C_6H_3$ | 52 | 47 | 112 |
| $H_2C=CHCH_2CH(CH_3)_2$ | $2\text{-}NO_2\text{-}4\text{-}CH_3\text{-}C_6H_3$ | 47 | 51 | |
| $H_2C=CHCH_2CH(CH_3)_2$ | $2\text{-}NO_2\text{-}C_6H_4$ | 44 | 54 | |
| $H_2C=CHCH_2CH(CH_3)_2$ | $2,4\text{-}(NO_2)_2\text{-}C_6H_3$ | 38 | 61 | |



*21% of $RSCH_2-C(CH_3)=CH_2$ was also obtained.

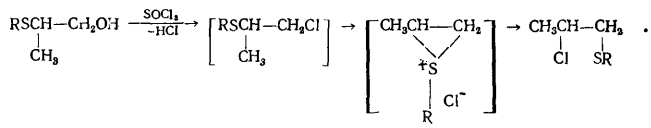
The application of NMR for the determination of the structures of the adducts enabled Mueller and coworkers[58,59] not only to establish a number of characteristics of the addition of sulphenyl chlorides to unsaturated compounds but also to explain some of them. Thus, in order to prevent isomerisation, alkane- and arene-sulphenyl chlorides were added in the presence of calcium carbonate to asymmetric olefins in methylene chloride at a low temperature. It was established that aM adducts are formed preferentially in the first instance (Table 1). The selectivity of the formation of the aM adducts increases with increase of the size of the substituent at the double bond from methyl to t-butyl. This shows that the mode of addition of sulphenyl chloride depends not only on electronic factors but also on the steric influence of the substituents. In the intermediate episulphonium ions (XII), they direct the attack by the chloride anion to the less substituted carbon atom with formation of the aM adduct[57,59].



(XII)

Only the M adduct is formed in the reaction with styrene, while in the reaction with 1,1-diphenylethylene the proportion of M is up to 90% (Table 1) owing to the stabilisation of the positive charge of the α-carbon atom in the transition state (XIII):[59]

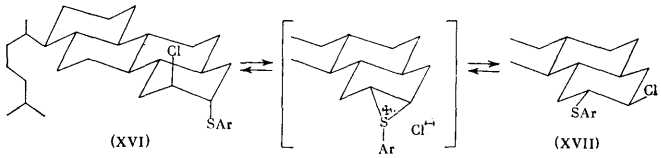
(XIII)



In the reaction with isobutene, the two methyl groups attached to the same carbon atom create conditions for the formation of an intermediate ion having some of the properties of a carbonium ion. On interaction with *OO*-dimethylphosphorylsulphenyl chloride, this olefin gives rise to the unsaturated sulphide (XV) apparently via the intermediate state (XIV) (Table 1). The electron-accepting phosphoryl group makes the sulphur less nucleophilic and facilitates the elimination of a proton from the methyl group[59,111]:

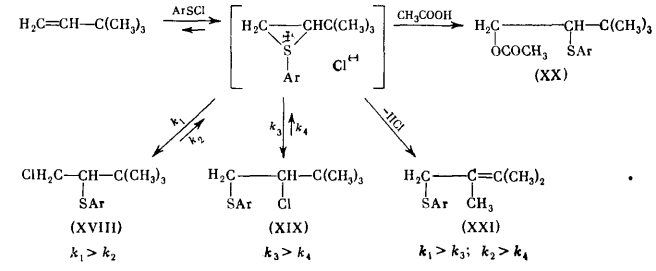
(XIV) (XV)

The ratio of the adducts in the reaction mixture is also influenced by the nature of the sulphenyl chloride (Table 1);[59,82,110-112] as the electron-accepting properties of the substituent R in the sulphenyl chloride become more marked, the amount of the M adduct increases. The explanation is that the electron-withdrawing group R in the intermediate episulphonium ion favours the formation of a positive charge on the substituted carbon atom, directing thereby the chloride ion to this atom.



Fuson et al. described for the first time the isomerisation of β-chloroalkyl sulphides in which the chloro- and alkylthio- or arylthio-groups change places[99]. The authors postulated that the isomerisation proceeds via an episulphonium ion:

A similar isomerisation was later observed by other workers, who synthesised β-chloroalkyl sulphides by various methods[114,118].



The rate of isomerisation of β-chloroalkyl sulphides in various solvents has been studied in relation to the adduct formed by arenesulphenyl chloride with 5-α-cholest-2-ene[119,120]. The addition reaction involves the initial formation of the diaxial adduct (XVI), which isomerises on heating to the diequatorial adduct (XVII). The isomerisation is accelerated by solvents promoting ionisation; for example, the isomerisation is 1600 times faster in butanol than in decalin. The introduction of the *p*-nitro-group into benzenesulphenyl chloride retards isomerisation in butanol to a greater extent than in decalin. This observation confirms the ionic mechanism of the

isomerisation process, which may proceed via an episulphonium ion:

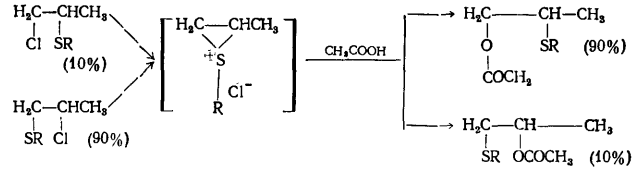
(XVI) (XVII)

The variation of the rate of isomerisation of β-chloroalkyl sulphides with temperature and the duration of heat treatment has been studied in relation to the addition of 2,4-dinitrobenzenesulphenyl chloride to 3,3-dimethylbut-1-ene in glacial acetic acid[65]:

(XVIII) (XIX) (XXI) (XX)

$k_1 > k_2$ $k_3 > k_4$ $k_1 > k_3$; $k_2 > k_4$

It is suggested that the activation energy for the stage involving the formation of the initial adduct (XVIII) is smaller than the activation energy for the formation of compound (XIX). At lower temperatures and for shorter reaction times, the kinetically controlled aM adduct (XVIII) is therefore formed, while at higher temperatures and for longer reaction times the product is the thermodynamically stable M adduct (XIX). This is accompanied by the simultaneous acetolysis and elimination of HCl with formation of compounds (XX) and (XXI).

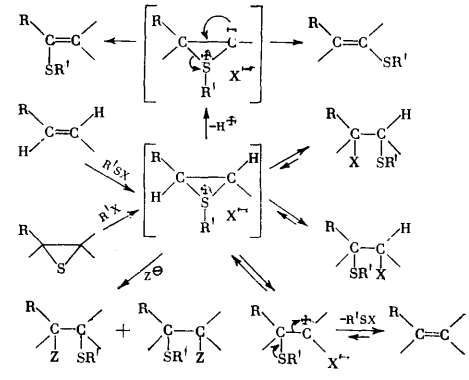


The ready isomerisation of the kinetically controlled aM adducts to thermodynamically stable isomers when the former are stored was observed by NMR.[57,59] At a temperature below 0°C in the presence of $CaCO_3$, the ratio of the aM and M isomers remain unchanged. In the absence of $CaCO_3$, slow isomerisation took place (to give 90% of the M adduct) until equilibration. At room temperature the equilibrium was attained after 200 h, the isomerisation being accelerated by traces of acids. The isomerisation of the aM adduct of 2,4-disubstituted benzenesulphenyl chlorides with 4-methylpent-1-ene to the M adducts took place to the extent of 92–95% on heating in glacial acetic acid[102].

The substituents at the sulphur atom have a significant influence on the isomerisation of β-chloroalkyl sulphides. The adducts of methanesulphenyl chloride isomerise comparatively rapidly, while those of benzenesulphenyl chloride isomerise much more slowly[57,59]. The rate of isomerisation of the adducts of substituted arenesulphenyl chlorides is reduced to a particularly marked extent by the *o*-nitro-group, which can be explained either by steric hindrance or by the reaction of the nitro-group with the sulphur atom[112]. The isomerisation of adducts of olefins with acetylthio- and *OO*-dimethylphosphorylsulphenyl chlorides takes place to a very slight extent or does not occur at all[59,111]. Only a slight isomerisation of the adducts of olefins with dimethylaminosulphenyl chloride has been noted[110]. Increasing electronegativity of the substituent at the sulphur atom makes the latter less nucleophilic and weakens or eliminates the ability of sulphur to attack a β-carbon atom with formation of an episulphonium ion.

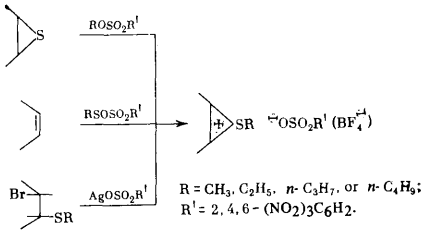
The rate of isomerisation depends also to some extent on the structure of the initial olefin. The M adduct formed in the reaction of methanesulphenyl or acetylthiosulphenyl chloride with styrene at room temperature does not isomerise. Slight isomerisation was achieved only on heating in the presence of acid catalysts[59,82].

β-Chloroalkyl sulphides isomerise with retention of configuration. Thus it has been shown by NMR that the aM *trans*-adducts of methanesulphenyl chloride with norbornene or acenaphthylene isomerise to the M adduct without change of the *trans*-configuration[57]. The *threo*- and *erythro*-configurations are retained in the isomerisation of the adducts of 4-chlorobenzenesulphenyl chloride with *cis*- and *trans*-1-phenylpropenes[35], which also confirms the hypothesis that the isomerisation proceeds via a three-membered episulphonium ion.



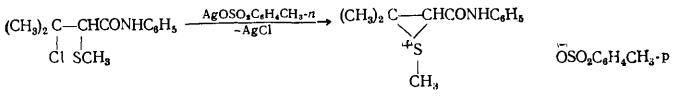
Acetolysis of diastereoisomeric pairs of adducts of arenesulphenyl chlorides with *trans*- or *cis*-but-2-ene gives rise to the diastereoisomeric pairs of the corresponding acetates[31]. The acetolysis of a mixture of the isomeric adducts of 2,4-dinitrobenzenesulphenyl chloride[31] and methanesulphenyl chloride[59] with propene led to identical mixtures of acetates, which is significant evidence for the existence of an intermediate episulphonium ion in the isomerisation of β-chloroalkyl sulphides:

## III. STABLE EPISULPHONIUM SALTS



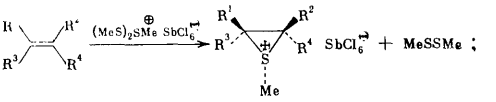
Thus experimental factors and kinetic evidence confirm indirectly that the addition of sulphenyl chlorides to olefins proceeds via the formation of an intermediate episulphonium ion. Subsequent nucleophilic attack by an anion on a ring carbon atom leads to the final reaction products with formation of the individual chloroalkyl sulphides or their mixture, consisting of the kinetically controlled aM adducts and the thermodynamically stable M isomers[23].

The initial ratio of the isomers is influenced both by steric and electronic factors in the initial olefin and by the nature of the substituents at the sulphur atom in the sulphenyl chloride, the solvent polarity, and the reaction temperature. At lower temperatures, the kinetically controlled aM adduct is formed preferentially, while at higher temperatures the M product is favoured:



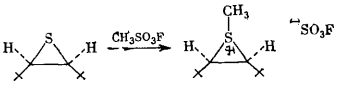
The concept of the formation of an intermediate episulphonium ion also proved important for the interpretation of a number of reactions of β-halogenalkyl sulphides. Thus it becomes clear from this point of view that the isomerisation of β-halogenalkyl sulphides (the conversion of the aM adducts into the M isomers) until equilibration proceeds via an intermediate episulphonium ion. The formation of a mixture of isomers in the nucleophilic substitution of the halogen atom in β-halogenalkyl sulphides occurs as a result of attack by the anion on one of the carbon atoms in the intermediate ion [120]. The elimination of the hydrogen halide from β-halogenalkyl sulphides with formation of isomeric vinyl sulphides evidently also proceeds with elimination of a proton from the episulphonium ion [2,59]. Finally the elimination of the sulphenyl halide from β-halogenalkyl sulphides with formation of an olefin on heating or on treatment with a nucleophile involves the same process [121] and the opening of the thiiran ring by electrophiles with formation of a mixture of isomeric compounds probably likewise proceeds via an episulphonium ion [122].

The episulphonium ion has not so far been isolated. The difficulty of its isolation is associated with its high reactivity and in most cases an equilibrium almost wholly displaced to the right is established under the usual conditions (see the scheme below). The stability of the episulphonium ion depends primarily on the nature of the nucleophile (on whether it is strong or weak), the electrophilic properties of the sulphur atom, and probably on steric factors.



The formation of stable episulphonium salts was first confirmed in relation to two examples—the formation of *cis*-cyclo-octenyl-*S*-methylepisulphonium 2,4,6-trinitrobenzenesulphonate and a steroid *S*-phenylepisulphonium hexafluoroantimonate, where the thiiran ring was part of a complex condensed system [123–126]. The high stability of the episulphonium salt in the first instance enabled the authors to obtain it in three different ways, which confirms that the same episulphonium ion is a common intermediate in these reactions.

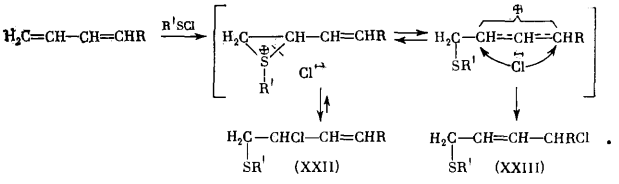
A stable episulphonium salt was obtained in this system (R = $CH_3$) also with the aid of silver tetrafluoroborate [125]. Stable episulphonium salts have been obtained recently for the acyclic series too. The anilide of β-chloro-α-methylthiovaleric acid reacts with silver toluene-*p*-sulphonate to form a stable salt, which is readily soluble in water and insoluble in ether [126]:



(m.p. 167–168°).

Stable episulphonium salts have been recently obtained also from alkenes [127]:

(a) R' = R² = R³ = R⁴ = Me;
(b) R' = R⁴ = Et; R² = R³ = H;
(c) R'R² = —(CH₂)₆—; R³ = R⁴ = H;
(d) R' = R³ = Me; R² = R⁴ = H;
(e) R' = R² = Me; R³ = R⁴ = H;
(f) R' = R⁴ = Me; R² = R³ = H;
(g) R' = R² = R³ = Me; R⁴ = H.



The first three salts were isolated in the form of analytically pure crystalline compounds, which are stable for a long time in the absence of moisture at temperatures below −10°C. The structure of the salts was also confirmed by NMR. It is noteworthy that analogous salts were obtained for selenium derivatives [128]. It was observed that, on methylation by methyl fluorosulphonate at 0°C in methylene chloride, *cis*-2,3-di-t-butylthiiran yields *cis*-2,3-di-t-butyl-*S*-methylepisulphonium fluorosulphonate in the form of crystals, which decompose at approximately 20°C: [129]

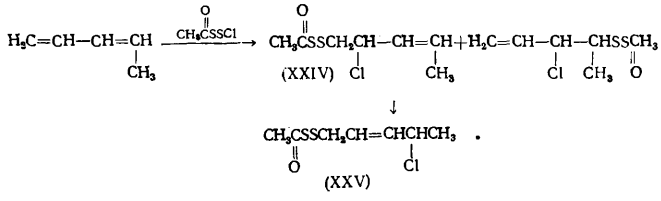
The geometrical parameters of the intermediate episulphonium ions have been calculated by the molecular orbital method for ethylene, propene, isobutene, and butadiene [130].

## IV. INTERACTION WITH CONJUGATED DIENES

It has been established by NMR that methane-, benzene-, and *p*-chlorobenzenesulphenyl chlorides add to 1,3-dienes with the initial formation of 1,2-adducts (XXII), mainly with the M structure, which isomerise to the 1,4-adducts (XXIII) (Table 2): [131–133]

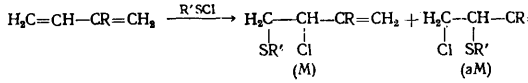
The ratios of the aM and M isomers of the 1,2-adducts is influenced by the position of the alkyl substituents in the diene. Thus in the case of piperylene and 4-methylpenta-1,3-diene, where the methyl group is in the 4-position, steric factors promote the addition of the sulphenyl chloride to the unsubstituted double bond. In the isoprene molecule, having a methyl group in the 2-position, steric factors do not have a significant influence and virtually equal amounts of the aM and M isomers are formed. In the reaction involving chloroprene, the influence of electronic factors becomes significant, the more nucleophilic unsubstituted double bond being preferentially attacked with formation of the M adduct.

1,2-Adducts readily isomerise at room temperature to 1,4-adducts. The ease of isomerisation increases in the following sequence of dienes: buta-1,3-diene < isoprene < piperylene < 4-methylpenta-1,3-diene [132]. This isomerisation is also influenced by the nature of the substituent



at the sulphur atom. The 1,2-adducts of benzenesulphenyl chloride with dienes do not isomerise, which has already been noted for the adducts with olefins. This also confirms that the intermediate episulphonium ion is involved in the isomerisation.

Table 2. The influence of the structure of the diene on the initial isomer ratio.



| Diene | Adducts | Ratio of adducts, % | |
|---|---|---|---|
| | | R=$CH_3$ | R=$C_6H_5$ |
| $H_2C{=}CHCH{=}CH_2$ | $RSCH_2CHClCH{=}CH_2$ | 95 | 98 |
| | $ClCH_2CHSRCH{=}CH_2$ | 5 | — |
| $H_2C{=}CHCH{=}CHCH_3$ | $RSCH_2CHClCH{=}CHCH_3$ | 86 | 82 |
| | $CH_3{=}CHCHClCHSRCH_3$ | 14 | 18 |
| $H_2C{=}CHCH{=}C(CH_3)_2$ | $RSCH_2CHClCH{=}C(CH_3)_2$ | 33 | — |
| | $RSCH_2CH{=}CHCl(CH_3)_2$ | 12* | — |
| $H_2C{=}C(CH_3)CH{=}CH_2$ | $RSCH_2CClCH_2CH{=}CH_2$ | 57 | 60 |

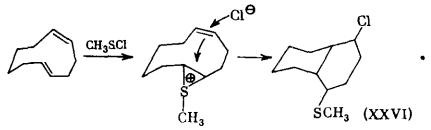
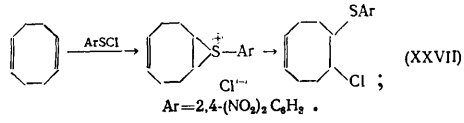
*This result most probably represents postisomerisation.

The 1,2-adduct (XXIV) with the M structure, obtained from piperylene and acetylthiosulphenyl chloride, isomerises appreciably to the 1,4-adduct (XXV):[82]

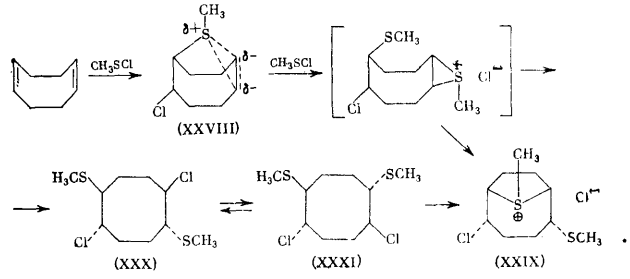


The M adduct predominates in mixtures of the M and aM isomers of the 1,2-adducts of *OO*-dimethylphosphorylsulphenyl chloride with butadiene and isoprene[99]. In an earlier study, where the structure of the adduct had been determined by a chemical method, only the presence of the M adduct was indicated[134];

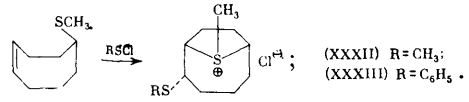


R=H (73% M and 27% aM); R=$CH_3$ (65% M and 35% aM); R'=$PO(OCH_3)_2$.

Methanesulphenyl chloride reacts with *cis,trans*-cyclodeca-1,5-diene to form the adduct (XXVI), whose structure has been demonstrated by NMR:[135]

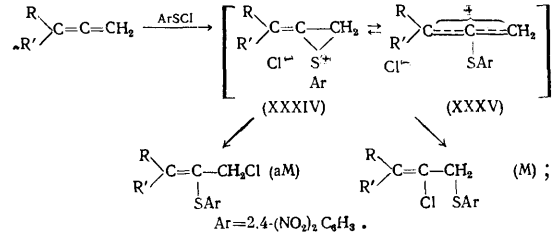


It has been shown that *cis,cis*-cyclo-octa-1,5-diene combines with 2,4-dinitrobenzenesulphenyl chloride to form the adduct (XXVII):[136,137]



Ar=2,4-$(NO_2)_2C_6H_3$.

On the other hand, when methanesulphenyl chloride adds to *cis,trans*-cyclo-octa-1,5-diene, 80–90% of the diadducts (XXIX), (XXX), and (XXXI) and 8–13% of the monoadduct (XXVIII) are formed[127,138], although dienes usually combine with one equivalent of the sulphenyl chloride. This unusual behaviour can be explained by the transannular effect of the sulphur atom, which makes the double bond in the monoadduct more nucleophilic.

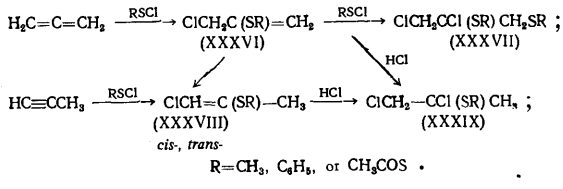


This mechanism is proved by the formation of the adducts (XXXII) and (XXXIII) together with adducts corresponding to (XXX) and (XXXI) when 5-methylthiocyclo-octene reacts with methane- and benzene-sulphenyl chlorides:

## V. REACTIONS WITH ALLENES

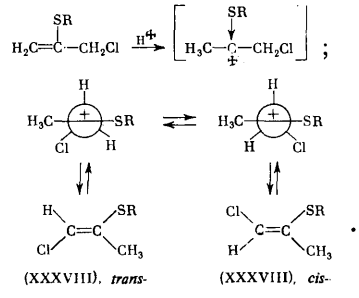
2,4-Dinitrobenzenesulphenyl chloride adds to allene with formation of two adducts: aM (87%) and M (13%).[139] The authors explained the observed proportions of the two adducts by the fact that the intermediate episulphonium ion (XXXIV) is attacked by the chloride anion at the terminal methylene carbon atom faster than at the vinyl carbon atom.

When the ring of the episulphonium ion is opened, the energetically more favoured carbonium ion (XXXV) is formed as an intermediate from the terminal carbon atom. The addition of $(CH_3O)_2POSCl$ to allene leads only to the aM adduct[58]:



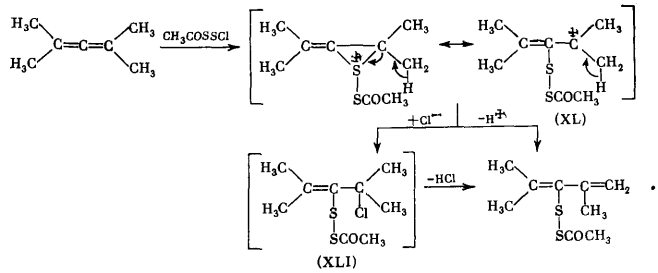
Ar=2,4-$(NO_2)_2C_6H_3$.

In the reactions with substituted allenes[140,141], steric factors direct the addition of sulphenyl chlorides to the unsubstituted double bond with formation of the aM adduct only. However, it was later shown that substituted allenes also form a mixture of adducts of types aM and M.[142]

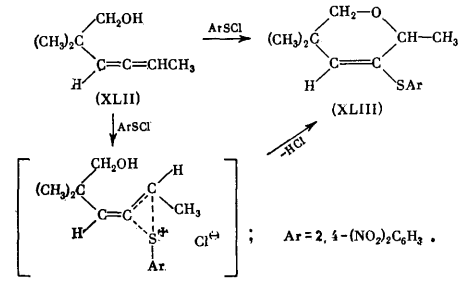


Methanesulphenyl, benzenesulphenyl, and acetylthiosulphenyl chlorides add to allenes with formation of a number of compounds, as shown by NMR and infrared spectroscopy[143]. Apart from the 1:1 adduct (XXXVI),

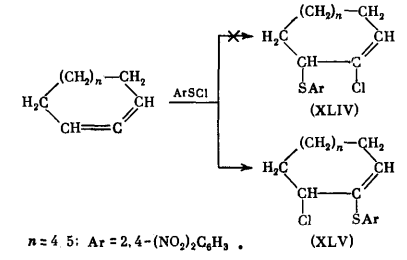
the 1 : 2 adduct (XXXVII) as well as the products of their subsequent reactions (XXXVIII) and (XXXIX) are formed:



The stability of the adducts (XXXVI) and (XXXVII) depends on the nature of the substituent at the sulphur atom and decreases in the sequence R = $CH_3COS \gg C_6H_5 > CH_3$. Compound (XXXVII) decomposes with liberation of HCl and the amount of compound (XXXIX) in the reaction mixture increases.



In the presence of acids, the monoadduct (XXXVI) isomerises to (XXXVIII). The authors postulate the possibility of the involvement in this isomerisation reaction of an intermediate carbonium ion, which is converted into the *cis*- or *trans*-isomer of compound (XXXVIII). The *cis*-isomer is kinetically controlled, being partly converted into the *trans*-isomer during the reaction. When the *trans*-isomer is acted upon by an acid, it may revert to the *cis*-isomer:



The addition of acetylthiosulphenyl chloride to tetramethylallene is accompanied by the subsequent elimination of HCl. The authors postulate the possibility of the formation of the allylcarbonium ion (XI), since additional signals due to the methylene groups in the postulated adduct (XLI) were detected in the NMR spectrum of the reaction mixture:

Sulphenyl chlorides add to allenes with rigorous stereospecificity. The optically active allene alcohol 2,2-dimethylhexa-3,4-dien-1-ol (XLII) combines with 2,4-dinitrobenzenesulphenyl chloride, forming the optically active adduct (XLIII). This indicates the absence of an intermediate carbonium ion in the addition reaction [144,145]:

The structure (XLIV) was initially adopted for the adduct of 2,4-dinitrobenzenesulphenyl chloride with the cyclic allenes cyclonona-1,2-diene and cyclododeca-1,2-diene [146]. However, it was later established by NMR that the adducts have the structure (XLV): [140]

## VI. ADDITION TO ACETYLENES

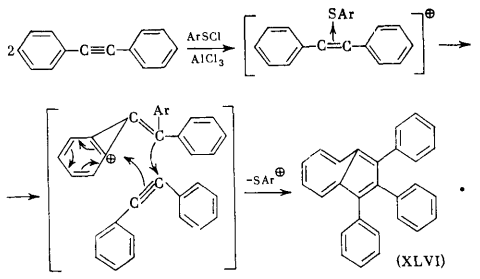
The addition of sulphenyl chlorides to acetylenes proceeds similarly to their addition to ethylene. However, the greater stability of the acetylenic $\pi$-bonds, in view of the reduced bond length compared with ethylene, and the greater degree of overlapping of $p$-orbitals require an elevated temperature in many instances of this reaction and sometimes also a catalyst. This is consistent with the addition of one mole of sulphenyl chloride exclusively to the double bond of vinylacetylene [147,148]. The rate of addition of 2,4-dinitrobenzenesulphenyl chloride to phenylacetylene is 0.01 of the rate of addition to styrene and the rate of addition to hex-3-yne is 0.1 of the rate of addition to cyclohexene [149].

The rate of addition of benzenesulphenyl chloride to the following olefin/acetylene pairs has been investigated: styrene/phenylacetylene, 1-phenylpropene/1-phenylpropyne, hex-1-ene/hex-1-yne, and hex-3-ene/hex-3-yne. The ratio of the rates in $Cl_2CHCHCl_2$ was 1 : 100, but it depends strongly on the solvent [150].

The rate of addition of various $p$-substituted arenesulphenyl chlorides to acetylene in ethyl acetate decreases in the following sequence of $p$-substituents: $OCH_3 > CH_3 > H > Cl > NO_2$. [151] The $o$-methyl and $o$-chloro-substituents have little influence on the rate of addition and only $o$-nitro- and 2,4-dinitro-benzenesulphenyl chlorides add to acetylenes 2000–3000 times more slowly than other benzenesulphenyl chlorides. This can be accounted by the strong interaction of the sulphur atom with the $o$-nitro-group [152].

The rate of addition of alkanesulphenyl chlorides to hex-1-yne increases with decrease of the degree of branching of the alkane from which the sulphenyl chloride

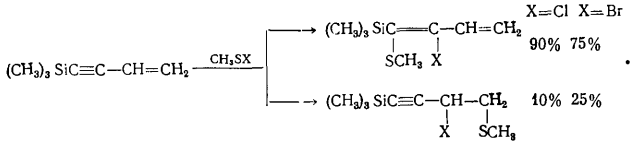
was derived and with increase of solvent polarity and temperature [153].



The addition of 2,4-dinitrobenzenesulphenyl chloride to acetylene in chloroethylene requires the presence of $AlCl_3$. Kharasch proposed the following mechanism for this reaction [154]:

$$ArSCl + AlCl_3 \rightleftarrows \overset{\oplus}{Ar}S\overset{\ominus}{AlCl_4}$$

$$\overset{\oplus}{Ar}S\overset{\ominus}{AlCl_4} + CH{\equiv}CH \rightleftarrows \left[\begin{matrix} CH{=}CH \\ | \\ ArS \end{matrix}\right]^{\oplus} AlCl_4^{\ominus} \rightarrow ClCH{=}CH{-}SAr + AlCl_3 ;$$



$$Ar = 2.4\text{-}(NO_2)_2C_6H_3 .$$

For the higher acetylenes but-2-yne, hex-3-yne, and diphenylacetylene, the presence of aluminium chloride is not obligatory. It has been shown that $AlCl_3$ complicates the addition of the arenesulphenyl chloride to phenylacetylene, since triphenylazulene (XLVI) is formed instead of the normal adduct [155]:

(XLVI)

Since electron-accepting groups deactivate the acetylenic bond towards attack by electrophiles, acetylenedicarboxylic acid and its diethyl ester do not react with 2,4-dinitrobenzenesulphenyl chloride [154]. However, methyl acetylenemonocarboxylate combines on heating with methane-, benzene-, and *p*-substituted arenesulphenyl chlorides [156]. Electron-donating substituents activate the triple bond in acetylenes. Thus methanesulphenyl halides add preferentially to the triple bond of 1-trimethylsilylbut-3-en-1-yne [157]:

Methanesulphenyl chloride adds to alkylthiovinylacetylenes at the acetylenic bond only [158]:

$$H_2C{=}CH{-}C{\equiv}C{-}SR \xrightarrow[CCl_4,\,-20^\circ]{CH_3SCl} H_2C{=}CHC(SCH_3){=}C\begin{matrix}SR\\Cl\end{matrix} ;$$

$$R = CH_3,\ C_2H_5,\ C_3H_7,\ \text{or}\ C_4H_9.$$

Various alkanesulphenyl chlorides add to acetylene with formation of both the monoadducts (XLVII) [43,47] and the diadducts (XLVIII). [105,159] The latter readily lose HCl on heating, undergoing conversion into the vinyl sulphides (XLIX), which tend to polymerise:

$$HC{\equiv}CH \xrightarrow{RSCl} \underset{(XLVII)}{RSCH{=}CHCl} \xrightarrow{RSCl} \underset{(XLVIII)}{RSCHClCHSR} \xrightarrow{-HCl} \underset{(XLIX)}{RSC(Cl){=}CHSR} ;$$

$$R = ClCH_2,\ ClCH_2CH_2,\ \text{or}\ CH_3CHCl .$$

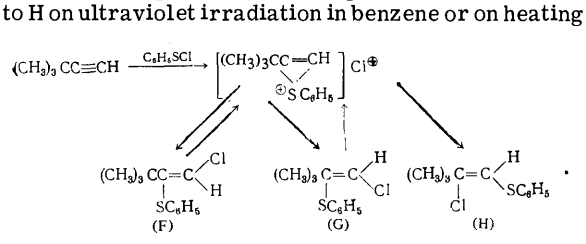
The reaction of asymmetric acetylenes with sulphenyl chlorides can yield two isomeric adducts, M and aM, and their ratio is influenced both by the solvent and the temperature in the addition reaction [160]. But the addition of benzenesulphenyl chloride to phenylacetylene in benzene gave the adduct (L) with the aM structure, established by conversion into benzyl phenyl sulphone (LI): [161]

$$C_6H_5C{\equiv}CH \xrightarrow{C_6H_5SCl} \underset{\substack{|\\SC_6H_5\\(L)}}{C_6H_5C{=}CHCl} \xrightarrow{H_2O_2} \underset{|\\SO_2C_6H_5}{C_6H_5C{=}CHCl} \xrightarrow{KOH/H_2O} \rightarrow [C_6H_5CH(SO_2C_6H_5)CHO] \rightarrow \underset{(LI)}{C_6H_5CH_2SO_2C_6H_5} .$$

The adduct of phenylacetylene and 2,4-dinitrobenzenesulphenyl chloride, obtained in glacial acetic acid, has the M structure (LII), which was confirmed by specific synthesis from acetophenone [139]:

$$C_6H_5C{\equiv}CH \xrightarrow{\cdot ArSCl} \underset{\substack{|\\Cl\\(LII)}}{C_6H_5C{=}CHSAr} \xleftarrow[-HCl]{} C_6H_5CCl_2CH_2SAr \uparrow PCl_5$$

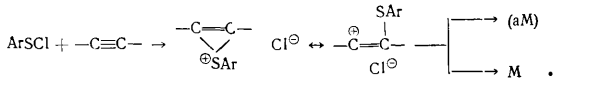
$$C_6H_5COCH_3 \xrightarrow[HCl]{ArSCl} C_6H_5COCH_2SAr ;$$



$$Ar = 2,4\text{-}(NO_2)_2C_6H_3 .$$

Studies by a group of Italian chemists helped to resolve the contradictions in the determination of the mode of addition of sulphenyl chlorides to acetylenes [142,143,162-169]. The reactions of *p*-methylbenzene-, *p*-nitrobenzene, and *o*-nitrobenzene-sulphenyl chlorides with but-1-yne, phenylacetylene, and other substituted acetylenes were investigated in various solvents: acetic acid, acetonitrile, and ethyl acetate in the presence of different amounts of trifluoroacetic or hydrochloric acid. The adducts were characterised either by the infrared spectra of the corresponding sulphones or chromatographically. It was shown that the nature of the *p*-substituents in the benzenesulphenyl chloride hardly influences the mode of addition and that aM adducts are formed preferentially. *o*-Nitrobenzenesulphenyl chloride gives rise to an approximately 1 : 1 mixture of the M and aM adducts under these conditions.

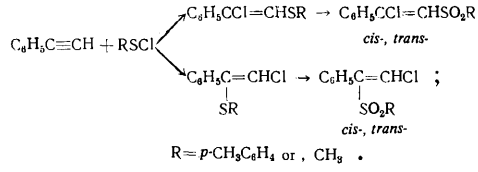
The influences of the solvent and the substituent at the acetylenic bond are mutually related. Thus the addition to but-1-yne or its homologues in any solvent gives rise to the aM adduct only, which has also been demonstrated by other investigations [170,171]. On the other hand, the mode of addition to phenylacetylene depends on the solvent: for example, more of the aM adduct is formed in ethylacetate and more of the M adduct is formed in acetic acid. Chloroform and acetonitrile occupy an intermediate position in this respect. As in the addition of sulphenyl chloride to olefins, this is associated with acid catalysis.



In the addition of sulphenyl chlorides to acetylenes in any solvent, the amount of the M adduct increases with increase of the concentration of acid. However, this effect was not noted for but-1-yne [169].

The addition of benzenesulphenyl chloride to isobutylacetylene gave three adducts (F, G, and H) in the proportions 75 : 17 : 8 respectively. Compounds F and G isomerised to H on ultraviolet irradiation in benzene or on heating [172]:

Kinetic studies on the addition of sulphenyl chlorides to acetylenes showed that this reaction is ionic and that its rate depends on the nucleophilic properties of the triple bond [149,153,164,166]. On the basis of these data, Calo et al. [152] proposed a reaction mechanism according to which the addition proceeds via a stage involving the formation

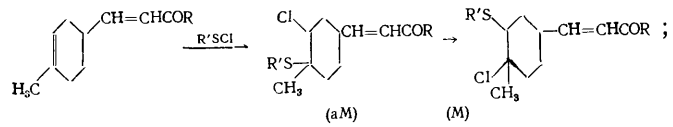


of an intermediate complex, consisting of the chloride ion and the organic cation. The degree of separation of this ion pair depends on the solvent and the structure of the cation determines the ratio of the aM and M adducts:

Later studies confirmed that the intermediate compound has the structure of an unsaturated episulphonium ion [127,128].

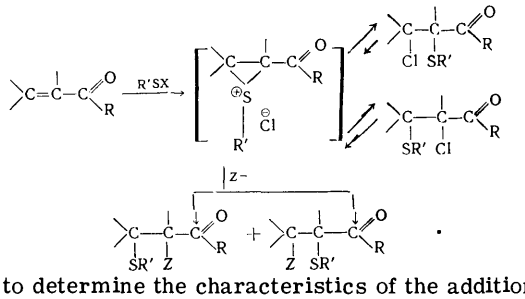
The addition of sulphenyl chlorides to acetylenes usually leads to the formation of *trans*-adducts, as shown by infrared [173] and NMR spectra [174] and by comparing the corresponding known *trans*- and *cis*-sulphones [152,153,170,175] as well as by studying the dipole moments [176-178].

*p*-Methylbenzene- and methane-sulphenyl chlorides interact with phenylacetylene in ethyl acetate in the presence of HCl to give a mixture of the *cis*- and *trans*-isomers, whose structure was determined by the NMR analysis of their sulphones and by specific synthesis [168,169]:



The formation of the *cis*-isomers in this reaction seemingly contradicts the results of other investigations showing the stereospecificity of the addition of sulphenyl chlorides, but the authors showed that the *cis*-isomers are formed owing to the isomerisation of the primary *trans*-adducts. The *trans*-adduct, obtained by the addition of *p*-methylbenzenesulphenyl chloride to phenylacetylene in acetic acid, is partly converted into the *cis*-isomer on storage in ethyl acetate containing 5% HCl.

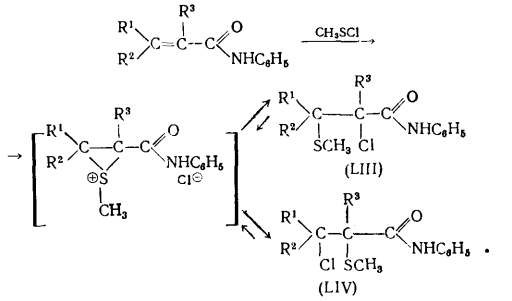
## VII. REACTIONS WITH $\alpha\beta$-UNSATURATED ACIDS AND THEIR DERIVATIVES



The double bond in $\alpha\beta$-unsaturated acids is little involved in electrophilic addition reactions owing to the electron-accepting properties of the carboxy- and related groups. The reactions of the $\alpha\beta$-unsaturated nitriles with sulphenyl chlorides are particularly difficult. Thus acrylonitrile and similar compounds do not react with 4-chloro-2-nitrobenzene- and 4-nitrobenzene-sulphenyl chlorides in chloroform [48]. 4-Substituted arene- and dichloromethane-sulphenyl chlorides add to acrylonitrile only on heating in glacial acetic acid [179-181]. In glacial acetic acid, the rate of addition of 2,4-dinitrobenzenesulphenyl chloride to vinylacetone, which also contains a powerful electron-accepting group, was 300 times lower than the rate of addition to styrene and 3000 times lower than the rate of addition to cyclohexene [182].

Alkanesulphenyl chlorides initially added in equimolar amounts to the ring double bonds of 3-(4′-methylcyclohex-3′-enyl)acrylic acid and its derivatives with formation of the aM adducts, which then readily isomerised to the M adducts [183]:

R=OH, OEt, $NH_2$, $NHC_6H_5$, or Cl; R′=$CH_3$, or $CH_2CH_2Cl$.



The interaction of sulphenyl halides with $\alpha\beta$-unsaturated acids may lead to a series of valuable polyfunctional compounds when specific addition and subsequent nucleophilic substitution are possible:

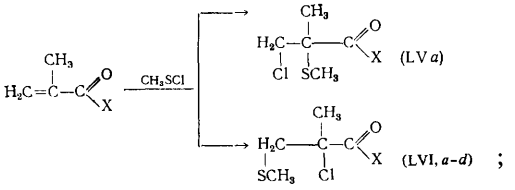
In order to determine the characteristics of the addition of sulphenyl halides to acrylic acids and their derivatives, a study was made of the influence of the position of the methyl groups and of the nature of the changes in the carboxy-group in homologues of $\alpha\beta$-unsaturated acids on the rate of addition of sulphenyl chlorides and also on the structures and stabilities of the adducts formed under these conditions.

The addition of various sulphenyl chlorides ($CH_3SCl$, $ClCH_2CH_2SCl$, $C_2H_5SCl$, $CH_3COSCl$, $CH_3COSSCl$, and $SCl_2$) to acrylic, methacrylic, crotonic, and dimethylacrylic acids and their derivatives (acid chlorides, esters, amides, substituted amides, and nitriles) was investigated. The studies elucidated the influence of the number and positions of the methyl groups in $\alpha\beta$-unsaturated acids, of the nature of the derivatives of $\alpha\beta$-unsaturated acids, and finally of the structure of the sulphenyl chloride on the rate of addition, the initial ratio of isomers, and the stability of the adducts formed. For this purpose, the reactions involving the addition of the same sulphenyl chloride to the same derivative of different $\alpha\beta$-unsaturated acids were compared. This was followed by a comparison of the additions of the same sulphenyl chloride to different derivatives of the same $\alpha\beta$-unsaturated acid and finally of the addition of different sulphenyl chlorides to the same derivative of the same $\alpha\beta$-unsaturated acid.

The studies on the influence of the position of methyl groups showed that, when methanesulphenyl chloride adds to the anilides of acrylic [184,185], crotonic [186], and dimethylacrylic acids [187], the kinetically controlled adducts of type (LIII) are formed preferentially in the initial stage:

Addition to methacrylic acid anilide [188] results in the initial preferential formation of the adduct (LIV), which is likewise unstable.

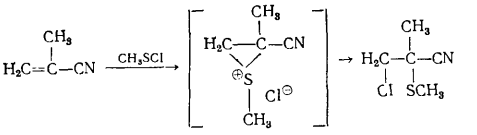
The addition of sulphenyl chlorides to $\alpha\beta$-unsaturated acids is also a process consisting of two consecutive steps: the initial formation of the intermediate episulphonium ion and further nucleophilic attack by the chloride ion on one of the carbon atoms in the ring with formation of a mixture of adducts (LIII) and (LIV). Evidently the preferred site of attack in acrylic, crotonic, and dimethyl-



acrylic acids is the carbon atom in the $\alpha$-position relative to the carboxy-group, since the electron density at the $\alpha$-carbon atom in the intermediate episulphonium ion is relatively lower owing to the inductive effect of the carboxy-group. Steric factors, the presence of one and two methyl groups in the $\beta$-positions in crotonic and dimethylacrylic acids, also promote the attack by the chloride ion on the $\alpha$-carbon atom. The presence of the methyl group in the $\alpha$-position of methacrylic acid partly compensates the influence of the carboxy-group and creates an additional steric hindrance to attack on the $\alpha$-carbon atom. For this reason, the kinetically controlled adduct (LIV) is formed preferentially in this case.

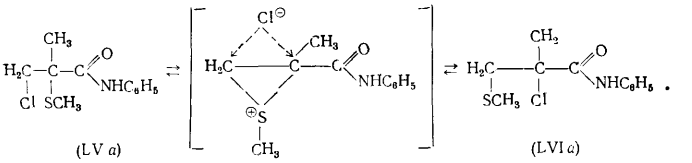
It was established that in this instance the rate of addition of methanesulphenyl chloride decreases in the series of anilides of acids ranging from acrylic and methacrylic to crotonic and dimethylacrylic. The addition to both *cis*- and *trans*-derivatives of crotonic acid was studied[189,190]. The results obtained are inconsistent with the successive enhancement of the nucleophilic properties of the double bond. The decrease of the reactivity of the double bond is probably due to steric factors. Adducts with cinnamic acid could be obtained only in glacial acetic acid[191]. The rate of isomerisation of the kinetically controlled adducts formed initially to thermodynamically stable adducts increases in the inverse sequence: $\alpha$-chloro-$\beta$-methylthiopropionic acid anilide < butyric acid anilide < isovaleric acid anilide. The anilide of $\alpha$-alkylthio-$\beta$-chlorobutyric acid is an exception.

Changes in the carboxy-group of the $\alpha\beta$-unsaturated acid have a significant influence on the rate of addition of sulphenyl chlorides. In all cases, sulphenyl chlorides react most easily with amides, than with acids and esters, the reaction with acid chlorides and nitriles being more difficult. This is consistent with the decrease of electron density in the double bond of $\alpha\beta$-unsaturated acids as a function of the derivative employed. The nature of the changes in the carboxy-group has a significant influence on the initial ratio of the kinetically controlled and thermodynamically stable isomers. The amount of the kinetically controlled adduct decreases in the same sequence, from the amide to the nitrile, and the amount of the thermodynamically stable isomer naturally increases. Thus $^1$H NMR made it possible to observe the preferential formation in the mixture of products of the reactions of $\alpha\beta$-unsaturated acids and their amides and methyl esters of kinetically controlled unstable adducts, which can sometimes be isolated in a pure form[192].



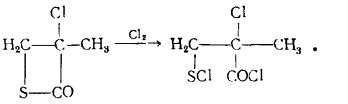
The addition of sulphenyl chloride to the chlorides and nitriles of $\alpha\beta$-unsaturated acids leads as a rule to the formation of a stable equilibrium mixture or of thermodynamically stable adducts.

The influence of the changes in the carboxy-group on the initial ratio of the isomers and on their stability has been demonstrated for the reaction of methanesulphenyl chloride with various derivatives of methacrylic acid. When methanesulphenyl chloride was allowed to add to methacrylic acid anilide, a single kinetically controlled isomer (LV*a*) was obtained:



X=NHC$_6$H$_5$ (*a*); OH (*b*); OCH$_3$ (*c*) or Cl (*d*).

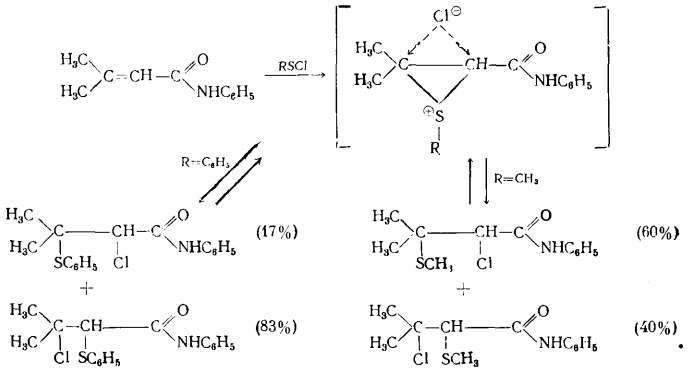
The reaction of methanesulphenyl chloride with methacrylic acid, its methyl ester, and chloride gives the following ratios of the isomers (LV, *b*–*d*) to the isomers (LVI, *b*–*d*): 89/11, 72/28, and 52/48 respectively. The addition of methanesulphenyl chloride to methacrylonitrile again leads to a single thermodynamically stable isomer: $\beta$-chloro-$\alpha$-methylthioisobutyronitrile (LV*e*):



The unstable adducts usually isomerise to the stable adducts on storage or heating. The isomerisation is accelerated in the presence of catalytic amounts of acid. The stability of the adducts formed, which depends mainly on the nucleophilic properties of the sulphur atom, is clearly confirmed by the data obtained for the isomerisation reaction. Thus the unstable anilide (LV*a*) isomerises almost completely to the stable anilide of $\alpha$-chloro-$\beta$-methylthioisobutyric (LVI*a*):

In the addition to methyl methacrylate, the simultaneous formation of a mixture of the isomers (LV*c*) and (LVI*c*) is observed, with the kinetically controlled adduct (LV*c*) predominating. The ratio of isomers obtained is displaced towards the accumulation of the isomers (LVI*c*), equilibrium being attained when (LV*c*) : (LVI*c*) = 60 : 40.

$\beta$-Chloro-$\alpha$-methylthioisobutyronitrile (LV) is a stable isomer and remains unaltered under comparable conditions. The structure of methacrylic acid derivatives was confirmed, apart from $^1$H NMR data, by the cleavage of $\alpha$-chloro-$\alpha$-methyl-$\beta$-thiolactone by electrophilic agents, in which the position of the sulphur atom is rigorously specified[193]:

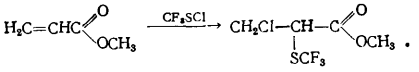


Thus the interconversions of the isomers, sometimes with formation of a single thermodynamically stable compound or an equilibrium mixture of isomers, can be explained by postulating an important role of the episulphonium ion in these processes. It follows from the above data that the outcome of the process is influenced significantly by changes in the carboxy-group and in the positions of the methyl groups, which affects in its turn the nucleophilic properties of the sulphur atom. The isomerisation of the adducts, based on the intermediate formation of the episulphonium ion, proceeds more readily as the sulphur atom of the adduct becomes more nucleophilic and the carbon atom subjected to nucleophilic attack by the sulphur atom becomes less effectively shielded in space.

Naturally, the nucleophilic properties of the sulphur atom decrease in the sequence $CON\langle$ > COOH > $COOCH_3$ > COCl > CN as a function of the substituent at the carboxy-group, which is consistent with the $-I$ and $-\epsilon$ effects of the substituents. This results in the complete absence of isomerisation of the nitriles.

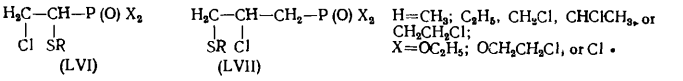
The influence of the nature of the sulphenyl chloride on the rate of addition of methane-, β-chloroethane-, benzene-, acetyl-, and acetylthio-sulphenyl chlorides and of sulphur dichloride to αβ-unsaturated acids and their derivatives and on the ratio of the adducts showed that the ease of addition of sulphenyl chloride to the same derivative of the αβ-unsaturated acid decreases in the following sequence: $AlkSCl > ClCH_2CH_2SCl$ [194] $> C_6H_5SCl$ [195] $> ClSCl$ [196] $> CH_3COSCl$.[197] $CH_3COSSCL$ could not be added at all to αβ-unsaturated acids.

The ratio of the isomers in reactions involving addition to αβ-unsaturated acids changes significantly as a function of the nature of the substituent in the sulphenyl chloride. Thus, whereas in the addition of methanesulphenyl chloride to dimethylacrylic acid anilide the kinetically controlled α-chloro-β-methylthioisovaleric acid anilide is initially formed preferentially (60 : 40), in the addition of benzenesulphenyl chloride, the preferred product is the stable anilide of β-chloro-α-phenylthioisovaleric acid (83 : 17):[192]



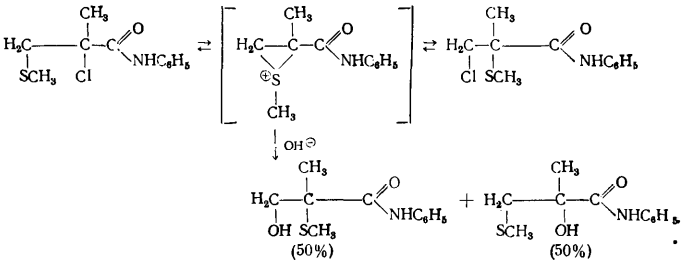
The results obtained were confirmed by kinetic data. The addition of benzenesulphenyl chloride to αβ- and βγ-unsaturated acids and their derivatives was investigated and it was shown that the rate of addition decreases in the sequence anilide > ester > acid > acid chloride as a function of the changes in the carboxy-group and in the sequence $H_2C{=}CH{-}CH_2COOCH_3 > H_2C{=}CHCOOCH_3 > H_2C{=}C(CH_3)COOCH_3 > CH_3CH{=}CHCOOCH_3 > (CH_3)_2C{=}CHCOOCH_3 > C_6H_5CH{=}CHCOOCH_3$ as a function of the changes in the molecular structure.

It was established that the addition of benzenesulphenyl chloride to unsaturated acids is a first-order reaction with respect to each reactant. The high negative activation entropy ($\sim -30$ cal mole$^{-1}$ K$^{-1}$) and energy are consistent with a polar mechanism of the addition reaction [198].



The above results, both for the addition of sulphenyl chlorides to αβ-unsaturated acids and their derivatives and for the isomerisation of the adducts, are consistent with the results of other workers [199-201].

When sulphenyl chlorides react with the nitriles of αβ-unsaturated acids, there is a possibility of addition not only to the C=C double bond but also to the nitrile group [200, 202].



The free-radical addition of trifluoromethanesulphenyl chloride to methyl acrylate leads to the preferential formation (90%) of methyl β-chloro-α-trifluoromethylthiopropionate [202]:

Sulphenyl chloride add also to other αβ-unsaturated compounds containing electron-accepting groups: keten [202], α-chloroacrolein [204], trichloromethylethylene [205], alkenyl phosphites and phosphinates [204,205], and methyl vinyl sulphone [199]. The mode of addition being similar to that observed in the addition to carboxylic acid derivatives. The aM structure (LVI) and the M structure (LVII) were attributed to the adducts obtained in the reaction with vinyl- and allyl-phosphinates respectively:

Nucleophilic substitution of the chlorine atom in the isomeric derivatives of β-alkylthio-α-chloro- and α-alkylthio-β-chloro-carboxylic acids has so far been little studied. The kinetic investigations which have been carried out have shown that the rate of nucleophilic substitution depends significantly on the structure of the initial adduct [208]. The kinetically controlled adduct is always hydrolysed faster, approximately by an order of magnitude, than the thermodynamically stable isomer [209]. It has been observed that α-chloro-β-methylthio-isomers always react faster than the corresponding derivatives of the α-chloro-β-phenylthio-carboxylic acid. The rate of nucleophilic substitution is also influenced significantly by the changes in the carboxy-group: amides react more readily than the corresponding esters. The proportions of the isomers formed are independent of the position of the halogen in the molecule (the α- or β-position) and depend primarily on the substituents in the molecule and on the nature of the nucleophile. According to preliminary data, the solvent also affects the ratio of the isomers. For example, the hydrolysis of the anilides of both α-chloro-β-methylthio- and β-chloro-α-methylthio-isobutyric acids gives rise to a 1 : 1 mixture of the isomeric anilides of α-hydroxy-β-methylthio- and β-hydroxy-α-methylthio-isobutyric acids [209]:

The relative amount of the β-hydroxy-isomer in the hydrolysis of the anilides of β(α)-chloro-α(β)-methylthioalkanoic acids increases in the following sequence as a function of their structure: β(α)-chloro-α(β)-methylthiopropionic acid (1 : 1 : 5); corresponding derivatives of butyric acid (1 : 3); corresponding derivatives of isovaleric and hydrocinnamic acid—β-hydroxy-isomer only [210].

Thus the study of the addition of sulphenyl chlorides to αβ-unsaturated acids and their derivatives showed that kinetically controlled (unstable) adducts can be obtained in some instances, but stable isomers are produced as a rule. When nucleophiles act both on individual β-halogenosulphides and on their mixtures, the intermediate is the same episulphonium ion, the opening of the ring of which by the nucleophile may be made specific with the preferential formation of the α- or β-isomer by altering the structure and conditions.

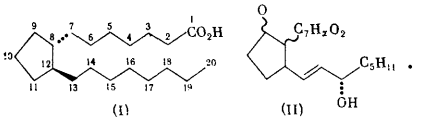
# The Synthesis of Heterocyclic Analogues of Prostaglandins

E.I.Levkoeva and L.N.Yakhontov

The available information about the methods of synthesis of prostaglandin analogues containing the oxygen, sulphur, and nitrogen heteroatoms in the cyclic part of the molecule is described.
The bibliography includes 101 references.

CONTENTS

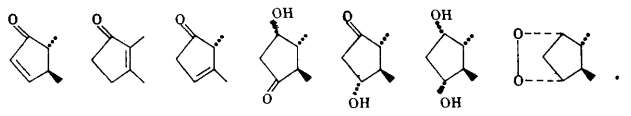


I. Introduction 565
II. Fundamental methods of synthesis of prostaglandins 565
III. Methods of synthesis of heterocyclic analogues of prostaglandins 567

## I. INTRODUCTION

Prostaglandins (PG) are a comparatively recently discovered class of naturally occurring physiologically active substances which have been the subject of continuous attention by biologists and chemists in the last 10–15 years. Pharmacological studies have shown that prostaglandins exhibit an extremely broad spectrum of activity; their influence on the smooth musculature of various organs, their mediating role in the central and peripheral nervous systems in inflammatory processes, and their hormone-like and antihormonal activities have been investigated in detail[1,2].

The need for large amounts of prostaglandins, which are required in experimental and clinical research, led to the vigorous development of methods for the extraction and purification of prostaglandins and stimulated the search for methods of synthesis of prostaglandins and their analogues. Biological research on prostaglandins began in 1930,[3] but it was not until 1962 that the structures of the first three compounds of this series were established[4]. Approximately twenty natural prostaglandins have now been isolated.

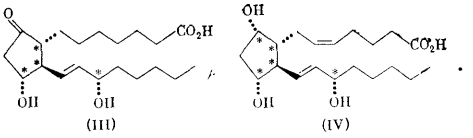


They are all derivatives of the hypothetical $C_{20}$ prostanoic acid (I), the $C_{(8)} - C_{(12)}$ atoms of which are part of the cyclopentane ring:

(I) (II)

The $C_{(1)} - C_{(7)}$ side chain, terminating in a carboxy-group, is designated by convention as the $\alpha$-chain and lies behind the plane of the cyclopentane ring. All prostaglandins have an oxygen-containing functional group attached to $C_{(9)}$ (OH or C=O), a hydroxy-group at $C_{(15)}$, and a *trans*-double bond (II) between $C_{(13)}$ and $C_{(14)}$.

Depending on the number and type of oxygen-containing functional groups, the degree of unsaturation of the cyclopentane ring, and the position of the double bond in the latter, prostaglandins are divided into groups designated by the letters A, B, C, D, E, F, G, and H:



(A) (B) (C) (D) (E) ($F_\alpha$) (G, H)

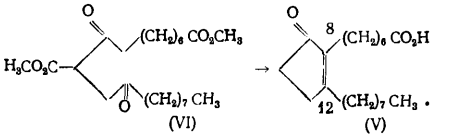
Natural prostaglandins may contain in the side chains, one, two, or three double bonds (apart from the obligatory 13,14-*trans*-bond, there may also be the 5,6-*cis*- and 17,18-*cis*-bonds). On the basis of the number of double bonds, each group is subdivided into series (for example $PGE_1$, $PGE_2$, and $PGE_3$). Natural PGF prostaglandins in which the hydroxy-group at $C_{(19)}$ is in the *cis*-position relative to the $\alpha$-side chain have come to be designated as $PGF\alpha$, in contrast to the $PGF\beta$ compounds, epimeric with respect to $C_{(9)}$, which can only be obtained by synthesis.

## II. FUNDAMENTAL METHODS OF SYNTHESIS OF PROSTAGLANDINS

The complete synthesis of natural prostaglandins presents considerable difficulties because of the complexity of their chemical structure rather than their lability. Thus the distinctive features of the $PGE_1$ (III) are as follows: 4 chiral centres, the $\beta$-oxo-group in the cyclopentane ring, the *trans*-disposition of all three ring substituents, and the presence of the acyclic hydroxy-group at $C_{(15)}$:

(III) (IV)

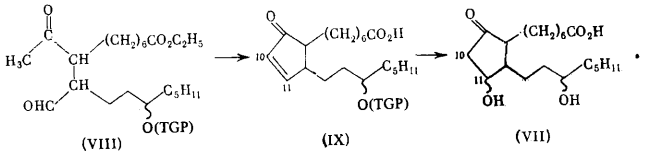
The complete synthesis of $PGF_2\alpha$ (IV) is further complicated by the presence of an additional chiral centre at $C_{(9)}$ and the necessity for the introduction of a second double bond. For this reason, the stereospecific syntheses of natural prostaglandins consist of many stages (up to 21 stages) and the yields of the final products are comparatively low.



Analysis of the literature on the methods of synthesis of prostaglandins shows that all the methods can be divided into two groups:

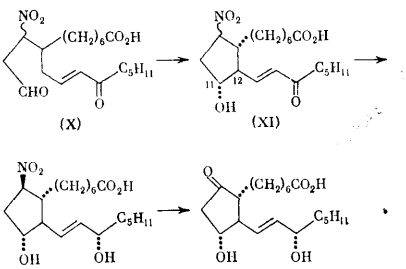
1. Syntheses of prostaglandins based on long-chain compounds in which the cyclopentane ring is formed at one of the last stages of the synthesis.

2. Syntheses of prostaglandins based on cyclopentane derivatives.



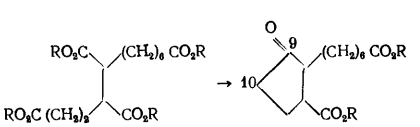
The synthetic methods of the first group can be conveniently regarded in their turn as a function of the C–C bond responsible for ring closure during the formation of the prostaglandin molecule. Thus one of the first attempts at the synthesis of prostaglandins was made in 1963 by

Samuelsson and Ställberg[5], who obtained 15-deoxy-13,14-dihydro-$PGB_1$ (V) by the intramolecular cyclisation of the diketone (VI) and the formation of the $C_{(8)} - C_{(12)}$ bond of the cyclopentane ring of $PGB_1$:



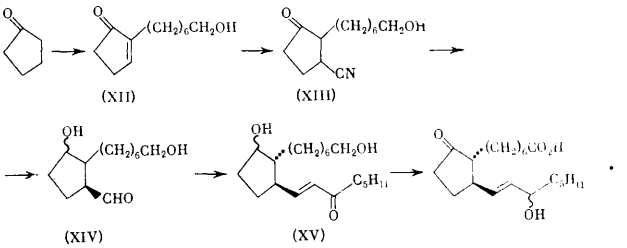
(VI) (V)

A stereoisomeric mixture of 13,14-dihydro-$PGE_1$ (VII) was obtained by Strike and Smith[6], who achieved during the synthesis the closure of the cyclopentane ring at the $C_{(10)} - C_{(11)}$ bond. For this purpose, they synthesised the aldehyde (VIII), which already contains both side chains of the prostaglandin molecule. The cyclisation of compound (VIII) led to the isolation of the enone (IX), which resulted in the formation of compound (VII) after epoxidation, hydrogenation, and the removal of the tetrahydropyranyl (TGP) protecting group:



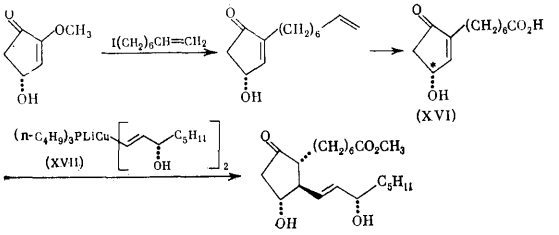
(VIII) (IX) (VII)

The methods for the formation of the $C_{(11)} - C_{(12)}$ bond in the prostaglandin molecule have been investigated in greatest detail. The study by Corey and coworkers[7,8] not only led to the preparation for the first time of pure crystalline prostaglandins, but also resulted in the development of methods which were subsequently used widely in prostaglandin chemistry; in particular, they employed the 9-nitrogroup as the precursor of the 9-oxo-group. The key compound in these syntheses was an aldehyde of type (X); it was subjected to aldol condensation to the enone (XI), which was shown to contain no 11-$\beta$-isomer whatsoever. Next, the 15-oxo-group was reduced with zinc tetrahydroborate, the nitro-group was transferred to the *trans*-position relative to the $\alpha$-chain with the aid of bases, the $C_{(15)}$ epimers were separated chromatographically, and the nitro-group was converted into the oxo-group via the amino- and *N*-bromoamino-groups:



(X) (XI)

The closure of the cyclopentane ring at the $C_{(9)} - C_{(10)}$ bond by the Dieckmann reaction was achieved[9] in the course of the synthesis of (±)-11-deoxy-$PGE_1$:

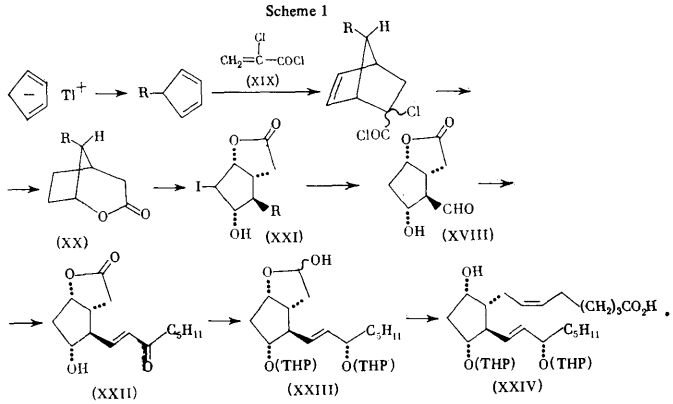


The second group of methods of synthesis of prostaglandins, from cyclopentane compounds, is based on both monocyclic and bicyclic systems containing the cyclopentane ring. An example of the synthesis achieved by the introduction of side chains into the molecule of a monocyclic cyclopentanone is provided by the scheme for the synthesis of 11-deoxy-$PGE_1$:[10]

(XII) (XIII) (XIV) (XV)

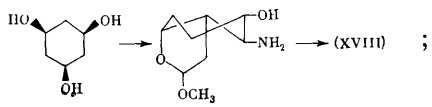
The enamine derived from cyclopentanone was alkylated by this method with $\omega$-hydroxyoenanthaldehyde. The alkylation product was dehydrated to the enone (XII), whose reaction with acetone cyanohydrin led to the nitrile (XIII). The reduction of the latter with di-isobutylaluminium hydride (DIBAL) involved the oxo- and cyano-groups simultaneously. The resulting hydroxyaldehyde (XIV) was converted by the Wittig reaction into compound (XV), in which both hydroxy-groups were subsequently oxidised with chromium trioxide and the 15-oxo-group was selectively reduced with sodium tetrahydroborate.

The syntheses of prostanoids from monocyclic cyclopentane derivatives, which also proceed via intermediates such as the aldehyde (XIV) or enones of type (XVI), are nowadays used on a fairly wide scale. This can be explained, on the one hand, by the availability of the initial cyclopentane and, on the other hand, by the comparative simplicity of the subsequent modification to give the prostaglandin molecule. Thus the enone (XVI) contains only one chiral centre, the required $\alpha$-chain is already present, and the stereospecific introduction of the second side chain can be successfully achieved[11] by means of the complex (XVII):



(XVI) (XVII)

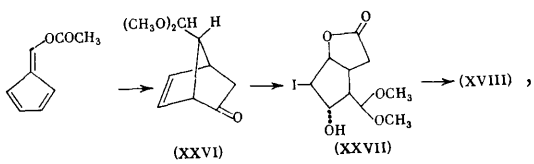
Among the numerous methods for the synthesis of prostaglandins from bicyclic compounds, those developed by the Harvard group under the leadership of Corey, are of greatest interest. The key compound in these syntheses is the formyl-lactone (XVIII), which has come to be called in the literature the "Corey aldehyde". This compound is synthesised by Scheme 1[12,13] from pentadienylthallium. The product of the reaction of the latter with benzyl chloromethyl ether was then converted by condensation with the dienophile (XIX) into the corresponding bicyclic compound. The latter was converted by a series of reactions into 2-oxabicyclo[3,2,1]nonane, which formed the iodolactone (XXI) after hydrolysis and further reaction with potassium tri-iodide. This compound has the required configuration of all the nuclear centres. Its acylation, deiodination, and the conversion of the hydroxybenzyl group (R) into the formyl group led to the formyl-lactone (XVIII)—the "Corey aldehyde", which was subsequently made to undergo the Wittig condensation with the corresponding phosphorane to form compound (XXII). The 15-oxogroup in the latter was then reduced stereospecifically and the $\alpha$-chain was



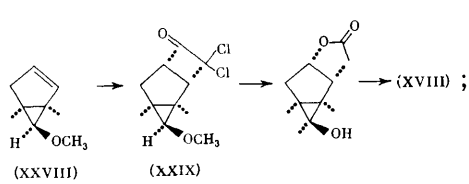
inserted (also by the Wittig reaction) after the conversion of the lactone into the lactol (**XXIII**).

Mild hydrolysis of the ether group led to the intermediate (**XXIV**) and then into $PGF_{2\alpha}$ after the removal of the THP protecting groups. Following the oxidation of the 9-hydroxy-group in compound (**XXIV**) and the removal of the THP protecting groups, $PGE_2$ was isolated. Compound (**XXIV**) was converted into a prostaglandin with a single double bond by hydrogenatoin over a palladium catalyst.

Scheme 1



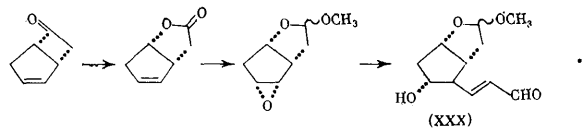
Corey's aldehyde (**XVIII**) became the key compound in various syntheses of prostaglandins. Several methods have been developed for its synthesis: from *cis*-cyclohexane-1,3,5-triol via the bicyclic aminoalcohol (**XXV**)[14]:



(**XXV**)

from acetoxyfulvene via bicyclo[2,2,1]heptene (**XXVI**) and the iodohydrin (**XXVII**):

(**XXVI**) (**XXVII**)



from the bicyclic ether (**XXVIII**) into which the elements of chloroketen are introduced stereospecifically with formation of the tricarbocyclic compound (**XXIX**)[16],

(**XXVIII**) (**XXIX**)

etc:

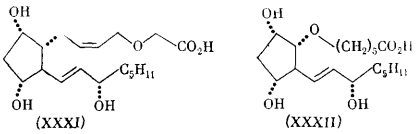
Another approach to the synthesis of prostaglandin structures involves the conversion of unsaturated bicyclic cyclopentanone derivatives into epoxides; the opening of the oxiran ring in the latter by specific reagents (for example[17], 1,3-bismethylthioallyl-lithium—the nucleophilic equivalent of the –CH=CH–CHO group) leads to an aldehyde of type (**XXX**):

(**XXX**)

A number of other novel methods for the synthesis of prostaglandins, which are outside the framework of the above schemes, have been described in special reviews, for example that of Mueller and Flanders[18].

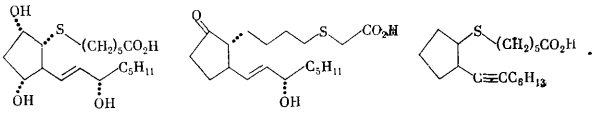
## III. METHODS OF SYNTHESIS OF HETEROCYCLIC ANALOGUES OF PROSTAGLANDINS

Research on methods of synthesis of prostaglandin analogues, which are easier to synthesise than natural prostaglandins but have the same or comparable biological activity, has developed on a wide scale in recent years.



The search for synthetic analogues of prostaglandins is also dictated by other factors. In the study of the effect of prostaglandins on human organisms, undesirable side effects are frequently observed; a disadvantage of natural prostaglandins as medicinal substances is the short duration of their action, which necessitates their frequent administration. Furthermore, the wide variety of pharmacological effects creates major difficulties in their practical application. Preparations similar in structure to natural prostaglandins but acting more selectively on individual systems and functions of the organisms, are more stable, less toxic, and more easily administered to man than their natural prototypes are being sought for this reason. Finally, in many instances the structural analogues are synthesised in order to obtain prostaglandin antagonists and to elucidate the physiological role of natural prostaglandins.

A fairly large number of prostanoids, differing from natural prostaglandins by individual structural elements, have now been synthesised and their pharmacology investigated. In most instances, these are cyclopentane derivatives. They include active compounds with an alkyl chain longer than in prostaglandins[19] and prostanoids with shorter side chains[20] and with additional alkyl[21] or aryl[22] substituents. A wide variety of derivatives involving the functional groups of the prostaglandin molecule have been obtained, including oximes, thiosemicarbazides, semicarbazides[23], salts[24], and ethers[25]. Halogens[26,27] and heterocyclic residues[28,29] have been introduced into the side chain; the carboxy-group has been replaced by the sulpho-group[30], etc. The degree of unsaturation of the side chains[31,32] and the positions of the double bonds[33] have also been varied and oxo- and hydroxy-groups have been eliminated or additional ones have been introduced.

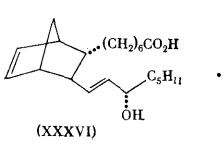


Such changes in the side chains led in most instances to a weakening of biological activity. On the other hand, many substances inhibiting the action of prostaglandins as well as a number of active preparations have been found.

The introduction of heteroatoms (sulphur or oxygen) into the $\alpha$-chain led to the formation of a series of prostanoids exhibiting both prostaglandin-like and antagonistic activity. Prostanoids containing oxygen atoms in the 3-, 4-, and 5-positions[34] and in the 7-position[35,36] of the prostaglandin

molecule [compounds (XXXI) and (XXXII)] as well as 7-thiaprostaglandin (XXXIII)[37] and 3-thiaprostaglandin (XXXIV)[38] have been obtained in recent years:

(XXXI) (XXXII)



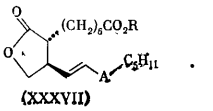
(XXXIII) (XXXIV) (XXXV)

The 7-thia-analogue (XXXV)[39], having a triple bond in the alkyl side chain and without an oxygen-containing functional group in the cyclopentane ring, showed a high activity in inhibiting PG-15-dehydrogenase. Analysis of compounds (XXXI)–(XXXIV) showed that a prostaglandin-like activity is shown only by the isomers in which all the chiral centres retain the absolute configuration characteristic of natural prostaglandins, while other isomers show little or no activity.

Various substituents, including halogen atoms[40,41] and alkoxy-[42], hydroxymethyl[44], alkyl[45], and other[46] groups, were introduced into the cyclic component of the prostaglandin molecule. The compounds synthesised, without an oxygen-containing functional group in the cyclopentane ring, for example[47], the 11-deoxy-analogue of PGE[32], 9-deoxyprostaglandin[48], etc. as well as prostaglandin analogues in which the cyclopentane ring was replaced by the benzene[49] or cyclohexane[50,51] rings, have also been synthesised.

Synthetic prostaglandin analogues having simpler structures in most cases did not show a distinctive effect on the smooth muscles in *in vitro* experiments, but interacted with the same receptors as prostaglandins, inhibiting their influence. Compound (XXXVI), which is a derivative of bicyclo[2,2,1]heptene, similar in structure to one of the postulated products of the biosynthesis of $PGE_1$, acts via a similar mechanism[52]. The authors[52] established that the compound inhibits selectively the isomerase responsible for the synthesis of $PGE_1$, but does not affect the reductase catalysing the formation of $PGF_{1\alpha}$.

(XXXVI)



The introduction of a heteroatom into the cyclic part of the prostaglandin molecule was the next step in the modification of the structures of natural prostaglandins. The syntheses of heterocyclic prostanoids are based on the experience already gained with methods for the synthesis of natural prostaglandins. Both prostaglandins and their heteroanalogues are synthesised via two different schemes: either the side chains are attached to the complete cyclic fragment or ring closure is achieved in one of the last stages of the synthesis. The first pathway appears to have many advantages, since it makes it possible to vary the structures of the side chains and to attach them to a ring already containing the necessary stereochemical centres.

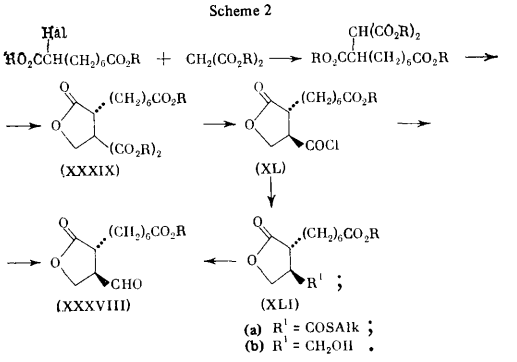
The syntheses of prostanoids containing oxygen, sulphur, and nitrogen atoms in the cyclic part of the molecule (oxa-, thia-, and aza-prostaglandins) have now been published.

## 1. Oxaprostaglandins

The majority of synthetic analogues of prostaglandins containing an oxygen atom in the cyclic part of the molecule are derivatives of tetrahydrofuran. In an attempt to obtain substances with potential antifertility activity, 9,10,11-mono-oxa- and 9,11-dioxa-prostaglandins were synthesised.

The first study on these lines involved the synthesis of 11-deoxy-10-oxaprostaglandin (XXXVII), carried out by Japanese workers in 1971[53]. The authors claimed that the compounds obtained exhibit a therapeutic activity similar to that of prostaglandins, and can be used in gastrointestinal disorders and in disturbances of blood pressure, as well as substances inducing natural birth and abortions.

(XXXVII)



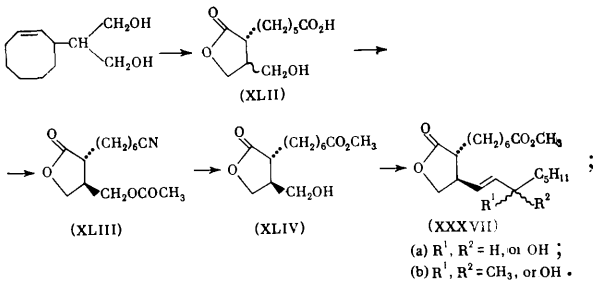
The key compound in the synthesis of a series of products (XXXVII) with R = H or alkyl and A = CO, CHOH, or CHOCOAlk is the aldehyde (XXXVIII), the synthesis of which is illustrated in Scheme 2.

The condensation of the diesters of $\alpha$-halogenoazelaic and malonic acids in the presence of bases (alkali metal hydrides and alkoxides) led to the formation of the corresponding 8,9,9-tricarboxy-derivative of pelargonic acid, the condensation of which with formaldehyde led to the trisubstituted tetrahydrofuranone (XXXIX). The latter was then partly decarboxylated at 150–170° and converted into the acid chloride (XL) by reaction with thionyl chloride. Compound (XL) was further converted into the aldehyde (XXXVIII) in different ways: by direct hydrogenation in the presence of a palladium catalyst, or via the thioester (XLIa), which was then reduced to compound (XXXVIII) over a deactivated nickel catalyst, or by oxidising with dicyclohexylcarbodiimide (DCC) the alcohol (XLIb) obtained as a result of the dehydrogenation of compound (XLIa) over active Raney nickel.

The second alkyl chain was attached to the aldehyde (XXXVIII) using dimethyl 2-oxoheptylphosphonate and the 15-oxo-group was reduced with various alkali metal tetrahydroborates. The mixture of epimeric alcohols formed in this process was separated chromatographically and the ester group was hydrolysed in a weakly acid or weakly alkaline medium.

*O*-Acyl derivatives [(XXXVII), R = H, A = CHOCOalk] were also obtained by acylating the 15-hydroxy-group.

Scheme 2



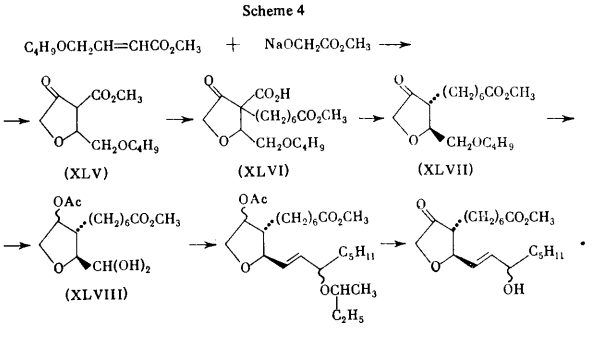
(XXXIX) (XL) (XXXVIII) (XLI)

(a) $R^1$ = COSAlk ;
(b) $R^1$ = $CH_2OH$ .

An alternative synthesis of 10-oxaprostaglandins was published in 1974 (Scheme 3).[54] The initial tetrahydrofuranone (XLII), obtained by oxidising 2-(3-cyclo-octenyl)-propane-1,3-diol, already contained the $\alpha$-chain, which was, however, shorter by one $CH_2$ group than in the prostaglandin. The $\alpha$-chain was lengthened in the following way; after protecting the 11-hydroxymethyl group, the carboxy-group was reduced with diborane to an alcoholic group and was then converted via the tosylate into a nitrile group [compound (XLIII)]. After the alkaline hydrolysis of compound (XLIII) and esterification, the ester (XLIV) was isolated and its hydroxymethyl group was oxidised to the formyl group.

The further conversion into the 10-oxaprostaglandin (XXXVII) was achieved by a series of reactions which had already been thoroughly tested previously in syntheses of prostaglandins: the interaction of the aldehyde with dimethyl 2-oxoheptylphosphonate resulted in the introduction of the alkyl side chain, in which the 15-oxo-group was then reduced with sodium tetrahydroborate to the hydroxy-group:

Scheme 3

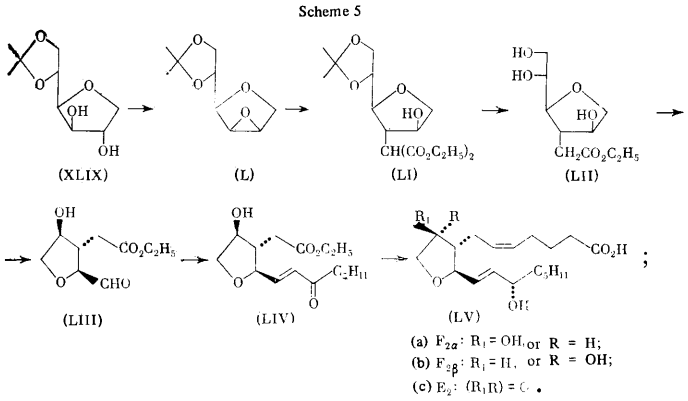


(XLII) (XLIII) (XLIV) (XXXVII)

(a) $R^1$, $R^2$ = H, or OH;
(b) $R^1$, $R^2$ = $CH_3$, or OH.

Fried and coworkers[55], who have been working for many years on the formation of prostanoids containing heteratoms in various parts of the molecule, achieved the synthesis of 11-oxaprostaglandin. The tetrahydrofuranone ring required to synthesise 11-oxaprostaglandin was formed by the condensation of 4-t-butoxybut-2-enoic acid with sodium methoxycarbonylmethoxide (Scheme 4). The resulting ketoester (XLV) was converted with alkali into the sodium salt, which was alkylated with methyl $\omega$-iodo-oenanthate. Analysis of the ketoester (XLVII) obtained as a result of decarboxylation of compound (XLVI), showed that both side chains are in the required more stable *trans*-configuration:

Scheme 4



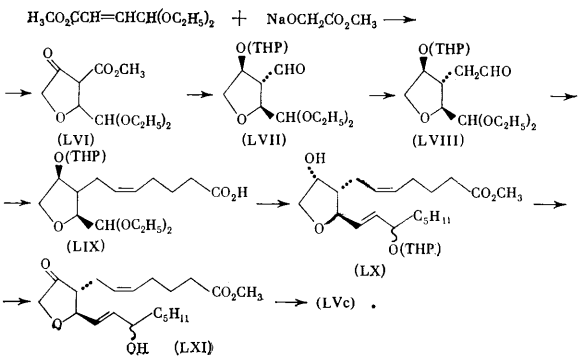
(XLV) (XLVI) (XLVII) (XLVIII)

The authors then reduced the t-butoxymethyl and 9-oxo-groups with zinc tetrahydroborate to alcoholic groups, selectively protected the 9-hydroxy-group, oxidised the 12-hydroxymethyl group with DCC to the aldehyde hydrate (XLVIII), and attached the alkyl chain via the Wittig reaction.

The 15-oxo-group was reduced with zinc tetrahydroborate; the resulting hydroxy-group was protected by ethyl vinyl ether, which permitted the oxidation of the 9-hydroxy-group to the carbonyl group with chromium trioxide after the removal of the 9-acetyl protecting group. The removal of the second protecting group in aqueous acetic acid led to a mixture of alcohols epimeric with respect to $C_{(15)}$, which were separated chromatographically. Both epimers exhibited a weak PGE-like activity in *in vitro* experiments (on the contraction of the smooth musculature of a section of the large intestine).

A novel stereospecific synthesis of 11-oxaprostaglandins containing a double bond in each side chain was developed by Canadian chemists[56] (Scheme 5). Starting with substituted 1,4-dihydrosorbitol (XLIX), the authors obtained via the monomethanesulphonate the epoxide (L), into which they subsequently introduced the malonic ester residue. After alkaline hydrolysis of compound (LI), partial decarboxylation, and esterification, the trisubstituted tetrahydrofuran (LII) was obtained, in which the ethylene glycol group was oxidised by sodium periodate to the formyl group. Treatment of the aldehyde (LIII) with dimethyl 2-oxoheptylphosphonate in the presence of sodium hydride gave an 80% yield of compound (LIV), which the authors regard as the key compound for the synthesis of 11-oxaprostanoids (LV):

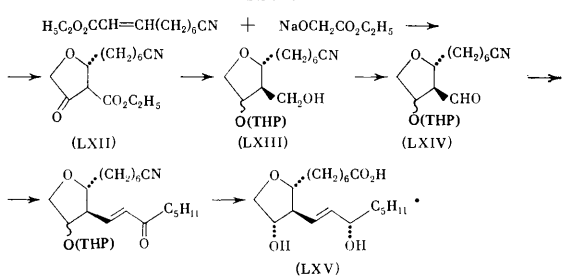
Scheme 5



(XLIX) (L) (LI) (LII) (LIII) (LIV) (LV)

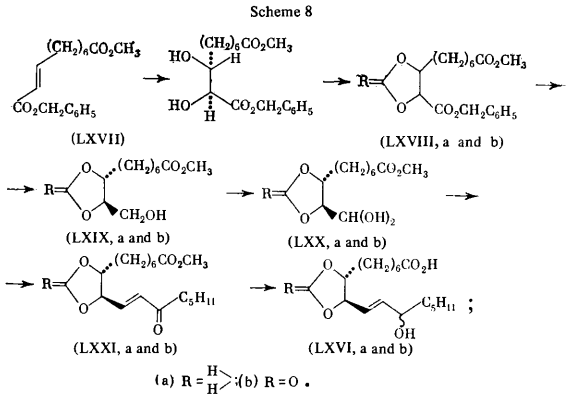
(a) $F_{2\alpha}$: $R_1$ = OH, or R = H;
(b) $F_{2\beta}$: $R_1$ = H, or R = OH;
(c) $E_2$: ($R_1$R) = O.

Vlattas and Lee[57] developed almost simultaneously with the Canadian workers[56] another version of the synthesis of the 11-oxa-analogue of $PGE_2$ [compound (LVc)] (Scheme 6). The disubstituted tetrahydrofuranone (LVI) was obtained by the condensation of methyl 4,4-diethoxycrotonate with sodium methoxycarbonylmethoxide. The reduction of compound (LVI) with sodium tetrahydroborate led to a mixture of epimeric alcohols. The main epimer was isolated chromatographically and, after protecting the hydroxy-group with THP, was converted into the aldehyde (LVII) by reaction with DIBAL. The following stage of the synthesis is of methodological interest: the formation of the homologous aldehyde (LVIII) via a vinyl sulphide. For this purpose, compound (LVII) was treated with triphenylphosphoranylidene(phenylthio)methane in dimethyl sulphoxide. The mixture of the *cis*- and *trans*-vinyl sulphides formed was converted by treatment with mercury acetate into an adduct, which was subjected to reductive cleavage with aluminium amalgam to the corresponding acetoxyphenylmercaptoacetal. Alkaline hydrolysis of the latter led to the aldehyde (LVIII), which was converted into compound (LIX) by reaction with sodium 5-triphenylphosphoranylidenepentanoate. The necessary alkyl chain was attached by the Wittig reaction with the corresponding phosphorane



and the alcohol (LX) was converted into the ketone (LXI) by oxidation with thiocyanogen in dimethyl sulphide.

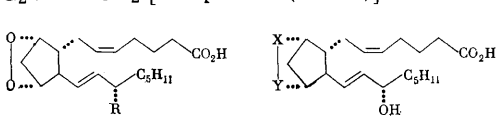
Scheme 6



The synthesis of 9-oxaprostaglandin, published by Vlattas and Della Vecchia towards the end of 1974,[58] was achieved in accordance with one of the traditional schemes for the synthesis of $PGE_1$ and $PGF_{1\alpha}$ (see, for example, Caton[10]) (Scheme 7). The initial tetrahydrofuran derivative was obtained by condensing sodium ethoxycarbonylmethoxide with the corresponding substituted vinyl ether. The tetrahydrofuranone (LXII) synthesised already contained the required $\alpha$-chain. The second chain was introduced into the ring after the reduction of the oxo- and ethoxycarbonyl group to alcoholic groups (in succession with sodium tetrahydroborate and lithium tetrahydroaluminate) and the conversion of the alcohol (LXIII) into the aldehyde (LXIV) under the influence of chromium trioxide by the Wittig reaction of compound (LXIV) with the corresponding phosphorane. After the reduction of the 15-oxo-group with sodium tetrahydroborate, the mixture epimeric with respect to $C_{(15)}$ was separated on a column of silica gel. The nitrile group was hydrolysed with potassium-hydroxide in the last stage of the synthesis of the 9-oxa-analogue of $PGE_1$ [compound (LXV)]:

Scheme 7

Scheme 8 describes the synthesis of prostanoids in the five-membered ring of which two hydroxymethine groups have been replaced by oxygen atoms. The authors[59] state that they undertook the synthesis of compounds of type (LXVI) after the interesting biological properties of prostaglandin analogues in the side chains of which the methylene groups have been replaced by heteroatoms [compounds (XXXII) and (XXXIII)[35,37]] became known.

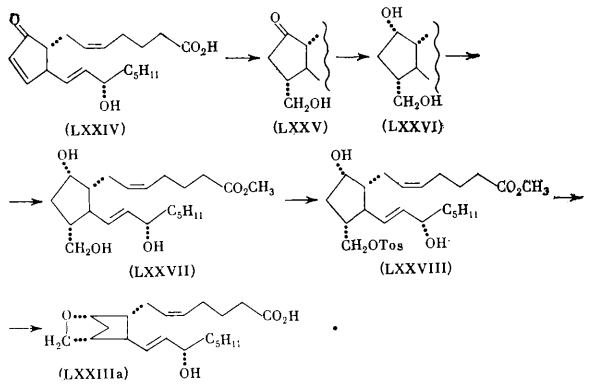


Scheme 8

Harrison et al. used as the initial compound the unsaturated *trans*-ester (XLVII), the synthesis of which they had developed previously for 9,11-bishydroxymethyl analogues of prostaglandins[44]. Hydroxylation of compound (LXVII) with osmium tetroxide in the presence of barium chlorate resulted in the formation of the corresponding diol, which was subsequently converted into the cyclic acetal (LXVIIIa) by heating with paraformaldehyde in benzene in the presence of perchloric acid. Hydrogenolysis of the benzyl group in compound (LXVIIIa) led to the corresponding acid which was converted into a mixed anhydride by a reaction with chlorocarbonic ester. The anhydride was reduced with sodium tetrahydroborate to the alcohol (LXIXa), whose oxidation with DCC led to the aldehyde hydrate (LXXa). The missing side chain was synthesised by the Wittig reaction and the 15-oxo-group was reduced with zinc tetrahydroborate. The mixture of epimers with respect to $C_{(15)}$ was separated chromatographically. The esters (LXXIa) were hydrolysed to the corresponding acids with a methanolic solution of sodium hydroxide.

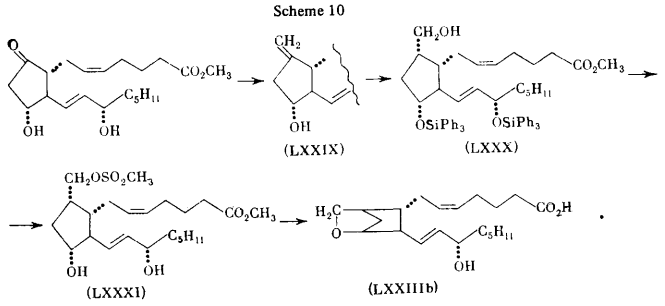
In addition, the authors[59] developed the synthesis of a dioxaprostaglandin containing an oxo-group in the 10-position. In the synthesis of the heterocyclic nucleus, paraformaldehyde was replaced by phosgene, whose condensation with the diol was carried out in tetrahydrofuran in the presence of pyridine. The series of subsequent reactions, analogous to those employed in the synthesis of compound (LXVIa), led to compound (LXVIb). Both compounds exhibited a weak $PGE_2$ activity in *in vitro* experiments on their effect on the smooth muscles of a section of the large intestine.

Among the syntheses of oxaprostaglandins, mention must be made of the methods of synthesis of 2-oxabicyclo-[2,2,1]heptane analogues of the prostaglandin endoperoxides $PGG_2$ and $PGH_2$ [compounds (LXXII)]:



The compounds $PGG_2$ and $PGH_2$, which are intermediates in the biosynthesis of prostaglandins, have been obtained recently by biosynthesis; they were isolated and

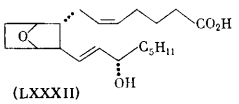
characterised[60]. It was found that, despite their short half-life in an aqueous buffer, these compounds have an interesting spectrum of biological activity. This led Bundy[61] to synthesise the prostaglandin analogues (LXXIII) by replacing one of the peroxide oxygen atoms in the $PGH_2$ molecule by the methylene group.



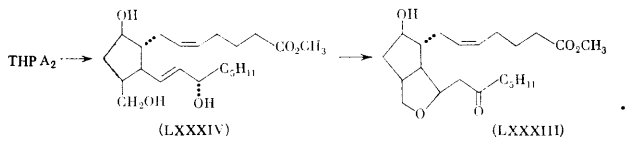
The 11-hydroxymethyl group was introduced (Scheme 9) into the carbon skeleton of $PGA_2$ [compound (LXXIV)], obtained from the coral *Plexaura Homomalla*, by irradiating a methanol solution of $PGA_2$ in the presence of benzoquinone. The resulting mixture of epimeric alcohols (LXXV), with the 11-$\alpha$-isomer predominating, was separated chromatographically. The oxo-group in the ring of the 11-$\alpha$-isomer isolated was reduced with lithium perhydro-9b-boraphenalyl hydride and the reaction was so stereospecific that the yield of the required 9-$\alpha$-isomer (LXXVI) reached 94%. After the esterification of the dihydroxy-acid (LXXVI) with diazomethane, the primary alcoholic group in compound (LXXVII) was selectively converted into the toluene-*p*-sulphonate ester (LXXVIII). Subsequent treatment of compound (LXXVIII) with potassium hydroxide in an aqueous methanol solution at room temperature made it possible to achieve both intramolecular substitution and hydrolysis of the ester group.

Scheme 9

The synthesis of compound (LXXIIIb), in which the oxygen atom attached to $C_{(9)}$ in the $PGH_2$ molecule has been replaced by a methylene group, is illustrated in Scheme 10.



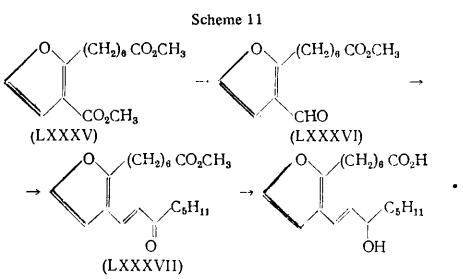
Scheme 10



The methylene group was introduced in the 9-position of the methyl ester of $PGE_2$ by treating the latter with *N*-methylphenylimidoylmethylmagnesium chloride in tetrahydrofuran and subsequent reductive cleavage of the resulting adduct with aluminium amalgam. The yield of the 9-methylene derivative (LXXIX) was 75%.

The subsequent stages of the synthesis—the protection of the 11- and 15-hydroxy-groups with triphenylsilyl groups and selective hydroboration of the 9-methylene group with 9-borabicyclo[3,3,1]nonane (9-BBH)—led to the corresponding primary alcohol (LXXX). The stereochemistry of compound (LXXX) was determined by the preferred attack by 9-BBH from the less shielded side of the molecule and was confirmed by the ease of the subsequent cyclisation involving the 11-$\alpha$-hydroxy-group. For this purpose, the methanesulphonate was obtained initially by reaction with the primary alcoholic group, the silyl protecting group was removed, and the resulting monomethanesulphonate (LXXXI) was treated with an aqueous methanol solution of potassium hydroxide. Like $PGH_2$, the cyclic ethers (LXXXIII, a and b) manifested a bronchoconstricting activity in experiments on animals.

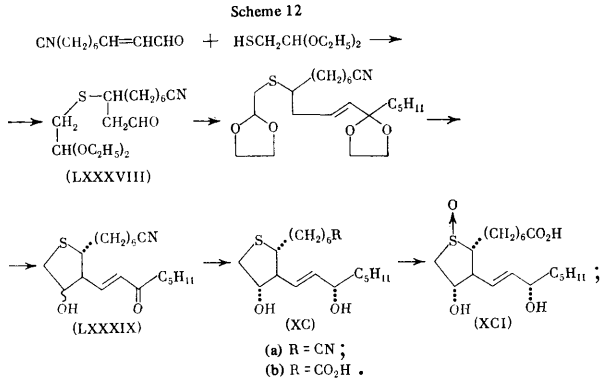
A report[62] of the synthesis of another series of endoperoxide analogues—derivatives of 7-oxabicyclo[2,2,1]-heptane (LXXXII)—was published recently. These compounds were obtained by the condensation of triethylphosphonosorbic acid esters and dimethyl 2-oxoheptylphosphonate with the corresponding derivatives of 7-oxabicyclo[2,2,1]heptane:



Yet another derivative of tetrahydrofuran, whose structure is similar to that of $PGE_2$, was obtained in the course of the synthesis of 9,11-bishydroxymethyl analogues of $PGE_2$.[63] Compound (LXXXIII) is formed when the triol (LXXXIV) is oxidised with 2,3-dichloro-5,6-dicyanobenzoquinone, which results in the conjugate addition of the *cis*-hydroxymethyl group to the intermediate enone:

The synthesis of oxygen-containing heteroaromatic prostanoids derived from furan and oxazole has also been described[64]. Scheme 11 was put forward for the synthesis of a furan analogue of prostaglandin. Dimethyl 3-oxosebacate was treated with chloroacetaldehyde; the resulting methyl 2-(6-methoxycarbonylhexyl)furan-3-carboxylate (LXXXV) was converted into the aldehyde (LXXXVI). The Wittig reaction of the latter with the corresponding phosphorane led to methyl 15-oxo-9-oxaprosta-8(12), 10,13-*trans*-trienoate (LXXXVII), in which the 15-oxo-group was then reduced and the ester group was hydrolysed:

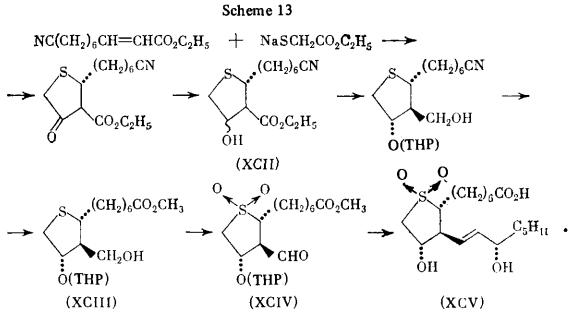
Scheme 11



## 2-, 9-, and 11-Thiaprostaglandins

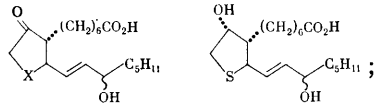
Literature data are available about the synthetic analogues of prostaglandins containing a sulphur atom in the 9- or 11-position in the molecule. They are all tetrahydrothiophen derivatives.

The synthetic scheme selected by Vlattas and Della-Vecchia[65] to obtain 9-thiaprostaglandins and their $C_{(11)}$ and $C_{(15)}$ epimers is fairly well known and is frequently used to synthesise natural prostaglandins (see, for example, Corey et al.[66]). A characteristic feature of the scheme is the closure of the cyclic components of the molecule (with formation of the $C_{(11)} - C_{(12)}$ bond) after both side chains have been synthesised (Scheme 12).



The condensation of 9-cyanononenal with the diethyl acetal of mercaptoacetaldehyde led to the adduct (**LXXXVIII**) which reacted under the conditions of the Wittig reaction with 1-tributylphosphoranylidene-2-heptanone to form the corresponding enone. After protecting both oxo-groups with ethylene glycol and subsequent intramolecular cyclisation of the dieketal (in the presence of toluene-*p*-sulphonic acid), a mixture of epimers of compound (**LXXXIX**) with respect to $C_{(11)}$ was obtained. Chromatographic separation of the isomers and subsequent reduction of the 15-oxo-group in the more polar isomer with zinc tetrahydroborate led to the formation of a new epimeric mixture with respect to $C_{(15)}$, from which the more polar isomer (**XCa**) was isolated on a column with silica gel. The isomer was then hydrolysed in an aqueous methanol solution of potassium hydroxide to (±)-9-thiaprostaglandin (**XCb**). In addition, a mixture of the isomeric sulphoxides (**XCI**) was obtained by oxidising compound (**XCb**) with sodium peroxide.

Scheme 12

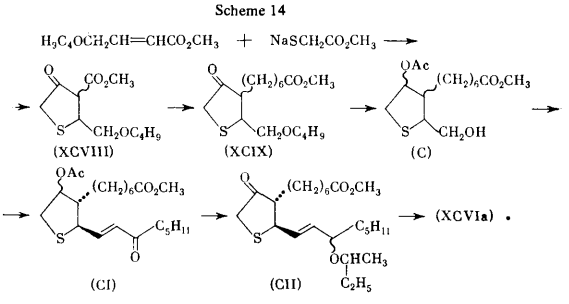


The same workers developed simultaneously an alternative scheme for the synthesis of 9-thiaprostaglandins[67] (Scheme 13). The tetrahydrothiophen ring was formed at the beginning of the synthesis. For this purpose, ethyl 9-cyanonon-2-enoate was condensed with the sodio-derivative of thioglycolic ester. The resulting substituted tetrahydrothiophenone was then reduced with sodium tetrahydroborate to a mixture of epimeric products (**XCII**) with respect to $C_{(11)}$, which was separated chromatographically. After protecting the 11-hydroxy-group in the more polar isomer (**XCII**) with THP, the ester group was reduced and the resulting hydroxynitrile was then converted into the corresponding hydroxyester (**XCIII**) by alkaline hydrolysis in methanol and esterification with diazomethane:

Scheme 13

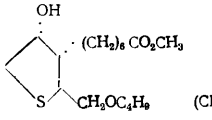
The sulphide (**XCIII**) was then oxidised with *m*-chloroperbenzoic acid to a sulphone, which was in its turn converted into the aldehyde (**XCIV**) by treatment with chromium trioxide. Compound (**XCIV**) was converted into (±)-9-thia-$PGE_1$ dioxide (**XCV**) with the aid of reactions usually employed in this series of conversions: the introduction of the alkyl chain by the Wittig reaction, the reduction of the 15-oxo-group by sodium tetrahydroborate followed by the chromatographic separation of the epimeric alcohols, and the hydrolysis of the ester group in the 11-position with potassium carbonate in methanol. The enantiomeric form of compound (**XCV**) was obtained by esterifying the 11-hydroxy-group of *R*(-)-α-methoxyphenylacetyl chloride at the enone stage.

Derivatives of 11-thiaprostaglandin in which the sulphur atom replaces the hydroxymethine group in the 11-position of the $PGE_1$ [compounds (**XCVI**, a and b)] and $PGF_{1\alpha}$ [compound (**XCVII**)] molecules, have been recently synthesised in accordance with Scheme 14:[68]



In this case the tetrahydrothiophen ring was formed from methyl 4-t-butoxybut-2-enoate and the sodio-derivative of thioglycolic ester. The resulting tetrahydrothiophenone (**XCVIII**) was alkylated with methyl 7-iodo-oenanthate and then the methoxycarbonyl group was eliminated by treatment with lithium hydride in boiling dimethylformamide. The 9-oxo-group in the resulting ketoester (**XCIX**) was reduced with sodium tetrahydroborate and the resulting hydroxy-group was protected by treatment with acetic anhydride, while the t-butyl group was eliminated by treatment with a mixture of 48% aqueous hydrofluoric acid and tetrahydrofuran.

The alcohol (**C**), isolated in this reaction, was subsequently converted into the corresponding aldehyde hydrate (as in Scheme 4) and then into the enone (**CI**). Analysis of the structure of compound (**CI**) enabled the authors to claim that the side chains in the compounds obtained are in the most stable *trans*-configuration. Next, compound (**CI**) was converted by treatment with zinc tetrahydroborate into a mixture of alcohols epimeric with respect to $C_{(15)}$ and the 15-hydroxy-group was protected with ethyl vinyl ether, after which the 9-hydroxy-group was oxidised with DCC in

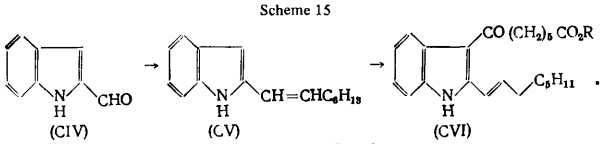


dimethyl sulphoxide to form the ketone (CII). Mild hydrolysis of the ester groups then led to the isolation of 15($\alpha$ + $\beta$)-hydroxy-9-oxo-11-thiaprost-13-enoic acid (XCVIa):

Scheme 14

In order to obtain the sulphoxide (XCVIb), the ketone (CII) was oxidised with *m*-chloroperbenzoic acid, which led to the formation of a mixture of the isomeric methyl esters of the sulphoxide.

Compound (XCVII), the thia-analogue of $PGF_1\alpha$, was synthesised by reducing the ketone (XCIX) with potassium tri-(s-butyl)hydroborate to the 8,9-*cis*-alcohol (CIII):



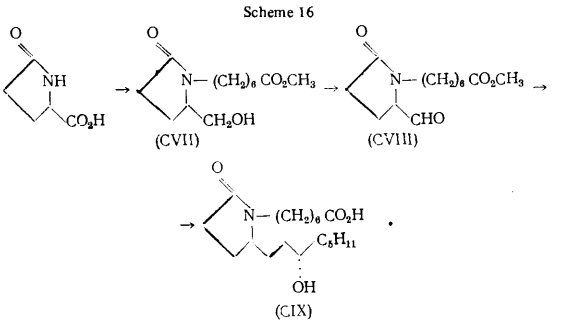
Using the methods described above, compound (CIII) was converted into the corresponding acetoxyalcohol and then into the aldehyde, the enone, and a mixture of alcohols epimeric with respect to $C_{(15)}$. Further hydrolysis yielded 9$\alpha$, 15($\alpha$ + $\beta$)-dihydroxy-11-thiaprost-13-enoic acid (XCVIII). 11-Thiaprostaglandins showed a weak $PGE_2$-like activity on the smooth muscles of a section of the large intestine in *in vitro* experiments.

### 3. Azaprostaglandins

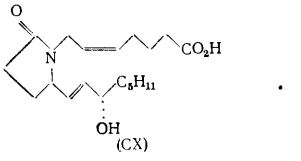
The prostaglandin analogues in which the cyclopentane ring has been replaced by a nitrogen-containing heterocycle synthesised hitherto are indole, pyrrolidine, pyrazolidine, oxazole, and thiazole derivatives.

2-Oct-1-enylindole (CV) was obtained from indole-2-aldehyde (CIV) and heptylidenephosphorane[69,70] (Scheme 15). The authors selected the chloride of the half-ester of pimelic acid in order to introduce the side chain with a carboxy-group, simulating the $\alpha$-chain of prostaglandin molecules. Acylation of the organomagnesium derivative (CV) with this reagent took place with a high yield (80%) and led to ethyl 7-[2-(oct-1-enyl)-3-indolyl]-7-oxoheptanoate (CVIa) (the ratio of the *cis*- and *trans*-isomers was 45 : 55):

Scheme 15

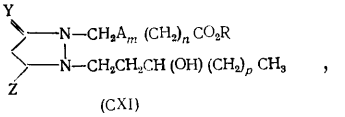


(a) R=$C_2H_5$; (b) R=H.



Alkaline hydrolysis of compound (CVIa) gave the *trans*-isomer of the corresponding acid (CVIb), whose structure was confirmed by $^1$H NMR.

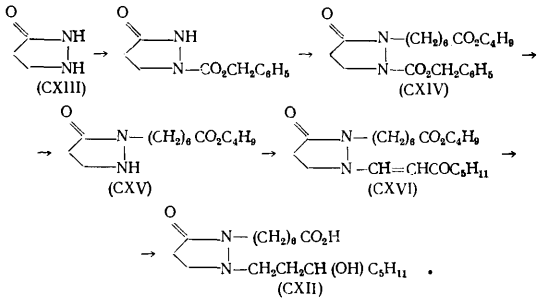
The authors based the syntheses of (±)-11-deoxy-8-aza-prostaglandins, the pyrrolidine analogues of $PGE_1$ and $PGE_2$,[71,72] also on the "complete" cyclic component of the molecule (Scheme 16). 5-Hydroxymethyl-1-(6-methoxycarbonylhexyl)pyrrolidin-2-one (CVII) was obtained from the readily available (±)-pyroglutamic acid (five stages):



Scheme 16

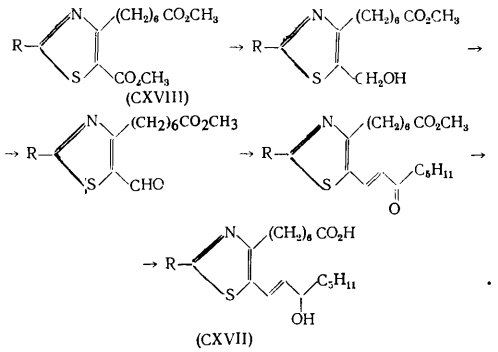
The subsequent formation of the side chain, involving the oxidation of the alcoholic group to the aldehyde group, the condensation of the aldehyde (CVIII) with dimethyl 2-oxoheptylphosphonate, and the reduction of the resulting enone, presented no difficulties according to the authors' report and led to a mixture of alcohols epimeric with respect to the $C_{(15)}$ and separated chromatographically. The 8-aza-analogue of $PGE_2$ [compound (CX)] was also synthesised on the basis of a suitably modified scheme[71]:

A series of diazaprostaglandins—derivatives of pyrazolidine having the general formula (CXI)—have been synthesised by Scribner[73] in order to obtain prostaglandin inhibitors (Scheme 17):



where A = CH = CH or C≡C, R = H, metal, amine salt, alkyl, or halogenoalkyl, $m$ = 0 or 1, $n$ = 0–6, $p$ = 0–6, and Y, Z = O or $H_2$.

According to the author[73], certain compounds of this class can be used as antipyretic, analgesic, and anti-inflammatory agents, and also in the treatment of certain forms of diarrhoea and shock. The synthesis of prostanoids of type (CXI) is facilitated relative to that of natural prostaglandin by the fact that compound (CXI) contains not more than one asymmetric carbon atom (in the side chain) and the asymmetric ring carbon atoms have been replaced by nitrogen atoms. As an example, Scheme 17 presents



the synthesis of one representative of this series, namely (±)-15-hydroxy-9-oxo-8,12-diazaprostanoic acid (CXII):

Scheme 17

The more basic nitrogen atom was first protected in the initial pyrazolidinone (CXIII) with the aid of benzyl chloroformate, after which the compound was alkylated at the second nitrogen atom with t-butyl 7-bromo-oenanthate to form the ester (CXIV). Hydrogenation of compound (CXIV) over palladium made it possible to remove the protecting group from the basic nitrogen atom in the pyrazolidinone ring, after which the product (CXV) was converted by refluxing with oct-1-yn-3-one in alcohol into the enaminoketone (CXVI), which was subsequently reduced, without prior purification, with hydrogen in the presence of a platinum catalyst (the $C_{(13)} - C_{(14)}$ bond) and with sodium tetrahydroborate (the 15-oxo-group). The mixture of alcohols epimeric with respect to $C_{(15)}$ was separated chromatographically. It is noteworthy that 8,12-diazaprostanoids (CXII) are the first example of synthetic basic analogues of prostaglandins.

Prostanoids containing nitrogen and sulphur atoms in the cyclic part of the molecule have been synthesised by Hungarian chemists[64]. In the synthesis of thiazole analogues of prostaglandins [compound (CXVII)], the heterocyclic ring is formed as a result of the condensation of dimethyl 2-chloro-3-oxosebacate with various thioamides. The resulting methyl 4-(6-methoxycarbonylhexyl)thiazole-5-carboxylate (CXVIII) was converted into compound (CXVII) in accordance with the scheme

Like the furan and oxazole analogues of prostaglandins (see Section III, subsection 2), the thiazole analogue (CXVII) inhibits enzymes which catalyse the further conversion of prostaglandins (15-hydroxy-PG-dehydrogenase and PGA-isomerase) and exhibits a prostaglandin-like effect in certain biological tests.

After the preparation of the article for publication, a number of communications on the subject of the review were published[74-101].

# Salting-out and Salting-in of Gaseous Non-electrolytes in Aqueous Solutions of Electrolytes

E.I.Konnik

Modern theories of salting-out and salting-in of gaseous non-electrolytes are reviewed and compared with experimental data. We conclude that a strict thermodynamic theory of salting-out and salting-in of non-electrolytes is not yet available. The use of salting-out and salting-in data to determine some physicochemical characteristics of solutions is described. 56 references.

## I. INTRODUCTION

Salting-out and salting-in effects of non-electrolytes in aqueous solutions of electrolytes are of general interest in physical chemistry as well as being used in applied chemistry.

Salting-out and salting-in effects are widely used in extraction. Quantitative data on the salting out of gases such as hydrogen, carbon monoxide, and oxygen are highly relevant to the design of electrochemical generators (fuel cells). Electrochemical generators operate in the diffusion-controlled regime for the supply of gaseous reagents to the electrodes. In electrolyte solutions the concentration of these gases is decreased by salting out, and as a result the diffusional flow to the electrodes and the available current density both decrease. Salting-in and salting out are directly related to changes in the activity coefficients of the gaseous non-electrolytes. A knowledge of the activity coefficients of the non-electrolytes is essential to the calculation of electrode equilibria involving these non-electrolytes. The calculation of the activity coefficients of non-electrolytes in solutions of electrolytes will provide the main stimulus for the development of the theory of salting in and salting out of non-electrolytes.

Allowance for salting-out and salting-in effects is necessary also in the application of polarographic methods and apparatus to the analysis of gases in solutions. This is because some of these methods measure the activity rather than the concentration of the gas. Hence we need to know the activity coefficients of the gases in solution in order to calculate their concentrations.

The fund of experimental data on the salting out and salting in of non-electrolytes has grown very considerably during the last 25 years. Substantial progress has been made in developing the theory of the phenomenon. These achievements are due primarily to progress in the development of the theory of solutions.

## II. THE "HYDRATION" THEORY

The "hydration" theory of salting out—the first theory of the phenomenon—was proposed at the end of the 19th century. The first quantitative experimental results on the salting-out of gaseous non-electrolytes from aqueous solutions of electrolytes were published by Sechenov in 1875.[1,2] The result of this work was Sechenov's empirical equation, which is still one of the most successful expressions for describing quantitatively the salting out and salting in of non-electrolytes:

$$\lg \frac{s^0_{ne}}{s_{ne}} = Kc_e, \qquad (1)$$

where $s^0_{ne}$ and $s_{ne}$ are the solubilities of the non-electrolyte in water and in the electrolyte solution respectively, $c_e$ is the concentration of electrolyte, and $K$ is the salting-out coefficient (or constant).

Sechenov first put forward the suggestion that the decrease in solubility of the non-electrolyte is due to the hydration of the electrolyte. Most workers at the turn of the century explained the salting out of non-polar non-electrolytes in terms of hydration of the electrolyte: the non-electrolyte molecules are repelled from the ionic atmosphere of the electrolyte ion by the polar water molecules, and the volume of water available for dissolving the non-electrolyte is less than the total volume of water in the solution.

According to the hydration theory of salting out the quantity $s^0_{ne}/s_{ne}$ is equal to the ratio of the volumes of "free" water in the solution before and after addition of the electrolyte:

$$\frac{s^0_{ne}}{s_{ne}} = \frac{1}{1 - \Sigma c_e V^h_e}, \qquad (2)$$

where $V^h_e$ is the volume of one mole of hydrated molecules of electrolyte.

The hydration theory tried to explain salting-out and salting-in phenomena by considering only the hydration of the electrolyte, and it could not give a physical interpretation of the significance of the salting-out coefficient $K$ in Eqn. (1). More recently, Ruetschi and Amlie [3] obtained an expression for $\ln(s^0_{ne}/s_{ne})$ by a series expansion of the logarithm of the right-hand side of Eqn. (2):

$$\ln\frac{s^0_{ne}}{s_{ne}} = \Sigma c_e V^h_e + \frac{1}{2}(\Sigma c_e V^h_e)^2 + \frac{1}{3}(\Sigma c_e V^h_e)^3 + \ldots \quad (3)$$

For an electrolyte at infinite dilution they retained only the first term of the series to give the approximate linear equation

$$\ln\frac{s^0_{ne}}{s_{ne}} = \sum_{c_e\to 0} c_e V^h_e = \Sigma c_e V^0_e, \quad (4)$$

where $V^0_e$ is the intrinsic volume of one mole of the electrolyte at infinite dilution. For a fully dissociated electrolyte $c_e = \nu_e c^M_e$ (where $\nu_e$ is the number of ions produced by the dissociation of the electrolyte and $c^M_e$ is the molar concentration of the electrolyte), and therefore

$$\ln\frac{s^0_{ne}}{s_{ne}} = c^M_e \Sigma \nu_e V^0_e. \quad (5)$$

Thus the empirical Sechenov equation (1) can be interpreted theoretically. In particular, the salting-out coefficient in Sechenov's equation should be given, according to the hydration theory, by the sum of the products $\nu_e V^0_e$ for all the electrolytes present in the solution. In this way the hydration theory can account for the relative insensitivity of the $K$ value of an electrolyte to the nature of the non-polar non-electrolyte. It is also found that the neglect of the higher terms of the series in Eqn. (3) is compensated by the decrease of $V^h_e$ with increasing concentration of electrolyte, so that the parameter $K$ in Sechenov's equation remains constant up to relatively high concentrations of electrolyte. At the highest electrolyte concentrations, or if the electrolyte is not fully dissociated, the quantity $c_e$ is no longer proportional to $c^M_e$, and as a result the plot of $\lg(s^0_{ne}/s_{ne})$ against $c^M_e$ deviates from linearity.

The hydration theory cannot explain the salting-in effect occasionally observed with non-electrolytes; it follows that the constant $K$ in Sechenov's equation is not determined simply by the intrinsic volume of the electrolyte at infinite dilution and by the number of ions formed by the dissociation of the electrolyte. The difference between the $K$ values for hydrogen and oxygen (~25%) in both NaOH and KOH [4] is another fact which the hydration theory cannot explain.

Thus the hydration theory in its original form has only historical value as the first attempt at a theoretical interpretation of salting-out and salting-in effects of non-electrolytes. Further developments in the theory of this complicated phenomenon had to wait the appearance of the Debye–Hückel electrostatic theory of electrolyte solutions. Even more recently Ruetschi and Amlie [3] introduced the elements of electrostatic theory into the hydration theory, enabling it to take fuller account of all the factors which influence the salting out and salting in of non-electrolytes.

## III. ELECTROSTATIC THEORIES

A qualitatively new approach to the salting out and salting in of non-electrolytes in terms of electrostatic interactions in electrolyte solutions was developed in 1925 by Debye and McAuley [5]. Their electrostatic theory of salting out, which treats the electrolyte solution as an ideal solution, allows for the effect of the non-electrolyte on the dielectric constant of the solution. The electrostatic field of the electrolyte ions is altered by the change in the dielectric constant of the solvent from its initial value $\epsilon_0$ to a new value $\epsilon$ resulting from the presence of the non-electrolyte, and as a result the activity coefficient $f_{ne}$ of the non-electrolyte is also altered. The quantity $f_{ne}$ is given, according to the Debye–McAuley theory, by the equation [5]

$$\ln f_{ne} = \frac{N\delta_{ne}e^2}{\epsilon_0 bRT}\cdot\frac{\Sigma c_e z^2}{2}, \quad (6)$$

where $N$ is Avogadro's number, $\delta_{ne}$ is the decrement in the dielectric constant of the solution produced by dissolution of the non-electrolyte, $e$ and $z$ are the electronic charge and the valency of the electrolyte ion respectively, and $b$ is the ionic radius of the electrolyte.

Debye and McAuley calculated the quantity $\delta_{ne}$ in Eqn. (6) by a formula which includes the number of molecules of non-electrolyte per 1 ml of solution ($n_{ne}$):

$$\epsilon = \epsilon_0(1 - \delta_{ne}\eta_{ne}). \quad (7)$$

The $\delta_{ne}$ values for hydrogen and oxygen were determined by Scatchard [6] in 1927 (0.05 and 0.06 respectively). To calculate the ionic radius of the electrolyte Debye and McAuley proposed a formula involving the radii of the cation ($r_c$) and of the anion ($r_a$), and $\nu_e$:

$$\frac{1}{b} = \frac{1}{\nu_e}\left(\frac{1}{r_c} + \frac{1}{r_a}\right). \quad (8)$$

The effect of hydration of the electrolyte on salting out is accounted for by the term $\Sigma c_e z^2/2$ in the Debye–McAuley equation. (This term appears also in the Born equation for the hydration energy of the electrolyte.)

Eqn. (6) has the same form as the empirical equation

$$\lg f_{ne} = K\mu, \quad (9)$$

where $\mu$ is the ionic strength of the solution. Eqn. (9) is also called the Debye–McAuley equation. In the electrostatic theory the salting-out coefficient is given by the expression

$$K = \frac{N\delta_{ne}e^2}{\epsilon_0 bRT}. \quad (10)$$

Debye and McAuley assumed that the electrolyte solution was ideal, and therefore confined the application of their electrostatic theory to the case of very dilute solutions.

Randall and Failey [7] showed that simple linear expressions such as Eqns. (6), (9), and (10) cannot be strictly correct. In particular, using Eqn. (9) to interpret experimental data on the salting out of hydrogen, oxygen, and other gases, they obtained varying values of $K$ for these gases in the same electrolyte at different concentrations, which is inconsistent with the definition of a salting-out constant.

The salting-out theory of Debye and McAuley correctly predicts an increase in $K$ with increasing charge and decreasing radius of the electrolyte ions. This theory allows for the decrease in the dielectric constant of the solvent caused by the presence of the non-electrolyte. However Debye and McAuley made no allowance for the decrease in the dielectric constant of the solvent caused by the presence of the electrolyte, which can be substantial [8]. The Debye–McAuley theory also fails to allow for specific interactions between the non-electrolyte and the solvent, and therefore it is powerless to explain the

salting-in effect of non-electrolytes. Experimental verification of the Debye–McAuley equation is not easy because the equation applies to very dilute solutions of electrolytes. The effect of non-electrolytes on the activity coefficient of electrolytes was first considered by Born[9]. Somewhat later Debye improved the Debye–McAuley theory[10] by treating the mixture of water and non-electrolyte as a heterogeneous medium. Assuming that the dielectric constant of the solution varies with distance $r$ from the ion in such a way that the overall free energy of the system is a minimum, he showed that

$$f_{ne} = \left(1 - \frac{4\pi N}{1000}\sum_i I_i c_i\right)^{-1}, \qquad (11)$$

where $c_i$ is the molar concentration of the solute. From the spherical structure of the ionic atmosphere he obtained the equation

$$I_i = \int_{r_i}^{\infty}\left[1 - \exp\left(-\frac{\bar{R}}{r}\right)^4\right] r^2\,dr, \qquad (12)$$

where $r_i$ is the radius of the ion of solute $i$.

Debye's improved electrostatic theory introduces, in addition to the quantity $\delta_{ne}$, also the change in the dielectric constant of the solution caused by the presence of the electrolyte. This leads to the equation

$$\bar{R}^4 = \frac{(ze)^2\,[v_{ne}(\partial\varepsilon/\partial c_w)\,c_{ne} - v_w(\partial\varepsilon/\partial c_{ne})\,c_w]}{8\pi RT\varepsilon^2 v_w}, \qquad (13)$$

where $c_w$ is the molar concentration of water, $v_{ne} = V_{ne}/N$, $V_{ne}$ is the molar volume of the non-electrolyte in the solution, $v_w = V_w/N$, $V_w$ is the molar volume of water. The difference in the numerator of Eqn. (13) determines whether salting out or salting in of the non-electrolyte will take place.

The integration of Eqn. (12) is not taken to infinity. As shown by Ruetschi and Amlie[3], the effect of the electric field of the ion on the dielectric constant of the solution extends over the layer of solution lying between the radius of the hydrated ion ($r_h$) and the radius of the ionic atmosphere ($r_n$). Hence the integration of Eqn. (12) can be taken from $r_h$ to $r_n$. The same workers[3] used the ideas of the improved Debye–McAuley electrostatic theory to develop the hydration theory, and obtained a more accurate form of Eqn. (2):

$$\frac{s^0_{ne}}{s_{ne}} = 1 - \Sigma c_e V^0_e - \Sigma I_i c_i. \qquad (14)$$

For the integral [see Eqn. (12)] which appears in Eqn. (14) Ruetschi and Amlie chose the limits $r_h$ and $r_n$. At low concentrations of electrolyte they obtained

$$\ln\frac{s^0_{ne}}{s_{ne}} = c^M_e \Sigma v_e V^0_e + \Sigma I_i c_i\ . \qquad (15)$$

The parameter $r_n$ can be calculated by the expression

$$r_n = \left(\frac{3}{4\pi n_e}\right)^{1/3}, \qquad (16)$$

where $n_e$ is the number of ions of electrolyte in 1 ml of solution.

Eqn. (15) combines the concepts of the hydration theory and of the Debye–McAuley electrostatic theory. It is only one of the many salting-out equations.

An equation similar to Eqn. (15) was put forward by Long and McDevit[4] on the basis of an equation given in Ref. 11. For solutions of intermediate concentration, without chemical interaction between the non-electrolyte and the solution and at not too high concentrations of non-electrolyte (the solubility of gaseous non-electrolytes being usually small), Long and McDevit obtained the equation

$$\lg f_{ne} = K_e c^M_e + K_{ne} s_{ne}. \qquad (17)$$

The authors point out[4] that most theories of salting out concentrate the attention on $K_e$, whereas we also need to know $K_{ne}$ to calculate $\lg f_{ne}$. Since the chemical potentials of the non-electrolyte in solution in equilibrium with the pure non-electrolyte or with the non-electrolyte in the gas phase are the same, we can write

$$f_{ne} s_{ne} = f^0_{ne} s^0_{ne}. \qquad (A)$$

It follows that

$$\lg\frac{f_{ne}}{f^0_{ne}} = \lg\frac{s^0_{ne}}{s_{ne}}, \qquad (B)$$

and

$$\lg f^0_{ne} = K_{ne} s^0_{ne}, \qquad (C)$$

and therefore Eqn. (17) can be re-written[4]

$$\lg\frac{f_{ne}}{f^0_{ne}} = K_e c^M_e + K_{ne}(s_{ne} - s^0_{ne})\ . \qquad (18)$$

The parameter $K_{ne}$ according to Long and McDevit is determined only by internal interactions of the non-electrolyte molecules. If the difference between $s^0_{ne}$ and $s_{ne}$ is not large Eqn. (18) becomes identical to Sechenov's Eqn. (1). The Sechenov equation is often obeyed also when the last term of Eqn. (18) is relatively large. The empirical coefficient $K$ of Eqn. (1) is not equal to the theoretical coefficient $K_e$ of Eqn. (18). Experimental studies of the solubility of non-electrolytes give $K_e$ values. However we need to know also $K_{ne}$ in order to calculate the activity coefficients of non-electrolytes having intermediate or high solubility. Eqn. (15) makes fuller allowance than Eqn. (18) for the effects of various factors on the salting-out process.

Givon and coworkers[12] further developed the ideas of Debye and McAuley. They obtained, by a series expansion, an approximate value of the integral in Eqn. (12) between the limits 0 and the radius of the hydrated electrolyte ion. Assuming that $K = \lim_{c_e \to 0}\dfrac{d\lg f_{ne}}{dc_e}$, and that the solubility of the non-electrolyte is much greater than the concentration of electrolyte (in order to simplify the calculation of the effect of the non-electrolyte on the $\epsilon$ value of the solution), they obtained the following equation as a first approximation (for 25 °C):

$$K = 0.025 z^{5/3} V^{5/6}_{ne}\left(\frac{\delta_e}{V^0_e + 18h^0_e} + \frac{\varepsilon_0 - \varepsilon_{ne}}{1000}\right)^{5/6}, \qquad (19)$$

where $\delta_e$ is the decrement in the dielectric constant of the solvent due to the presence of the electrolyte, $h^0_e$ is the hydration number of the electrolyte at infinite dilution, and $\epsilon_{ne}$ is the dielectric constant of the non-electrolyte.

Eqn. (19) is one of the most accurate equations of the electrostatic theory of salting-out effects of non-electrolytes. All the parameters in the equation can be determined. The $\delta_e$ values for many electrolytes are known,[7,13] and $V^0_e$ and $h^0_e$ values are also available[14,15].

Eqn. (19) correctly predicts an increase of $K$ with increasing charge on the electrolyte ion, with the molar volume of the non-electrolyte, and with the decrement $\epsilon_0 - \epsilon_{ne}$. This equation takes account of the hydration of the electrolyte and also (unlike the Debye–McAuley theory) of the correction $\delta_e$ due to the electrolyte. As a result Eqn. (19) predicts an increase of $K$ with the

decrement in the dielectric constant of the solvent due to the presence of the electrolyte. This prediction agrees with experimental results. Eqn. (19) also allows the possibility of salting in of the non-electrolyte, which occurs when $(\epsilon_0 - \epsilon)/1000$ is negative and greater than $\delta_e/(V_e^0 + 18h_e^0)$ in absolute value. However Eqn. (19) was obtained from an approximate solution of Eqn. (12). Furthermore, several values, differing by 50–70%, have been reported[14,15] for $V_e^0$ and $h_e^0$, suggesting that available data on the hydration of electrolytes have a low precision. A more exact solution of Eqn. (12) and more accurate numerical values of the parameters of Eqn. (19) can be expected to result from a better understanding of the structure of solutions of electrolytes and non-electrolytes.

Frank[16] described a derivation of the basic equation of the electrostatic theory of salting out which is stricter than Debye and McAuley's but equivalent to it. He envisaged the role of the ion as merely to generate an electrostatic field, and he assumed that the non-electrolyte forms an ideal solution. He also assumed that local fluctuations in the concentration of water are negligibly small in comparison to changes in the concentration of the non-electrolyte during salting out, and that the chemical potentials of the electrolyte and of the water are constant. Conway and coworkers[17] calculated the dielectric decrement $\partial\epsilon/\partial c_{ne}$ in Frank's equation in terms of Kirkwood's theory[18] of the polarisation of non-electrolytes in polar liquids:

$$\left(\frac{\partial\varepsilon}{\partial c_{ne}}\right)_{T,p,n_w} = \frac{9}{2}P_{ne} - V_{ne}\varepsilon_0, \qquad (20)$$

where $n_w$ is the number of water molecules in 1 ml of solution, and $P_{ne}$ is the total molecular polarisation of the non-electrolyte.

The integral form of the Frank–Conway equation is

$$K = \frac{V_e^h}{1000} + \frac{(ze)^2}{2000\varepsilon_0 kT}\left(V_{ne}\varepsilon_0 - \frac{9}{2}P_{ne}\right)\left(\frac{1}{r_h} - \frac{1}{r_n}\right), \qquad (21)$$

where $k$ is Boltzmann's constant.

In the case of non-polar non-electrolytes the quantity $\frac{9}{2}P_{ne}$ can be ignored in comparison to $V_{ne}\epsilon_0$.[16] We then have

$$K = \frac{V_e^h}{1000} + \frac{(ze)^2 V_{ne}}{2000\varepsilon_0 kT}\left(\frac{1}{r_h} - \frac{1}{r_n}\right). \qquad (22)$$

$V_e^h$ can be evaluated by the equation[19]

$$V_e^h = V_e + hv_s^h. \qquad (23)$$

Where $V_e$ is the intrinsic molar volume of the electrolyte, $h$ is the hydration number of the ion pair, and $v_s^h$ is the molar volume of the solvent in the hydration shell of the electrolyte. Formulae for the calculation and for the experimental determination of $V_e$, $h$, and $v_s^h$ are given in Ref. 19.

However Conway and coworkers[17] in their derivation of the integral equation for $K$ failed to take account of the dielectric decrement of the electrolyte. They also carried out the integration in two steps (from the crystal-chemical radius $r$ to $r_h$, and from $r_h$ to $r_n$) because of the difference in dielectric saturation between these two regions. However the maximum of the integrand was not always found at a distance $r_h$ from the centre of the ion: its position is a function of the nature of the electrolyte and of the non-electrolyte. Because of these simplifications the $K$ values calculated by Eqn. (21) differ significantly from experimental values: for example the discrepancy for the noble gases is at least 50%.[17]

According to Kirkwood's theory[18] the parameter $P_{ne}$ in Eqn. (21) is

$$P_{ne} = \frac{4}{3}\pi N[\alpha_0 + (n^2+2)\mu_0^2/27kT], \qquad (24)$$

where $\mu_0$ is the dipole moment of the non-electrolyte in the gaseous state, $\alpha_0$ is its polarisability, and $n$ is the refractive index. The value of the parameter $P_{ne}$ in the quantitative treatment of salting-in and salting-out phenomena is demonstrated by the good correlation between the $K$ and $\mu_0$ values of different types of non-electrolyte (Table 1).

**Table 1.** Dipole moments and salting-out coefficients of various non-electrolytes in KCl.[4]

| Non-electrolyte | $K$, litre mole$^{-1}$ | $\mu_0$, D | Non-electrolyte | $K$, litre mole$^{-1}$ | $\mu_0$, D |
|---|---|---|---|---|---|
| $O_2$ | 0.132 | 0.0 | $NH_3$ | 0.057 | 1.4 |
| $H_2$ | 0.102 | 0.0 | HCN | 0.006 | 2.7 |
| $N_2O$ | 0.099 | 0.1 | $SO_2$ | −0.022 | 1.7 |
| $CO_2$ | 0.072 | 0 0 | $NH_4NO_3$ | −0.070 | 3.6 |
| $H_2S$ | 0.067 | 1.0 | | | |

Conway and coworkers[17] have proposed and experimentally confirmed an expression for the quantity $V_e^h$ in Eqns. (21) and (22). The expression was derived from "free-water" considerations adopted from the hydration theory: it can be written

$$V_e^h = \frac{18h_e^n}{1000d - mM}, \qquad (25)$$

where $h_e^p$ is the primary hydration number of the electrolyte, $m$ is the molarity and $d$ is the density of the electrolyte solution, and $M$ is the molecular weight of the electrolyte.

Cohn and Edsell[11] obtained an expression for $P_{ne}$ different from Eqn. (24):

$$P_{ne} = 4\pi N\mu_0^2/9kT. \qquad (26)$$

Using Eqn. (26) they arrived at the following expression for the dielectric decrement of the non-electrolyte:

$$\delta_{ne} = \frac{V_{ne}(\varepsilon_1 - j)}{\varepsilon_0} - \frac{hP_{ne}}{1000\varepsilon_0}. \qquad (27)$$

Cohn and Edsell combined Eqn. (27) with the Debye–McAuley equation (6) in order to facilitate the application of the latter in practical calculations.

Kirkwood's electrostatic theory of the salting-out effect[20,21] is based on the polarisation of the non-electrolyte in solutions of electrolytes. Using his theory[18] of the polarisation of non-electrolytes in polar liquids, Kirkwood calculated the total electrostatic energy of a spherical ion and a neutral molecule, and obtained the following expression for the activity coefficient of the non-electrolyte in an electrolyte solution:

$$\ln f_{ne} = \Sigma K_e z^2 c_e. \qquad (28)$$

The quantity $K_e$ in Eqn. (28) is defined by the expression

$$K_e = \frac{2\pi Ne^2}{2.303\varepsilon_0 kT}\left[\frac{3\mu_0^2}{2\varepsilon akT} - \frac{r_{ne}^3\Gamma(\rho)}{a}\right], \qquad (29)$$

where

$$\Gamma(\rho) = \frac{1}{3\rho^4}[(\rho^3-2)\lg(1+\rho) - (\rho^3-2)\lg(1-\rho) - 2\rho^2], \qquad (D)$$

$$\rho = r_{ne}/a,$$

$a$ is the distance of closest approach between the non-electrolyte molecule and the electrolyte ion, and $r_{ne}$ is the radius of the non-electrolyte molecule.

The salting-out coefficients calculated by Kirkwood's equation (29) agree better with experiment than those calculated by either the Debye–McAuley or the Debye theory. However even the $K$ values given by the Kirkwood equation differ from the experimental values by much more than the experimental error.

Long and McDevit, in an attempt to allow for the Van der Waals forces in the salting-out effect, obtained the equation[4]

$$\lg f_{ne} = A\Sigma z^2 c_e - B\Sigma\alpha_e c_e, \qquad (30)$$

where $A$ and $B$ are parameters depending on the non-electrolyte and (to a lesser extent) on the electrolyte, and constant to a first approximation for a series of similar electrolytes (e.g. halides); $\alpha_e$ is the polarisability of the electrolyte ion. The first term of Eqn.(30) depends on the ion–molecule interaction, the second term depends on the Van der Waals' forces between water molecules opposing the replacement of water molecules by electrolyte ions. The constancy of $A$ and $B$ implies that the distance of closest approach between ions and molecules must be similar to the distance of closest approach between ions.

Bockris and coworkers[22] allowed for the effect of dispersion forces by using the London formula[23] for the dispersion potential, and obtained the equation

$$\frac{\Delta s_{ne}}{s^0_{ne}} = \left(P_{ne} - P_w\frac{V_{ne}}{V_w}\right)\frac{2\pi Ne^2}{1000\varepsilon^2 kT}\sum\frac{z^2c_e^2}{r_i} + \left(\frac{\alpha_{ne}\nu_{ne}}{\nu_{e\pm}+\nu_{ne}} - \frac{\alpha_w\nu_w}{\nu_{e\pm}+\nu_{ne}}\cdot\frac{V_{ne}}{V_w}\right)\frac{2\pi N\hbar}{1000\varepsilon kT}\sum\frac{\alpha_e\nu_{e\pm}c_e}{r_i^3}, \qquad (31)$$

where $\nu_{ne}$ and $\nu_e^{\pm}$ are the characteristic frequencies of the non-electrolyte and of the electrolyte respectively, $\alpha_{ne}$ is the polarisability of the non-electrolyte, $\hbar$ is Planck's constant, and $P_W$ is the molar polarisation of water. Eqn.(31) is generally similar to Eqn.(30), but in Eqn.(31) the second term, which determines the salting-in effect, is much less sensitive to the nature of the electrolyte and of the non-electrolyte than is found in practice. This is because of the approximation used in Eqn.(31) for the distance of nearest approach (taken as the ionic radius $r_i$ rather than the sum of the radii of the ion and of the neutral molecule). In practice the factor $r_i^3$ nullifies the attempt to allow for the change in polarisability of the ions, and as a result the theory predicts far less specificity in the effect of various ions on salting out and salting in than is found in practice. However the theory does predict the experimentally observed salting in of non-electrolytes by large ions such as tetra-alkyl-ammonium ions.

Neither the Kirkwood theory[20,21] nor the equations of Long and McDevit[4] [Eqn.(30)] and of Bockris and coworkers[22] [Eqn.(31)] can explain the anomalously small salting out observed in the presence of electrolytes containing $H^+$ or $Li^+$ cations. Because of these shortcomings, and of their theoretical limitations pointed out above, Eqns.(28)–(31) cannot be said to give an adequate representation of the role of dispersion forces in the salting out and salting in of non-electrolytes.

Danckwerts[24] has suggested the use of salting-out coefficients in conjunction with the Henry constants of the non-electrolytes in water ($He^0$) to calculate the Henry constants of gaseous non-electrolytes in solutions. He obtained an equation similar in form to the Sechenov equation (1) and to the empirical Debye–McAuley equation (9):

$$\lg\frac{He}{He^0} = K\mu. \qquad (32)$$

The salting-out coefficient in Eqn.(32) is defined as

$$K = h_+ + h_- + h_g, \qquad (33)$$

where $h_+$ and $h_-$ are constants relating to the cation and the anion of the electrolyte (litre g-ion$^{-1}$), and $h_g$ is a constant relating to the gaseous non-electrolyte (litre mole$^{-1}$).

Danckwerts considers that the change in $K$ with temperature is due entirely to the change in $h_g$ with temperature. Values of $h_g$ for hydrogen, oxygen, carbon dioxide, hydrogen sulphide, ammonia, and sulphur dioxide are given in Ref. 24 together with $h_+$ and $h_-$ values for a large number of ions. However Danckwerts does not give any theoretical justification of Eqn.(33), which is merely a sum of empirical constants for the electrolyte and the non-electrolyte and therefore cannot be reconciled with any of the theories of salting out and salting in. Furthermore Danckwerts does not state the considerations used in selecting values for the $h_+$, $h_-$, and $h_g$ constants for different ions and non-electrolytes.

## IV. THE "EFFECTIVE PRESSURE" THEORY

As its name implies, this theory treats the salting out and salting in of non-electrolytes as a consequence of the internal pressure generated in solutions of electrolytes by the electrostatic interaction between electrolyte and solvent.

Geffcken[25], and later Tammann[26], established a correlation between salt effects in solutions and the relative effects of salts on the compressibility of solutions. On the basis of this work McDevit and Long[27] developed the "effective pressure" theory of salting out and salting in of non-electrolytes. They derived an expression for $K$ by considering the electro-striction effect resulting from the interaction between electrolyte and solvent following the addition of an electrolyte to a solution of a non-polar non-electrolyte. This effect gives rise to an effective pressure $p_e$ within the solution which tends to eject the non-electrolyte molecules from the solution because they are non-polar and they oppose the electrolyte–solvent interaction. Thus according to the "effective pressure" theory the salting in or salting out of a non-electrolyte is determined by the extent to which the solution is compressed or dilated by the addition of the electrolyte.

McDevit and Long based their quantitative conclusions on a calculation of the change in free energy attending the transfer of the non-polar non-electrolyte from water to the electrolyte solution. They found that the change in free energy of the non-electrolyte due to this process is $p_e V_{ne}$, and they obtained the following theoretical equation for $K$ [27]:

$$K = \lim_{c_e\to 0}\frac{V^0_{ne}}{2{,}3RT}\cdot\frac{dp_e}{dc_e} = \frac{V^0_{ne}(V^g_e - V^0_e)}{2.3\beta_w RT}, \qquad (34)$$

where $V^0_{ne}$ is the partial molar volume of the non-electrolyte at infinite dilution in the solution, $V^g_e$ is the hypothetical molar volume of the pure supercooled electrolyte in the liquid state, and $\beta_W$ is the compressibility of water.

The McDevit–Long equation (34) predicts an increase of $K$ with increasing molar volume of the non-electrolyte at infinite dilution. The main advantage of the "effective pressure" theory is its ability to account for

salting in in terms of the properties of the electrolyte only, in keeping with experimental results. According to Eqn. (34) salting in of non-electrolytes occurs when the difference ( $V_e^g - V_e^0$) for the electrolyte is negative.

The $K$ values for a range of structurally different non-electrolytes (hydrogen, oxygen, nitrogen dioxide, benzene) in the same electrolytes are very similar [4]. Hence we may conclude that salting-out and salting-in effects are far more sensitive to the properties of the electrolyte in solution than to the nature of the non-electrolyte or its interaction with the solution. This conclusion is implicit in Eqn. (34), according to which the salting in and salting out of the non-electrolyte is determined mainly by the ion–solvent interaction and by the effect of this interaction on the volume difference $V_e^g - V_e^0$. Values of $V_e^g$ for various electrolytes are given in Ref. 28.

When the electrolyte is added to the water the primary effect is the attraction of the water dipoles towards the electrostatic field of the ions. At ordinary temperatures most of the water molecules are in a quasi-crystalline state with an open structure, and when the water dipoles are attracted towards the field of the ions the rearrangement of this open structure to give a more closely packed structure around the ions is primarily responsible for the compression effect. If the size of the ions added to the solution is increased the electro-striction of the solution decreases for two reasons. Firstly, the electrostatic field of the ion decreases with increase in the ionic radius, and its effect on the breakdown of the water structure is less marked (decrease in the structure factor). Secondly, water molecules are replaced by ions (replacement factor). If the electrolyte ions had been uncharged spheres the replacement would have led to a decrease in the breakdown energy of the system accompanied by an increase in volume. Both the structure factor and the replacement factor make a large contribution to the decrease in the difference $V_e^g - V_e^0$ with increasing size of the electrolyte ion. The "effective pressure" theory indicates that the difference $V_e^g - V_e^0$ may become negative as the influence of both these factors increases, leading to salting in of the non-electrolyte.

The salting-out effects of the very small hydrogen and lithium ions are not quantitatively consistent with the small size of these ions, suggesting that the quasi-crystalline structure of water is stabilised rather than broken down by hydrogen and lithium ions [4]. One possible explanation is that these ions are incorporated in the water structure in sites normally occcupied by hydrogen atoms. The result is the formation of electrostatic bridges between the oxygen atoms of the water molecules, with an energy comparable to the energy of the hydrogen bond [4].

The electrostatic theories of salting in and salting out ignore the structure factor and the replacement factor, which depend on the size of the electrolyte ion. Hence these theories give best results when these terms are small (e.g. in solutions of sodium or potassium chloride [4]).

Gibson showed [29] that the linear plots of $p_e$ against $c_e$ and of lg ($s_{ne}^0/s_{ne}$) against $c_e$ lie in the same relative sequwnce, indicating a common underlying cause. This observation confirms that the "effective pressure" theory offers, on the whole, a correct description of the main features of the salting out and salting in of non-electrolytes.

One weakness of this theory is its failure to allow for the non-electrolyte–solution interaction of a given non-electrolyte in different electrolytes. Furthermore, the value of Eqn. (34) for calculating $K$ is doubtful as long as published values of $V_e^g$ remain scarce and inaccurate.

## V. EFFECT OF TEMPERATURE ON SALTING OUT AND SALTING IN OF NON-ELECTROLYTES

Experimental and theoretical studies of the effect of temperature on the salting out and salting in of non-electrolytes began in 1907. [30] Changes in temperature affect the state of all three components of the non-electrolyte–electrolyte–solvent system. Ion hydration decreases as the temperature increases. At the same time the energy needed to break down the structure of pure water decreases, and exothermic effects in concentrated solutions (formation of ion pairs and of undissociated molecules of electrolyte) also decrease. It was pointed out [31] that the enhanced translational motion of the water and mobility of the electrolyte ions at elevated temperatures may even convert the positive hydration of the ions into negative hydration. Simultaneously, the solubility of the non-electrolyte decreases, both in water and in the electrolyte solution.

Because so many parameters of the three-component system are affected by temperature changes, the theoretical interpretation of the effect of temperature on the salting out and salting in of non-electrolytes is a complex problem. The temperature coefficient of the quantity $\ln (f_{ne}/f_{ne}^0)$ can be obtained (as first pointed out by Rothmund [30]) by differentiating the Gibbs–Helmholtz equation:

$$\Delta G_{ne}^0 = \Delta H_{ne} - T\Delta S_{ne} = RT \ln \frac{f_{ne}}{f_{ne}^0}, \qquad (35)$$

where $\Delta G_{ne}^0$ is the change in standard free energy of the non-electrolyte attending the transfer of one mole of non-electrolyte dissolved in water into the electrolyte solution. From Eqn. (35) Rothmund obtained [30] the following expression for the temperature coefficient of $\ln (f_{ne}/f_{ne}^0)$:

$$\frac{d\left(\ln \frac{f_{ne}}{f_{ne}^0}\right)}{dT} = -\frac{\Delta H_{ne}^0}{RT^2}. \qquad (36)$$

He also derived the equation

$$\frac{d\left(T \ln \frac{f_{ne}}{f_{ne}^0}\right)}{dT} = -\frac{\Delta S_{ne}^0}{R}. \qquad (37)$$

In Eqns. (36) and (37) $\Delta H_{ne}^0$ and $\Delta S_{ne}^0$ are the changes in standard enthalpy and entropy of the non-electrolyte when 1 mole (dissolved in water) is transferred to the electrolyte solution at the same temperature.

Frank and Evans [32] obtained an expression for $\Delta S_{ne}^0$ during the transfer of the non-electrolyte from water into the solution of electrolyte:

$$\Delta S_{ne}^0 = -\left(\frac{\partial \Delta G_{ne}^0}{\partial T}\right)_{p_{ne} m_{ne}} = R \ln f_{ne} + RT \left(\frac{\partial \ln f_{ne}}{\partial T}\right)_{p_{ne} m_{ne}}, \qquad (38)$$

where $p_{ne}$ is the partial pressure of the gaseous non-electrolyte (atm) and $m_{ne}$ is the molar concentration of the non-electrolyte.

Using the Debye–McAuley electrostatic theory Frank and Evans derived the expression [32]

$$\Delta S_{ne}^0 = -RT \ln f_{ne} \left(\frac{\partial \ln \varepsilon_0}{\partial T} - \frac{\partial \ln \delta_{ne}}{\partial T} + \frac{\partial \ln b}{\partial T} + \frac{\partial \ln V}{\partial T}\right), \qquad (39)$$

where $V$ is the volume of the solution.

If the internal interactions of the non-electrolyte molecules are negligibly small, or if the solubility of the

non-electrolyte is very low, Eqn.(18) becomes similar to Eqn.(1) and we can write

$$\lg \frac{s^0_{ne}}{s_{ne}} = \lg \frac{f_{ne}}{f^0_{ne}} = Kc_e. \quad (40)$$

Combining Eqns.(36), (37), and (40) we can evaluate $dK/dT$ from the known quantities $\Delta H^\circ_{ne}$ and $\Delta S^\circ_{ne}$. This is because the difference between $s^0_{ne}$ and $s_{ne}$ is small and the internal interactions of the gaseous non-electrolyte molecules can be ignored.

The heat of dissolution of the non-electrolyte in a given solution of electrolyte can be calculated from solubility data at different temperatures. We use an equation analogous to the Clapeyron–Clausius equation

$$\frac{d \ln s_{ne}}{d(1/T)} = -\frac{\Delta H_{ne}}{R}, \quad (41)$$

where $\Delta H_{ne}$ is the heat of dissolution of the non-electrolyte. $\Delta H_{ne}$ is given by the slope of a plot of ln $s_{ne}$ against $1/T$.

On general grounds we would expect $dK/dT$ to be negative, since the properties of solutions tends towards ideality on raising the temperature, and ideal solutions do not exhibit salting-out effects. Negative temperature coefficients of $K$ were indeed obtained by Long and McDevit[4] for nitric oxide in various electrolytes, and by Yatskovskii [33] and by David and coworkers [34] for oxygen in KOH solutions. Knaster [35] found that in KOH solutions the temperature coefficient of $K$ is negative for oxygen and positive for hydrogen, but this discrepancy is neither discussed nor explained by Knaster [35].

Morrison has pointed out [36] that the Debye–McAuley equation (10) cannot give a negative value of $dK/dT$, since the product $\epsilon_0 T$ in Eqn.(10) decreases as the temperature increases. However the parameter $\delta_{ne}$ in the same equation should also change with temperature, but there are no data on the sign and magnitude of this change.

An expression for $dK/dT$ for non-polar, gaseous non-electrolytes (oxygen, hydrogen, methane, ethane, etc.) was obtained[4] by differentiating the McDevit–Long equation (34):

$$\frac{dK}{dT} = -\frac{V^0_{ne}}{2.3\beta_\infty RT^2} \cdot \frac{dV^0_e}{dT}. \quad (42)$$

Values of $dV^0_e/dT$ for various gases and electrolytes are given in Refs. 37 and 38. However no experimental test of Eqn.(42) has yet been reported.

Knaster [35] combined the Sechenov equation with the thermodynamic equation for the temperature dependence of the solubility of gases in water and in electrolyte solutions, and obtained the expression

$$K = A' + \frac{B'}{T}, \quad (43)$$

where $A'$ and $B'$ are temperature-independent constants:

$$A' = \frac{\Delta S^1_{ne} - \Delta S^2_{ne}}{2.303 c_e R}, \quad (44)$$

$$B' = \frac{\Delta H^1_{ne} - \Delta H^2_{ne}}{2.303 c_e R}. \quad (45)$$

In these equations $\Delta S^1_{ne}$ and $\Delta S^2_{ne}$ are the entropy changes of the non-electrolyte when dissolved in water and in the electrolyte respectively for the same activity of non-electrolyte in the gas phase; $\Delta H^1_{ne}$ and $\Delta H^2_{ne}$ are the corresponding enthalpy changes of the non-electrolyte.

Eqn.(43) is obeyed up to 7 $N$ concentration of KOH in the salting out of hydrogen from KOH solutions [35]. The constants $A'$ and $B'$ in this equation are determined (for a given electrolyte and non-electrolyte) by using two known values of $K$ for a non-electrolyte in the electrolyte of interest.

Thus both Eqns.(36), (37) and Eqn.(43) for $dK/dT$ require a separate experimental determination of the relevant thermodynamic quantities (the enthalpy and entropy of dissolution of the non-electrolyte). This is because of the inadequacy of the existing theory of solutions, which does not provide an analytic expression for calculating the change in entropy and enthalpy of gases dissolved in water and in electrolyte solutions.

The $K$ values of highly soluble non-electrolytes are much more sensitive to temperature than those of sparingly soluble non-electrolytes such as non-polar gases [4]. $K$ usually changes in the same sense as the solubility of non-electrolytes in water [36]. For readily soluble non-electrolytes the quantity $K_{ne}(s_{ne} - s^0_{ne})$ in Eqn.(18) changes significantly with temperature even if $K$ is practically temperature-independent, because of the strong temperature dependence of the solubility of the non-electrolyte. As a result $K_{ne}(s_{ne} - s^0_{ne})$ can change sign, and salting in of the non-electrolyte occurs instead of salting out.[36].

Experimental information on the effect of temperature on the salting-in and salting-out behaviour of non-electrolytes is still scarce, and the development of a theory of this effect is shown by our review to be only in its initial stages.

## VI. EXPERIMENTAL DATA. COMPARISON OF THEORY AND EXPERIMENT

A large body of experimental information on the salting out and salting in of gaseous non-electrolytes in aqueous solutions of electrolytes is available in the published literature. The data appear either as salting-out coefficients or, more often, as tabulations of the solubility of the non-electrolyte for different concentrations of electrolyte.

Salting-out coefficients and solubilities in various electrolytes have been reported for oxygen[4,25,33,34,37,39-45], hydrogen [4,33,41-43,45], carbon dioxide [45,46], hydrogen sulphide [47], and ethylene [45]. Some of the other published data on the salting out of gaseous non-electrolytes are fragmentary and unsystematic, and their reliability is doubtful. The salting-out coefficients for oxygen, hydrogen, carbon dioxide, hydrogen sulphide, and ethylene quoted in the above references or calculated from the published data on the solubility of these gases are listed in Tables 2 and 2'.

The salting-out and salting-in effects of oxygen and hydrogen in solutions of acids, salts, and bases with cations from Group Ia of the Periodic Table have been investigated most fully. In some cases there are discrepancies between the $K$ values reported by different workers or calculated from the published solubilities of the gaseous non-electrolytes. Occasionally the discrepancy between $K$ values from different sources reaches 50–60%.

The solubility of non-electrolytes at different concentrations of electrolytes has been measured[4,25,33,34,37,39-47] by different methods, but the precision of the concentration measurements (2–5%) is quoted in only five of the fourteen papers [33,34,40,41,44]. Only three of these [34,41,44] include evidence that the equilibrium concentration (solubility)

of the non-electrolyte was measured, i.e. that the non-electrolyte had come to equilibrium with the electrolyte solution.

Table 2 shows that the agreement between the salting-out coefficients reported by different workers for oxygen and hydrogen in solutions of electrolytes with cations from Group Ia is usually better than 5%. We may conclude that the published $K$ values for oxygen and hydrogen in these electrolytes are reliable.

Differences between experimental $K$ values for hydrogen in excess of 100% (see Tables 2 and 2′) are found only in solutions of $CaCl_2$, $AlCl_3$,[42,45] and $MgSO_4$.[43,45] These results are unacceptable, particularly since neither the experimental method of measuring the solubility of hydrogen nor the magnitude of the measurement error is mentioned in those papers[42,43,45].

Because of the small number of publications on the salting-out and salting-in behaviour of carbon dioxide, hydrogen sulphide, and ethylene, a discussion of the consistence and reliability of the data (Tables 2 and 2′) is not justified.

The theories of salting out and salting in of non-electrolytes discussed above differ very substantially in their treatment of the phenomenon. Hence a comparison of the theoretical $K$ values for oxygen and hydrogen with experimental data should provide a reliable criterion of the relative success of the various theoretical treatments.

It is evident from our view of the existing theories that a strict thermodynamic theory of the salting in and salting out of non-electrolytes is not available at present. Hence we cannot expect full agreement between theory and experiment. Furthermore, some of the physicochemical quantities which appear in the theoretical equations are not known with high precision, and therefore any observed discrepancy between theory and experiment cannot be ascribed wholly to inadequacies of the theory.

The salting-out coefficients for oxygen in electrolyte solutions calculated by various theoretical equations are listed in Table 3. The ionic radius $b$ which appears in formula (10) was calculated (for a 1–1 electrolyte) by the expression

$$b = r_a + r_c,$$

where $r_a$ and $r_c$ are the radii of the hydrated anion and cation.

For polyvalent electrolytes the ionic radius was determined as suggested by Debye and McAuley[5] by formula (8); the hydrated ion radii for $Li^+$, $Na^+$, $K^+$, $Rb^+$, $Cs^+$, $F^-$, $Cl^-$, $Br^-$, and $I^-$ were taken from Ref. 48, those for $H^+$, $Mg^{2+}$, $Ca^{2+}$, $Ba^{2+}$, $OH^-$, $NO_3^-$, $ClO_4^-$, and $SO_4^{2-}$ from Ref. 15. The $r_1^h$ value for the $CO_3^{2-}$ ion was taken from Ref. 49.

In the calculation of $K$ by formula (19) we took $V_{ne}$ from Ref. 50, $\delta_e$ from Refs. 8 and 12, $V_e^0$ from Refs. 14, 15, and 51, $h_e^0$ from Refs. 14, 15, 52, and 53, and $\epsilon_{ne}$ from Ref. 54. In the calculation of $K$ by formula (34) $V_{ne}^0$ was taken from Ref. 50 and $(V_e^g - V_e^0)$ from Ref. 27. The $K$ values for hydrogen in electrolyte solutions (Table 4) were calculated with constants taken from the same sources as those for oxygen.

Table 4. Comparison of experimental mean values of $K$ for hydrogen at 25°C with values calculated by formulae (10), (19), (22), and (32), and from Ref. 24.

Inspection of Tables 3 and 4 shows that the agreement between calculated and experimental values of $K$ is best when Eqn. (33) is used to calculate $K$. However, as we have already pointed out, this equation is merely the sum of empirical constants for the electrolyte ions and for the

non-electrolyte which allow the salting-out coefficient to be calculated to some approximation. In the case of 1–1 electrolytes this approximation is adequate both for hydrogen and for oxygen (see Tables 3 and 4). With polyvalent electrolyte solutions Eqn. (33) gives an error approaching 100% in some cases.

Eqn. (34), obtained by the "effective pressure" theory, is the next most succesful. This suggests that the electrostriction of non-electrolyte solutions produced by the addition of electrolytes can adequately account for all the phenomena involved in the salting out and salting in of non-electrolytes in solutions of electrolytes. However the range of application of this equation is limited by the lack of published values of $(V_e^g - V_e^0)$ for many electrolytes, and for the same reason the equation cannot be tested against a comprehensive range of experimental data. The agreement with experimental data is again unsatisfactory when $K$ values are calculated by Eqn. (34) for polyvalent electrolytes.

In all cases, agreement to within 10% between theoretical and experimental values of $K$ was considered satisfactory.

It is interesting to note from Tables 3 and 4 that the fairly complicated equation (19), proposed[12] as an improved expression of the Debye–McAuley electrostatic theory, produces $K$ values for hydrogen and oxygen less consistent with experimental data than the simpler equation (10) of the electrostatic theory. This is because the parameters which appear in Eqn. (19) are not accurately known, published values differing by as much as 50–70%. Under these conditions even the mean of the published values, used in the calculations of $K$ by Eqn. (19), could be seriously in error.

Table 5. Values of $V_e^h/1000$ in Eqn. (22) for different electrolytes.

| Electrolyte | $V_e^h/1000$, litre mole$^{-1}$ | Electrolyte | $V_e^h/1000$, litre mole$^{-1}$ |
|---|---|---|---|
| LiCl | 0.107 | KBr | 0.109 |
| LiBr | 0.097 | KI | 0.096 |
| LiI | 0.089 | RbCl | 0.096 |
| NaF | 0.148 | RbBr | 0.095 |
| NaCl | 0.125 | RbI | 0.090 |
| NaBr | 0.118 | CsCl | 0.094 |
| NaI | 0.110 | CsBr | 0.099 |
| KF | 0.135 | CsI | 0.093 |
| KCl | 0.112 | | |

Eqn. (22), derived from the Frank–Conway electrostatic theory, is difficult to test against experimental data for purely mathematical reasons: the second term of Eqn. (22) depends on the concentration of the electrolyte through the concentration dependence of the radius of the co-ordination sphere $r_n = (3/4\pi n_e)^{1/3}$. Thus the salting-out coefficient given by Eqn. (22) will have different values, according to the concentration of the electrolyte. This is incompatible with the definition of the salting-out coefficient as a constant for a given non-electrolyte in a given electrolyte. But if we assume that the $K$ value given by Eqn. (22) is dominated by the term $V_e^h/1000$, and we calculate $V_e^h/1000$ by formula (23), we arrive at $K$ values for hydrogen and oxygen fairly close to the experimental values. However there can be no doubt that the equation should take account of the specific aspects of the salting-out behaviour of the non-electrolyte, and in this respect Eqn. (22) is practically useless. Calculated values of $V_e^h/1000$ are given in Table 5.

The values of $V_e$, $h$, and $v_s^h$ which appear in Eqn. (23) were taken from Ref. 19. The following approximation is suggested[19] for $v_s^h$:

$$v_s^h = v_s + 2 \text{ ml mole}^{-1},$$

where $v_s$ is the molar volume of the solvent. If the solvent is water $v_s^h = 20$ ml mole$^{-1}$.

The effect of temperature on the salting-out coefficient has been studied only for hydrogen and oxygen in KOH solutions[34,41]. Only the "effective pressure" theory gives an analytic expression for $dK/dT$ [see Eqn. (42)]. However there are no published data on $dV_e^0/dT$ for hydrogen and oxygen in KOH solutions, and without such data the temperature coefficient of $K$ cannot be calculated by Eqn. (42).

We must conclude from this attempt at comparing the various theories of salting out and salting in of non-electrolytes with experiment that none of the present theories gives acceptable agreement with the experimental values for hydrogen and oxygen in all electrolytes. This conclusion is not unexpected, since none of the theories takes account of all the factors which have a bearing on salting out and salting in. However the three main theoretical approaches described in this review have laid the foundations for a generalised thermodynamic treatment of the salting out and salting in of non-electrolytes in solutions of electrolytes. Eqn. (15) is a good example of the adoption by one theory of some aspects of a different theory which approaches the theoretical interpretation of the phenomenon from an entirely different direction[3]: this equation combines the best features of the hydration theory and of the improved Debye–McAuley electrostatic theory.

## VII. USE OF EXPERIMENTAL DATA ON SALTING OUT AND SALTING IN TO DETERMINE SOME PHYSICO-CHEMICAL CHARACTERISTICS OF SOLUTIONS

The activity coefficient is one of the most important characteristics of dissolved substances. The $f_e$ values for electrolytes have been fully investigated up to quite high concentrations. On the other hand, until recently the $f_{ne}$ values could be determined experimentally only by complex laboratory methods requiring high-precision equipment as well as being very time-consuming.

By using the salting-out coefficient of the non-electrolyte in conjunction with Eqn. (40) the $f_{ne}$ values for the non-electrolyte at various electrolyte concentrations can readily be calculated. The use of this equation is justified because the solubility of gaseous non-electrolytes in water and in electrolyte solutions is usually small (~$10^{-3}$ to $10^{-5}$ mole litre$^{-1}$). Since $f_{ne}^0 = 1$ Eqn. (40) can be re-written

$$\lg f_{ne} = Kc_e. \qquad (46)$$

A new electrochemical method has been developed in our laboratory[55] to measure $f_{ne}$ and other physico-chemical properties of three-component solutions (water–electrolyte–gaseous non-electrolyte) by using salting out data for the non-electrolyte. The method is based on the measurement of the limiting diffusion currents for the electrolytic reduction or oxidation of the dissolved non-electrolyte at an electrode separated from the solution by a polyethylene, polypropylene, or Teflon-4 membrane 10–40 μm thick. We have shown[55] that the limiting diffusion current $I_d$ for a dissolved gas on such an electrode is

proportional to the activity rather than to the concentration of the gas in solution:

$$I_d = k_1 a_{ne} = k_1 f_{ne} c_{ne}. \quad (47)$$

If $I_d$ is measured at saturation of the electrolyte solution by the gaseous non-electrolyte we have

$$I_d = k_1 f_{ne} s_{ne}. \quad (48)$$

Since according to Eqn. (1) $s_{ne} = s^0_{ne} - 10^{Kc_e}$, by substituting this expression into Eqn. (48) we obtain

$$f_{ne} = \frac{I_d}{k_1 (s^0_{ne} - 10^{Kc_e})}. \quad (49)$$

The coefficient $k_1$ in Eqn. (49) is determined by measuring $I^I_d$ for a saturated solution of the non-electrolyte in water, for which $s_{ne} = s^0_{ne}$, so that $k_1$ becomes

$$k_1 = I^I_d / s^0_{ne}.$$

From measurements of $I_d$ in non-electrolyte–water–electrolyte solutions we can determine the volume of 1 mole of hydrated electrolyte molecules $V^h_e$. It has been shown[56] that

$$\lg f_{ne} = -\lg (1 - c_e V^h_e). \quad (50)$$

Thus we can calculate the volume of 1 mole of hydrated molecules of the electrolyte in solution by using Eqn. (50) together with the $f_{ne}$ value calculated by Eqn. (49).

By measuring limiting diffusion currents of non-electrolytes in water and in electrolyte solutions saturated with one of the non-electrolytes we can determine the hydration numbers of the electrolytes at different electrolyte concentrations. The method relies on the observation[55] that the $I_d$ values of non-electrolytes at an electrode covered by a membrane are the same in water and in electrolyte solutions of different concentrations if the solvent is saturated with the non-electrolyte. This shows that the $I_d$ value for an electrode of this type is proportional to the activity rather than to the concentration of the non-electrolyte. The activity of the non-electrolyte in the liquid phase is proportional to the partial pressure of the non-electrolyte over the saturated water or electrolyte solution of the non-electrolyte. But since both the water and the electrolyte solutions are saturated with the non-electrolyte at the same partial pressure, the activity of the non-electrolyte is constant.

The number of free water molecules per non-electrolyte molecule ($n^I_w$) in water saturated with the non-electrolyte is given by

$$n^I_w = \frac{c^I_w}{s^0_{ne}} = \frac{c^I_w k_1}{I^I_d}, \quad (51)$$

where $c^I_w$ is the molar concentration of water in the solution of non-electrolyte in water. This quantity is given by

$$c^I_w = c_w - V_{ne}. \quad (52)$$

If we add electrolyte to water saturated with the non-electrolyte to a molar concentration $c_e$ of the electrolyte the number of free water molecules per molecule of the non-electrolyte ($n^{II}_w$) decreases as a result of the hydration of the electrolyte and becomes

$$n^{II}_w = \frac{c^{II}_w - c^h_w}{s^{II}_{ne}} = \frac{(c^{II}_w - c^I_w) k_2}{I^{II}_d}, \quad (53)$$

where $c^{II}_w$ is the molar concentration of water in the water–electrolyte–non-electrolyte solution, $c^h_w$ is the number of moles of water in 1 litre of this solution taken up by the hydration shells of the dissolved electrolyte, $s^{II}_{ne}$ is the solubility of the non-electrolyte in a solution of electrolyte of concentration $c_e$ expressed in mole litre$^{-1}$. Eqn. (53) was obtained by using the expression

$$s^{II}_{ne} = \frac{I^{II}_d}{k_2}.$$

The quantity $c^{II}_w$ in Eqn. (53) is given by

$$c^{II}_w = c_w - V_{ne} - V_e, \quad (54)$$

where $V_e$ is the intrinsic volume of 1 mole of electrolyte.

Since $I^I_d = I^{II}_d$, we obtain from Eqns. (51) and (53)

$$c^I_w k_1 = (c^{II}_w - c^h_w) k_2, \quad (E)$$

or in other words

$$c^h_w = (c^{II}_w k_2 - c^I_w k_1)/k_2. \quad (55)$$

By using Eqn. (55) the hydration number $h_e$ of the electrolyte at the given concentration $c_e$ can easily be determined:

$$h_e = \frac{c^h_w}{c_e} = \frac{c^{II}_w k_2 - c^I_w k_1}{c_e k_2}. \quad (56)$$

The quantities $k_1$ and $k_2$ are calculated from the measured values of $I^I_d$ and $I^I_d$ in water saturated with the non-electrolyte and in the water–electrolyte–non-electrolyte solution. The required values of $s^{II}_{ne}$ are determined from Eqn. (1) using the known salting-out coefficient of the non-electrolyte in the solution of interest.

Ruetschi and Amlie[3] suggested the use of Eqn. (2) of the hydration theory together with their Eqn. (5) to calculate the volume of a mole of hydrated electrolyte molecules ($V^h_e$) and the intrinsic volume of a mole of the electrolyte at infinite dilution. They inserted $s^0_{ne}/s_{ne}$ from Eqn. (5) into Eqn. (2) and, knowing $V^h_e$, they calculated $\nu_e V^0_e$ for KOH. Hence they arrived at the radius $r_h$ of the hydrated KOH molecule, and they obtained a value in good agreement with those reported by other workers. By the same procedure Ruetschi and Amlie calculated $V^0_e$ for HCl, LiCl, NaCl, KCl, NaOH, and KOH. However Eqns. (2) and (5) of the hydration theory of salting out and salting in are only approximate, as was pointed out above, and therefore Ruetschi and Amlie's calculations must also be treated as approximate.

# Computational Procedures for the Determination of the Physical Characteristics of Polymers

A.A.Askadskii

Methods are described for the calculation of the principal physical characteristics of polymers from data for the chemical structure of the repeating polymer unit. These characteristics include the density, coefficient of thermal expansion, glass point, melting point, refractive index, coefficient of optical sensitivity to stress, and the solubility parameters of low-molecular-weight liquids and polymers. A consistent relation between these characteristics and the chemical structure of polymers has been traced.
The bibliography includes 27 references.

## I. INTRODUCTION

As a consequence of the extension of the range of chemical substances involved in polymerisation and polycondensation processes, the problem of the synthesis of polymers with specified properties has now become even more acute. Such properties include the glass point, the density, the coefficient of volume expansion, the refractive index, etc. The solution of the problem associated with the solubility of the polymer in a particular solvent is particularly important. The above properties of polymers are the most important ones and in many respects they determine the many other properties. It is shown in the present review that all the parameters enumerated above can be determined even before synthesising the polymer solely on the basis of the chemical structure of the repeating unit.

We shall examine primarily problems associated with the packing of macromolecules in monolithic polymeric materials and with the calculation of their densities.

## II. THE PACKING OF MACROMOLECULES AND THE DENSITIES OF POLYMERS

The packing coefficient $k$, which is defined as the ratio of the van der Waals volume of atoms and groups of atoms in the molecule to the true volume determined from experimental data, serves as a measure of the packing density of the macromolecules[1-3]. The calculation of the packing coefficients of molecules is usually based on the molar volumes of the repeating units. Then

$$k = \frac{N_A \sum_i \Delta V_i}{M/d}, \qquad (1)$$

where $\Delta V_i$ are the increments of the van der Waals volumes of the atoms in the repeating unit of the polymer, $m$ the molecular weight of the repeating unit, $d$ the density of the polymer, and $N_A$ the Avogadro number. In order to evaluate the packing coefficients $k$, the volume increments $\Delta V_i$ for a large number of atoms, linked by valence bonds with a wide variety of other atoms, have been calculated in a number of studies[1-8]. Since the values of $\Delta V_i$ will be convenient subsequently for the calculation not only of the densities but also of other properties of polymers, a detailed table of their values is included (Table 1).

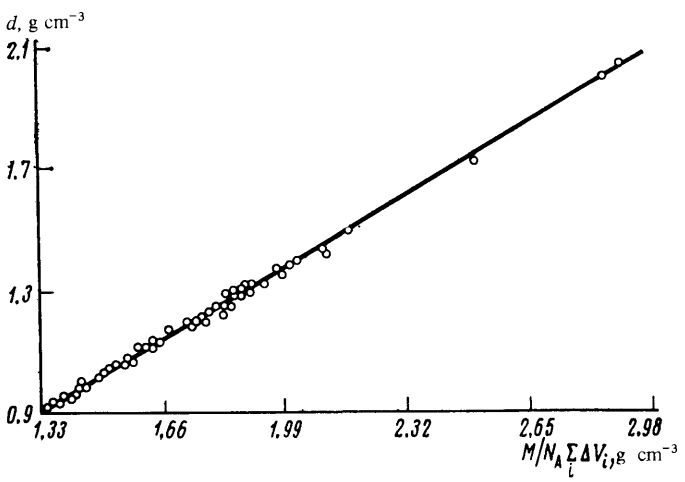

Figure 1. Variation of the densities of amorphous and amorphous-crystalline polymers with the ratio $M/N_A \sum_i \Delta V_i$.

In the calculation of the packing coefficients of amorphous monolithic polymers, it was found[2] that, regardless of the chemical structure of the polymers, their packing coefficients are approximately the same and amount to 0.681 at 20°C. In order to demonstrate this experimental finding, Table 2 lists the values of $k$ for a number of amorphous polymers and Fig. 1 illustrates the variation of the densities of polymers having different chemical structures with the ratio $M/N_A \sum_i \Delta V_i$. Evidently this relation is described by a straight line on which the experimental

values of $d$ fit satisfactorily. Its slope is equal to the packing coefficients $k = 0.681$. Since $k$ is to a first approximation a constant for amorphous monolithic bodies, the density of the polymer may be calculated solely from the chemical structure of the repeating unit by the equation

$$d = \frac{k_{av} M}{N_A \sum_i \Delta V_i}, \qquad (2)$$

where $k_{av} = 0.681$.

The calculations[2] have shown that the density of an amorphous polymer may be calculated as a rule to within 0.01 g cm$^{-3}$. Table 3 presents as an example the experimental and calculated densities $d$ at 20°C for representatives of various classes of polymers in the amorphous monolithic state. It can be seen that these agree with adequate accuracy. We may note immediately that the

packing coefficients for crystalline polymers depend significantly on the chemical structure of the polymers and their values lie within very broad limits. It should also be noted that calculations of the densities of polymers have been performed in a study[9] where the increments of the van der Waals volumes obtained by different workers were used.

The packing coefficients of crystalline polymers have been calculated[4] from the crystallographic densities evaluated from the results of X-ray diffraction analysis, namely the unit cell volumes and the masses of the atoms in the unit cell. Calculations were performed for 80 polymeric systems with a wide variety of chemical structures. It was found as a result that crystalline polymers have a very broad distribution curve with regard to the packing coefficients, which depend on the chemical structure of the polymer (Table 4). The distribution curve with respect to the packing coefficients is illustrated in Fig. 2, which also shows an analogous curve for amorphous polymers. It can be seen that the distribution curve with respect to the values of $k$ for amorphous systems is extremely narrow.

Table 4. The packing coefficients $k$ for crystalline polymers.

| Poly(pentamethylene tetramethylene sulphone) | monoclinic | 3.06 | 126.4 | 254 | 0.761 |

*In the crystallographic data [3] for polymers containing the sulphone group, an error was made in the calculation of the density, which is too high by a factor of two.

We shall now consider the temperature variation of the packing coefficient. It was calculated [10] by Eqns. (3) and (4), which follow directly from Eqn. (1):

$$k(T) = \frac{N_A \sum_i \Delta V_i}{MV_g[1 + \alpha_G (T - T_g)]}; \quad T < T_g, \tag{3}$$

and

$$k(T) = \frac{N_A \sum_i \Delta V_i}{MV_g[1 + \alpha_L (T - T_g)]}; \quad T > T_g, \tag{4}$$

where $V_g$ is the specific volume of the polymer at the glass point $T_g$ and $\alpha_G$ and $\alpha_L$ are the coefficients of volume expansion of the polymer below and above the glass point respectively. The calculations carried out using Eqns. (3) and (4) have shown [10] that the temperature variation of the packing coefficients of a number of polymers is of the form shown in Fig. 3. A remarkable properties of these temperature variations is that the packing coefficients are the same to a first approximation for all polymers at any selected temperature below their glass points. To a second, more accurate approximation, the packing coefficient is the same for each polymer at its glass point and amounts to $k_g = 0.667$.

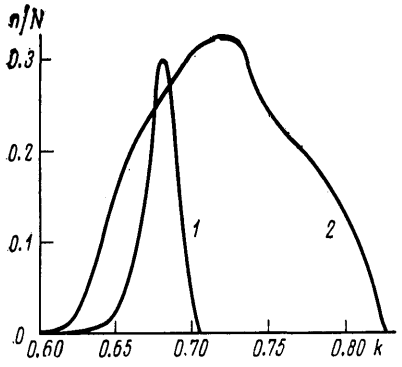

Figure 2. Distribution curves with respect to packing coefficients for amorphous (curve *1*) and crystalline (curve *2*) polymers.

At low temperatures ($T_0 \simeq 6$ K), the packing coefficients of polymers, determined by the extrapolation of the temperature variations of $k$ to $T \to 0$, are also approximately the same and calculations have shown [10] that they can be estimated as $k_0 = 0.731$.

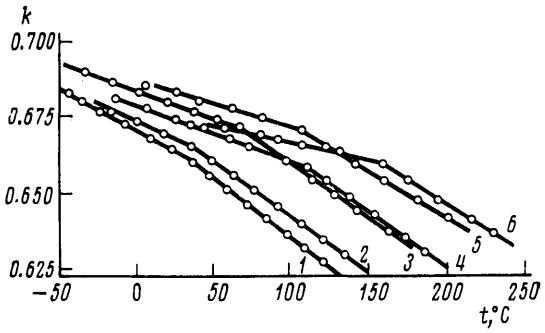

Figure 3. Temperature variation of the packing coefficients of polymers: 1) poly(n-butyl methacrylate); 2) poly(n-propyl methacrylate); 3) poly(ethyl methacrylate); 4) polystyrene; 5) poly(methyl methacrylate); 6) polycarbonate of di-(4-hydroxyphenyl)propane.

## III. CALCULATION OF THE GLASS POINTS, COEFFICIENTS OF THERMAL EXPANSION, AND MELTING POINTS OF POLYMERS

An empirical relation has been proposed [11] whereby one can calculate the glass points $T_g$ of polymers from the chemical structure of the repeating unit of the macromolecule and the density of the polymer:

$$\lg T_g = \frac{d}{M} \sum_i K_i' + A, \tag{5}$$

where $M$ is the molecular weight of the repeating unit, $d$ the density of the polymer, and $\sum_i K_i'$ the effective volume of the repeating unit, which consists of the effective volumes of the atoms and groups of atoms in this unit, and the parameter $A$ is constant for a given class of polymers. Eqn. (5) holds satisfactorily for several classes of polymers (aromatic polyesters and polyamides, polymethacrylates).

Subsequently a more accurate universal computational scheme was proposed [12], which is valid for polymers of different classes. According to this scheme, the glass point is determined from the relation

$$\lg T_g = \frac{\sum_i K_i^*}{N_A \sum_i \Delta V_i} + A^*, \tag{6}$$

where $A^* = 1.435$ for any polymer and $\sum_i K_i^*$ is the effective volume of the repeating unit, differing from $\sum_i K_i'$ in Eqn. (5) by the fact that the values of $K_i^*$ are determined by solving the excess system of equations based on Eqn. (6), which includes the van der Waals volume, while the $K_i'$ are determined by the same procedure on the basis of Eqn. (5), which includes the molar volume.

In order to calculate the glass points of polymers, it is necessary to know the parameters $K_i^*$ characterising the contributions of each atom and type of intermolecular interaction to the glass point. These quantities are listed in Table 5. Knowing them, it is easy to calculate the glass points of many polymers using Eqn.(6).

Table 5. The increments $K_i^*$ for various atoms and types of intermolecular interaction.

| Element or type of interaction | Designation | Value |
|---|---|---|
| Carbon | $K_C^*$ | 10.739 |
| Oxygen in side group | $K_{O,s}^*$ | 3.925 |
| Oxygen in main chain | $K_{O,m}^*$ | −5.244 |
| Hydrogen | $K_H^*$ | −1.248 |
| Hydrogen in side group | $K_{N,s}^*$ | 9.520 |
| Hydrogen in main chain | $K_{N,m}^*$ | 2.185 |
| Chlorine | $K_{Cl}^*$ | 7.242 |
| Silicon | $K_{Si}^*$ | 19.570 |
| Hydrogen bond | $K_h^*$ | 7.333 |
| Dipole-dipole interaction | $K_d^*$ | 7.333 |
| Symmetry coefficient | $K_p^*$ | 10.500 |

Note. The coefficient $K_d^*$ is introduced in all cases when a hydrogen atom is replaced by a group of any type other than phenyl. This rule does not extent to polyisoprene and polychloroprene. When two hydrogen atoms are replaced by identical groups, the quantity $0.5K_d^*$ is introduced. The coefficient $K_p^*$ is introduced when all the aromatic rings in the main chain are substituted in the *p*-position.

Table 6. The increments $a_i$, $b_i$, $\alpha_i$, and $D_i$ for various atoms and types of intermolecular interaction.

| Atom or type of interaction | Designation | $a_i \cdot 10^3$ ($b_i \cdot 10^3$), K$^{-1}$ | $\alpha_i \cdot 10^4$, K$^{-1}$ | $D_i$, kcal mole$^{-1}$ |
|---|---|---|---|---|
| Carbon* | $a_C$ | 0.021 | — | — |
| Hydrogen | $a_H$ | 10.98 | 1.92 | 0.45 |
| Oxygen in main chain | $a_{O,m}$ | 22.95 | 2.21 | 0.39 |
| Oxygen in side chain | $a_{O,s}$ | 7.03 | 0.68 | 1.28 |
| Nitrogen in main chain | $a_{N,m}$ | 8.62 | 0.83 | 1.04 |
| Nitrogen in side chain | $a_{N,s}$ | 6.35 | 0.61 | 1.43 |
| Chlorine | $a_{Cl}$ | 4.01 | 0.39 | 2.25 |
| Sulphur in main chain | $a_{S,m}$ | 3.53 | 0.34 | 2.56 |
| Dipole-Dipole interaction | $b_d$ | −55.37 | — | — |
| Hydrogen bond** | $b_h'$ | −206.78 | — | — |
| Symmetry coefficient*** | $b_h$ | −139.60 | | |
| Coefficient for polydienes taking into account the greater freedom of rotation in the presence of double bonds in the main chain | $b_C$ $b_{=}$ | −90.50 92.22 | | |

*$\alpha_i$ and $1/D_i$ are negligibly small.
**$b_h'$ is introduced for aliphatic polyamides.
***$b_h$ is introduced in all other instances when the polymer contains hydrogen bonds.

Eqn.(6) makes it possible to estimate with adequate accuracy the glass points of polymers, but the physical significance of its parameters has not been established. An attempt was therefore made[10] to construct a computational scheme based on the previously proposed[12] principle of the additivity of the contributions of the individual atoms to the glass point, taking into account the physical ideas concerning volume expansion.

We shall now consider this scheme. According to Eqn. (1), $k_g/k_0 = V_0/V_g$, where $V_0$ is the specific volume of the polymer at the temperature $T_0$. Taking into account this equation, it was found[10] that

$$T_g = \frac{k_0/k_g - 1}{\alpha_G}. \tag{7}$$

The coefficient of volume expansion $\alpha_G$ can be expressed[10] in terms of the equation

$$\alpha_G = \frac{\sum_i a_i \Delta V_i}{\sum_i \Delta V_i} + \frac{\sum_i \beta_i}{\sum_i \Delta V_i}, \tag{8}$$

where $\alpha_i$ is the partial coefficient of volume expansion of the $i$th atom or groups of atoms in the repeating unit of the polymer, $\Delta V_i$ the volume increment of the $i$th atom or atomic group, and $\beta_i$ are increments taking into account the contribution of strong intermolecular interactions to the coefficient of volume expansion (hydrogen bonds, dipole−dipole interaction, etc.; see Table 6).

The initial expression establishing the relation between $T_g$ and the structure of the repeating unit has been obtained[10] by substituting Eqn.(8) in Eqn.(7):

$$T_g = \frac{\sum_i \Delta V_i}{\sum_i a_i \Delta V_i + \sum_i b_i}. \tag{9}$$

where

$$a_i = \alpha_i/(k_0/k_g - 1); \quad b_i = \beta_i/(k_0/k_g - 1). \tag{10}$$

The numerical values of $a_i$ and $b_i$ characteristic of each atom and of each type of intermolecular interaction have been determined[10] by a statistical treatment of the experimental data using the method of least squares. These results are presented in Table 6.

We shall now trace the relation between the coefficient $\alpha_i$ in Eqn.(10) and the intermolecular interaction parameters (the intermolecular bond energy and the distance between the interacting atoms). It is known[13] that the coefficient of volume expansion is described by the expression

$$\alpha_i = 3R\beta_i'/\gamma_i^2 r_{0i}, \tag{11}$$

where $\beta_i' = -\frac{1}{2}\partial^3\varphi/\partial r^3|_{r_{0i}}$ is the anharmonic coefficient, $\gamma_i = \partial^2\varphi/\partial r^2|_{r_{0i}}$ the harmonic force constant, $r_{0i}$ the distance between the given $i$th and neighbouring atoms, $\varphi$ the potential of the interaction of the $i$th atom with a neighbouring atom, and $R$ the gas constant.

When the Lennard-Jones potential is used in the form for the determination of $\beta_i'$ and $\gamma_i$ [14]

$$\varphi(r) = D\left[\left(\frac{r_0}{r}\right)^{12} - 2\left(\frac{r_0}{r}\right)^6\right],$$

where $D$ is the bond energy (the depth of the potential well) and $r_0$ the equilibrium distance between the atoms, then

$$\gamma_i = 72D_i/r_{0i}^2, \quad \beta_i' = 666D_i/r_{0i}^3;$$

or

$$\alpha_i = \frac{7}{16}\cdot\frac{R}{D_i}, \quad D_i = \frac{7}{16}\cdot\frac{R}{\alpha_i}. \tag{12}$$

Estimates of the values of $D_i$ for bonds of different types have shown [10] that the bond energies derived from experimental data correspond to the intermolecular interaction energies (and not to chemical bonds).

Calculations carried out by Eqn.(12) demonstrated [10] that the average bond energies $D_i$ assume the values listed in Table 6. Since, according to the literature [15,16] the bond energies $D_i^0$ for different atoms, included in Table 6, are several times smaller than the observed values of $D_i$, it follows that [10]

$$D_i = zD_i^0, \qquad (13)$$

where $z$ is the coordination number.

Table 7. The calculated and experimental glass points of polymers.

| Polymer | $\sum_i \Delta V_i$, Å³ | $T_g$, K (calc.) | $T_g$, K (expt.) |
|---|---|---|---|
| Polyisoprene | 81.8 | 198 | 200 |
| Polychloroprene | 79.15 | 213 | 225 |
| Polydimethylsiloxane | 72.1 | 150 | 150 |

| Polyarylate of isophthalic acid and phenolphthalein | 388.9 | 522 | 543 |
| Polyarylate of terephthalic acid and phenolphthalein | 388.9 | 594 | 583 |
| Polyarylate of isophthalic acid and phenolphthalein anilide | 470.9 | 532 | 563 |
| Polyarylate of terephthalic acid and phenolphthalein anilide | 470.9 | 593 | 593 |
| Polyarylate of diphenylphthalide-4,4'-dicarboxylic acid phenolphthalein | 571.6 | 581 | 598 |
| Polyarylate of biphenyl-4,4'-dicarboxylic-acid and phenolphthalein | 464.5 | 569 | 603 |
| Polyarylate of isophthalic acid and phenolfluorene | 436.8 | 516 | 543 |
| Polyarylate of biphenyl-4,4'-dicarboxylic acid and phenolfluorene | 512.5 | 558 | 587 |
| Polyarylate of diphenylphthalidedicarboxylic acid and 4,4'-dihydroxybiphenyl | 465.2 | 569 | 585 |
| Polyarylate of oxydi(4-carboxybenzene) and phenolphthalein | 473.8 | 547 | 573 |
| Polyarylate of terephthalic acid and dimethyldian | 367.8 | 412 | 423 |
| Polyamide of terephthalic acid and anilinephthalein imide | 399.6 | 590 | 618 |
| Polyamide of sebacic acid and anilinephthalein imide | 460,7 | 458 | 451 |
| Polyamide of diphenylphthalidedicarboxylic acid and anilinephthalein imide | 582,9 | 637 | 641 |
| Polyimide of the dianhydride of oxydi(3,4-dicarboxybenzene) and anilinefluorene | 537.9 | 640 | 670 |
| Polyimide of the dianhydride of oxydi(3,4-dicarboxybenzene) and anilinephthalein | 490.6 | 658 | 664 |
| Polyimide of the dianhydride of 3,3',4,4'-tetracarboxybiphenyl and anilinefluorene | 530.1 | 669 | 687 |
| Polypyromellitimide of anilinephthalein | 407.2 | 766 | 789 |

The initial Eqn.(9) can then be written in the form

$$1/T_g = 4.55R\left\langle \frac{1}{zD_0} \right\rangle, \qquad (14)$$

where

$$\left\langle \frac{1}{zD_0} \right\rangle = \sum_i \frac{1}{z_i D_i^0} \Delta V_i \Big/ \sum_i \Delta V_i.$$

Eqn.(9) can be used conveniently for the calculation of the glass points of polymers. A test of the applicability of Eqn.(9) has shown [10] that, for many polymers with a wide variety of chemical structures, the calculated and experimental values of $T_g$ agree satisfactorily. These data are compiled in Table 7. Fig.4 illustrates the variation of $T_g$ with $\sum_i \Delta V_i/(\sum_i a_i \Delta V_i + \sum_i b_i)$ for a number of polymers. The figure also includes the theoretical straight line based on Eqn.(9), the points corresponding to the experimental values of $T_g$. Fig.4 shows that Eqn.(9) holds over a very wide range of temperatures. Thus there is a possibility, in principle, of calculating the glass point of a polymer before its synthesis, regardless of the class to which it belongs. It is possible to calculate at the same time the coefficient of volume expansion $\alpha_G$ of the solid amorphous polymer from Eqn.(8). Calculations for a number of polymers showed a satisfactory agreement between the calculated and experimental data (Table 8).

Table 8. The volume expansion coefficients of polymers.

| Polymer | $\sum_i \Delta V_i$, Å³ | $\sum \alpha_i \Delta V_i \cdot 10^4$, Å³K⁻¹ | $\alpha_G \cdot 10^4$, K⁻¹ | |
|---|---|---|---|---|
| | | | calc. | expt. |
| Poly(methyl methacrylate) | 97.0 | 208.5 | 2.15 | 2.73 |
| Poly(ethyl methacrylate) | 114.4 | 314.6 | 2.75 | 2.99 |
| Poly(n-propyl methacrylate) | 131.5 | 414.2 | 3.15 | 3.19 |
| Poly(n-butyl methacrylate) | 148.6 | 564.7 | 3.80 | 3.34 |
| Poly(methyl acrylate) | 79.6 | 214.9 | 2.70 | 3.03 |
| Polystyrene | 109.9 | 274.7 | 2.50 | 2.34 |

We shall now consider how the change in the packing density of the macromolecules on passing from the amorphous to the crystalline state of the polymer affects its melting point. We note first that, according to Beaman's data [17], the ratio of the glass point $T_g$ to the melting point $T_m$ is approximately constant for many polymeric systems and can be estimated as $\gamma = T_g/T_m \simeq 0.67$. However, a detailed analysis [18] showed that this relation does not always hold. The ratio $\gamma = T_g/T_m$ can assume a wide variety of values (ranging from 0.25 to 0.97).

Calculations have shown [4] that $\gamma$ depends on the ratio of the packing coefficients of the fully amorphous and fully crystalline polymers ($k_{am}/k_{cr}$). This dependence is illustrated in Fig.5, from which it follows that $\gamma$ increases approximately linearly with increase of $k_{am}/k_{cr}$. Consequently $\gamma$ depends on the difference between the packing densities of the macromolecules in the amorphous and crystalline states. The greater the increase of packing density on crystallisation of the polymer, the greater the difference between the melting and glass points.

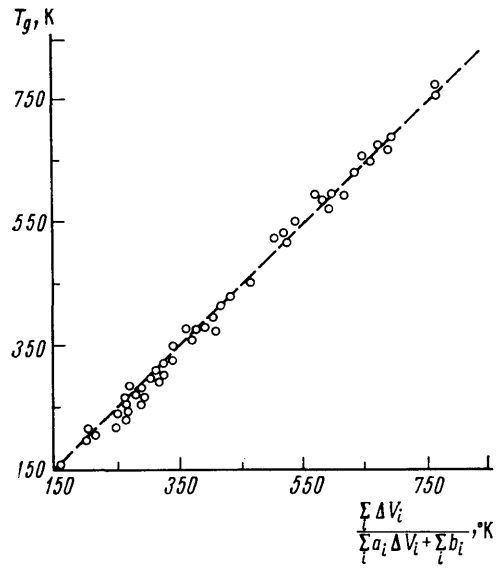

Figure 4. Variation of $T_g$ with the ratio $\sum_i \Delta V_i / (\sum_i a_i \Delta V_i + \sum_i b_i)$.

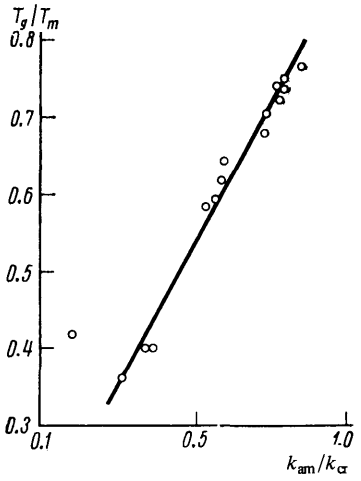

Figure 5. Variation of $T_g/T_m$ with $k_{am}/k_{cr}$.

An attempt has been made [19] to establish a relation between $\gamma$ and the parameters of the chemical structure of the repeating units of the polymer. The approach developed by Askadskii et al. [10] in devising a computational scheme for the estimation of the glass points of polymers was used. The initial relation for the determination of the melting point $T_m$ can be written in the form [19]

$$V_m = V_0[1 + \alpha_{cr}(T_m - T_0)] \approx V_0(1 + \alpha_{cr} T_m), \quad (15)$$

where $V_m$ is the specific volume of the polymer at the melting point, determined by the extrapolation of the dilatometric relation from temperatures $T < T_m$ to $T_m$, $V_0$ the specific volume of the crystalline polymer at the characteristic temperature $T_0$, which is approximately 6 K according to Askadskii et al. [10], and $\alpha_{cr}$ the coefficient of volume expansion of the crystalline polymer in the range of temperatures below the melting point.

Bearing in mind that $V_m/V_0 = k_{0,cr}/k_{m,cr}$, where $k_{0,cr}$ and $k_{m,cr}$ are the coefficients of molecular packing of the crystalline polymer at the temperatures $T_0$ and $T_m$ respectively, we find from Eqn. (15)

$$\frac{T_g}{T_m} = \frac{k_{0,a} - k_{g,a}}{k_{0,cr} - k_{g,a}}. \quad (16)$$

Eqn. (16) was obtained [19] from the familiar experimental observation that the coefficients of volume expansion of amorphous and crystalline polymers having the same structure are virtually identical. The quantities $k_{0,a} = 0.731$ and $k_{g,a} = 0.667$ in Eqn. (16) are constant [10].

Taking into account the additivity of the volume, the packing coefficients of crystalline polymers can be expressed in the form [19]

$$k_{0,cr} = \sum_i \Delta V_i / V = \sum_i \Delta V_i / \sum_i \frac{1}{k_i} \Delta V_i, \quad (17)$$

where $k_i$ is the partial packing coefficient of the $i$th atom, $\Delta V_i$ the increment of the van der Waals volume of the $i$th atom, and $V$ the total volume of the given body.

When account is taken of Eqn. (8), Eqn. (16) becomes

$$\frac{T_g}{T_m} = \left[ \frac{\sum_i \Delta V_i}{\sum_i \delta_i \Delta V_i} - A \right]^{-1}, \quad (18)$$

where

$$A = k_{g,a}/(k_{0,a} - k_{g,a}) = \text{const}, \quad (19)$$

$$\delta_i = (k_{0,a} - k_{g,a})/k_i. \quad (20)$$

Table 9. The parameters $\delta_i$ and $\gamma_i$ for various atoms and types of intermolecular interaction.

| Atom or type of interaction | Designation | $\delta_i$ | $\gamma_i$, Å³ |
|---|---|---|---|
| Silicon | $\delta_{Si}$ | 0.0840 | — |
| Carbon | $\delta_C$ | 0.08685 | — |
| Hydrogen | $\delta_H$ | 0.0740 | — |
| Oxygen in main chain | $\delta_{O,m}$ | 0.0621 | — |
| Oxygen in side chain | $\delta_{O,s}$ | 0.0963 | — |
| Nitrogen in main chain | $\delta_{N,m}$ | −0.0212 | — |
| Dipole-dipole interaction | $\gamma_d$ | — | −0.0727 |
| Hydrogen bond | $\gamma_h$ | — | −0.0188 |

It follows from the computational scheme described that fusion of a crystalline polymer and the transition from the vitreous state to the viscoelastic state occur when the same molecular packing coefficient $k_{g,a} = k_{m,a}$, which is equal to 2/3 for all polymers, is attained. Consequently, the fusion of crystalline and the softening of amorphous polymers of any chemical structure require a definite fraction of the free volume, equal to 0.333. The difference between $T_g$ and $T_m$ (or their ratio $T_g/T_m$) will then be determined by the difference between (or the ratio) of the packing coefficients of the amorphous ($k_{am}$) and crystalline ($k_{cr}$) polymers, which has been demonstrated independently in another study [4].

In order to determine the parameters $\delta_i$,[19] the excess system of equations derived from Eqn.(18) was solved by least squares. The results showed that a satisfactory calculation of $T_g/T_m$ (or $T_m$) requires the introduction of the parameters listed in Table 9. These parameters take into account the influence of the type of atom on the melting point. Knowing the parameters $\delta_i$, it is possible to calculate $T_g/T_m$ (or $T_m$) for a large number of polymers. The results of the analysis showed that the calculated and experimental values of $T_m$ agree as a rule to within 2–3% and that the error reaches a higher value only in a few instances (see Table 10).

Table 10. The melting points $T_m$ of polymers ($T_g$ obtained from dilatometric data).

## IV. OPTICAL PROPERTIES

Among the parameters of the optical properties of polymers, the refractive index $n$ is most important. The relation

$$\frac{n^2-1}{n^2+2}\cdot\frac{N_A\sum_i \Delta V_i}{k_{av}} = R = \sum_i m_i A_i r_i, \qquad (21)$$

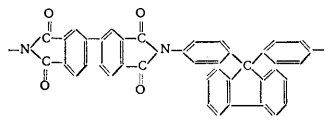
where $k_{av}$ is the average molecular packing coefficient (for monolithic block materials, $k_{av} = 0.681$ and for films, $k_{av} = 0.695$), $R$ the molar refraction, $m_i$ the number of atoms of the $i$th kind in the repeating unit, $r_i$ the specific refraction of atoms of the $i$th kind, and $A_i$ the atomic weight, was derived[20]. It is based on the Lorenz–Lorentz equation and Eqn.(2). The relevant investigation[21] demonstrated a satisfactory agreement between the calculated and experimental refractive indices for aromatic systems (Table 11).

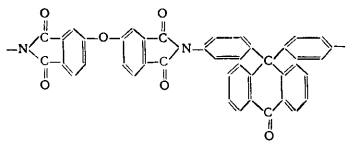
Another important parameter is the coefficient of optical sensitivity to stress $C_\sigma$, which is defined as the proportionality coefficient between the double refraction $\Delta n$ and the stress $\sigma$ responsible for it:

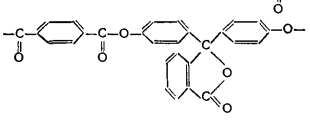
$$\Delta n = C_\sigma \sigma . \qquad (22)$$

The coefficient $C_\sigma$ is extremely sensitive to the chemical structure of the polymer. Heat resistant card polymers are particularly interesting in this respect. It was found[21] that the optical sensitivity of such systems is an order of magnitude higher than the optical sensitivity of all the polymers investigated previously. Table 12 lists the optico-mechanical properties of many polymers.

Table 11. The refractive indices of certain aromatic polymers.







| Structure of repeating unit | Density (calc.), g cm⁻³ | $n$ | |

The elastic mechanical behaviour of vitreous polymers, characterised by the modulus of elasticity $E$ and the glass point $T_g$, can be influenced by two factors—the rigidity of the chains and the intermolecular interaction energy. If the polymer includes groups of the type

which lead to an increase of the skeletal and kinetic rigidity, it has as a rule a high modulus of elasticity.

The high optical sensitivity of these polymers is due to their structure—the presence of a large number of condensed rings, which are characterised by a considerable anisotropy of polarisability. Compounds saturated by nitrogen and sulphur atoms and aromatic rings have the highest values of $C_\sigma$, as can be seen from Table 12.

The optical sensitivity can also be greatly influenced by the type of substitution in the aromatic ring contained in the main chain. Thus a polymer where the aromatic ring in the main chain is substituted in the *p*-position has a higher optical sensitivity than a polymer where the ring is substituted in the *m*-position (see polymers 13 and 17 in Table 12).

The presence of a large number of polar groups leads to a decrease of optical sensitivity. For a given series of polymers, this behaviour is observed in relation to the C=O group. Having a high negative anisotropy of polarisability, it reduces the overall positive effect. The fact that the C=O group is a carrier of the negative effect has also been noted by Bazhenov et al.[21]

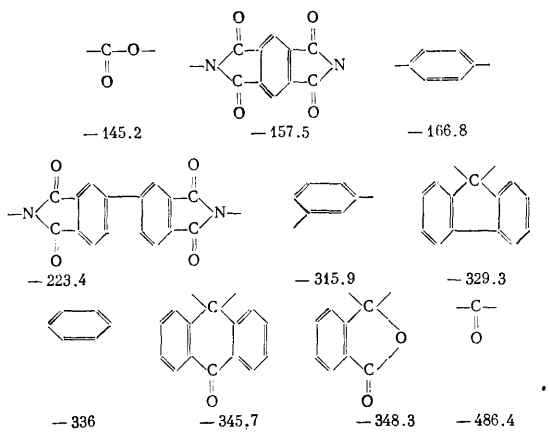
The data compiled in Table 12 show that there is a clearly defined relation between the structure of polymers and their optico-mechanical properties, which can be expressed in quantitative terms[21]. It has been shown[21] that the variation of $C_\sigma$ with the parameters of the structure of the polymer chain can be determined by means of an additive scheme analogous to that used previously[11] to estimate the glass points.

Table 13. The increment $C_i$ for various atoms and types of intermolecular interactions.

| Atom or type of interaction | Designation | Value |
|---|---|---|
| Carbon | $C_C$ | −2.0492 |
| Hydrogen | $C_H$ | −0.5227 |
| Oxygen in main chain | $C_{O,\,m}$ | 3.198 |
| Oxygen in side group | $C_{O,\,s}$ | −0.7568 |
| Nitrogen in main chain | $C_{N,\,m}$ | 7.175 |
| Nitrogen in side group | $C_{N,\,s}$ | 1.303 |
| Chlorine | $C_{Cl}$ | −3.476 |
| Sulphur | $C_S$ | −0.790 |
| Dipole-dipole interaction* | $C_d$ | −2.512 |
| Hydrogen bond in aromatic polyamides | $C_h$ | −6.21 |
| Symmetry coefficient** | $C_n$ | 6.791 |
| Universal parameter | Π | 0.3544 |

*The coefficient $C_d$ is introduced for each polar group of any type; if there are two identical polar groups attached to the same atom, they are counted as one group. When the benzene ring is present in the substituent, the increment $C_{Ph} = -1.70$ is introduced instead of $C_d$.
**The symmetry coefficient is introduced if all the aromatic rings in the main chain are substituted in the *p*-position.

Interpretation of a large amount of experimental data led[21] to a relation between $C_\sigma$ and the parameters of the chemical structure of the repeating unit of the polymer:



$$C_\sigma = \frac{\sum_i C_i}{N_A \sum_i \Delta V_i} + \Pi, \qquad (23)$$

where $C_i$ are increments characterising the contribution of each atom and type of intermolecular interaction to the coefficient of optical sensitivity (see Table 13).

$\Sigma V_i$ is the van der Waals volume of the repeating unit, consisting of the volumes of all the atoms in this unit, and $\Pi = 0.3544 \times 10^{-4}$ cm$^2$ kg$^{-1}$ is a universal parameter.

In order to determine the increments $C_i$, an excess system of equations, derived on the basis of Eqn.(23) for the polymers listed in Table 12, was solved[21] by the method of least squares using the matrix theory. The calculation showed[21] that, for an adequate assessment of the influence of various atoms on $C_\sigma$, it is necessary to know at least 11 increments, which are listed in Table 13.

A test of the validity of Eqn.(23) showed that the calculated values of $C_\sigma$ agree fairly satisfactorily with experimental data (Table 12). A separate calculation demonstrated that $C_{ph} = -1.700 \times 10^{-4}$ for a benzene ring in the side chain. Knowing the numerical values of $C_i$, which are listed in Table 13, it is possible to calculate the values of $C_\sigma$ for polymers incorporating the corresponding atoms. A quantitative estimate of the contribution of each group of atoms to the coefficient of optical sensitivity is also possible on the basis of Eqn.(23). This contribution is characterised by the quantity $\sum_i C_i / N_A \sum_i \Delta V_i$, and, since this ratio is negative, the highest value of $C_\sigma$ corresponds to the smallest absolute value of $\sum_i C_i / N_A \sum_i \Delta V_i$. Individual groups can be arranged in the following sequence in terms of the contribution of the ratio $\sum_i C_i / N_A \sum_i \Delta V_i$ to the coefficient of optical sensitivity (the ratios have been multiplied by $10^7$):

Thus the computational scheme described for the determination of the coefficient of optical sensitivity makes it possible to estimate the expected optical sensitivity of the polymer and has a definite practical value for the synthesis of polymers with specified properties. It is also noteworthy that the high optical sensitivity of thermostable polymers can be of great practical value when the latter are used as models in a polarisation-optical study on stresses. The disadvantages of the usual polymeric materials are, on the one hand, the occurrence of distinct relaxation processes following the application of a mechanical load, and, on the other hand, a low optical sensitivity. In order to obtain a distinct pattern of the distribution of stresses in a given structure, it is necessary to employ fairly high stresses, which are undesirable owing to the intense relaxation processes (creep and relaxation of the stress). The availability of materials with an extremely high coefficient of optical sensitivity

permits their use with comparatively small loads, for which the relaxation processes are weak and Hooke's law virtually holds.

## V. INTERMOLECULAR INTERACTION ENERGY AND SOLUBILITY

One of the principal parameters of the extent of intermolecular interaction in liquids is the density of cohesion energy, which is numerically equal to the potential energy $E/V$ of 1 $cm^3$ of the substance. For a liquid, this parameter is usually estimated from its heat of evaporation $\Delta H_v$ and is calculated by the formula

$$\delta^2 = E/V = (\Delta H_v - RT)/V \ , \qquad (24)$$

where $\delta$ is the Hildebrand solubility parameter and $V$ the molar volume of the liquid.

$\Delta H_v$ can be determined experimentally only for low-molecular-weight substances capable of evaporating without decomposition; naturally, this cannot be done for polymers. For this reason, many investigators [22-25] have attempted to calculate $\delta$ by resolving $E$ and $V$ into their constituent increments; other methods have also been proposed. However, evidently such resolution is not legitimate, since the volumes occupied by the same atom in different molecules are different owing to the differences between the molecular packing coefficients of liquids. This applies also to the cohesion energy $E$.

It has been shown [26] that the calculation of the increments of the cohesion energy density, when the latter is referred to the van der Waals (intrinsic) volume of the atoms and not to the molar volume, is physically justified in this case. For this purpose, Eqn. (24) is written [26] in the form

$$\delta^2 = \frac{Ek}{N_A \sum_i \Delta V_i} = \frac{E^*}{N_A \sum_i \Delta V_i} \ , \qquad (25)$$

where $k$ is the molecular packing coefficient of the liquid and $\sum_i \Delta V_i$ the van der Waals volume of the molecule, consisting of the van der Waals volumes of the atoms $\Delta V_i$.

Table 14. The values of $\Delta E_i^*$ for each atom and type of intermolecular interaction.

| Atom | Designation | $\Delta E_i^*$ kcal/mole | Interaction | Designation | $\Delta E_i^*$ kcal/mole |
|---|---|---|---|---|---|
| Carbon | $\Delta E_C^*$ | 550.67 | dipole-dipole | $\Delta E_d^*$ | 1623 |
| Hydrogen | $\Delta E_H^*$ | 47.71 | dipole-dipole in dipolar aprotic solvents of the amide type | $\Delta E_{a,N}^*$ | 1623 |
| Oxygen | $\Delta E_O^*$ | 142.6 | dipole-dipole in solvents of the dimethyl sulphoxide type | $\Delta E_{a,S}^*$ | 2600 |
| Nitrogen | $\Delta E_N^*$ | 1205 | hydrogen bond | $\Delta E_h^*$ | 3929 |
| Fluorine | $\Delta E_F^*$ | 24.2 | aromatic ring (skeleton) | $\Delta E_{Ph}^*$ | 713 |
| Sulphur | $\Delta E_S^*$ | 1750 | double bond | $\Delta E_{\neq}^*$ | −323 |

The quantity $E^* = Ek$ is in essence the molar cohesion energy of the liquid decreased by a factor equal to the factor by which the intrinsic molar volume of the molecule is smaller than the true molar volume. The quantity $E^*$, called the effective molar cohesion energy, has been expressed [26] as $E^* = \sum_i \Delta E_i^*$, where $\Delta E_i^*$ is the contribution of each atom and type of intermolecular interaction to $E^*$. Then

$$\delta^2 = \frac{\sum_i \Delta E_i^*}{N_A \sum_i \Delta V_i} \ . \qquad (26)$$

In order to calculate the values of $\Delta E_i^*$, an excess system of equations was derived [26] on the basis of Eqn. (26) and was solved by least squares. The results show that a sufficiently accurate calculation of the solubility parameters $\delta$ requires the introduction of the increments $\Delta E_i^*$ listed in Table 14. Knowing $\Delta E_i^*$ and $\Delta V_i$, it is possible to calculate the values of $\delta$ for organic liquids having different chemical structures. Table 15 presents as an example the calculated and experimental values of $\delta$ for many organic liquids, which are the same to a high degree of accuracy.

Table 15. The solubility parameters for solvents and polymers.

| Name | $\sum_i \Delta E_i^*$, cal mole$^{-1}$ | $N_A \sum_i \Delta V_i$, cm$^3$ mole$^{-1}$ | $\delta$, cal$^{1/2}$ cm$^{-3/2}$ | |

| Polyisobutylene | 2584 | 41.6 | 7.9 | 7.85; 7.8 8.05 |
| Polyacrylonitrile | 4623 | 32.6 | 11.9 | — |
| Poly(ethylene terephthalate) | 10418 | 102.4 | 10.1 | — |
| Nylon 6,6 | 18210 | 139.2 | 11.4 | — |

Fig. 6 illustrates the theoretical variation of $\delta$ with the [square root of the] ratio $\sum_i \Delta E_i^* / N_A \sum_i \Delta V_i$, on which the experimental points fit satisfactorily.

All the considerations described above permit the application of this method to the calculation of the cohesion energy density of polymers. Table 15 shows that the calculated [26] values of $\delta$ for many polymers agree with the available experimental data [27]. However, one should note that the experimental methods employed are not sufficiently accurate and the calculated values of $\delta$ may therefore prove to be more reliable.

Since the increments $\Delta E_i^*$ and $\Delta V_i$ have been determined (see above) for almost all atoms and groups in polymers of all structures, the proposed method can be used to calculate the values of $\delta$ for virtually any polymer, which is very important for the estimation of their solubilities and compatibilities with plasticisers and with one another.

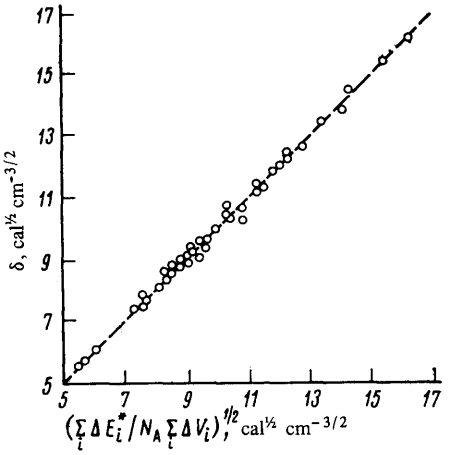

**Figure 6.** Variation of $\delta$ with [the square root of] the ratio $\sum_i \Delta E_i^* / N_A \sum_i \Delta V_i$ for low-molecular-weight liquids.

# The Application of the Spectroscopy of Light Scattering Media in Physicochemical Research

S.M.Baranov and N.M.Bazhin

The theoretical and applied aspects of the spectroscopy of light scattering media are examined and approximate methods for the solution of the radiative transfer equation are described. The data obtained with the aid of certain approximations are compared with the results of accurate calculations and certain experimental light scattering data are analysed. The bibliography includes 123 references.

## I. INTRODUCTION

In order to follow and investigate the mechanisms of a wide variety of chemical processes, optical spectroscopy is frequently used. However, its scope is most completely realised only for transparent (non-scattering) systems. On the other hand, many important chemical processes, for example catalytic, photochemical, polymerisation, etc. reactions, proceed in light-scattering media, where optical spectroscopy in its usual version developed for transparent media is inapplicable.

In a study of such processes, the optical spectroscopy of scattering media is a very important and sometimes the only physical method which can yield the required information about the course of the chemical reaction. However, despite the probable utility of the spectroscopy of light scattering media (SLM) in the solution of many physicochemical problems, it has not been adequately developed, particularly compared with the spectroscopy of transparent media. This is due to the following causes: firstly, the complexity of the mathematical description of the processes involving light transmission through scattering systems and the difficulties associated with the solution of the corresponding equations (thus the spectroscopy of transparent media involves only two parameters—optical density and the optical path length, while a light-scattering

layer is characterised, together with these parameters, also by the scattering coefficient, the angular distribution of the scattered light, and the refractive index of the layer. In real systems, the scattering coefficient and the angular structure of the scattered light may also depend on the direction of propagation of light); secondly, the lack of simple, reliable, and well founded experimental methods, which is related directly to the foregoing considerations.

In the spectroscopy of transparent media, one usually measures the optical density, which is related to the extinction coefficient and the concentration of the test substance by a simple linear expression. In SLM, the measured quantities are usually the integral reflectance ($R$) or transmittance ($T$) defined as the ratios of the amount of reflected radiation or radiation which has passed through the layer to the incident light flux. Furthermore, one can measure the angular dependence of the reflected and transmitted light as well as the angular dependence of the radiation within the medium.

Unfortunately, none of the experimentally measured quantities is linked by simple relations to the system parameters. In the general case, the measured quantity depends on the characteristics of the medium in a fairly complex manner, and this relation frequently cannot be expressed in an analytical form. Nevertheless, in terms of certain approximations, it is possible to put forward analytical relations whereby one can derive information from the experimental data about the characteristics of the medium and ultimately about the concentrations and extinction coefficients of the chemical compounds present in the scattering specimen.

There have been a number of extensive reviews and books on the theory of light scattering and its practical applications[1-13]. Some of these[1,2,11-13] are devoted mainly to the consideration of the theoretical problems of light scattering using a complex mathematical procedure. Other studies also deal with the analysis of the experimental data. However, we may note that, among these studies, only two[5,7] are specifically concerned with the application of SLM to physicochemical research, although some results of physicochemical experiments are given in the other investigations.

Analysis of the available studies[1-13] shows that there is a significant gap between the work of theoreticians and experimental chemists. Also the conditions under which particular approximate expression used in the interpretation of the experimental data are applicable are frequently not clearly defined in chemical literature.

The aim of the present review is, on the one hand, to give an account of various methods for the approximate description of light scattering processes, to indicate the limits of their applicability, and to compare the different approximate methods with one another, and, on the other hand, to demonstrate the possibility of applying these approximations to the solution of practical chemical problems.

## II. EQUATION OF RADIATIVE TRANSFER. NOTATION

Processes involving the transmission of light through scattering media are described by the integrodifferential equation of the transmission of radiation[1-3,8,9]:

$$\mu \frac{\partial I(z, \mu, \varphi)}{\partial z} = -(\alpha+\sigma) I(z, \mu, \varphi) + \frac{\sigma}{4\pi} \int_{(4\pi)} I(z, \mu', \varphi') \chi(\mu, \varphi, \mu', \varphi') \, d\mu' \, d\varphi' + Q(z, \mu, \varphi), \quad (1)$$

where $I(z, \mu, \varphi)$ is the intensity of the light beam, $z$ the coordinate, $\theta = \arccos\mu$ and $\varphi$ are the polar and azimuth angles respectively, $\alpha$ and $\sigma$ are the absorption and scattering coefficients of the volume element of the medium, the function $\chi$ specifies the angular distribution of the scattered light (the scattering indicatrix for the volume element), and the function $Q$ characterises the internal sources of photons.

The equation of radiative transfer [Eqn.(1)] reflects the change in the intensity of the light beam during its passage through a volume element of the scattering medium[2,8]. The first term on the right-hand side of the equation takes into account the weakening of the intensity owing to absorption and scattering and the second represents the contribution of the light beams incident on the volume element from all sides (these beams are characterised by variable angular coordinates $\mu'$ and $\varphi'$) and scattered with particular scattering indicatrix in the direction of the beam under consideration ($\mu$ and $\varphi$). Finally, the third term $Q(z, \mu, \varphi)$ takes into account the contribution of the internal sources of photons in the direction considered.

In the solution of practical problems, it is very important to determine from the known light fluxes the parameters of the medium: $\alpha$, $\sigma$, and $\chi$. Among all the parameters of the scattering medium, the absorption coefficient is of greatest interest in chemical research, since it is related to the concentration of the light absorbing substance $c$ by the usual expression

$$\alpha = 2.3 \varepsilon c,$$

where $\epsilon$ is the molar extinction coefficient on the decadic scale.

In view of the complexity of Eqn.(1), the procedures used for its solution involve either certain simplifying assumptions or specific experimental conditions. In particular, a generally accepted method involves the consideration of a plane-parallel layer illuminated with monochromatic light at right angles to the layer ($\mu_0 = 1$ is the cosine of the angle of incidence of the light) or with diffuse light (diffuse light is light whose intensity is independent of angular variables[14]).

In view of the planar symmetry of the problem and the selected illumination conditions (light incident at right angles or diffuse light), the intensity depends only on two variables: the coordinate $z$ at right angles to the bulk of the layer and reckoned from the upper boundary of the layer and the cosine of the angle $\mu$ between the direction of the light beam and the normal. With these assumptions, Eqn.(1) becomes[9,12]

$$\mu \frac{\partial I(z, \mu)}{\partial z} = -(\alpha+\sigma) I(z, \mu) + \frac{\sigma}{2} \int_{-1}^{1} I(z, \mu') \chi(\mu, \mu') \, d\mu' + Q(z, \mu). \quad (2)$$

A number of simplifying assumptions are usually introduced. In order to eliminate the edge effects, the dimensions of the layer and of the light source are assumed to be infinite in the $z$ = const. plane. Next, it is postulated that the layer is uniform, i.e. the parameters $\alpha$, $\sigma$, and $\chi$ are independent of the coordinates. To simplify the notation, we also assume that the layer is illuminated with a light flux having a single intensity both for light at normal incidence and for diffuse light. Finally we exclude from consideration polarisation effects, luminescence, and departure from steady-state conditions.

Although the media considered do not contain internal sources of radiation, in directional illumination one must regard the direct light quanta, i.e. quanta which penetrate

to a depth $z$ without scattering, as such sources. In this case, the function $Q$ is [1,9]

$$Q(z, \mu) = \frac{\sigma}{2} \chi(\mu) \exp[-(\alpha+\sigma)z]. \quad (3)$$

In diffuse illumination, the function $Q$ is assumed to be zero and the incident radiation is taken into account in the boundary conditions. We may note that in Eqn. (2) the quantity $I(z, \mu)$ should be understood as the intensity of scattered light only.

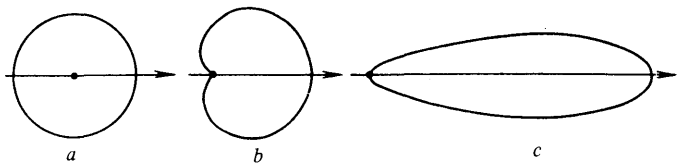

Figure 1. The scattering indicatrices of a volume element. The arrow indicates the direction of the light beam incident on the volume element (point): *a*) $\chi_1$; *b*) $\chi_2$; *c*) $\chi_3$.

Fig. 1 illustrates certain scattering indicatrices of the volume element described by the following expressions:

$$\chi_1 = 1, \ \chi_2 = 1+\mu, \ \chi_3 = 0.21/(1.1-\mu)^2. \quad (4)$$

We may note that the scattering indicatrices are normalised:

$$\frac{1}{2}\int_{-1}^{1} \chi(\mu) \, d\mu = 1.$$

For the practical analysis of data obtained with the aid of SLM, it is necessary to define the relation between the experimental quantities $R$ and $T$ and the characteristics of the layer. The coefficients $R$ and $T$ are related to the light fluxes directed along the $z$ axis $[F_1(z)]$ and in the opposite direction $[F_2(z)]$:

$$R = F_2(0), \ T = F_1(l), \quad (5)$$

where $l$ is the thickness of the layer and the fluxes are defined as follows:

$$F_1(z) = \int_0^1 I(z, \mu) \mu \, d\mu, \quad F_2(z) = -\int_{-1}^0 I(z, \mu) \mu \, d\mu. \quad (6)$$

The minus sign of $F_2$ was chosen so that the flux should be positive. We may point out that Eqn. (5) for the coefficient $T$ is valid only for diffuse illumination, while in directed illumination it must be supplemented by the term $\exp[-(\alpha+\sigma)z]$ taking into account the direct light which has passed through the layer. Thus, in order to relate the coefficients $R$ and $T$ to the parameters of the layer, it is necessary to know the light fluxes emerging from the layer, which may be found by solving Eqn. (2). However, this problem is mathematically very difficult and algorithms for its solution have been developed only in relatively simple cases and largely in a numerical form [1-3,8-12].

Approximate methods for the solution of the radiative transfer equation therefore play an important role and an advantage of some of them is the possibility of obtaining a solution in an analytical form. Physically reasonable postulates and agreement with the results of the accurate numerical solution of the radiative transfer equation should serve as the criteria of the accuracy of the approximate methods.

In conclusion, we may point out that the characteristics of the medium are sometimes formulated in the form of the following relations: the attenuation factor:

$$k = \alpha + \sigma,$$

the probability of the survival of a quantum in a single scattering step or the albedo of a single scattering step:

$$\Lambda = \sigma/(\alpha+\sigma),$$

the coefficient of the specific absorption of the layer:

$$\beta = \alpha/\sigma,$$

and the optical thickness of the layer

$$\tau_0 = \int_0^l (\alpha+\sigma) \, dz = k l.$$

In considering the instances of the illumination of the layer by diffuse light, we shall henceforth use the superscript (or subscript) $d$ in all the expressions and the coefficients for layers with a refractive index $N$ differing from unity will be formulated thus: $R(N)$ and $T(N)$.

## III. THE TWO-FLUX APPROXIMATION METHOD

The two-flux approximation method is one of the simplest and most widely used approximation procedures, the main idea of which is as follows. One considers the light fluxes $F_1$ and $F_2$ [see Eqn. (6)], whereupon the radiative transfer equation is replaced by a system of differential equations, which is solved with certain additional postulates. We shall consider the principal features of the two-flux approximation method.

### 1. Diffuse Illumination of the Layer

Suppose that the layer is illuminated by diffuse light and $Q(z, \mu) = 0$. We integrate Eqn. (2) with respect to the upper and lower hemispheres, i.e. the integral is evaluated with respect to $d\mu$ from $-1$ to 0 and from 0 to 1. We obtain as a result a system of equations for the fluxes $F_1$ and $F_2$: [8,9]

$$\frac{dF_1(z)}{dz} = -\frac{\alpha+\sigma\psi_1(z)}{\nu_1(z)} F_1(z) + \frac{\sigma\psi_2(z)}{\nu_2(z)} F_2(z),$$
$$\frac{dF_2(z)}{dz} = \frac{\alpha+\sigma\psi_2(z)}{\nu_2(z)} F_2(z) - \frac{\sigma\psi_1(z)}{\nu_1(z)} F_1(z). \quad (7)$$

$$\nu_1(z) = \frac{\int_0^1 I(z, \mu) \mu \, d\mu}{\int_0^1 I(z, \mu) \, d\mu}, \quad \nu_2(z) = -\frac{\int_{-1}^0 I(z, \mu) \mu \, d\mu}{\int_{-1}^0 I(z, \mu) \, d\mu}. \quad (8)$$

The following notation has been introduced here: the average cosines of the angles of inclination of the light beams (the minus sign of $\nu_2$ was chosen so that $\nu_2$ is positive)

$$\psi_1(z) = \frac{1}{2} \frac{\int_0^1 I(z, \mu') \, d\mu' \int_{-1}^0 \chi(\mu, \mu') \, d\mu}{\int_0^1 I(z, \mu') \, d\mu'}, \quad (9)$$

$$\psi_2(z) = \frac{1}{2}\frac{\int_{-1}^{0} I(z,\mu')\,d\mu' \int_{0}^{1} \chi(\mu,\mu')\,d\mu}{\int_{-1}^{0} I(z,\mu')\,d\mu'}$$

are the components of the light flux scattered by an infinitessimal layer (for its illumination from above and below respectively) backwards in relation to the entire scattered light. We may note that, when the light intensity in the layer is diffuse, then $\nu_1 = \nu_2 = 0.5$ and $\psi_1(z) = \psi_2(z)$.

All the numerous versions of the two-flux approximation reduce to the different selections of the functions $\nu_i(z)$ and $\psi_i(z)$ ($i$ = 1 or 2) and the solution of Eqns.(7) with the corresponding boundary conditions. This problem has already been discussed in detail [9]. However, in most cases in the interpretation of the experimental data one uses the two-parameter equation of the two-flux approximation (TFA) in which it is assumed *a priori* that the following conditions hold: $\nu_1 = \nu_2 = \nu$ and $\psi_1 = \psi_2 = \psi$. [3,9] We may note that such averaging of the quantities defined by Eqns.(8) and (9) with respect to the thickness of the layer is justified only when the bulk-phase conditions obtain and only far from the boundaries of the layer [9].

The boundary conditions for Eqn.(7) in TFA are chosen in the form [9] ($N$ = 1)

$$F_1(0) = 1,\ F_2(l) = 0. \tag{10}$$

The solution of Eqns.(7) with the boundary conditions (10) makes it possible to find the coefficients $R$ and $T$ [Eqns. (5)] [8,9]

$$R_d = \frac{[1-\exp(-2al)]\,R_\infty^d}{1-(R_\infty^d)^2\cdot\exp(-2al)},$$
$$T_d = \frac{[1-(R_\infty^d)^2]\exp(-al)}{1-(R_\infty^d)^2\exp(-2al)}, \tag{11}$$
$$R_\infty^d = 1+\frac{\alpha}{\sigma\psi}-\left[\left(\frac{\alpha}{\sigma\psi}\right)^2+2\frac{\alpha}{\sigma\psi}\right]^{1/2}.$$

Here $R_\infty^d$ is the reflectance of an infinitely thick layer and $a$ is the attenuation coefficient under bulk-phase conditions defined by

$$a = \frac{1}{\nu}[\alpha(\alpha+2\sigma\psi)]^{1/2}.$$

Similar expressions have been obtained by Gurevic [15].

Eqns.(11) are known in the literature as the Gurevic–Kubelka–Munk (G–K–M) relations [5,9]. The Kubelka–Munk (K–M) function can be readily obtained from them:

$$f(R_\infty^d) = (1-R_\infty^d)^2/(2R_\infty^d) = \alpha/(\sigma\psi). \tag{12}$$

The TFA formulae (11) and (12) are widely used in the interpretation of the experimental data. However, unfortunately many workers ignore the multiplier $1/\psi$ and use the G–K–M relations for directed illumination of the layer, although the relations can be obtained only for the layer illuminated with diffuse light.

Zege [9] examined in detail the possibility of applying the TFA formulae to the description of the light-scattering properties of a planar layer and arrived at the following conclusion as a result of comparison with data derived by the numerical solution of Eqn.(2) and also as a result of extrapolation to the bulk-phase light conditions in weakly absorbing media. When the parameters $\nu$ and $\psi$ were chosen in the form

$$\nu = 0.5,\quad \psi = \frac{3}{8}(1-\bar{\mu}), \tag{13}$$

where $\bar{\mu}$, defined by the expression

$$\bar{\mu} = \frac{1}{2}\int_{-1}^{1}\chi(\mu)\,\mu\,d\mu, \tag{14}$$

is the cosine of the scattering angle averaged with respect to the scattering indicatrix of the volume element, calculation by the TFA formulae (12) agrees with the results of the accurate calculation with an accuracy sufficient for practical purposes (the relative error is less than 10%). We may note that, for isotropic scattering ($\chi_1$), $\psi \simeq 3/8$ was also obtained in other investigations [16,17]. Henceforth in calculations employing TFA formulae we shall likewise select the parameters $\nu$ and $\psi$ defined by Eqns. (13).

Mention should also be made of the criterion imposed on the degree of extension of the scattering indicatrix of the volume element for which the TFA relations are valid [9]:

$$\frac{(8\psi_d q-1)^2}{8\psi_d q} \ll 1, \tag{15}$$

where

$$\psi_d = \frac{1}{2}\int_{0}^{1}\int_{-1}^{0}\chi(\mu,\mu')\,d\mu\,d\mu',\quad q = \frac{1}{3(1-\bar{\mu})}. \tag{16}$$

Evaluation of the left-hand side of inequality (15) for the scattering indicatrices of the volume elements $\chi_1$, $\chi_2$, and $\chi_3$ yields 0.08, 0.17, and 0.64 respectively. Thus, for layers with the indicatrix $\chi_3$, one may expect a less satisfactory agreement of the results of approximate calculations with accurate data compared with the calculations for the layers with $\chi_1$ and $\chi_2$ for which the criterion defined by formula (15) may be regarded as valid.

We shall now consider a scattering layer the refractive index of which is different from that of the surrounding medium. To simplify the treatment, we shall assume that the layer has optically smooth interfaces. The deviation of the refractive index of the layer from unity must be taken into account in the boundary conditions, since in this case the light flux supplied to the boundary no longer emerges from the layer in its entirety. This is due to the reflection of the light from the boundaries of the layer, the main contribution arising from the effect of the total internal reflection. In addition, we shall introduce yet another simplification, namely we shall assume that the light approaching the boundary from within the layer is diffuse.

We introduce the following notations for a layer with optically smooth boundaries: the coefficient $\rho$ of reflection from the boundary of the diffuse light incident on the layer from outside and the reflectance $r$ of the light incident on the boundary and directed outward from the layer. Explicit expressions for the coefficient $\rho$ and the relation between $\rho$ and $r$ have been given, for example, by Gershun [14].

When account is taken of the refractive index, the boundary conditions become [14]

$$F_1(0) = 1-\rho+rF_2(0),\ F_2(l) = r\cdot F_1(l).$$

The reflectance and transmittance are defined as follows:

$$R_d(N) = \rho+(1-r)F_2(0),\quad T_d(N) = (1-r)F_1(l). \tag{17}$$

Eqns.(17) have been published in an explicit form [14,18,19] and we shall merely formulate the coefficient of reflection for a semi-infinite layer:

$$R_\infty^d(N) = 1-(1-\rho)(1-R_\infty^d)/(1-rR_\infty^d),$$

where $R_\infty^d$ is described by Eqn.(11).

For weakly absorbing layers, the asymptotic relation between $1/T_d(N)$ and the thickness of the layer may be found from the TFA formulae. The intercept which this straight line makes on the ordinate axis is $(1+r)/(1-\rho)$. This is qualitatively consistent with Gurevic's data [14] for the transmission of light through weakly absorbing milky glasses (Fig. 2).

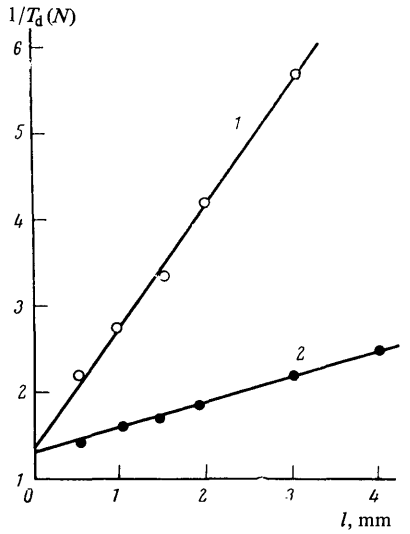

Figure 2. Dependence of $1/T_d(N)$ on the thickness of the layer (diffuse illumination): 1) highly opalescent (dense) milky glass [14]; 2) weakly opalescent milky glass [14].

## 2. Layers Illuminated with a Light Flux at Right Angles

The problem of the transmission of a directed light beam through a scattering layer is of practical importance. In this case Eqns. (7) are supplemented by terms taking into account the internal sources of photons [Eqn. (3)]. The solution of such equations for a layer with $N = 1$ and the boundary conditions

$$F_1(0)=0,\ F_2(l)=0$$

leads to the following expressions for the coefficients defined by Eqns. (5): [9]

$$\begin{aligned} T &= c_1 T_d + (1-c_1+c_2R_d)\exp(-(\alpha+\sigma)l), \\ R &= c_1R_d + c_2T_d\exp(-(\alpha+\sigma)l) - c_2, \\ R_\infty &= c_1R_\infty^d - c_2, \end{aligned} \qquad (18)$$

where the coefficients $R_d$, $T_d$, and $R_\infty^d$ are defined by Eqns. (11) and the parameters $C_1$ and $C_2$ satisfy the following equations when account is taken of Eqn. (13):

$$c_1=\frac{(1-\omega)(3\beta+1)+2\psi}{1+2\beta(1-4\psi)-3\beta^2},\quad c_2=\frac{\omega(\beta-1)+2\psi}{1+2\beta(1-4\psi)-3\beta^2}; \qquad (19)$$

the quantity $\omega$ is defined by the expression

$$\omega=\frac{1}{2}\int_{-1}^{0}\chi(\mu)\,d\mu.$$

Zege [9] suggests that, as for diffuse illumination, the quantities $\nu$ and $\psi$ should be defined by Eqns. (13). Calculations carried out on this assumption within the framework of TFA are presented in Tables 1–5, which show that the proposed TFA version gives rise to a satisfactory accuracy of the calculation of the coefficients $R$ and $T$ for different scattering indicatrices over a wide range of variation of $\beta$.

We shall now turn to the consideration of a scattering layer with optically smooth interfaces and $N \neq 1$. We introduce the following notation: the coefficient of the specular reflection of the beam illuminating the layer

$\rho_{sp} = (N-1)^2/(N+1)^2$ and the coefficient of reflection of the light directed from the layer to the outside $r$. As before, $r$ may be calculated from Gershun's formulae[14] on the assumption that the light incident on the boundary from inside is diffuse.

The boundary conditions for the equations describing the fluxes for directional illumination are as follows:

$$F_1(0) = rF_2(0), \quad F_2(l) = rF_1(l). \tag{20}$$

Reflectance and transmittance can be formulated by analogy with Eqns.(17), but in the expression for the coefficient $T(N)$ account must be taken of the direct light quanta which have passed through the layer. In particular, the coefficient $R_\infty(N)$ assumes the following form in this case:

$$R_\infty(N) = \rho_{sp} + (1-\rho_{sp})(1-r)\left[\frac{(c_1 - rc_2)R_\infty^d}{1 - rR_\infty^d} - c_2\right]. \tag{21}$$

All the quantities in this formula were defined above [see Eqns.(11) and (19)]. Some of the values of $R_\infty(N)$ calculated from Eqn.(21) are listed in Tables 6 and 7 and their comparison with the results of the numerical solution of Eqn.(2) demonstrates a satisfactory agreement.

In concluding this Section, we shall formulate the expression defining the coefficients $R(N)$ and $T(N)$ for a non-absorbing layer ($\alpha = 0$):

$$R(N) = 1 - T(N) = \rho_{sp} + (1-\rho_{sp})\left(1 - \frac{2p + (8\psi - 4\omega - p + 2)(1 - \exp(-\sigma l))}{8\sigma\psi l + 2p}\right), \tag{22}$$

where

$$p = 2(1+r)/(1-r). \tag{23}$$

## IV. THE DIFFUSION APPROXIMATION

The diffusion approximation method is also widely used in practical calculations[12,20-27]. It is a special case of the $P_n$ approximation, the essential feature of which is as follows. The functions $I$, $\chi$, and $Q$ at each point in the scattering medium are expanded in series in Legendre polynomials, the expansions being limited to the $n$th term. They are then substituted in the radiative transfer equation and, having multiplied the latter in succession by the Legendre polynomials ranging from $P_0$ to $P_n$, we carry out the integration with respect to the angular variable $\mu$ from $-1$ to 1. We obtain as a result a system of $n+1$ first-order differential equations, which may be solved with the appropriate boundary conditions.

The diffusion approximation is the lowest-order approximation ($P_1$). It has been used successfully in the description of the diffusion of neutrons[20-24] and of light scattering[25-28]. We shall now consider certain specific instances.

1. Isotropic Scattering; $\mu_0 = 1$, $N = 1$

The light intensity is represented by an expansion in terms of the first two Legendre polynomials ($P_0 = 1$, $P_1 = \mu$):

$$I(z, \mu) = \frac{1}{2}[n(z)c + 3\mu F(z)]. \quad (24)$$

The coefficients of the expansion have a simple physical significance[25]: $n(z)$ is the concentration of the diffusing quanta, $F(z)$ is their overall flux, and $c$ is the velocity of light.

The applicability of the $P_1$ approximation depends on how well the intensity can be represented by a linear function of $\mu$; this condition is equivalent to the inequality $n(z)c \gg F(z)$. In particular, this should hold for a virtually isotropic light intensity distribution (a non-absorbing medium with isotropic scattering)[3].

In conformity with the above procedure, we obtain the following system of equations:

$$\frac{dF}{dz} + \alpha cn - \sigma \exp(-(\alpha+\sigma)z) = 0$$
$$F = -\frac{c}{3(\alpha+\sigma)}\frac{dn}{dz}. \quad (25)$$

The second equation (25) resembles the form of Fick's law for diffusion in a gas and relates the light flux to the density gradient (this is the reason for the term diffusion approximation). The diffusion coefficient $D$ in isotropic scattering is

$$D = c/3(\alpha+\sigma),$$

in agreement with the ideas of the gas-kinetic theory[29] on the assumption that the mean free path in the transport process is $1/(\alpha + \sigma)$. Clearly, the consideration of the diffusion of photons is significant only for weakly absorbing media ($\beta \ll 1$).

After eliminating the function $F(z)$ from Eqn.(25) we pass to the steady-state diffusion equation for diffusing quanta:

$$D\frac{d^2n}{dz^2} - \alpha cn + \sigma \exp(-(\alpha+\sigma)z) = 0. \quad (26)$$

We may note that Eqn.(26) may be obtained directly from general considerations when light scattering processes are treated as the diffusion of photons within the framework of the gas diffusion theory. In this case, the second term of Eqn.(26) describes the disappearance of quanta with a rate constant $\alpha c$, and the third term describes the generation of the diffusing quanta from the direct beam as a result of scattering.

According to Eqns.(6) and (24), the expressions for the fluxes are

$$F_1 = \frac{nc}{4} - \frac{D}{2}\frac{dn}{dz}, \quad F_2 = \frac{nc}{4} + \frac{D}{2}\frac{dn}{dz}, \quad (27)$$

and the boundary conditions (17) become

$$\frac{nc}{2}\Big|_{z=\begin{cases}0\\l\end{cases}} = \pm D\frac{dn}{dz}\Big|_{z=\begin{cases}0\\l\end{cases}}. \quad (28)$$

The solution of Eqn.(26) can be formulated thus:

$$n = A\exp(-az) + B\exp(az) + E\exp(-(\alpha+\sigma)z), \quad (29)$$

where

$$A = \frac{E}{3\Delta}[-5(1+b)\exp(al) + (1-b)\exp(-(\alpha+\sigma)l)],$$
$$B = \frac{E}{3\Delta}[5(1-b)\exp(-al) - (1+b)\exp(-(\alpha+\sigma)l)],$$
$$a = [3\alpha(\alpha+\sigma)]^{1/2}, \quad b = 2[\alpha/3(\alpha+\sigma)]^{1/2},$$
$$E = -3\sigma/c(\sigma-2\alpha),$$
$$\Delta = (1+b)^2\exp(al) - (1-b)^2\exp(-al).$$

The coefficients $R$ and $T$ are defined on the basis of Eqns. (5) and (27):

$$R = \frac{c}{2}[A+B+E],$$
$$T = \frac{c}{2}\left[A\exp(-al) + B\exp(al) + \left(E + \frac{2}{c}\right)\exp(-(\alpha+\sigma)l)\right], \quad (30)$$

and the expression for the coefficient $R_\infty$ is fairly simple:

$$R_\infty = \left[1 + 3\beta + \frac{5}{3}(3\beta(1+\beta))^{1/2}\right]^{-1}. \quad (31)$$

It is of interest to compare results of the calculation using the $P_1$ approximation with the results of the exact calculation. This is done in Tables 1 and 2, which show that the coefficients $R$ and $T$, calculated in terms of the $P_1$ approximation with the boundary conditions (28), agree satisfactorily with the results of the exact solution of the radiative transfer equation and virtually agree with the TFA version.

2. Allowance for the Refractive Index. Isotropic Scattering ($\mu_0 = 1$)

We shall consider a scattering layer with optically smooth interfaces and $N \neq 1$. As before, the influence of the refractive index will be taken into account in the boundary conditions (20). Retaining the notation introduced in the previous section, the boundary conditions (20) will be reformulated as follows by simple transformations taking into account Eqn.(27):

$$\frac{nc}{p}\Big|_{z=\begin{cases}0\\l\end{cases}} = \pm D\frac{dn}{dz}\Big|_{z=\begin{cases}0\\l\end{cases}},$$

where $p$ is defined by Eqn.(23). The expression for $R_\infty(N)$ then assumes the following form:

$$R_\infty(N) = \rho_{sp} + (1-\rho_{sp})/[1 + (1+p)\beta + (1+p/3)(3\beta(1+\beta))^{1/2}]. \quad (32)$$

The main contribution to the coefficient $r$ comes from the effect of the total internal reflection. Taking only this into account and assuming that the light incident on the layer boundary from the inside is diffuse, it is easy to find[30]

$$r = 1 - 1/N^2. \quad (33)$$

The exact expression for the reflectance of diffuse light with allowance for Frenel's formulae is[14,31,32]

$$r = 1 - \frac{1}{N^2}\left[1 - \frac{3N^8 - 10N^7 - 6N^6 - 4N^5 + 16N^4 - 10N^3 + 2N^2 + 1}{3(N^4-1)^2} - \right.$$
$$\left. - \frac{N^2(N^2-1)^2}{(N^2+1)^3}\ln\frac{N+1}{N-1} + \frac{8N^4(N^4+1)}{(N^2-1)^2(N^2+1)}\ln N\right]. \quad (34)$$

However, the numerical difference between Eqns.(34) and (33) is small; for example, $r = 0.6$ and 0.56 respectively when $N = 1.5$. In approximate calculations, it is therefore fully justifiable to use the simpler formula (33).

When account is taken of Eqns.(33) and (23), the parameter $p$ can be expressed thus:

$$p = 2(2N^2 - 1). \quad (35)$$

The coefficients $R_\infty(N)$ for a layer with an optically smooth boundary have been calculated[31] by the numerical

solution of the radiative transfer equation. These data are compiled in Table 6 for $N = 1.5$ and compared with the values calculated by Eqn.(32) taking into account Eqn. (35). The discrepancy does not exceed 3% (absolute deviation), which demonstrates the possibility of the practical application of the formulae based on the $P_1$ approximation. Similar results were obtained in calculations by the TFA Eqn.(21) taking into account Eqn.(35) [see Eqn.(6)].

### 3. Non-Isotropic Scattering ($\mu_0 = 1$)

For a layer with an optically smooth interface, the coefficient $R_\infty(N)$ is described by the formula

$$R_\infty(N) = \rho_3 + \frac{(1-\rho_3)\,[y - \bar{\mu}\,(3\beta y)^{1/2}]}{y[1+\beta\,(1+p)] + \left[y + \frac{p}{3}\,(1+\beta)(3\beta y)^{1/2}\right]}, \qquad (36)$$

where $\bar{\mu}$ is the cosine of the scattering angle [Eqn.(14)] averaged with respect to the scattering indicatrix of the volume element and $y = 1 + \beta - \bar{\mu}$.

Tables 3 and 7 present the results of the study by Giovanelli [31] and the calculations based on Eqns.(36), (18), and (21) for layers with a scattering indicatrix $\chi_2$ [see Eqn.(4)]. The agreement between these results is quite satisfactory.

Analysis of Eqn.(36) makes it possible to determine readily the limitations imposed on the degree of anisotropy of the scattering indicatrix of the volume element in the $P_1$ approximation. Thus, when $\mu > 1/\sqrt{3}$, the coefficient $R_\infty(N)$ becomes negative starting from a certain value of $\beta$, which has no physical significance for the given problem. The application of the $P_1$ approximation is therefore limited to the range $0 \leq \bar{\mu} \leq 1/\sqrt{3}$. This postulate is satisfactorily consistent with the fact that the light intensity in the medium should differ only slightly from the isotropic intensity.

Finally, we have the formula for the coefficients of the non-absorbing layer:

$$R(N) = 1 - T(N) = \rho_{sp} + (1-\rho_{sp})\left[1 - \frac{(3+p) - (3-p)\exp(-\sigma l)}{2p + 3\sigma l\,(1-\bar{\mu})}\right]. \qquad (37)$$

For the scattering indicatrices $\chi_1$ and $\chi_2$ [Eqn.(4)], Eqn. (37) agrees with the TFA formula (22).

## V. THE TRANSPORT APPROXIMATION

It is seen from the above considerations that the $P_1$ approximation can be used only for the scattering indicatrices of the volume element, which are not unduly extended in the forward direction ($\bar{\mu} < 1/\sqrt{3}$). On the other hand, in real systems $\bar{\mu}$ can probably be greater [33,34]. In order to apply the formulae of the $P_1$ approximation to systems with the scattering indicatrices of the volume element extended forward, use is made of the so called transport approximation (TA). In this case, the true scattering coefficient is replaced in the approximate solution of the problem for isotropic scattering by the effective coefficient $\sigma_{eff}$, which takes into account both $\sigma$ and the form of the indicatrix [12,30,35] (the coefficient $\alpha$ then remains unchanged):

$$\sigma_{eff} = \sigma/m, \qquad (38)$$

where $m$ is the parameter taking into account the anisotropy of the scattering.

The physical significance of the transport approximation consists in the replacement of, for example, a scattering indicatrix extended forward by a spherical indicatrix with a larger number of direct light quanta for compensation of the preferential forward scattering. In practice the choice of $m$ makes it possible to bring into fairly good agreement with the exact calculation either the coefficient $R$ or $T$. The transport approximation can be applied also to other approximate methods for the solution of the radiative transfer equation, for example to the TFA version. We may note that the transport approximation is empirical, since the exact TFA Eqn.(21) and the $P_1$ equation (36) contain both $\sigma$ and $\sigma_{eff} = \sigma(1 - \bar{\mu})$.

The exact $R_\infty(\beta)$ relations for layers with the scattering indicatrices $\chi_1$, $\chi_2$, and $\chi_3$ [Eqn.(4)] have the form of monotonically decreasing functions. By selecting the parameter $m$, it is possible to bring these curves into satisfactory agreement with the relation for isotropic scattering. The possibility of achieving the compatibility of the $R_\infty$ curves for the $\chi = 1 + P_i(\mu)$ indicatrices, where $i = 0$, 1, 2, or 3 and $P_i$ is the $i$th Legendre polynomial, has been demonstrated [36] by means of a similar operation. This factor also supports the validity of the transport approximation. As an example, Table 3 presents the values of $R_\infty$ for a layer with the scattering indicatrix $\chi_2$ [Eqn. (4)] calculated in the terms of the transport $P_1$ approximation and TFA for $m = 1.8$. They evidently agree satisfactorily with the results of the exact calculation over a wide range of variation of $\beta$. The principal feature of the transport approximation is that in this case the theory involves only two parameters: $\alpha$ and $\sigma_{eff}$. It is therefore very convenient to use it in the analysis of experimental data.

For a layer with an optically smooth interface ($N = 1.5$) and the indicatrix $\chi_2$, the values of $R_\infty(N)$ were calculated in terms of the $P_1$ approximation and TFA as well as the transport approximation with $m = 1.8$ and compared with Giovanelli's results [31] (Table 7). The extent of the agreement of all the results is quite satisfactory and the TA data differ little from those obtained from the exact $P_1$ and TFA formulae.

Table 4 presents the results of the calculation of the coefficients $R$ and $T$ ($P_1$ and TFA) for all layers of final thickness with the indicatrix $\chi_2$. As before, the extent of the agreement with the transport approximation is quite acceptable, although the difference between the $T$ coefficients is greater. This is because the choice of the parameter $m$ [Eqn.(38)] is determined by the best agreement between the coefficients $R_\infty$. Similar calculations for layers with the scattering indicatrix $\chi_3$ [Eqn.(4)] are presented in Table 5. The parameter $m$, found from the condition for best agreement between the coefficients $R_\infty$ ($m = 6.86$), differs from $1/(1 - \bar{\mu}) = 4.55$. Table 5 shows that the agreement between the coefficients $R$ is fairly good, but that between the coefficients $T$ is only qualitative, which is also consistent with the method of selection of $m$.

The above data suggest that the transport approximation can yield satisfactory results when it is applied to real systems with anisotropic scattering.

Finally, we may note an important fact. The calculations of the coefficients $R$ and $T$ within the framework of the transport, TFA, and $P_1$ approximations reveals a discrepancy between the results, which does not exceed three units in the third decimal place. The range of the values covered was very wide:

$$0.01 \leqslant \beta \leqslant 3;\ 0.2 \leqslant (\alpha+\sigma)\,l \leqslant 15;\ 1 \leqslant m \leqslant 10.$$

This permits the conclusion that the transport, TFA, and $P_1$ approximations yield quantitatively concordant integral values of $R$ and $T$, i.e. they are virtually equivalent.

## VI. OTHER METHODS FOR THE DESCRIPTION OF LIGHT SCATTERING PROCESSES

These include in the first place the layer model where the scattering layer is regarded as an assembly of plane-parallel layers with a thickness equal to the average size of the scattering centre [37-40]. In this approach, the expressions for the coefficients $R$ and $T$ are analogous to the TFA formulae [Eqn.(11)].[37]

A novel approach to the solution of the radiative transfer equation was proposed by Rozenberg, who expanded the solution in series in terms of a small parameter $\gamma$ equal to the ratio of the decay coefficient under bulk-phase conditions ($a$) to the attenuation coefficient of the medium [4,6,41,42]. For the diffuse illumination of weakly absorbing media, Rozenberg obtained the following expression ($N = 1$) with an accuracy to within a quantity of the order of magnitude of $\gamma^3$:

$$T_d = \frac{\sinh y}{\sinh(x+y)}, \quad R_d = \frac{\sinh x}{\sinh(x+y)}, \quad R_\infty^d = e^{-y}, \tag{39}$$

where $x = al$ and $y = 4q\gamma$. When the illumination is directional, the coefficients are expressed as follows:

$$T = gT_d, \quad R = R_\infty - T_d \exp(-x-y), \quad R_\infty = \exp(-Sy).$$

Here $T_d$ and $R_d$ are described by Eqns.(39) and $g$, $q$, and $S$ are so called Rozenberg parameters, whose detailed investigation has already been carried out [8]. It is noteworthy that the unambiguous relation between the reflectance and transmittance, on the one hand, and the parameters $x$ and $y$, on the other, makes it possible to obtain a simple expression for the absorption coefficient [6]:

$$\alpha = xy/4l.$$

We may also point out that Eqns.(39) are equivalent to the TFA formulae (11).[43] Rozenberg used a similar approach also for strongly absorbing media [44,45].

Yet another approach to the consideration of light scattering processes in powders was proposed by Melamed [46], assuming that a semi-infinite layer consists of spherical particles and, using a soundly based treatment of the light passing through the upper monolayer (similarly to the layer model), he obtained [46] the following expression:

$$R_\infty = 2x\rho + \frac{(1-2x\rho)(1-\rho R_\infty)xt}{(1-\rho R_\infty) - (1-x)(1-\rho)tR_\infty},$$

where $x$ is the fraction of light emerging from the particle in the upward direction, $t$ the transmission coefficient of the particle, and $\rho$ a quantity having the same significance as in subsection 1 of Section III. Melamed has published these expressions in an explicit form [46].

The problem of the reflectances of a semi-infinite layer with $N \neq 1$ was dealt with by Giovanelli [31], who considered two types of interfaces of the layer: optically smooth and diffuse. We shall assume that the diffuse interface has a hypothetical property such that the radiation which has passed through it or which has been reflected from it is diffuse regardless of the type of incident radiation [31]. In order to find the reflectance of the layer, the author [31] separated the processes involving the passage of light through the surface of the layer from the reflection processes. Then, considering the radiation fluxes immediately at the boundary, directed inwards and outwards, Giovanelli obtained the following expression:

$$R_\infty(N) = \rho + \frac{(1-\rho)^2 R_\infty^d}{N^2(1-rR_\infty^d)}.$$

Either the exact function [1,2,11] or approximate expressions, for example Eqn.(11), may be used as the coefficient $R_\infty^d$.

A similar approach was also used for a layer with an optically smooth interface. Assuming that the light intensity is independent of the angle, an approximate expression is obtained [31]:

$$R_\infty(N) = \rho_{sp} + (1-\rho_{sp})\frac{(1-\rho)R_\infty}{N^2(1-2J)},$$

where

$$J = \int_0^1 r(\mu) R_\infty(\mu)\mu\, d\mu;$$

$r(\mu)$ is the Fresnel reflectance for the light incident on the interface from within and the coefficients $r$, $\rho$, and $\rho_{sp}$ have the previous significance. Giovanelli evaluated by numerical integration the coefficients $R_\infty(N)$ also taking into account the angular structure of the light [31]. Some of these data are presented in Tables 6 and 7.

An attempt at a description of photochemical reactions in powdered substances made by Simmons and Wendlandt [47,48] is noteworthy. Assuming that the powder consists of spherical particles which are capable of ideal scattering of radiation, the authors [48] obtained the following relation for the reaction $A \xrightarrow{h\nu} B$ within the framework of the one-dimensional layer model:

$$g(R_\infty) - g(R_\infty(A)) = \varphi\varepsilon N^2 I_0 t, \tag{40}$$

where $R_\infty$ is the reflectance at time $t$ from the start of the photochemical reaction, $R_\infty(A)$ refers to the pure substance A, $\varphi$ is the quantum yield, $\epsilon$ the molar extinction coefficient of the substance A, $I_0$ the intensity of the incident light, and $g(R_\infty)$ a function whose explicit form has been published [48], Thus the plot of $g(R_\infty)$ against $t$ should be linear and the quantum yield of the photochemical reaction can be estimated from the slope. In conclusion, we may indicate approximate methods for the solution of the radiative transfer equation analogous to the $P_n$ approximation. In contrast to the usual method of spherical harmonics, an expansion in different series is carried for the upper ($\mu < 0$) and lower ($\mu > 0$) half-planes [the so called double $P_n$ method $(DP)_n$] [12,49] or for four regions (with additional subdivision of the half-planes) [50]. In this approach, the light intensity can have a discontinuity at $\mu = 0$. However, as a result of the double expansion, the accuracy of the $DP_1$ method is higher than that of the $P_3$ approximation for the same complexity of the mathematical expressions [12]. In particular, one can formulate an expression for the coefficient $R_\infty$ for an isotropically scattering layer obtained in the $DP_0$ approximation with the usual boundary conditions ($\mu_0 = 1$, $N = 1$):

$$R_\infty = [1 + 3\beta + 3(\beta(1+\beta))^{1/2}]^{-1}.$$

This formula resembles Eqn.(31), but agrees better with the results of the exact calculation, which probably also indicates a higher accuracy of the $DP_0$ method compared with the $P_1$ approximation.

## VII. THE APPLICATION OF THE SPECTROSCOPY OF LIGHT SCATTERING MEDIA TO THE INTERPRETATION OF EXPERIMENTAL DATA

This section is devoted to the practical applications of the SLM. Naturally since not all the studies in this field can be described, we shall confine ourselves to the most typical investigations. These include in the first place the determinations of the absorption band maxima in the diffuse reflection spectra [51-58]. Studies designed to elucidate the coordination and valence states of transition metal ions on the surfaces of different carriers are related to these. By comparing the energies of the electronic transitions of the ions on the surface with the analogous transitions in solutions, it is possible to reach a conclusion, within the framework of the crystal field theory, about the coordination of valence states of the ion investigated. The study of the state of molybdenum [59] and cobalt [60] ions on the surfaces of magnesium and aluminium oxides, of cobalt and chromium ions on silica gel [61-63], and of copper [64], nickel [65], and neodymium [66] ions, as well as the study of the properties of nickel catalysts [67-69], the acid properties of catalysts [70,71], and the interaction of certain organic compounds with the surface of the catalyst [72,73] are typical investigations of this kind.

In practice, one encounters fairly frequently the problem of the determination of the optical characteristics of substances from diffuse reflection or transmission spectra and hence the problems of the determination of the structures of compounds and their concentrations. Most of the approximate models for the description of light scattering systems were described in previous sections. Among these, the TFA model, yielding relatively simple G–K–M relations [Eqns. (11)], is most widely used. We may recall that Eqns. (11) were obtained for homogeneous layers illuminated with diffuse light. Outwardly similar formulae are obtained when a one-dimensional scattering medium [2] or a layer model [37] are considered.

Numerous studies on the application of the spectroscopy of light scattering media in chemistry have been carried out by Kortüm and his coworkers [74-85]. Using the K–M functions [Eqn. (12)], the authors determined the form of the absorption spectra of molecular compounds of trinitrobenzene as a function of concentration, adsorbent, temperature, and degree of adsorption, and also estimated the dissociation constants of these compounds [76,77]. Kortüm and Vogel [78] described the dependence of the absorption spectra of powdered $K_3Fe(CN)_6$ and $KMnO_4$ on particle size taking into account certain refinements of the G–K–M theory [78,79]. Using polarised light, an attempt was made to separate the diffuse and specular components of the reflected radiation, and the influence of the particle size on the reflection spectra of the powders was demonstrated [80]. The luminescence characteristics of powdered substances were calculated [81] within the framework of the G–K–M model. Using the K–M function [Eqn. (12)], the photochemical reactions of adsorbed substances (anthracene, anthraquinone, substituted pyridines, and spiropyrans) were studied qualitatively [82-84]. However, all the studies enumerated above are only qualitative, owing to the use of a simplified model for the description of the properties of real systems (we may note that the K–M formula does not take into account the refractive index of the medium and, in addition, diffuse light was sometimes replaced by directed light in the experiments).

Ivanov et al. [86] determined the concentrations of dyes adsorbed on fibres. Several types of dyes and fibres were investigated, the results were interpreted with the aid of the K–M function, and the layer was illuminated at normal incidence. Satisfactorily linear relations between $f(R_\infty)$ and the dye concentration are quoted for the individual dyes and it was shown experimentally that the absorption coefficients for a mixture of dyes are additive quantities [86]. A method for the determination of microamounts of mercury from the coefficient of reflection from paper dyed with a mercury complex of diphenylcarbazone was described in a similar study [87]. As in the usual photometry, mercury was determined by comparing the experimental data with a calibration curve obtained by plotting $f(R_\infty)$ against [Hg].

Oelkrug [88] investigated the structure of copper complexes on the basis of reflection spectra with the aid of the K–M function and Gavrilova et al. [89] described the correlation between $f(R_\infty)$ for cellulose and the degree of its acetylation. Toporets [90] studied the light scattering processes in pigments and obtained a linear relation between $f(R_\infty)$ and the concentrations of various pigments in magnesium, zinc, and titanium oxides.

The light scattering processes in weakly absorbing milky glasses have been investigated within the framework of the TFA version [18,19,91]. Voishvillo [91] interpreted the results in terms of the G–K–M formulae, although light at normal incidence had been used in the experiments. The attenuation coefficient under bulk-phase conditions [the parameter $a$ in Eqns. (11)] was estimated from the dependence of the coefficients $R$ and $T$ on the thickness of the layer, the error in the determination of this parameter was analysed, and the absorption coefficient of the glass was determined. The average cosines of the angles of inclination of the light beams [$\nu_1$ and $\nu_2$ in Eqn. (8)] were estimated by measuring the indicatrix of the radiation emerging from the layer [91]. They were found to be [virtually] equal, but their average (0.63) differs from the value (0.5) proposed by Zege [9]. This may be due both to the elongation of the scattering indicatrix and to the use of radiation emerging from the layer rather than the radiation within the layer. Voishvillo [18,19] interpreted experimental data in terms of the TFA formulae, taking into account the refractive index of the glass.

The limits of applicability of the G–K–M relations have been determined by Rozenberg et al. [92], who claim that the absorption coefficients of weakly absorbing media can be determined correctly with the aid of the K–M function by introducing an effective scattering coefficient. This postulate was confirmed experimentally for magnesium oxide and zinc oxide layers [92-95]. The region where the two-flux approximation is applicable has also been considered by Sakhnovskii and Kotik [96].

The experimental data have been interpreted within the framework of the layer model in a number of investigations [37-40], where the reflection spectra of powdered phosphors [39] and ground coloured glasses [37,38,40,97] were studied.

The absorption coefficients of powdered didymium glasses and GaP have been obtained [46] with the aid of Melamed's theory from reflection spectra. The results agree well with the true absorption coefficients of transparent specimens. Pool and Itzel [98] used the reflection spectra of chromium and aluminium oxides to determine the structures of the electronic transitions and the state of ions. The results were interpreted and, in particular, the extinction coefficients were determined on the basis of Melamed's theory [46].

The photochemical decomposition of powdered $K_3[Mn.(C_2O_4)_3].3H_2O$ was investigated by Simmons and Wendlandt [48]. The plot of $g(R_\infty)$ against $t$ [Eqn. (40)] was indeed

linear for different wavelengths and light intensities and the observed quantum yields were 0.41 ($\lambda$ = 400 nm) and 0.13 ($\lambda$ = 350 nm).[48]

The $P_1$ approximation for the description of light scattering processes has been examined in a study[28] whose authors investigated the scattering properties of layers consisting of spherical methyl methacrylate particles. The extinction coefficient of methyl methacrylate was found within the framework of the diffusion model and the optical characteristics of such layers were predicted. In a subsequent study[99], the authors estimated theoretically the parameters of the scattering layers in dispersed radiation detectors and confirmed experimentally the calculated results.

The diffusion model for the description of radiative transfer processes from point sources in weakly absorbing media was used by Brinkworth[100]. The solution of the diffusion equation in the spherical coordinate system, taking into account the influence of the reflecting walls surrounding the given space, agreed satisfactorily with experimental data for the passage of light through aqueous solutions of poly(methyl methacrylate) and poly(vinyl chloride) [100]. The diffusion approximation method has been used successfully by Gribakin and Istomin to determine the optical behaviour in photographic emulsions and to find certain parameters of such emulsions[10,101]. The scattering properties of photographic emulsions have also been described in other studies[102,103].

The diffusion theory of neutron scattering has been used to describe the light scattering processes[104]. The specimens (blue and green glasses) were used to determine the absorption spectra from the reflection spectra of ground glasses with the aid of the $P_1$ approximation. A satisfactory agreement was achieved between the absorption spectra observed for the transparent glasses and the absorption spectra calculated from the reflection spectra. The $P_1$ approximation has been examined for diffuse illumination without taking into account the refractive index of the glass[104]. A similar approach has been used in another study[105] to determine the scattering cross-sections in dense suspensions of spherical particles (polystyrene latex).

The transport $P_1$ approximation has been used[30] to describe the scattering properties of pure and coloured filter paper. It follows from Eqn.(37) of the $P_1$ approximation that the following relation holds for weakly absorbing media with a fairly considerable optical thickness of the layer

$$\frac{1}{T(N)} = \frac{1}{(1-\rho_{sp})}\left[\frac{2p}{(3+p)} + \frac{3\sigma_{eff}}{(3+p)}l\right]. \qquad (41)$$

$\sigma$eff can be found from the dependence of the coefficient $T(N)$ on the thickness of the paper (the number of filter papers) by Eqn.(41), since the paper absorbs only slightly in the visible part of the spectrum. Fig. 3 illustrates the variation of $1/T(N)$ with $l$ for the filter paper ($\lambda$ = 600 nm) from whose slope and the intercept on the ordinate axis it is possible to estimate $\alpha$ and $\sigma$eff.[30] Using the characteristics of the medium found from the experiments on light transmission, it is possible to calculate $R_\infty(N)$ in terms of the $P_1$ approximation (Table 8). Table 8 shows that these data agree satisfactorily with experiment.

The reflectivity of coloured filter paper was also investigated. Nitratohexamminecobaltate(III), potassium hexacyanoferrate(III), and anthraquinone-2-sulphonate were used as dyes. This choice was dictated by the fact that the above substances show no tendency towards specific adsorption on the paper and it is therefore easy to determine their concentration on the paper. By measuring the reflection coefficient of the coloured paper and knowing the characteristics of the layer ($\alpha$ and $\sigma$eff), it is possible to find from the Eqn.(32) of the $P_1$ approximation, taking into account the relation $\alpha = 2.3\epsilon c$, the concentration of the dye or its optical characteristics when the concentration is known.

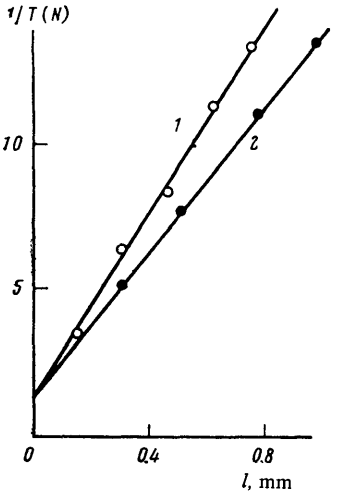

**Figure 3.** Dependence of $1/T(N)$ on the thickness of the layer ($\mu_0$ = 1): 1) filter paper; 2) MS-14 milky glass[33].

As an example, Figs. 4 and 5 present the variation of the coefficients of specific absorption of the paper with the concentrations of the dyes and also the absorption spectra calculated from the diffuse reflection spectra[30], obtained on the assumption that the introduction of the dye does not alter $\sigma$eff and that the dye is uniformly distributed throughout the paper.

Table 8. The coefficients $R_\infty(N)$ of filter paper [Eqn.(32)] ($\beta$ determined from data for the transmission of light through the paper[30]).

| $\lambda$, nm | 400 | 420 | 450 | 480 | 500 | 600 |
|---|---|---|---|---|---|---|
| $R_\infty(N)$, (calc.) | 0.837 | 0.856 | 0.882 | 0.897 | 0.905 | 0.940 |
| $R_\infty(N) \pm 0.02$, (expt.) | 0.834 | 0.851 | 0.875 | 0.906 | 0.922 | 0.950 |

We shall now consider certain literature data which we interpreted in terms of the $P_1$ approximation. Fischer and Vratny[106] published the coefficients $R_\infty(N)$ for magnesium carbonate as a function of the amount of the light absorbing additive. We shall assume that the absorption coefficients are proportional to the weight fraction of the substance whereupon

$$\frac{1}{\beta} = \frac{m\sigma_d + \sigma_{MgCO_3}}{m\alpha'_d + \alpha'_{MgCO_3}}, \qquad (42)$$

where $m$ is the weight fraction of the additive (subscript $d$) and $\alpha'$ are quantities proportional to the true parameters $\alpha$. Since $R_\infty(N) \simeq 0.97$ in the visible part of the $MgCO_3$ spectrum[107], we neglect the term $\alpha'_{MgCO_3}$. In this case, the plot of $1/\beta$ against $1/m$ should be linear. Indeed, measurements of the reflection of light from a mixture of $MgCO_3$ and Congo Red[106], interpreted in terms of Eqn. (42) ($N = 1.515$),[107] fit satisfactorily on a straight line (Fig. 6).

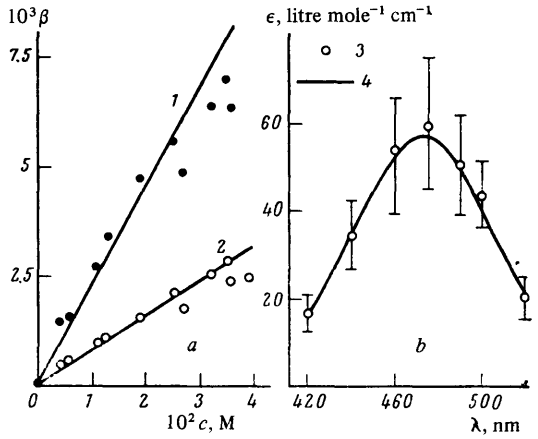

Figure 4. Nitratohexamminecobaltate(III) in filter paper[30]: *a*) dependence of $\beta$ on concentration [1) $\lambda$ = 475 nm; 2) $\lambda$ = 520 nm]; *b*) [3) extinction coefficient calculated from reflection spectra; 4) ditto for an aqueous solution].

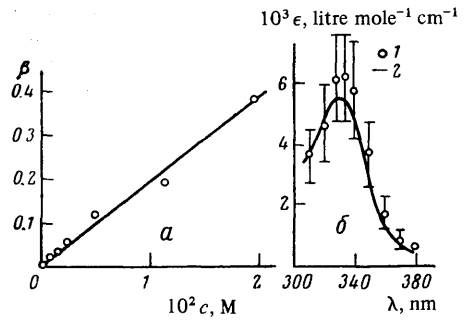

Figure 5. Anthraquinone-2-sulphonate in filter paper[30]: *a*) dependence of $\beta$ on concentration ($\lambda$ = 330 nm); *b*) [1) extinction coefficient calculated from reflection spectra; 2) ditto for aqueous solution].

A linear relation between the specific absorption coefficient and the concentration of the light absorbing additive (carbon black), analogous to the Beer–Lambert law, has been observed for aqueous suspensions of $BaSO_4$, ZnO, and $TiO_2$ ($N = 1.33$). The values of $R_\infty(N)$ for such systems, quoted by Blevin and Brown[108], have been interpreted in terms of Eqn. (32) (Fig. 7). We obtained a similar straight line from data[109] for eosin adsorbed on alumina.

We shall now consider the reflection spectra of coloured glass powders[97,110] ($N = 1.5$). General considerations suggest that $1/\sigma$ should be proportional to the average particle size in the layer. Indeed, knowing the absorption coefficients of ZhZS-1, NS-3, and ZS-6 coloured glasses and having calculated $1/\sigma$ in terms of the $P_1$ approximation, we obtain satisfactorily linear relations between $1/\sigma$ and the average particle size in the powder ($\bar{a}$), which are almost unaffected by the absorption coefficient (see, for example, Fig. 8).

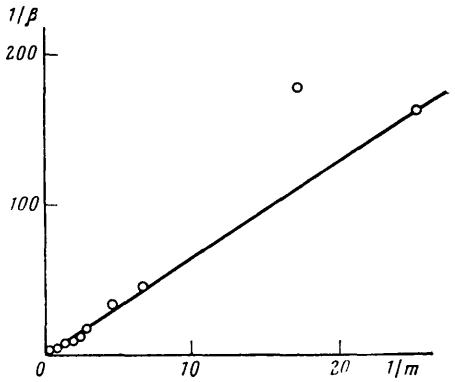

Figure 6. Dependence of $1/\beta$ on $1/m$ for a mixture of $MgCO_3$ and Congo Red powders. Data[106] interpreted in terms of the $P_1$ approximation.

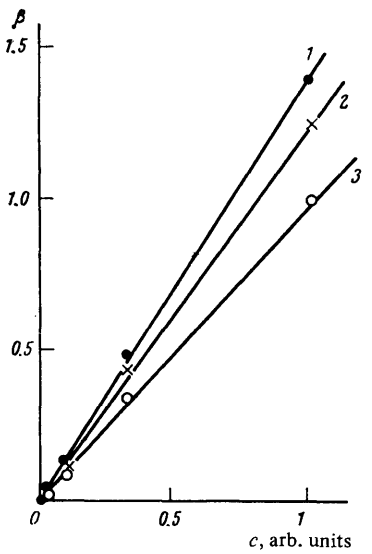

Figure 7. Dependence of $\beta$ for an aqueous suspension of ZnO on the concentration of carbon black $c$. Data[108] interpreted in terms of the $P_1$ approximation; $\lambda$ (nm): 1) 400; 2) 500; 3) 700.

The reflection and transmission coefficients of the MS-14 glass have been published[33] as a function of the layer thickness ($\mu = 1$, $N = 1.5$). Fig. 3 illustrates the variation of $1/T(N)$ with $l$ ($\lambda$ = 550 nm) based on these

data, which is linear, in agreement with Eqn. (41). The intercept on the ordinate axis is approximately 1.3, which is close to the values predicted by Eqn. (41). We may recall that a similar straight line for milky glasses has been found [14] to make an intercept greater than unity (Fig. 2). These findings apparently indicate the necessity for taking into account the refractive index of the scattering medium. The effective scattering coefficient of the MS-14 glass can be estimated from the slope of its straight line (Fig. 3) and $\alpha$ can then be found from the value of $R_\infty(N)$. Using the values of $\alpha$ and $\sigma_{eff}$ obtained in this way, we calculated in terms of the $P_1$ approximation $R(N)$ and $T(N)$ for the MS-14 glass as a function of the layer thickness, the results agreeing with experimental data within the limits of the accuracy of the latter [33].

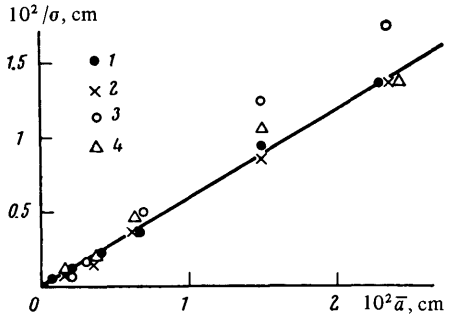

Figure 8. Dependence of $1/\sigma$ on $\bar{a}$ for ZS-6 glass powder ($\bar{a}$ is the average particle size). Data [97] interpreted in terms of the $P_1$ approximation; $\alpha$ ($cm^{-1}$): 1) 11; 2) 55; 3) 21.2; 4) 47.

Bearing in mind that the sum $[A] + [AH_2]$ is constant, it is possible to obtain the following expression for the initial section of the kinetic curve for the photolytic reaction [111]:

$$\varphi = -\frac{(d\beta/dt)_e \cdot \sigma_e/\sigma_p}{2.3(\varepsilon_A - \varepsilon_{AH_2})_e \cdot (\beta - \beta_0)_p c n_p}, \quad (43)$$

where the subscript $e$ refers to the quantities corresponding to the experimental wavelength, $p$ refers to photolysis, $\beta_0$ corresponds to pure paper, and $n_p$ is the density of the quanta in the layer taking into account its illumination from both sides. A similar expression for $\varphi$ is obtained also when it is assumed that the light which has entered the layer is fully absorbed by compound A.

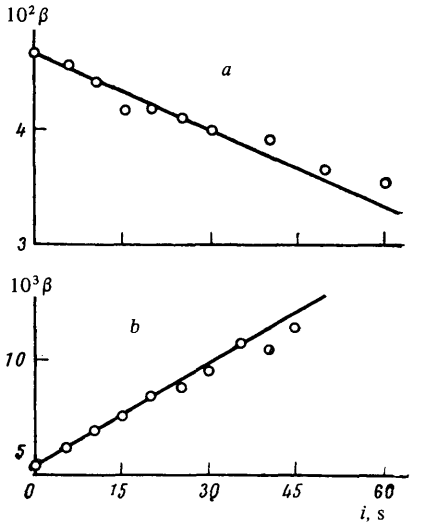

Figure 9. Initial sections of the kinetic curves for the photolysis of compound A in paper [111]; $\lambda_p$ = 335 nm, $\lambda_e$ = 335 nm (*a*); $\lambda_e$ = 385 nm (*b*).

We estimated with the aid of SLS the quantum yield $\varphi$ in the photochemical hydrogenation of anthraquinone-2-sulphonate (A) in filter paper [111]. A is reduced under the action of light to anthrahydroquinone-2-sulphonate ($AH_2$). The absorption band maxima for compounds A (335 nm) and $AH_2$ (385 nm) are well separated so that it is convenient to follow the photochemical reaction from the change in $R_\infty$ (and hence also $\beta$) at the absorption band maxima. The methods described above, in particular the $P_1$ approximation, presuppose the homogeneity of the absorption coefficients throughout the layer, while the light profile has the form of a sharply decreasing function [Eqn. (29)]. As a result, the concentrations of A and $AH_2$ are significantly different throughout the layer. To a rough approximation, the light profile can be regarded as constant if thin sheets of paper are illuminated from both sides and then stacked to form a thick pile in order to measure $R_\infty$.

Thus, assuming that the intensity of the photochemically active light is constant along the layer, we have at a certain instant $t$

$$\beta_e = \frac{2.3}{\sigma_e}(\varepsilon_A [A] + \varepsilon_{AH_2} [AH_2])_e + (\beta_0)_e.$$

The quantum yield of the photochemical hydrogenation of A, estimated by Eqn. (43), proved to be 0.12 ± 0.07, which agrees satisfactorily with the value obtained by an indirect chemical method. As an example, Fig. 9 presents the initial sections of the photolysis curves calculated by Eqn. (32) from the measured coefficients $R_\infty(N)$ for $[A] = 1.7 \times 10^{-3}$ M and $I_0 = 6 \times 10^{-14}$ quanta $cm^{-2}$ $s^{-1}$, where $I_0$ is the intensity of the light incident on the layer.

The propagation of light in a medium having the shape of an infinitely long cylinder has been described with the aid of the diffusion theory [112], the description agreeing well with data for light scattering in polystyrene latices [113,114].

## VIII. CONCLUSION

Approximate methods. The transport, two-flux, and diffusion approximations are most suitable for the analysis of experimental data and, when the specimen is illuminated with diffuse light, it is best to use the two-flux approximation. For directional illumination, both

approaches can be employed. However, we give preference to the transport diffusion approximation, since it can be used without resorting directly to the radiative transfer equation with which it is possible to take into account readily a wide variety of conditions within the specimen and on its surface. On the other hand, the diffusion equation is very frequently used to solve various chemical problems and for this reason physical chemists are much more accustomed to it than to the radiative transfer equation.

The Kubelka – Munk formula. The Kubelka–Munk formula [Eqn.(12)] is widely used in the analysis of experimental data even for directed illumination of the specimen. If the experimenter is satisfied with deducing a relation of the type $\alpha \propto c$, the application of the K–M formula does not lead to qualitatively incorrect results. However, in quantitative analysis it is best to employ the formulae of the transport, diffusion, or two-flux approximations, since the application of the K–M function for directed irradiation of the specimen is theoretically unjustified.

The radiative transfer equation. In the analysis of experimental data obtained for physicochemical systems such as powders, papers, fabrics, etc., the direct use of the radiative transfer equation can hardly be regarded as useful not only owing to mathematical difficulties, but because of certain fundamental considerations. The point is that it is not altogether clear how to formulate the radiative transfer equation for polydisperse systems such as powders or paper[115]. Furthermore, in complex polydisperse systems the coefficients $\alpha$, $\sigma$, and $\chi$ depend not only on the coordinates but also on the direction of the incident beam. Consequently quantities averaged in some way must be substituted in the radiative transfer equation. However, the usefulness of employing average quantities within the framework of the exact radiative transfer equation is far from evident. The approach within the framework of the various approximations, some of which have been discussed above, appears more justified. Nevertheless, the rigorous solution of the problem of radiative transfer for different conditions should be the starting point for testing approximate methods.

There is apparently no great risk in extrapolating the solutions obtained to the region of strong absorption, provided that the treatment is restricted to the analysis of the coefficient $R_\infty$ only, since the formal application of approximate theories to the region of strong absorption yields the following qualitative relation: $R_\infty \propto \beta^{-1} \propto c^{-1}$. We may note that the analogous relation $R_\infty \propto c^{-1}$ follows from Rozenberg's theory[4,6]. The proportionality coefficient between $R_\infty$ and $c^{-1}$ may be found experimentally.

The possibility of the quantitative measurement of the absorption coefficient. The spectroscopy of light scattering media is nowadays used inadequately in chemical research. With a few exceptions, no attempts have been made to determine the absorption coefficients. We may note that, in order to determine the absorption maximum of a substance in a scattering medium, no theories are required, since it is sufficient for this purpose to have, for example, the $R_\infty - \lambda$ or $(1 - R_\infty) - \lambda$ curves.

One of the ways of determining absorption coefficients quantitatively may be as follows. One may hope that in certain cases light scattering will be determined mainly by the light scattering matrix and not the admixtures introduced into it. This can be demonstrated by introducing into the matrix different substances which do not interact with it assuming at the same time that the absorption coefficient of the added substance does not change and is equal to that for the same substance in solution. The problem now is to what extent this assumption can be justified. One may note that the introduction of a substance into a light scattering matrix does not differ in principle in any way from dissolution. For this reason, the change in the extinction coefficient should be close to the change in the extinction coefficient when the compound is dissolved in various solvents. According to Stern and Dammons[116], in most cases it does not exceed 5–10%. The data quoted in their book[116] for the extinction coefficients of the $n - \pi^*$ transition of the acetone molecule in various solvents, show that it does not change by more than 25% on either side of the average value. We may note that the $n - \pi^*$ transitions are most sensitive to the environment. On the other hand, when molecules with internal transitions of the type $\pi - \pi^*$ or $a - d$, for example $Co(NH_3)_6^{3+}$, are used, one may hope that their extinction coefficients do not vary markedly when they are introduced into a light scattering matrix. By using several specially selected compounds, it is possible to determine the dependence of the scattering coefficient on the wavelength. This would make it possible to determine subsequently the absorption coefficient of any other compound introduced into the matrix. Naturally the objection arises that this procedure is not very accurate; however, the accuracy of the above approach is not lower than that of the ESR method, widely used in physicochemical research, for which the accuracy of the quantitative determination of free radicals is usually assumed to be approximately 40%.

Thus the present state of SLM permits the quantitative determination of the absorption coefficient. The absence of the relevant reports from the literature is incomprehensible.

The problem of the separation of $\epsilon$ and $c$. The knowledge of the absorption coefficient $\alpha$ does not of course permit the separate determination of $\epsilon$ and $c$. It is therefore necessary to employ other methods whereby the concentration can be measured directly, for example, the ESR method. Such combinations of ESR and SLM methods appears to be fairly promising, particularly in catalytic research.

Procedures involving the transition of the given substance from one form to another under the influence of some agent, for example chemical or radiation-chemical, are very important for the problem of the resolution of the two parameters. This factor also appears to have been overlooked by experimenters.

The size of light beams. In the approximate methods considered, light beams of infinite extent are postulated. On the other hand, in practice light beams of finite dimensions are used. However, they satisfy the problem formulated if their size is significantly greater than the characteristic parameter of the specimen: $1/(\alpha + \sigma\text{eff})$. The existence of halos, for example in the case of milk, indicates the unsuitability for research of beams approximately 1 cm long, since the characteristic size of the halos is of the same order of magnitude. Beams whose size is significantly greater than the geometrical dimensions of the powder particles are probably suitable for powders.

The specular component in the diffuse reflection spectra. For layers with an optically smooth surface, the specular component may be readily taken into account [31]. For powdered specimens, whose boundary cannot be clearly determined, the allowance for the specular component in the measurement of the reflection spectra is much more difficult. It apparently depends on the packing density of the powder particles [75]. On the other hand, in view of the uneveness of the boundary of the powdered medium, the specular component may be actually smaller than for an optically smooth surface. The problem has not been finally solved and is by no means always taken into account in experimental research.

Allowance for the effect of total internal reflection. The existence of total internal reflection must be taken into account for specimens with an optically smooth surface, for example solutions. The necessity for this in the case of powdered specimens is less clear. The elucidation of the above problem requires further experiments, although one can adduce arguments in support of allowance for total internal reflection in these media too.

Illumination of specimens at an angle. It is sometimes suggested that specimens be illuminated at an angle, for example 45°, since in this case the values of $R_\infty$ obtained from the exact solution of the radiative transfer equation for a spherical scattering indicatrix and calculated from the Kubelka–Munk equation are approximately the same [2,31]. However, this approach has no appreciable advantages compared with the usual illumination of specimens at right angles ($\mu_0 = 1$) and may actually suffer from disadvantages. The point is that it is not clear how to proceed when the scattering indicatrix deviates from the spherical shape and in practice this situation does in fact occur. On the other hand, in the study of systems with an optically smooth surface one must take into account the refraction of the light beam and the angle must be varied in order that the light should enter the medium at an angle of 45°. Furthermore, for illumination at an angle the coefficient $R_\infty$ increases and the method becomes less sensitive to small amounts of impurities.

The reference specimen. By analogy with the spectroscopy of transparent media, diffuse reflection spectra are sometimes measured relative to the light-scattering matrix assuming thereby that the absorption in the initial matrix, for example owing to impurities, is taken into account. However, as a result of the absence of a linear relation between $R_\infty(\lambda)$ and $\alpha(\lambda)$, this method of taking absorption into account is incorrect. $R_\infty(\alpha)$ can of course be measured relative to the initial light-scattering material, but in quantitative calculations the data obtained ($R_\infty^{exp}$) must be converted into the true reflectance ($R_\infty^{true}$) by means of the formula

$$R_\infty^{true} = R_\infty^{org} R_\infty^{ref},$$

where $R_\infty^{ref}$ is the reflection coefficient relative to a specimen giving 100% reflection. Either milky glasses [117–119] or white powders, for example MgO, ZnO, and $BaSO_4$ with known reflectances [120,121], are normally used as reference specimens with 100% reflection.

The apparatus. All types of apparatus for measurement of the integral coefficients $R$ and $T$ can be divided into two classes: devices with an integrating sphere [122] (SF-10 and SF-14 apparatus) and devices with elliptical or parabolic mirrors [4,8] (the PDO-1 and PDO-2 attachments). In both systems, light is directed in succession to the experimental and reference specimens. We may note that the PDO-1 attachment does not measure the entire reflected radiation but only its component reflected within conical angles of 10–80° relative to the normal. In the measurement of the true coefficient $R_\infty$, it is therefore necessary that the angular characteristics of the radiation reflected from the test and reference specimens should be similar. Simpler devices can also be used to measure $\alpha_{max}$ for reflection spectra [123].

Prospects. The present state of SLM is such that it permits quantitative measurements with an accuracy close to that of the ESR method (approximately 40%). One may hope that SLM will find much wider applications in studies on photochemical, radiation-chemical, and, particularly, catalytic processes.

# The Reactions of Mono-olefins in the Presence of Alkali Metals and Their Derivatives

V.R.Ansheles and I.I.Pis'man

Studies devoted to reactions of mono-olefins in the presence of alkali metals and their derivatives—mainly metallation, dimerisation, codimerisation, and isomerisation reactions—are reviewed. The catalysts, the reaction conditions, the product composition, and the problems of the reaction mechanisms are considered. It is shown that the specificity of the action of alkali metal catalysts is associated with the common features of the formation and reactions of organic derivatives of the alkali metals and that the reactions in the presence of such catalysts may serve as a basis for the development of promising procedures for the processing of mono-olefins.
The bibliography includes 274 references.

CONTENTS

I. Introduction 620
II. Reactions of olefins with alkali metals and their compounds 620
III. Reactions of olefins catalysed by dispersed alkali metals and their compounds 622
IV. Reactions of olefins under the influence of alkali metals on carriers 625

## I. INTRODUCTION

Mono-olefins are the main raw material in modern petrochemical industry; their world-wide manufacture runs into many millions of tonnes per year. For this reason, studies on the reactions of these hydrocarbons are as a rule of great practical importance.

Mono-olefins are known to have a dual nature: they are regarded as weak acids and bases, since they are capable of exchanging hydrogen for a metal, of combining with a proton, or of behaving as an electron donor. The dimerisation, codimerisation, metallation, alkylation, and isomerisation reactions of mono-olefins in the presence of basic catalysts give rise to extensive possibilities for the synthesis of individual hydrocarbon monomers and intermediates in petrochemical synthesis. The high selectivity of these reactions makes it possible to obtain in useful amounts such relatively thermodynamically unstable olefins as 4-methylpent-1-ene, 3-methylpent-1-ene, 3-ethylpent-1-ene, etc. The content of these $\alpha$-alkenes in the petroleum processing products (cracking or pyrolysis products) is negligible and their isolation is hindered by the similarity of the physicochemical properties of the isomers.

The isomerisation of mono-olefins and certain diolefins in the presence of alkali metal catalysts makes it possible to shift the double bond to the required position under mild conditions without affecting the carbon skeleton. The alkylation of alkylbenzenes [by olefins] in the presence of these catalysts results in the selective addition of the olefins to the side chain only, so that subsequent dealkylation can yield also chain olefins with a specific structure, for example isopentenes.

The first attempt at a broad survey of the reactions catalysed by bases was made in 1962 by Pines and Schaap [1]. Pis'man's monograph was devoted to the industrial synthesis of 4-methylpent-1-ene [2]. Two reviews [3,4] dealt mainly with the dimerisation and codimerisation of olefins in the presence of transition metal complexes, the problems of the reactions on basic catalysts being only partly considered.

The present review is concerned with the extensive data published in recent years and also with certain early studies on the reactions of unsaturated compounds, mainly mono-olefins, in the presence of alkali metals and their derivatives in the light of modern ideas about the nature and mechanism of acid–base catalysis.

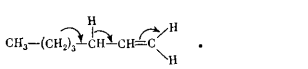
## II. REACTIONS OF OLEFINS WITH ALKALI METALS AND THEIR COMPOUNDS

The hydrogen in many hydrocarbons can be replaced by an alkali metal, which is characteristic of acids, and an organometallic compound may be obtained. The substitution can occur both on direct treatment with the metal and on treatment with another organometallic compound containing the alkali metal. With increase of the atomic weight of the alkali metal, the rate of metallation as a rule increases. The rate can also increase when the metal in the fused or finally comminuted state, solutions in liquid ammonia, and the sodium–potassium eutectic mixture are used [5]. The rate of metallation depends on the mobility of the hydrogen in the molecule of the organic compound too. Olefins exhibit a comparatively weak acidity and are only slowly metallated directly by alkali metals [6]. The transmetallation reaction, described for the first time by Shorygin [7], proceeds much more readily:

$$HR + R' - M \rightleftarrows R - M + R'H ,$$

where M = Li, Na, K, Cs, or Rb and R and R' are hydrocarbon groups.

Kocheskov and Talalaeva [8] formulated the rules for metallation: (a) the yield of the organometallic compound increases with acidity when the same metallating agent acts on different hydrocarbons; (b) under identical conditions, the hydrocarbon with greater acidity is metallated faster; (c) in the presence of a deficiency of the metallating agent, the compound which is a stronger acid is also metallated preferentially.



The presence of multiple bonds or rings in the molecule of the organic substance greatly alters the energy required to abstract a proton. Thus it amounts to 95

kcal mole$^{-1}$ in propane and 98 kcal mole$^{-1}$ in ethane, while in toluene it is only 77.5 kcal mole$^{-1}$ and the abstraction of the allyl hydrogen atom in propene requires 77 kcal mole$^{-1}$.[9] Alkylbenzenes are alkylated at a high rate at the $\alpha$-carbon atom of the aliphatic substituent[10-12]. The substitution of hydrogen in naphthalene by a metal is much faster than in benzene[13-15]. The acidity of alkynes is still higher, increasing in the sequence[14] $HC{\equiv}CH < HC{\equiv}C-C_5H_{11} < {\equiv}C-C_6H_5$.

Ethylene is a much weaker acid than acetylene; it is metallated only by strong bases, for example by pentylsodium[11]. The substitution of protons in ethylene by alkyl groups increases the acidity of the olefin, because the vinyl group activates the hydrogen atoms at the carbon atom nearest to it. For this reason, propene is metallated more readily than ethylene, the hydrogen in the methyl group being preferentially substituted by the metal[5,6,17,18]. Its dimetallation leads to the formation of $NaCH_2-CH{=}CHNa$.[19] Mono- and di-substituted products were also obtained in the metallation of isobutene[17]: $CH_2{=}C(CH_3)CH_2Na$ and $CH_2{=}C(CH_2Na)_2$.

The metallation of but-1-ene by pentylsodium and subsequent carbonation yield mainly $CH_2{=}CHCH(CH_3)COOH$ and smaller amounts of $CH_3CH{=}CHCH_2COOH$, $CH_3CH_2CH{=}CHCOOH$, and dimetallation products[17]. Pent-1-ene is metallated[17] mainly with formation of $CH_2{=}CHCHNaCH_2CH_3$ and $NaCH{=}CH(CH_2)_2CH_3$. Under the influence of pentylsodium, hex-1-ene also gives rise to two compounds[16]: the first corresponds to the metallation of the methylene group in the $\alpha$-position relative to the multiple bond and the second is formed, as in the case of but-1-ene, as a result of the migration of the double bond: $CH_3(CH_2)_2CH{=}CHCH_2Na$. Such isomerisation with migration of the double bond to the centre of the chain has been described for reactions with phenyl-, benzyl-, and pentylsodium[20]. The metallation of hexenes with a branched chain also involves mainly the substitution of the allyl hydrogen atom; for example 2,3-dimethylbut-1-ene is converted, after metallation and carbonation, into $CH_2{=}C(i\text{-}C_3H_7)CH_2.COOH$. When there is no allyl hydrogen atom, as in 3,3-dimethylbut-1-ene, the terminal carbon atom in the vinyl group is metallated[16].

Studies on the metallation of $C_7$ and higher $\alpha$-olefins[21-28] have shown that, with increase of the carbon chain length in olefins, their acidic properties are weakened[5] and the nature of their reactions changes somewhat. For example, it has been established experimentally[25,26] that already in the case of hept-1-ene vinyl substitution products predominate in the reaction mixture at the beginning of the reaction. It appears that in $\alpha$-olefins with more than six carbon atoms the double bond not only withdraws electrons from the C–H bond in the allyl position but is also responsible for the successively decreasing inductive shift of electron pairs in the same direction[26]:

This shift compensates to some extent the decrease of electron density in the C–H allyl bond, which leads to the predominance of vinyl substitution products. This phenomenon has not been observed in low-molecular-weight $\alpha$- and $\beta$-olefins and their acidity changes in the following sequence[5]: $(CH_3)_2C{=}CH_2 > CH_3-CH{=}CH_2 > CH_3CH{=}CHCH_3 > CH_3CH_2CH{=}CH_2 > (CH_3)_2C{=}CHCH_3 > (CH_3)_2C{=}C(CH_3)_2$.

Conant and Wheland[30] estimated the acidity by a calorimetric method and by carboxylating organosodium or organopotassium compounds; McEwen[31] and Shatenshtein[32] used in addition the polarimetric method. Streitwieser and coworkers[33,34] measured the equilibrium constant in the reactions of lithium or caesium cyclohexylamide with C–H acids. Cram[35] attempted to establish a universal acidity scale for all classes of hydrocarbons using the above data and the results obtained in other studies[36-38]. In an extensive review, Reutov et al.[39] examined the available methods for the determination of the equilibrium acidity and concluded that it is so far possible to determine the acidity of hydrocarbons in aprotic solvents only up to $pK_a \simeq 30$. The acidity of weaker acids (alkenes, arenes, alkanes, etc.), which is estimated by indirect methods, is lower than the value predicted by Cram's scale. This somewhat limited information about the relative acidities and basicities of hydrocarbons, enabled Shatenshtein[5,40,41] and Cram[35] to correlate the above properties of organic compounds with their behaviour in different chemical reactions.

Isotope exchange of hydrogen with strong bases[40] makes it possible not only to estimate the acidities of individual C–H bonds but also to characterise simultaneously the base functioning as the nucleophile[42]. For example, examination of the rate of exchange of hydrogen in propene showed that at 25 °C three hydrogen atoms are already exchanged after 15 min. The exchange of five atoms takes place comparatively rapidly (up to 1.5 h), while the last hydrogen atom exchanges at a much lower rate[32]. The rate of exchange of six hydrogen atoms in the two methyl groups of isobutene is approximately an order of magnitude lower than in the $CH_3$ group of propene but an order of magnitude higher than the rate of exchange of the last two atoms. When isobutene is compared with tetramethylethylene (whose molecule has the same group of atoms but its structure is symmetrical and for this reason it has no dipole moment), the rate of reaction is seen to decrease by almost two orders of magnitude[5].

Thus the acidity of individual hydrogen atoms varies significantly as a function of the structure of the olefin molecule and in metallation one must expect the formation of an organometallic compound in which the most acidic hydrogen atom has been replaced by the metal. However, according to Morton and Holden's data[17], the structure and proportions of straight-chain butene metallation product are independent of the position of the double bond in the initial olefin. It has been shown for crotyl-lithium[43] that the ratio of different forms of organometallic compounds of the allyl type is determined by the reaction conditions, in particular by the temperature and the nature of the solvent. It has been established by NMR methods[44] that the first and third hydrogen atoms are equivalent in allyllithium $CH_2{=}CH-CH_2Li$, which indicates either the possibility of a rapid reversible migration of lithium between these atoms or the formation of a compound in which the lithium atom is delocalised[45]. It has been shown similarly[46] that the following species coexist in ethereal solutions of crotyl-lithium: $CH_3-CH{=}CH-CH_2Li$ and $CH_3-CH(Li)-CH{=}CH_2$.

A number of workers[42,47-49] explained the nature of such organometallic compounds in terms of the concept of "polar" quantum-mechanical resonance, for the description of which the ground state of the anionic component is represented by a set of classical structural formulae for all possible electronic isomers, each of which is characterised by a definite contribution to this state[42]. The delocalisation of bonds, lone electron pairs, charges, and spins is energetically favourable and leads to resonance stabilisation of the molecule[42]. Delocalisation of the

negative charge facilitates the formation of a carbanion, but lowers the reactivity of the given compound[50].

Lefebvre and Chauvin[4] quote stability and reactivity series for carbanions:

| | | |
|---|---|---|
| Increasing reactivity ↓ | $R-CH-\bar{C}H-\bar{C}H-\bar{C}H_2$ | Increasing stability ↑ |
| | $R-CH=\bar{C}H$ | |
| | $R-\bar{C}H_2$ | |
| | $R_1-\bar{C}H-R_2$ | |
| | $R_1-\bar{C}(R_3)-R_2$ | |

In the metallation and isotope exchange reaction under consideration, which proceeds via the mechanism of an acid–base interaction, one must expect the formation in the limit of ions with a tervalent negatively charged carbon atom (free carbanions). In practice, polarised transition complexes with more or less stable hydrogen bonds are probably formed[5,32]. Their structure can be represented by the scheme[51,52]

The organic derivatives of alkali metals, formed as a result of metallation, can be highly reactive intermediates in many chemical reactions which are discussed below. This is explained by the greater ionic character of the C–M bond in these compounds compared with other organoelement compounds[53]. Alkenylsodium compounds can also be used to synthesise various unsaturated derivatives with functional groups and also unsaturated carboxylic acids, unsaturated sulphonic acids, unsaturated alcohols, etc.[54]

## III. REACTIONS OF OLEFINS CATALYSED BY DISPERSED ALKALI METALS AND THEIR COMPOUNDS

The first reports about the catalytic reactions of olefins in the presence of alkali metals were published as early as 1936.[55] Thirteen years later Freed took out patents for the dimerisation and codimerisation of alkenes in the presence of these catalysts[56,57]. The liquid products of the codimerisation of ethylene and propene, catalysed by metallic sodium, contained hydrocarbons with less than 10 carbon atoms, mainly pentenes and heptenes. The process was carried out under fairly severe conditions at temperatures and pressures in the range 275–400°C and 250–1000 atm respectively[56]. Under the same conditions, mainly hexenes were obtained from ethylene and isobutene and heptenes from propene and isobutene. The use of promoting agents (anthracene and naphthalene) made it possible to reduce the reaction temperature to 125–250°C.[57] The individual compositions of the olefins obtained were not determined.

Having investigated the dimerisation and codimerisation reactions of olefins in the presence of the "sodium with anthracene" catalyst, Mark and Pines[58] concluded that this reaction proceeds via the intermediate formation of resonance-stabilised carbanions, which determine the position where the olefin molecule adds. In the dimerisation of propene via the mechanism

the resulting isohexenyl carbanion, which is not stabilised by resonance, is rapidly involved in an acid–base reaction with the excess olefin. This leads to the regeneration of the allyl carbanion and the formation of 4-methylpent-1-ene:

The codimerisation of cyclohexene with ethylene, propene, and isobutene yielded mainly the products of the addition of olefins to cyclohexenyl carbanion, which confirms the postulated mechanism. 2,4,4-Trimethylpent-1-ene was obtained on dimerisation of isobutene[58].

The low content of the thermodynamically least stable hexene, namely 4-methylpent-1-ene, in the products of the dimerisation of propene in the presence of the "sodium with anthracene" catalyst can be explained by its isomerisation with migration of the olefinic double bond to more stable methylpentenes with the double bond in the inner part of the molecule, in consequence of the high reaction temperature and the presence of the aromatic promoting agent. Indeed, subsequent studies[59–61] showed that propene can be successively dimerised to 4-methylpent-1-ene in the presence of dispersions of potassium, rubidium, and caesium in hydrocarbon solvents (such as alkanes, mineral oil, naphthenes, and aromatic hydrocarbons) as well as ethers and ammonia. The highest rates were achieved in benzene, but in this case a much greater amount of propane and solid condensation products is formed[61].

In the absence of aromatic promoting agents, dispersions of sodium and lithium are as a rule ineffective. However, their mixtures with "heavier" alkali metals (potassium and caesium) as well as mixtures of these metals are much more effective in the oligomerisation of olefins than potassium and caesium individually[62]. The dispersion of lithium obtained by the exchange reaction between an organolithium compound LiR (where R is an alkyl group) and a free alkali metal (as a rule potassium) is highly active[63–65]. Possibly in this case the high activity is associated with the fact that the catalytic complex incorporates a mixture of potassium and lithium. It has been shown[66] that preliminary heating of the catalyst to temperatures preceding codimerisation and its maintenance at these temperatures in the presence of olefins (for example, but-2-ene) greatly increases the rate of codimerisation of this olefin with ethylene and increases the yield of 3-methylpent-1-ene from 38 to 55 wt.%. It is suggested that the alkali metal catalyst be regenerated by heating it to 200–400°C in an inert solvent[67], but it has been stated[68] that such regeneration is ineffective.

A detailes study of the dimerisation of propene in the presence of dispersions of alkali metals[69] led to the conclusion that the yield of 4-methylpent-1-ene depends on the experimental conditions and the nature of the alkali metal used. A higher content of 4-methylpent-1-ene (up to 86 wt.%) in the reaction products was achieved in the presence of potassium dispersions without aromatic promoting agents at a reaction temperature not exceeding 150°C and an alkali metal concentration not exceeding 50 g litre$^{-1}$;[70–72] admittedly, under these conditions the degree of conversion fell appreciably (to 10–15%). Simultaneous experiments on the isomerisation of 4-methylpent-1-ene and 4-methylpent-2-ene in the presence of a dispersion of sodium containing anthracene and a dispersion of potassium without aromatic additives[69] showed that, under the conditions of the dimerisation of propene, the double

bond of 4-methylpent-1-ene migrates. The use of dispersions of heavy alkali metals without aromatic promoting agents in inert alkane solvents complicates somewhat the formation of the organometallic initiator derived from the alkali metal. It is most likely that it proceeds via unstable intermediates, formed as a result of electron transfer from the alkali metal to the olefin $\pi$-bond (radical-anions) [69].

When the dimerisation and codimerisation reactions of olefins are carried out in the presence of alkali metals in aromatic hydrocarbons [60] or using aromatic promoting agents such as biphenyl, naphthalene, and anthracene [73,74], the induction period decreases and (under the conditions of periodic experiments) the degree of conversion rises owing to the high acidity of the aromatic hydrocarbons. The highest degree of conversion and selectivity were achieved in the presence of the "potassium with biphenyl" catalyst [73]. The authors state that this is due to the higher rate of metallation of this aromatic hydrocarbon with formation of the "complex"

The modification of alkali metal catalysts by aliphatic or aromatic ethers and ketones [75] did not lead to a significant increase of the rate of reaction and process selectivity. It is recommended that catalysts consisting of a mixture of alkali metals with their oxides, hydroxides, or fluorides be used [76-78]. Catalysts having the general formula $A(MR^1, R^2, R^3)$, where A is the alkali metal, M is zinc, mercury, cadmium, or tin, and $R^1$, $R^2$, and $R^3$ are hydrocarbon groups or hydrogen, have been described [79,80]. The selectivity of the formation of 4-methylpent-1-ene in the presence of these catalysts is not more than 80%.

Promotion of catalysts based on alkali metals by alkyl halides [81-83], alkylphenols [84,85], allyl or aryl ethers [86], alkylamines [87], and other organic compounds [88-92] did not increase significantly their activity and selectivity in the formation of $\alpha$-olefins in the dimerisation and codimerisation reactions of low-molecular-weight alkenes.

The formation mainly of 3-ethyl-substituted products in the codimerisation of ethylene with but-2-ene and pent-2-ene [66,68] instead of the straight-chain olefins expected from the relative acidity, can be accounted for in terms of the characteristics of the metallation reaction. These results can probably be explained by the formation from both $\alpha$- and $\beta$-olefins of the same organometallic compounds, the carbanionic component of which can be described by the resonance involving the following structures:

$$R-\bar{C}H-CH=CH_2 \longleftrightarrow R-CH=CH-\bar{C}H_2 .$$

The authors [68] represent the intermediate in combination with the alkali metal cation and not in the form of an individual kinetic species, as was suggested previously [58], but the influence of the cation on the reaction is not discussed.

Wilkes [70,74,93-97] attempted to reproduce the laboratory data [56,57] on a larger scale in a pilot apparatus (reactor volume 38 litres) and to test the schemes for industrial processes developed by the authors of these investigations [62,67]. He concluded [74] that a dispersion of potassium is appreciably reactive only for a particle size in the range 1–10 $\mu$m. With increase of particle size, the access of the starting material to lower layers of the metal is hindered, which leads to reactions between organopotassium compounds with formation of condensation products which hinder access to the catalyst surface. Potassium is in the fused state at the reaction temperature (120–170°C) and the maintenance of suspensions with such fine particles is difficult, since they combine into larger aggregates on collision. In order to avoid the coagulation of the liquid metal particles, it is suggested [74] that oleic acid be added and that potassium be deposited on 50 $\mu$m talc particles. The use of such a stabilised dispersion, or the "precipitation catalyst" in Wilkes' terminology, ensures more satisfactory results. However, they are not quite as good [74] as in the gas-phase process in the presence of catalysts consisting of "alkali metals on inorganic carriers", which will be described below.

Analysis of studies on the codimerisation of olefins [68] led Wilkes to the conclusion that the reactivity of olefins with respect to metallic potassium decreases in the sequence ethylene > propene > isobutene and that a radical-anion is not formed as an intermediate. On the basis of these data as well as the results of the alcoholysis of the catalysts—metallic potassium and potassium hydride in a dispersed form and on a carrier ($K_2CO_3$), Wilkes suggested that the catalyst is formed on two centres, the hydride and a vinyl substitution product being generated [98]:

$$R-\underset{R_1'}{\overset{}{C}}=CH_2 + 2K \rightleftarrows \underbrace{\left[R-\overset{R'}{\overset{|}{C}}=CH\right]^-}_{(I)} K^+ + KH ,$$

where R, R′, and $R_1'$ are hydrogen or alkyl groups.

In the subsequent reaction with propene, the vinyl carbanion (I) gives rise to the thermodynamically more stable allylpotassium and the initial olefin is regenerated. The reaction of potassium hydride with propene yields propane and allylpotassium.

This mechanism is inconsistent with later experimental data [68]. Preferential vinyl metallation would be expected to result in the formation of a product of the addition of propene to vinylsodium (3-methylbut-1-ene) in the codimerisation reactions between ethylene and propene and in vigorous dimerisation of ethylene with formation of but-1-ene. However, appreciable amounts of 3-methylbut-1-ene were not detected under these conditions [68,97], while the dimerisation of ethylene proceeds at a rate approximately two orders of magnitude lower than the dimerisation of butenes [100]. It is interesting to note that even insignificant amounts of but-1-ene, formed in the dimerisation of ethylene, rapidly combine with another ethylene molecule, and up to 27.0 wt.% of the ethylene trimer 3-methylpent-1-ene was detected in the reaction product [100].

All these findings permit the conclusion that the metallation of ethylene (vinyl metallation) proceeds, as shown previously [6,16,17], at a much lower rate than the allyl metallation (for example, the metallation of propene). The stage involving the formation of the catalyst, where the metallation takes place in the presence of a relatively inactive metallating agent (alkali metal), therefore proceeds via a stage in which a radical-anion is formed and not the product of the vinyl metallation of the olefin. The cause of the high rate of codimerisation of ethylene with propene or straight-chain butenes is probably the greater ease of addition of ethylene to anions compared with other olefins [58].

The dimerisation and codimerisation reactions of olefins are regarded not only as the addition of alkenes to carbanions but also as a specific instance of limited (degenerate) anionic homopolymerisation or copolymerisation of olefins [4,102]. This approach makes it possible to explain certain features of these reactions, for example the

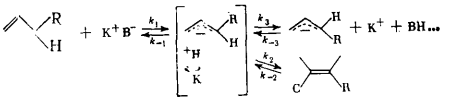
dependence of the yield of oligomerisation products on the monomer ratio and the degree of conversion [102,103].

Having examined the possible pathways to the formation of dimerisation and codimerisation products of monoolefins in the presence of alkali metal catalysts, we shall now proceed to the prototropic shifts induced by the isomerisation of unsaturated hydrocarbons which is catalysed by bases as well as other substances. It has been established [104] that in an anhydrous medium KOH causes the stereospecific isomerisation of straight-chain butenes at 320°C to *cis*-but-2-ene. But-1-ene has been obtained from *cis*- or *trans*-but-2-ene. Sodium hydroxide catalyses this reaction at 400°C, while LiOH, which is a weaker base, catalyses it at 440°C. The isomerisation of high-molecular-weight $\alpha$-olefins with migration of the double bond in the presence of sodium isopropoxide [105] and potassium butoxide [106] has been described.

A number of workers [107-113] investigated the isomerisation of olefins under the influence of potassium amide at the boiling points of the hydrocarbons. They put forward for the first time the idea that the first stage of this reaction is the partial dissociation of hydrogen from the C–H bond in the allyl position relative to the double bond [108]:

$$R{-}CH_2{-}CH{=}CH_2 + MNH_2 \rightarrow [R{-}\overline{C}H{-}CH{=}CH_2]\,M^+NH_3 .$$

The negative charge in the resulting carbanion can shift in the direction of the double bond with formation of the carbanion (III):



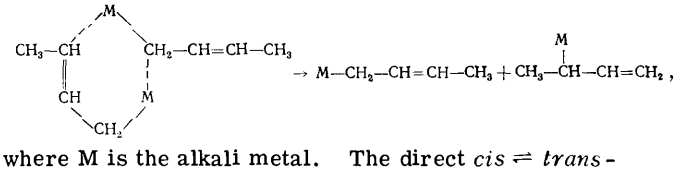
$$\underset{(II)}{[R{-}\overline{C}H{-}CH{=}CH_2]\,M^+NH_3} \rightarrow \underset{(III)}{[R{-}CH{=}CH{-}\overline{C}H_2]\,M^+NH_3} .$$

After the addition of a proton, the carbanion gives rise to an olefin with the double bond in a new position. As was to be expected on the basis of the proposed mechanism, the hexenes where the allyl position contains the maximum number of hydrogen atoms isomerise faster [109], since substitution of hydrogen by electron-donating alkyl groups entails a decrease of the mobility of the remaining hydrogen atoms.

Shatenshtein and coworkers [5,114,115] showed that not only calcium amide but also potassium amide in liquid ammonia cause the isomerisation of alkenes. Later it was noted that the reactions catalysed by these amides involve the isotope exchange of hydrogen [32] together with the migration of the double bond, which constitutes a clear confirmation of the views of Gostunskaya et al. [108]

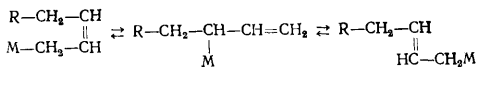
The participation of the carbanion in the isomerisation process in the presence of basic catalysts has also been demonstrated by Astaf'ev and Shatenshtein [116]. The C–H bonds in allylbenzene $C_6H_5{-}\overset{*}{C}H_2{-}CH{=}CH_2$ located at the position marked with as asterisk are involved in conjugation with the electronic system of the aromatic ring and with the multiple bond. The hydrogen in this position therefore ionises in an ammonia solution of potassium amide and a carbanion is formed with the characteristic absorption spectrum [5]. When the amide is neutralised with an ammonium salt, mainly propenylbenzene $C_6H_5CH{=}C{-}CH_3$ is formed, i.e. the double bond migrates [117]. However, a free carbanion is by no means always formed during isomerisation. According to Shatenshtein [5], in most cases partial dissociation of hydrogen in the form of a proton is most likely to occur with its simultaneous migration, for example in the trimolecular complex in the transition state.

Certain observations confirming these views have been described [118-121]. It has been established that the isomerising activity of potassium t-butoxide depends on the nature of the solvent [119]. At a temperature as low as 40–60°C, albeit for a comparatively long contact time (24 h for linear and up to 500 h for branched olefins), it was possible to achieve thermodynamic equilibrium in butene, pentene, and 2-methylpentene isomers. The use of labelled olefins showed that the isomerisation occurring in the potassium t-butoxide–dimethylsulphoxide system proceeds within the complex of the olefin and the catalyst [118-121]. Hydrogen transfer from one molecule to another was not observed; there is only an intense isotope exchange between the olefin and the solvent–dimethyl sulphoxide. These results were interpreted on the basis of a model with a chemically bound ion pair [120]:



$k_3 < k_1$; $k_2$

$B^- = O^-$-Bu-t .



The rate of isomerisation of hydrocarbons depends both on the strength of the base and on the acidity of the allyl hydrogen atom in the olefin. For example, penta-1,4-diene, which has very acidic hydrogen atoms, isomerises under the influence of potassium t-butoxide in dimethyl sulphoxide approximately $10^8$ times faster than does pent-1-ene [121]. It has been noted [118,120] that 2-methylpent-1-ene isomerises to 2-methylpent-2-ene faster than 2-methylpent-2-ene isomerises to 4-methylpent-2-ene. The authors [118,120] explained the kinetic observations by the relative stability of the carbanions formed as intermediates.

The migration of the multiple bond is also catalysed by organosodium compounds formed as a result of the reaction of sodium with the promoting agent, for example *o*-chlorotoluene or anthracene [122-125]. The possibility of using the product of the reaction of lithium with ethylenediamine as a homogeneous catalyst of this reaction has been reported [126,127]; the replacement of lithium by sodium in this instance lowers the activity of the catalyst.

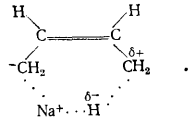
Wittig [128] established that organolithium compounds are dimerised in solution. On this basis, Kropachev et al. [43] suggested that this facilitates the isomerisation step, as a result of which one of the molecules isomerises, while the other remains unchanged:

where M is the alkali metal. The direct *cis* $\rightleftharpoons$ *trans*-transition is known to require an appreciable activation energy, so that the reaction may proceed via the mechanism [43]

All the studies of the isomerisation reactions of olefins in the presence of basic catalysts have shown that the catalysts examined accelerate only the migration of the double bond in the molecule and do not affect the carbon skeleton. The alkylation of alkylbenzenes by monoolefins, catalysed by alkali metals and some of their compounds, exhibits a remarkable selectivity: olefins add only to the side chain of the alkylbenzene. A detailed

examination of these reactions suggested[1] that the characteristic features of these transformations are associated with the formation of intermediates—alkylbenzene carbanions.

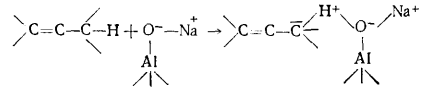
Thus the investigators who studied both the hydrogen isotope exchange in hydrocarbons in the presence of bases and the base-catalysed dimerisation, codimerisation, isomerisation, and alkylation reactions of olefins concluded that all these reactions proceed via a stage involving the formation of carbanions. However, free carbanions are not as a rule produced. Only an electron shift in the direction of the formation of $\equiv C^-$ may occur in the transition state[5].



## IV. REACTIONS OF OLEFINS UNDER THE INFLUENCE OF ALKALI METALS ON CARRIERS

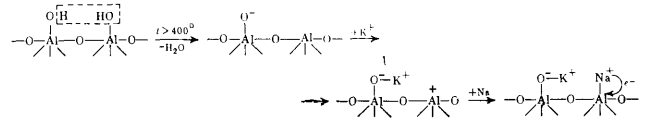
Alkali metals on solid inorganic carriers are more effective catalysts of the isomerisation, dimerisation, codimerisation, oligomerisation, and hydrogenation reactions of olefins than dispersions of alkali metals or solutions of their compounds in hydrocarbon solvents. Thus, in their early studies of the isomerisation of olefins in the presence of basic catalysts, Pines and coworkers[129,130] already investigated a whole series of catalysts consisting of sodium or lithium on inorganic carriers and showed that alkali metals "with a large surface area as a result of their deposition on activated alumina"[1] are the most active catalysts. According to the authors, they are capable of abstracting protons from olefin molecules with formation of intermediates, stabilised as a result of the resonance involving the following structures:[130]

$$\underset{\text{(IV)}}{R-\overset{Na^+}{\overline{C}H}-CH=CH_2} \leftrightarrow \underset{\text{(V)}}{R-CH=CH-\overset{Na^+}{\overline{C}H_2}}\ .$$



In the presence of an excess of the olefin, the metal is exchanged for an allyl proton, which leads to the formation of the isomerised olefin with structure (V) and the regeneration of the intermediate (IV). This reaction may be interrupted as a result of the formation of a compound which is insufficiently basic to metallate the olefin, for example a polyene, when a hydride ion is split off[1].

Study of the isomerisation kinetics[130] showed that, after a short contact time, but-1-ene is converted preferentially into *cis*-but-2-ene and not into the thermodynamically more stable *trans*-isomer. The stereospecificity of the catalyst may be accounted for either by the fact that but-1-ene reacts faster with the *cis*-butenyl carbanion or by the fact that the *cis*-butenyl carbanion is present in the reaction mixture at higher concentrations. The latter interpretation is more probable[130], which may be accounted for by the additional resonance stabilisation of the structure[1]



It has been shown[123] that a dispersion of lithium on $\gamma$-$Al_2O_3$ is not as active as the corresponding sodium catalyst. The authors[130] believe that one of the causes of the high activity of the latter catalyst may be the formation of organosodium compounds from the alkali metal and reactive impurities in the olefin. This view is based on data[122,123,129,131-134] showing that sodium isomerises olefins much more readily in the presence of such an organic compound, for example chlorobenzene and chlorotoluene.

Another cause may be the replacement of the protons of the hydroxy-groups on the surface of alumina by sodium, which leads to the suppression of the Brønsted acidity with the simultaneous appreciable enhancement of the basicity of the oxygen anions[130,135]. The formation of carbanions can be explained in this case by the mechanism[135]

This hypothesis makes it possible to explain also the increased activity of the "Na on $\gamma$-$Al_2O_3$" catalyst in reactions involving the migration of the multiple bond in hexenes and vinylnorbornene {5-vinylbicyclo[2,2,1]hept-2-ene} when alumina is modified by solutions of potassium carbonate[136-140]. Preliminary vacuum heat treatment or treatment in a stream of inert gas is known to entail the dehydration of the surface of this oxide and the formation of Lewis acid or basic centres[141,142]. The $K^+$ ions in the potassium carbonate solution deactivate the Lewis basic centres and the residual Brønsted acid centres[143,144], while sodium apparently forms an ion linked by a one-electron bond to the $Al_2O_3$ surface[102]. The ionisation of sodium is clearly demonstrated by the appearance of a blue colour when it is deposited[102]. A similar pattern of colour changes is observed when alkali metals are dissolved in ammonia. The formation of ions under these conditions is known and has been confirmed by many methods, in particular by the high electrical conductivity of the solution[145].

The increase of the activity of the "Na on $\gamma$-$Al_2O_3$" catalyst when the carrier has been thermally activated at 400–500°C is probably associated with the fact that the sodium atom forms with a surface-unsaturated aluminium atom (a Lewis acid centre) an active catalytic complex, for example of the kind represented schematically below[102]:

Other workers[146], who investigated the isomerisation of $\alpha$-butene on potassium deposited on $\gamma$-, $\eta$-, and $\alpha$-$Al_2O_3$ and quartz, reached similar conclusions.

The use of not only the "sodium on $\gamma$-alumina" catalysts[147-151] or others where sodium is deposited on molecular sieves[152,153] but also catalysts of a similar type, namely potassium or potassium amide on $\gamma$-$Al_2O_3$[154-156] and a complex of graphite with an alkali metal[157], has been recommended for the isomerisation of butenes, pentenes, and hexenes[157]. The enhancement of the isomerising capacity of the "Na on $\gamma$-$Al_2O_3$" catalyst has been observed when the latter is flushed with air[151]. The kinetics of the isomerisation of vinylnorbornene on potassium amide in liquid ammonia have been described[158]. In contrast to the thermal isomerisation of this hydrocarbon[159], which leads to the formation of tetrahydroindene {bicyclo[4,3,0]-nonadiene}, the base-catalysed reaction leads only to the migration of the multiple bond without affecting the ring.

As a rule, in the processes described alkenes with the double bond in an internal position are obtained from $\alpha$-olefins. However it has been suggested[160,161] that

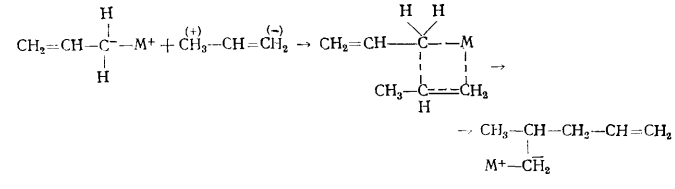
$\alpha$-alkenes be obtained from their $\beta$- and $\gamma$-isomers using the shift of thermodynamic equilibrium, by distilling from the reaction zone the required $\alpha$-olefins, which are as a rule more volatile than their isomers. Although this idea arouses no objections in principle, when it is applied one encounters the difficulty of isolating the required products from the equilibrium mixture where their content is relatively small. A more effective procedure involves the formation of 4-methylpent-1-ene from 2-methylpent-1-ene and 2-methylpent-2-ene by the method of the so called "antithermodynamic isomerisation" in the presence of borides, which Ziegler developed[162,163]. The products of this reaction contain 45–70% of the required compound.

The vapour-phase dimerisation and codimerisation of alkenes in the presence of catalysts on carriers containing an alkali metal or its compound is characterised by a high degree of conversion of the starting material, improved selectivity, and long duration of the continuous operation of the catalyst. Potassium and sodium or their mixtures and more rarely lithium, rubidium, and caesium are usually recommended for the preparation of such catalysts. Inorganic oxides, for example MgO, $Al_2O_3$, CaO, ZnO, alumino- and magnesio-silicates[164-175], inorganic acid salts ($K_2CO_3$, $K_2SiF_6$, NaCl, KCl, etc.)[173,176,177], alkaline earth metal hydrides[179], metallic aluminium, magnesium, copper, silver, iron, cobalt, nickel, and their mixtures[180-184], and crystalline zeolites[185] are used as the carriers.

An active catalyst for the conversion of olefins was obtained by depositing potassium on magnesium oxide. It is pointed out that the selectivity of the dimerisation and codimerisation of alkenes with respect to the required $\alpha$-olefin improves when the carrier has been heat-treated at 500–1000°C.[166] It has also been suggested[167-173] that potassium and potassium amide on alumina be used. The authors believe that the composition of the propene dimer obtained in the presence of these catalysts is determined by the specific surface of the carrier. Judging from the data which they quote, the highest yield of $\alpha$-olefins is attained when the oxide has a small specific surface. The surface was reduced by the heat-treatment of the carrier at temperatures up to 1200°C, but the authors[167-169] did not take into account the fact that this entails also the conversion of the $\gamma$-form of the oxide into the $\alpha$-form, i.e. a change not only in the specific surface but also in other surface properties for example, acidity.

The study of the influence of the porosity of the carrier on the yield of 4-methylpent-1-ene in the dimerisation of propene[74] showed that, with decrease of pore radius, the content of this $\alpha$-olefin in the dimerised product diminishes and the yield of its $\beta$-, $\gamma$-, and $\omega$-isomers increases.

Alkali metal hydrides are more advantageous than the pure alkali metals because of the higher rate of dimerisation and the greatly reduced period required for the formation of the catalyst[186-191]. It is suggested that not all alkali metal hydrides but only the hydrides of the most reactive metals (potassium, rubidium, caesium, or their mixtures) be used on the following carriers: carbon black, potassium, rubidium, and caesium carbonates, or powdered glass[186,189,190]. A high activity of the catalyst and selectivity of the dimerisation of propene to 4-methylpent-1-ene (approximately 90–92%) were attained on a catalyst consisting of a mixture of potassium, copper, and sodium[192] or potassium[183] alkoxide. Catalysts comprising alkali metals or their hydrides and charcoal have been described[193-210]. Mainly methylpentenes with the multiple bond in an internal position have been obtained in their presence. Exceptions are catalysts containing an amino-group[193] as well as layer complexes having the overall formula $MC_X$ with a definite alkali metal : carbon ratio[195,197,198,209,210]. The physicochemical principles of the reactions in the presence of such complexes have been examined[211].



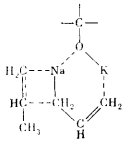
Comparison of various catalysts for the dimerisation of propene to 4-methylpent-1-ene[102,212-236] led to the conclusion that elemental alkali metals on alkali metal carbonates are the most effective catalysts[177,213-232]. It has been noted that the composition of the products of this reaction changes only slightly on passing from one alkali metal to another. The nature and surface properties of the carrier have a decisive influence on the direction of the reaction towards the formation of a particular isomer[102]. Thus, when the alkali metal is deposited on potassium carbonate (specific surface $S = 0.15$ m$^2$ g$^{-1}$), propene dimerises mainly to 4-methylpent-1-ene[213-220], while in the presence of $\gamma$-$Al_2O_3$ ($S = 250$ m$^2$ g$^{-1}$) the product is 2-methylpent-2-ene[167]. Mainly *cis*- and *trans*-4-methylpent-2-enes are formed on the "Na on $\alpha$-$Al_2O_3$" catalyst ($S = 14$ m$^2$ g$^{-1}$).[102,169]

However, the surface area is not apparently the only factor determining the efficiency of the carrier. For example, sodium deposited on a ceramic, pumice, or a faience carrier with a low surface area proved to be inactive in the dimerisation of propene[102].

Catalysts containing an alkali metal on inorganic alkali metal salts (halides, sulphates, silicates, and carbonates) showed a high activity[213,228].

The experimental data described cannot be accounted for in terms of a reaction mechanism providing for the intermediate formation of carbanions as separate kinetic species[58]. Evidently, when a carbanion is really the reaction centre, then in such a mechanism of the propagation reaction the capacity for oligomerisation should be shown only by electron-accepting vinyl compounds, because a carbanion is an electron-donating agent. Ethylenic and diethylenic hydrocarbons, which are electron-donating substances[237,238], should not combine with a carbanion and should not therefore oligomerise under the influence of substances capable of forming carbanions[237].

These findings can be best explained in terms of an anionic-coordination mechanism[239] based not on a carbanion but on an ionic aggregate containing the metal ion as well as the carbanion. In this case, the transition state consists of a four-membered ring[239] and the dimerisation of propene can be represented schematically as follows[102]:



A definite coordination in the addition of the monomer to the active centre is probably promoted also by the polarisation of the olefin molecule as a result of the $\pi$–$\delta$ conjugation, which has been observed in many ways, for example with the aid of isotope exchange[5,240,241].

It was shown previously[212] that sodium catalysts show a low activity in the dimerisation of propene in the presence of alkali metals dispersed in inert hydrocarbon solvents. However, when sodium is deposited on an inorganic acid salt (for example, on potassium carbonate) or $\gamma$-$Al_2O_3$, catalysts for the dimerisation of propene more effective

than the potassium catalysts are obtained[228]. This phenomenon has been attributed by some workers to the displacement of potassium from the inorganic acid salt by sodium[74,242]. However, the hypothesis[243] that the activation of allylsodium compounds by inorganic acid salts proceeds in consequence of the formation on the surface of the carrier of the so called "double coordination complex" appears more likely. Such complexes are formed with compounds where the metal–carbon bond is conjugated with a double bond or a phenyl group[17,243]. They consist of ionic aggregates, where alkali metal atoms exhibit both basic and coordination valences[237,244]. The reaction is believed[244] to proceed via the adsorption of a monomeric molecule on the ionic aggregate with the coordination and activation of the former on the surface of the latter and the subsequent interaction with the anion located on the same site. The increase of activity is attributed to the enhancement of the polarisation of the $M^{\delta+}-\overset{\delta-}{C}<$ bond on formation of the complex. It has been shown that the activity of the catalyst increases when the distance $r$ in the inorganic salts employed, equal to the sum of the ionic radii, is greater than 2.75 Å and the complex contains different alkali metals[245].

The results of studies on the selection of catalysts for the dimerisation and codimerisation of olefins agree well with the investigations of polymerisation processes carried out by Morton[243,244]. This justifies the hypothesis that the activation of allylsodium by potassium carbonate is associated with the formation of a "double coordination complex" and that the selectivity of the reaction can be explained by the selective adsorption of a monomeric molecule in its field and that the transition state in the dimerisation of propene may be represented schematically as follows[102]:

These views on the reaction mechanism are confirmed by data[246] showing that the addition of mercury or transition metals to the "sodium on potassium carbonate" catalyst alters fairly appreciably the rate but not the proportions of reaction products. The authors concluded[246] that the rate-limiting stage of the reaction is the adsorption of propene. It has been shown[102,247] that the rate and selectivity of the dimerisation of propene depend on the content of metallic sodium in the catalyst. Hambling[247] attributed the change in selectivity to the isomerisation of 4-methylpent-1-ene catalysed by allylsodium. However, this mechanism appears unlikely, since the allyl carbanion is a comparatively weak base, while 4-methylpent-1-ene is a very weak acid. The Shaw mechanism[69], with chain termination via the dimer, where a strong base, namely the isohexenyl carbanion

$$M^+[CH_3-\underset{\displaystyle CH_2}{\underset{|}{CH}}-CH-CH=CH_2]^-$$

acts as the metallating agent, appears to be more likely.

The study of the composition of high-molecular-weight side products of the dimerisation of propene in the presence of the "sodium on potassium carbonate" catalyst showed that they consist mainly of $C_9$ olefins, formed via the mechanism involving the addition of the dimer to the active allyl centre responsible for the dimerisation[248].

In contrast to the dimerisation of propene, that of ethylene in the presence of the "Na on $K_2CO_3$" catalyst proceeds at insignificant rates, apparently owing to the difficulty of the substitution of a proton in the vinyl group[100]. The reaction products consist mainly of but-1-ene and 3-methylpent-1-ene. The latter is probably formed via the mechanism involving the addition of an ethylene molecule to the *s*-butenyl carbanion† [100,247].

But-1-ene dimerises at a higher rate than ethylene, because, as already pointed out, but-1-ene is metallated faster. The two structures of the carbanions formed under these conditions,

$$Na^+\left[\begin{array}{l}CH-CH=CH_2\\ |\\ CH_3\end{array}\right]^- \leftrightarrow Na^+\left[\begin{array}{l}CH=CH-CH_2\\ |\\ CH_3\end{array}\right]^-,$$

give rise to 3,4-dimethylhex-1-ene and 5-methylhex-2-ene following the addition of the next but-1-ene molecule[100], as was to be expected on the basis of the postulated mechanism.

The codimerisation of ethylene and but-1-ene in the presence of the "Na on $K_2CO_3$" catalyst is approximately an order of magnitude faster than the dimerisation of butenes. This can be explained by the involvement in the given reaction of a readily metallated alkene (but-1-ene and ethylene), which adds to the carbanion at a higher rate. The principal products of this reaction—3-methylpent-1-ene and hex-2-enes (with the former predominating)—are formed as a result of the addition of ethylene to the first or second structure of the s-butenyl carbanion respectively[100,247]. The codimerisation of ethylene with propene in the presence of this catalyst at 80–120°C gave 92 wt.% of pentenes, 5.2 wt.% of heptenes, and only 2.6 wt.% of hexenes. Thus the addition of ethylene to the allyl anion in the above temperature range is approximately 40 times faster than the addition of propene (pent-1-ene and 4-methylpent-1-ene predominate in the pentene and hexene fractions respectively)[247].

The yield of high-molecular-weight olefins, particularly $C_7$ and $C_8$ olefins, is much higher in the codimerisation reactions involving ethylene. Furthermore, the rate of formation of octenes in the codimerisation of ethylene and but-1-ene increases with increase of the content of ethylene in the starting material[103]. The composition of the $C_8$ olefins (the main products are 3-methylhept-1-ene, oct-4-enes, 3-ethyl-3-methylpent-1-ene, 3-methylhept-3-ene, 4-ethylhex-2-ene, and 5-methylhept-3-ene) shows that these alkenes are formed as a result of the successive addition of two ethylene molecules to the butenyl carbanion and not as a result of the dimerisation of butenes[103].

The heptenes formed as side products in the codimerisation of ethylene and propene in the presence of the "sodium on potassium carbonate" catalyst contain mainly 3-pent-1-ene and also admixture of *cis*- and *trans*-hept-3-enes and *cis*- and *trans*-4-methylhex-2-enes[247,249]. The formation of these alkenes can be explained by the addition of ethylene to three types of anions, which may be produced on metallation of straight-chain pentenes:

$$Na^+\left[\begin{array}{l}CH-CH=CH_2\\ |\\ CH_2\\ |\\ CH_3\end{array}\right]^- \quad (VI);$$

$$Na^+\left[\begin{array}{l}CH_2-CH=CH\\ \qquad\quad |\\ \qquad\quad CH_2\\ \qquad\quad |\\ \qquad\quad CH_3\end{array}\right]^- \quad (VII);$$

$$Na^+\left[\begin{array}{l}CH_3-CH-CH\\ \qquad\quad \|\\ \qquad\quad CH\\ \qquad\quad |\\ \qquad\quad CH_3\end{array}\right]^- \quad (VIII)$$

† Here and henceforth the abbreviation "...addition to carbanion..." has been adopted, which will be understood as "addition of an olefin molecule to the active centre containing the given carbanion".

The same olefins have been obtained in a direct synthesis of heptenes from ethylene and pent-1-ene [247,249]. However, the contents of 3-ethylpent-1-ene and hept-3-enes are approximately 86 and 11 wt.% respectively, which gives a somewhat higher ratio than that of the carbanions (VI) and (VII) in metallation products, which is 4 : 1. [17] The content of 4-methylhex-2-enes, the products of the addition of ethylene to the carbanion (VIII), is lower still, namely 2.6 wt.%, which might be accounted for by the low content of pent-2-enes in the reaction zone. However, in the codimerisation of ethylene and pent-2-enes, the reaction rate was somewhat higher, but the content of 4-methylhex-2-enes increased insignificantly [249]. An improved yield of straight-chain heptenes in this reaction was achieved only after the simultaneous alteration of the nature of the alkali metal as the "active component" and of the catalyst carrier. Thus, on replacing the "Na on $K_2CO_3$" catalyst by the "K on $Li_2CO_3$" catalyst, the yield of linear $C_7$ olefins was sharply increased (up to 50%). [250]

These results can be explained on the basis of a mechanism taking into account not only the relative stabilities and reactivities of various anions but also the influence of the cations derived from the organometallic compound and the inorganic carrier. The decisive factors responsible for the specificity of the action of the catalyst are apparently the stability and reactivity of the complex formed by the anion, the cation, and the inorganic alkali metal salt [102].

The possibility of employing $\beta$-olefins as the starting materials for codimerisation reactions is extremely attractive, since it makes it possible, in the first place, to obtain on their basis valuable $\alpha$-olefin monomers for the synthesis of heat-resistant plastics (with melting points in the range 350–420°C) [251] and, in the second place, to make use of new sources of starting materials, for example industrial petroleum fractions [252] and the disproportionation [253–255] or isomerisation products of lower mono-olefins [249]. By altering the composition of the starting material and the carrier for the alkali metal, a number of workers [254,256–261] obtained a wide range of methylpentene and ethylpentene positional isomers.

Reactions involving the addition of propene to olefins in the presence of the "Na on $K_2CO_3$" catalyst require the use of more severe temperature conditions (140–170°C) [262] than the reactions in which ethylene adds to the same alkenes (80–100°C) [247]. It has been shown that, for an equimolecular mixture of propene and but-1-ene, the rate of addition of propene to a mixture of allyl and butenyl anions is approximately 15 times higher than the rate of addition of but-1-ene. The presence of a methyl substituent at the butenyl anion lowers the rate of addition of olefins by a factor of seven compared with the allyl anion [247].

The effective oligomerisation reaction on catalysts with an acid-free carrier is as a rule preceded by a fairly long period involving the formation of the complex during which the olefins are metallated and active centres containing carbanions are formed. The duration of this period diminishes in the presence of alkali metal catalysts with an acid carrier. It can be shortened by treating the catalyst with hydrogen or a readily metallated olefin before the start of the reaction [223,256]. It has been suggested that alkali metal hydrides themselves be deposited instead of the treatment with hydrogen [191]. At the end of the induction period, the rate of reaction is stabilised for a long time [225,247], which supports the hypothesis that the reaction proceeds in the presence of a constant number of active centres. Activity is lost owing to the gradual shielding of the surface by the extensive condensation products, which are probably formed as a result of the dehydrogenation [63], dehydrocyclisation, and the so called "internal alkylation" described by Richey and coworkers [263]. As a result of the last reaction, cyclic compounds, for example methylcyclopentane, may be formed [68].

This type of catalyst may be regenerated with hydrogen [220,221], but this probably entails the hydrogenation of condensation products with a deficiency of hydrogen (one hydrogen atom for two carbon atoms) [68]. Although alkali metals are not transition metals, they catalyse the hydrogenation of aromatic molecules and their catalytic activity increases from lithium to rubidium. The most active catalyst of this reaction is sodium on potassium carbonate [242]. The possibility of the regeneration of alkali metal catalysts on carriers combined with the long period of their operation between regenerations (not less than 800 h) and high selectivity and activity [217,224,247,264], make these catalysts promising for the oligomerisation of olefins. It is not fortuitous that the first industrial process involving the dimerisation of propene to 4-methylpent-1-ene has in fact been achieved in the presence of these catalysts [264]; studies on their modification are being continued [180–185,246,265–267].

A tendency has arisen to employ alkali metals on carriers, particularly "Na on $K_2CO_3$" [268] or alkali metal complexes with carbon [269], in alkylation reactions which had been studied previously in the presence of dispersions of alkali metals or their complexes with aromatic hydrocarbons.

So many studies have been devoted to the polymerisation of diolefins in the presence of basic catalysts that even their simple enumeration is difficult within the framework of the present review. We shall only note that the view according to which these reactions proceed via "anionic-coordination" [239] or "coordination" [237] mechanisms, presupposing the formation of active centres containing organometallic compounds of alkali metals [270], has predominated in recent years. The reactions of dienes, which occur at higher rates, are undesirable side processes in the reactions of the less reactive mono-olefins, since the formation of dehydrocyclisation of high-molecular-weight diene polymers lead to the rapid deactivation of the catalyst. It is therefore recommended that the content of diene and acetylenic impurities in the olefinic starting materials be kept at the level of five parts per million [213]. It has been shown [271,272] that, in the presence of mono-olefins, dienes form not only homopolymers but also copolymers with the alkenes on the alkali metal catalysts.

Although the synthesis of polyolefins in the presence of alkali metal catalysts on carriers was achieved as early as 1954, [273] these studies were not developed further and research was continued mainly on the dimerisation and codimerisation of olefins. Reports concerning the preparation of $C_{10}$–$C_{16}$ oligomers with a narrow molecular weight distribution appeared only recently [274]. Using the "Na on $\gamma$-$Al_2O_3$" catalyst containing 0.2–2.1% of OH groups, it is possible to obtain detergent olefins [274] containing up to 50% of $\alpha$-olefins. This comparatively high content of surface hydroxyls distinguishes the above catalyst from those for the dimerisation of olefins, where the OH content is reduced to a minimum by the thermal activation of the carrier at 500°C.

---o0o---

Thus examination of certain reactions of alkenes in the presence of basic catalysts has shown that they probably

occur with the intermediate formation of organic compounds of the alkali metals, the characteristics of the synthesis and reactions of which are of decisive importance for the specificity of the reactions investigated and the composition of their products. Being highly reactive compounds in consequence of the ionic character of the C—M bond, these substances accelerate the dimerisation, codimerisation, oligodimerisation, isomerisation, alkylation, and hydrogenation reactions of low-molecular-weight mono-olefins. The interaction of the carbanionic and metallic components of these compounds is most likely to be determined not only by electrostatic but also by exchange forces and depends significantly both on the structure of the carbanion and on the nature of the alkali metal. Free carbanions are apparently not formed in the transition state and there is merely an electron shift in the direction of the formation of $\rangle C^-$. The involvement of two catalyst centres in the transition state tends to increase the selectivity of the reaction. Modification of the catalysts (organic derivatives of alkali metals) by inorganic carriers and additives to the latter makes it possible to increase the activity and selectivity of the catalysts and in many cases constitutes an effective method for altering the mode of reaction. The results achieved using alkali metal catalysts on carriers show that promising methods for the processing of olefins can be devised on their basis.

# Methods of Synthesis of Imidazopyrimidines with a Bridgehead Nitrogen Atom and Their Benzo-analogues

I.A.Mazur, B.E.Mandrichenko, and R.I.Katkevich

The methods of synthesis of imidazopyrimidines with a bridgehead nitrogen atom, namely imidazo[1,2-*a*]pyrimidines, imidazo[1,2-*c*]pyrimidines, and their benzo-analogues, are examined, particular attention being devoted to methods of synthesis of preparative value. Certain theoretical problems associated with the formation of these heterocyclic condensed systems are discussed.
The bibliography includes 157 references.

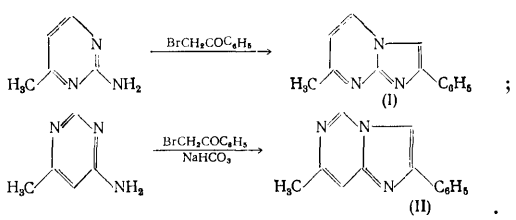
## I. INTRODUCTION

Among the nitrogen-containing heterocycles which are constituents of alkaloids, vitamins, nucleic acids, enzyme systems, etc. imidazolines with a bridgehead nitrogen atom, namely imidazo[1,2-*a*]- and imidazo[1,2-*c*]-pyrimidines, have attracted attention in recent years. Derivatives of the latter type—the alkaloids alchornine, alchornidine, and alchorneine—have been recently isolated from plants of the genus *Alchornea*.[1-3]

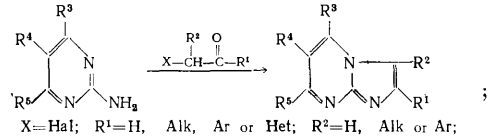


The search undertaken in recent years for biologically active imidazopyrimidines with a bridgehead nitrogen atom, which are structural analogues of purines, led to the detection among them of compounds with a broad spectrum of biological activity[4-18]. This resulted in an increased interest in the development of procedures and methods for the synthesis of these heterocyclic sytems.

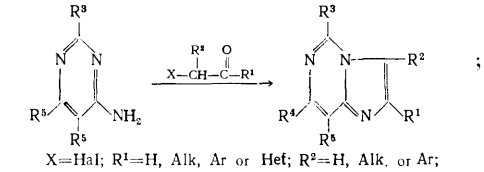
The present review is in essence the first attempt at a survey and a critical examination of the literature data, mainly those obtained recently, on the methods of synthesis of imidazopyrimidines with a bridgehead nitrogen atom, since the information on this problem quoted in Shvachkin's review[19], published 20 years ago, is extremely limited and already obsolete. In the present review, a systematic account is given of all the available literature data and the methods of synthesis of imidazo[1,2-*a*]- and imidazo[1,2-*c*]-pyrimidine systems and the limits of their applicability and preparative value are estimated.

## II. ALKYLATION OF AMINOPYRIMIDINES AND AMINOIMIDAZOLES

### 1. Alkylation of 2(4)-aminopyrimidines

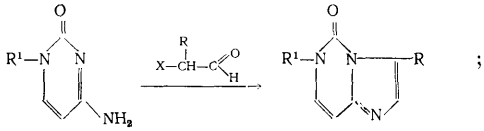


The classical method for the preparation of imidazo[1,2-*a*]- and imidazo[1,2-*c*]-pyrimidines, the alkylation of 2-amino- and 4-amino-pyrimidines, was achieved for the first time by Ochiai and Jamai[20] in 1939. By heating 2-amino-6-methyl- and 4-amino-6-methyl-pyrimidines with phenacyl bromide, they synthesised 7-methyl-2-phenylimidazo[1,2-*a*]-pyrimidine (I) and 7-methyl-2-phenylimidazo[1,2-*c*]-pyrimidine (II):



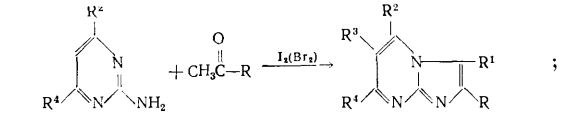
Subsequently, the method was applied to the synthesis of a whole series of unsubstituted and *C*- or *N*-substituted 2- and 4-aminopyridines[12-14,21-46]. The wide scope of this reaction, which is suitable for the synthesis of virtually all imidazopyrimidines with functional groups, is illustrated in Scheme 1.

The method discussed is fairly promising, since it permits the use of a whole series of alkylating agents and an appreciable variation of the experimental conditions. The alkylating agents employed were $\alpha$-bromo(chloro)-ketones and $\alpha$-bromo(chloro)aldehydes or their acetals. The alkylation process is usually carried out by heating equimolar amounts of the reactants to 60–100°C in an organic solvent (pure alcohols, dioxan, toluene and dimethylformamide) or in water. In order to prevent the formation of salts by the aminopyrimidines[46], which hinders the reaction, basic reagents are used: sodium hydroxide, sodium bicarbonate, and trialkylamines[31].

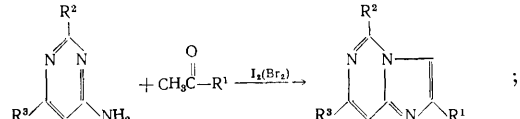


Scheme 1

X=Hal; $R^1$=H, Alk, Ar or Het; $R^2$=H, Alk or Ar; $R^1R^2$=$-(CH_2)_n-$; $R^3$=H, OH, Alk or Ar; $R^4$=H, OH, OAlk, Hal or $NO_2$; $R^5$=H or Alk; $R^4R^5$=$-(CH_2)_n-$.



X=Hal; $R^1$=H, Alk, Ar or Het; $R^2$=H, Alk or Ar; $R^3$=H, Alk, OH or OAlk; $R^4$=H, OAlk or Hal; $R^5$=H or Hal.



X=Cl or Br; R=H or Alk; $R^1$=Alk .

Apart from its advantages, the method suffers from a significant defect associated with the powerful lachrymatory action of α-halogenocarbonyl compounds. A version of the single-stage synthesis of imidazopyrimidine derivatives [47-49] (Scheme II), which excludes the stages involving the preparation and purification of the halogenocarbonyl component, is therefore of interest. A second undoubted advantage of this type of synthesis is the possibility of obtaining pure non-halogenated imidazopyrimidines and also their mono- and di-halogeno-derivatives, which is achieved by a strict control of the quantitative proportions of bromine and the other reagents.

Scheme 2

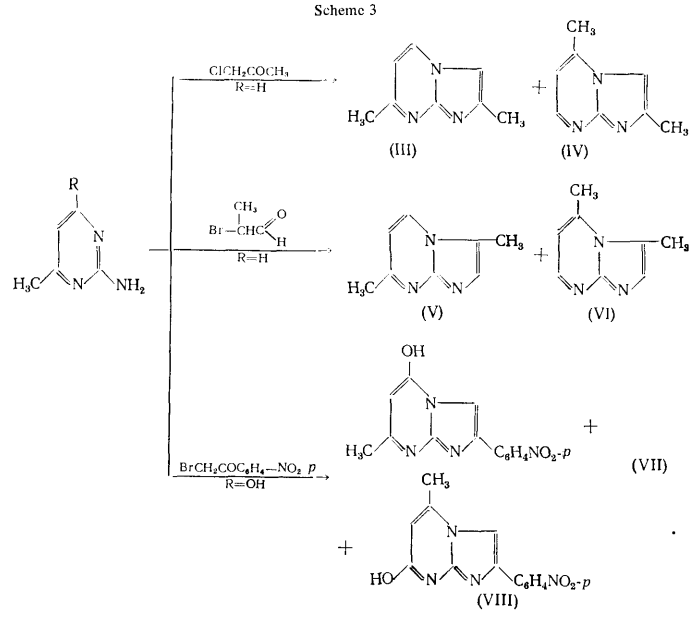
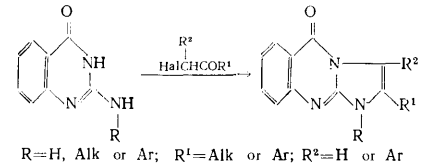
$R^1$=Alk or Ar; $R^2$=H or OAlk; $R^3$=OAlk or Cl; $R^4$=H or Br.



The interaction of aminopyrimidines with α-halogenoaldehydes (and α-halogenoketones) can proceed in theory via an initial stage involving the quaternisation of the pyrimidine nitrogen atom or via the formation of Schiff bases. Shvachkin [19] shares the view of Ochiai and Jamai [20], who believe that the initial step in this reaction is the formation of azomethines, which cyclise in the presence of bases. Recent studies [37,38,41-43,46] have shown that aminopyrimidines are quaternised, forming extremely labile salts, which are readily converted into imidazopyrimidines on heating or when an attempt is made to isolate the free bases. There is no doubt about the formation of the quaternary salts and it is convincingly supported by spectroscopic data:

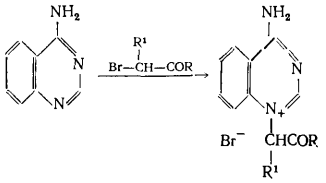


X=CH or N; Y=CH or N; $R^1$=Alk or Ar; $R^2$=H or Alk; $R^3$=H, OH or OAlk; $R^4$=H, Alk, OAlk or Hal.

The alkylation of asymmetric 2-aminopyrimidines [38,43,46] by α-halogeno ketones and α-halogenoaldehydes can involve the $N_{(1)}$ and $N_{(3)}$ atoms, which leads to an isomeric mixture of products (III) and (IV), (V) and (VI), and (VII) and (VIII) respectively. Determination of the isomeric composition of the reaction products showed that compounds (III), (V), and (VII) predominate, which can probably be accounted for by steric factors (Scheme 3).

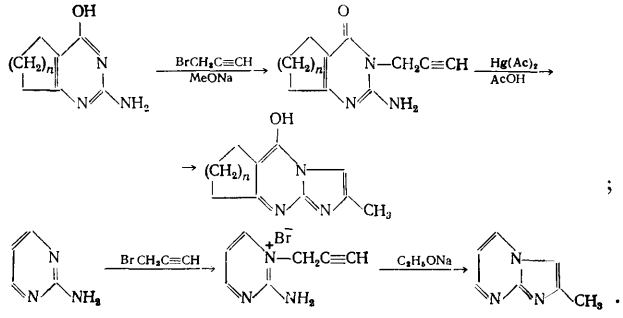
Scheme 3

The alkylation method proved to be suitable for the synthesis of 1,5-dihydroimidazo[2,1-*b*]-5-quinazolone derivatives from 2-amino(alkyl or aryl-amino)-4-quinazolones and α-halogenoketones [49,50]:



R=H, Alk or Ar; $R^1$=Alk or Ar; $R^2$=H or Ar

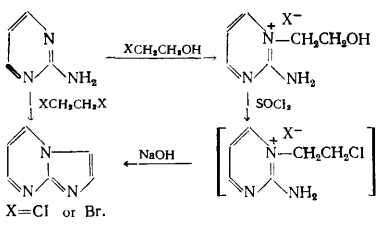
It is remarkable that, in contrast to the majority of α-amino-substituted nitrogen-containing heterocycles, which are alkylated at the endocyclic nitrogen atom adjoining the amino-group, 4-aminoquinazoline interacts with α-halogenoketones preferentially with formation of



1-acylalkyl-4-aminoquinazolinium quaternary salts [49,51]. The attack by the alkylating agent on the $N_{(1)}$ atom can be explained on the basis of the molecular diagrams in Armarego's monograph [52].

The specificity of the alkylation of 4-aminoquinazolines by α-halogenoketones precluded the synthesis of imidazo-[1,2-*c*]quinazoline derivatives by this method [49,51]:

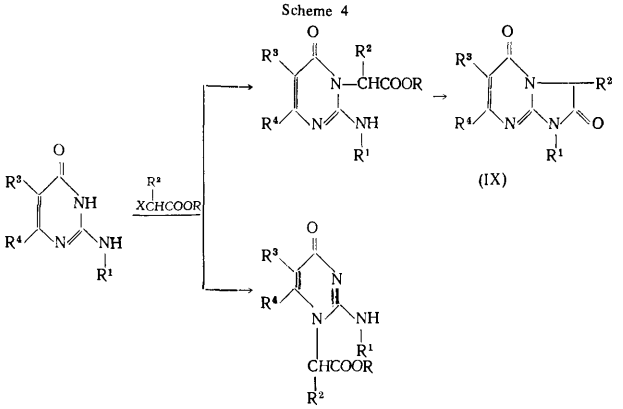
R=Alk, Ar or Het; R¹=H or Alk



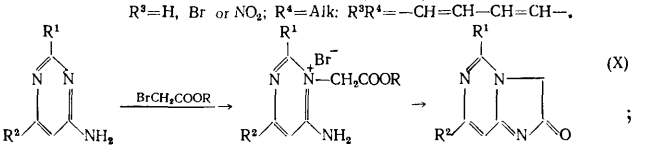
Together with α-halogenocarbonyl compounds, propargyl bromide can be used as the alkylating agent to obtain 2-methyl-substituted imidazopyrimidines [14,54,54]:

It follows from the above scheme that *N*-propargyl derivatives can be converted into methylated imidazo-pyrimidines in two different ways: by the Kucherov hydration of the triple bond with subsequent cyclisation of via the nucleophilic amination of the triple bond under the conditions of base catalysis.

β-Halogenoalcohols and 1,2-dihalogenoalkanes [46,49,55-57], which alkylate 2-amino-, 2-arylamino-, and 4-amino-pyrimidines and 2-amino(alkyl- or arylamino)-4-quin-azolones, have been used to synthesise hydrogenated analogues of imidazopyrimidines (quinazolines). [49,57]



In practice it is better to use dihalogenoalkanes in this reaction, since the latter can then be carried out in one stage [46,56,57]:

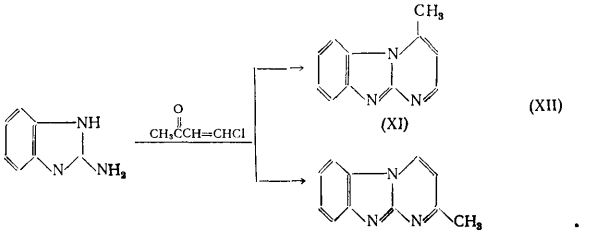


X=Cl or Br.

The use of α-halogenocarboxylic acids and their esters makes it possible to obtain a series of different 2-oxo-derivatives of imidazopyrimidine (quinazoline) from 2-amino- and 4-aminopyrimidines [46,49,58-60] and 2-amino-(alkyl- or arylamino)-4-quinazolinones [49] (Scheme 4).

Scheme 4

X=Cl, Br or I; R=H or Alk; R¹=H, Alk or Ar; R²=H or Alk; R³=H, Br or $NO_2$; R⁴=Alk; R³R⁴=—CH=CH—CH=CH—.

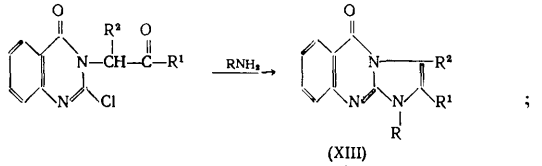


R=Alk; R¹=H or OAlk; R²=Cl or OAlk

It should be noted particularly that alkylation of asymmetric 2-aminopyrimidines by α-halogenocarboxylic acids (or esters) involves simultaneously the $N_{(1)}$ and $N_{(3)}$ atoms [46,49,58]. The intermediate *N*-carboxyalkyl-(alkoxycarbonylalkyl)pyrimidines (quinazolines) are extremely labile and frequently cyclise under reaction conditions to hydrogenated 2-oxo-derivatives of imidazo-pyrimidine (quinazoline). [46,49,58-60] The presence of active centres in compounds (IX) and (X) makes them important intermediates in the syntheses of potential biologically active substances or dyes [46,49,59,60].

The use of the anhydrides of α-halogenocarboxylic acids in the reaction leads to the initial formation of *N*-acyl derivatives of 2-aminopyrimidines, which cyclise under conditions which are relatively unsuitable for practical purposes and with fairly low yields [19,61-69].

## 2. Alkylation of 2-Aminoimidazoles

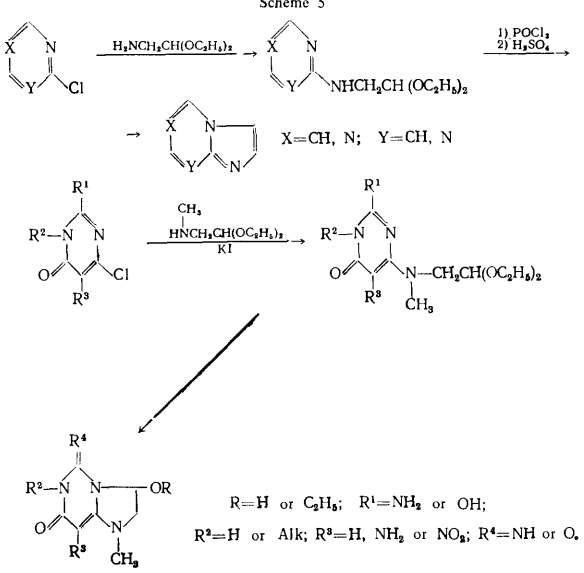


Imidazopyrimidines with a bridgehead nitrogen atom can be synthesised by alkylating 2-aminoimidazoles. On treatment with β-chlorovinyl methyl ketone, 2-amino-benzimidazole is known to be converted [70] into 4-methyl-pyrimido[1,2-*a*]benzimidazole (XI) and 2-methylpyrimido-[1,2-*a*]benzimidazole (XII) in proportions of 8 : 1.

Kochergin [71] demonstrated the possibility of obtaining tetrahydropyrimido[1,2-*a*]benzimidazole from 1-alkyl-2-aminobenzimidazole and 1,3-dihalogenopropane.

## III. AMINATION OF HALOGENO-, ALKYLTHIO-, AND ARYLOXY(ALKOXY)-DERIVATIVES OF PYRIMIDINE AND IMIDAZOLE

The amination of halogeno-, alkylthio-, and aryloxy-(alkoxy) derivatives of pyrimidine (quinazoline) and imidazole constitutes a method of preparation of imidazopyrimidines and their benzo-analogues which is no less important on a preparative scale. In most cases, this method is more laborious than the previous one, but it has nevertheless found applications in the synthesis of imidazopyrimidine systems and their hydrogenated analogues. The nucleophilic substitution of the halogeno-, alkylthio-, and aryloxy(alkoxy)-groups in the above systems is usually carried out in organic solvents over a wide temperature range. Armarego[72] and other workers[73,74] modified the general method somewhat. They synthesised imidazo[1,2-*a*]- and imidazo[1,2-*c*]pyrimidines from 2-chloro- and 4-chloro-pyrimidines and aminoacetals[72-74] in the presence of potassium iodide. The conversion of the initial chloropyrimidines into the more reactive iodopyrimidines made it possible to achieve quantitative yields of $\alpha$-pyrimidinylaminoacetals. Depending on the type of cyclising agents, the latter are converted into the corresponding imidazo-, 3-hydroxyimidazolino-, and 3-alkoxyimidazolino-pyrimidines (Scheme 5). The reaction with 4-chloroquinazoline proceeds similarly[4].



(XIII)

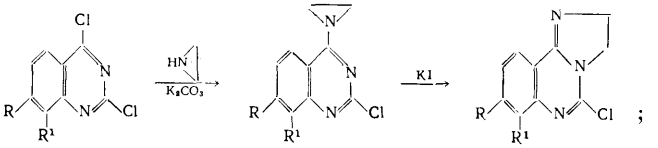
R=H, Alk or Ar; $R^1$=Alk, or Ar; $R^2$=H or Ar.

Pfleiderer et al,[74] who aminated 4-chloro-5-nitropyrimidine-2,6-diones with glucosamine in an aqueous alkaline medium, demonstrated the possibility, in principle, of obtaining 2-formyl-3-hydroxy-8-nitro-1,2,3,5,6,7-hexahydroimidazo[1,2-*c*]pyrimidine-5,7-dione and its 6-substituted derivatives.

An interesting method for the synthesis of imidazoquinazolin-5-ones has been proposed recently[49,75]: 3-acylalkyl-2-chloroquinazolin-4-ones are aminated with ammonia and primary amines[76] and are readily converted into compounds of type (XIII)

Scheme 5

X=CH, N; Y=CH, N



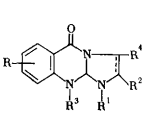
R=H or $C_2H_5$; $R^1$=$NH_2$ or OH; $R^2$=H or Alk; $R^3$=H, $NH_2$ or $NO_2$; $R^4$=NH or O.

There have been a number of communications[4,72,79-82,87,126,140-146] in which the results of studies of the interaction of chloro- and alkylthio-pyrimidines (quinazolines, purines) with aminoalcohols and their ethers are presented. In this case, the hydrogenated imidazopyrimidine systems are synthesised in two stages involving the formation of $\beta$-hydroxyalkylaminopyrimidines with their subsequent conversion into the corresponding cyclising $\beta$-chloro-derivatives. For this reason, it is better to use $\beta$-halogenoalkylamines instead of $\beta$-aminoalcohols in this reaction[77,79-86].

Hornyak and Lempert[87] replaced the stage involving the halogenation of the intermediate heterylaminoalcohols by their oxidation with chromium trioxide in acetic acid or anhydride. It is remarkable that the use of this procedure leads to the formation of 3-hydroxyimidazopyrimidines.

Reiter and coworkers[88,89] developed a method for the thermal cyclisation of $\beta$-aryloxyethylaminopyrimidines, which greatly simplified the preparation of imidazopyrimidines.

The method of synthesis of imidazolinoquinazolines, using aziridine as the aminating agent, is of some interest. According to patent data[11], the initial 2,4-dichloroquinazolines are selectively aminated in the 4-position under fairly mild conditions. Subsequent treatment of the aminated product with potassium iodide in acetone leads to the formation of a tricyclic product:

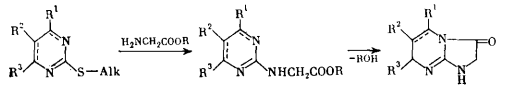


R=$R^1$=H or $OCH_3$.

The amination of 4-chloroquinazoline with ethylenediamine results in the formation of imidazolino[1,2-*c*]-quinazoline[90], but the ambiguity of the reaction pathway lowers sharply the advantage of this method.

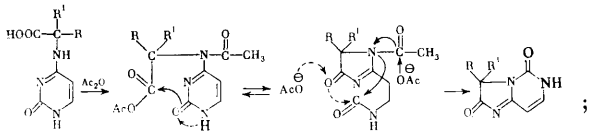
Hydrogenated imidazo[1,1-*b*]quinazoline and pyrimido[1,2-*f*]xanthine systems have been obtained by treating 2-chloro-3-($\beta$-chloroethyl)quinazolin-4-one[91-93] and 8-bromo-7-($\gamma$-bromopropyl)theophylline[94] with ammonia, primary amines and hydroxylamine. The scope of this method is limited owing to the low availability of the labile halogeno-components.

A number of publications have appeared in recent years indicating the possibility of using alkylthio-derivatives of imidazoles and benzimidazoles for the synthesis of imidazopyrimidine systems. 2-Alkylthioimidazolines and their *N*-substituted derivatives[95-99] as well as 2-alkylthiobenzimidazoles[100,101] give rise to tri- and tetra-cyclic products on heating with *o*-aminobenzoic acids, their anhydrides, isatin, or isatoic acids:



R=H, OH, OAlk, Hal, Het, $SO_2Cl$ or $SO_2NH_2$; $R^1$=H or Alk; $R^1R^2$=$-(CH_2)_4-$; $R^3$=H, Alk or Ar; $R^3R^4$=—CH=CH—CH=CH—; ═══ single or double bond.

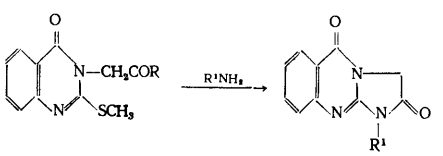
Similar compounds may be obtained from 2-halogenoimidazoles[100-105].



There exist two radical approaches to the solution of the problem of synthesising hydrogenated imidazopyrimidin-2(3)-ones. One of these involves the amination of halogeno- or alkylthio-pyrimidines by aminoacids or their esters. This method has been used successfully to synthesise hexahydroimidazo[1,2-*a*]pyrimidin-3-one[106-107], tetrahydroimidazo[1,2-*c*]pyrimidin-2-ones[69], tetrahydroimidazo[2,1-*a*]quinazolin-3-ones[108,109], dihydroimidazo[1,2-*c*]quinazolin-2-ones[49], and dihydroimidazo-[1,2-*i*]purin-2-ones[110-112].

The reaction of 2(4)-halogeno- or alkylthio-pyrimidines (quinazolines) with aminoacids or their esters, which is distinguished by its simplicity, proceeds with high yields on heating (as a rule in lower alcohols) to 20–100°C:

R=H or Alk; $R^1=R^2=2H$; $R^1R^2=-CH=CH-CH=CH-$; $R^3$=H or OH; ═══ single or double bond.

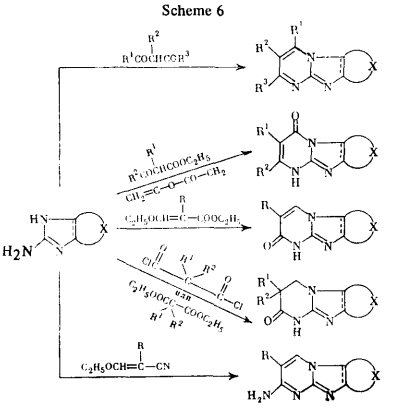


Tetrahydropyrimidin-2-ylaminoacetic acid and its esters obtained in this way[106,107] are unstable in the form of the hydrochlorides; their neutralisation leads to the formation of hexahydroimidazo[1,2-*a*]pyrimidin-3-one. In contrast to these, *N*-(4-oxoquinazolin-2-yl)aminoacetic acid is entirely stable and its cyclisation in the presence of dicyclohexylcarbodiimide or acetic anhydride proceeds preferentially along the "*a*" edge of the quinazoline ring with formation of cyclic 3-oxo-derivatives[108,109]. The reactions of *N*-(pyrimidin-4-yl, quinazolinyl, and adenin-6-yl)-α-aminocarboxylic acids under the conditions of cyclisation by glacial acetic acid or the acetic acid–acetic anhydride mixture have been described[49,69,110-112]. The thorough investigation by Ueda and Fox[69], where two alternative pathways to the cyclisation of *N*-(2-oxopyrimidin-4-yl)-α-aminocarboxylic acids were considered, is noteworthy. The authors showed that the only reaction products are 3-alkyl-1,2,3,5-tetrahydroimidazo-[1,2-*c*]pyrimidine-2,5-diones and proposed the following mechanism for their formation:

R=$R^1$=H or Alk.

Similar results were obtained in the cyclisation of *N*-(quinazolin-4-yl, adenin-6-yl)-α-aminocarboxylic acids[49,110-112]. Using a tracer atom method, Chheda and coworkers[110,111] finally confirmed in recent years the validity of Ueda's theoretical postulates.

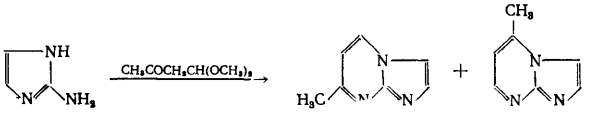
Another version involves the use of the esters or amides of 2-methylthioquinazolin-3-ylacetic acid[91,108,109,113-116]:



R=OAlk or $NH_2$; $R^1$=H, Alk or Ar.

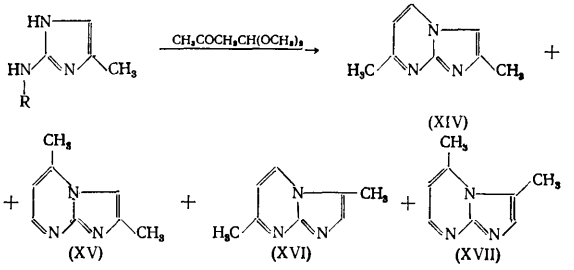
Unfortunately, this method, which is synthetically more promising since it does not require the use of aminoacids or their esters, has not been extended to other systems.

## IV. CONDENSATION OF 2-SUBSTITUTED IMIDAZOLES WITH ALDEHYDES, 1,3-DICARBONYL COMPOUNDS, ACIDS, AND THEIR DERIVATIVES



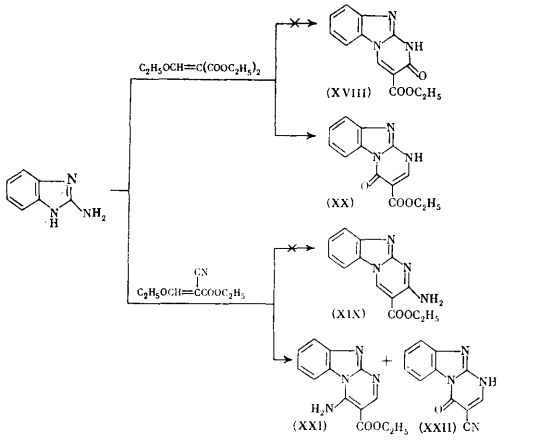
Condensation as a method of synthesis of imidazopyrimidine systems has been known for a long time. Using 2-aminoimidazoline and acetoacetic ester, Kawai[117] obtained for the first time in 1931 7-methyltetrahydroimidazo[1,2-*a*]pyrimidine. Subsequently the preparative possibilities of this method were widely investigated by many workers. The extensive study of this reaction was favoured by the relative availability of the initial 1,3-dicarbonyl compounds and 2-aminoimidazoles (benzimidazoles) and their hydrogenated analogues. This type of condensation (Scheme 6) is convenient for the synthesis of polynuclear heterocyclic systems with an imidazopyrimidine fragment. At the same time, one should note the ambiguity of this reaction, which leads to the formation of a mixture of isomeric products. Despite the difficulty of separating the isomers, this method can be regarded as sufficiently preparative, permitting the variation of the experimental conditions (temperature, reaction time, solvent, and pH of the medium).

Scheme 6

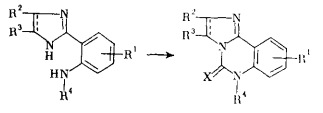


Here ═══ is a single or double bond and X are different substituents in the imidazole ring or the condensed benzene ring.

Imidazo[1,2-*a*]pyrimidine systems have been obtained by the condensation of 2-aminoimidazoles[30,34,38,118,119], 2-aminoimidazolines[117,120-125], and 2-aminobenzimidazoles[118,119,126-139] with 1,3-dicarbonyl compounds or substances which can be converted into these reagents under the reaction conditions. The 1,3-dicarbonyl compounds used were dialdehydes and their acetals, formylketones, diketones, ketoacids or their esters, diketens, dicarboxylic acids or their esters, and acid halides, as well as α,β-unsaturated acids, their chlorides, and esters. The composition of reaction products is determined by the structural characteristics of the reactants. Two isomeric products are usually obtained when 2-aminoimidazole or its 4,5-disubstituted derivatives with identical substituents are treated with asymmetric 1,3-dicarbonyl compounds[38,118,119,132,139]:



The condensation of 2-amino-4(5)-methylimidazole with the acetal of acetoacetaldehyde in a neutral medium leads to a four-component mixture of isomers (XIV)–(XVII), while in an acid medium a two-component mixture of compounds (XV) and (XVII) is obtained [38]:



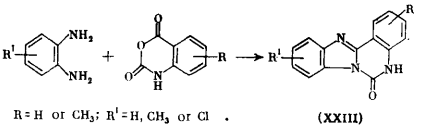
The study of Chow et al. [139], who investigated the reaction of 2-aminobenzimidazole with bifunctional carboxylic acid derivatives, merits special attention, as they obtained results conflicting with earlier conclusions [119]. De Cat and von Dormael [119] claim that the condensation of 2-aminobenzimidazole with diethyl ethoxymethylenemalonate leads to compound (XVIII) and the reaction with ethyl cyanoethoxymethyleneacetate gives rise to compound (XIX).

Chow et al. [139] reproduced these reactions under identical conditions and obtained, instead of compound (XVIII), its isomer (XX) and, instead of compound (XIX), the products were compounds (XXI) and (XXII):

In order to solve the structural problems, Chow et al. [139] carried out a series of chemical transformations of compounds (XX)–(XXII) and analysed their $^1$H NMR spectra. In view of all these considerations, their data are fairly convincing, in contrast to earlier investigations, whose conclusions are doubtful and require additional tests.

Imidazo[1,2-*c*]quinazolines, which are of biological value [4-10,17,18], become available as a result of the condensation of imidazole-containing compounds, which serve as the diamino-components, with aldehydes [7,8,10], carboxylic acids, their chlorides, and thioanhydrides [5,8,10,15,147-150]:

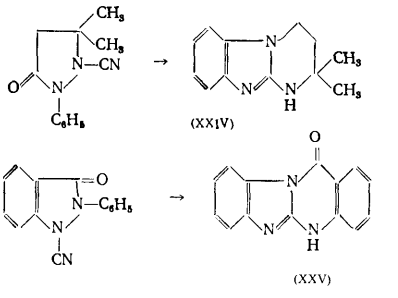
X=O or S; $R^1$=Alk or Hal; $R^2$=$R^3$=H or Alk; $R^2R^3$=—CH=CH—CH=CH—; $R^4$=H or Alk; ═══ single or double bond.



The study of Franchetti and Grifantini [151], who reduced 2-(*o*-nitrophenyl)-1-hydroxyimidazole 3-oxide with zinc to a tricyclic 5,6-dihydroimidazoquinazoline derivative, is of some interest.

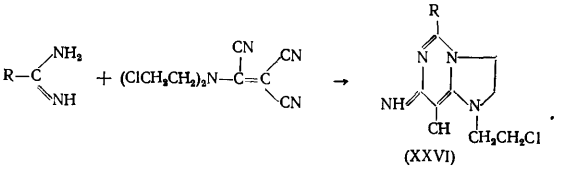
Methods of synthesis of hexahydroimidazoquinazolines based on ethylenediamines and 1-acylaminobenzophenones have been patented [6,9].

The preparation of tetrahydroimidazo[1,2-*c*]quinazolines together with diazepines [152] or a mixture of imidazo[1,2-*c*]- and imidazo[2,1-*b*]-quinazolines [92] has been claimed.



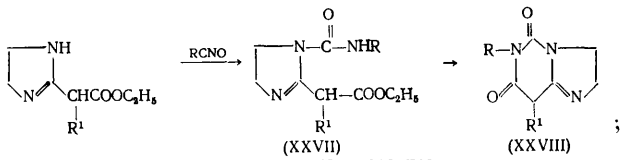
## V. OTHER METHODS OF SYNTHESIS

Apart from the general methods discussed above, there are specific procedures for the synthesis of imidazopyrimidines and their benzo-analogues, which are important in particular instances and which have not found extensive use. Thus compounds of type (XXIII) are formed when *o*-phenylenediamine is fused with isatoic acids [148,153]:



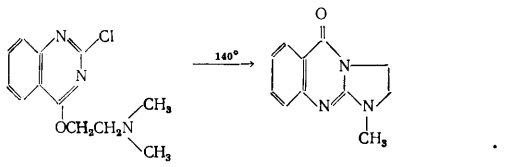
R=H or $CH_3$; $R^1$=H, $CH_3$ or Cl (XXIII)

The reaction of ethylenediamine with 2,6-dithiobenzothiazine—the thio-analogue of isatoic acid—proceeds similarly [154]. A novel method has been described for the synthesis of benzimidazopyrimidines (XXIV) and (XXV) by heating 2-cyano-1-phenyl-3,3-dimethylpyrazolidin-5-one and 1-cyano-2-phenylbenzopyrazolidin-3-one at 270°C [155]:



The authors do not discuss the mechanism of the formation of the above compounds.

1-β-chloroethyl-5-R-8-cyano-7-imino-1,2,3,7-tetrahydroimidazo[1,2-*c*]pyrimidines (XXVI) have been synthesised from amidines under the influence of bis-(β-chloroethylamine)tricyanoethylene [156]:



The use of cyanates in the reaction with ethyl imidazoline-2-acetates in benzene made it possible to obtain derivatives of hexahydroimidazo[1,2-*c*]pyrimidine-5,7-dione (XXVIII).[157] This process proceeds via a stage involving the formation of the intermediate (XXVII), which is converted into compound (XXVIII) on boiling in alcohol:

(XXVII) (XXVIII)

R=H or $C_6H_5$; $R^1$=H or $C_6H_5NHCO$.

It has been observed[92] that heating compound (XXIX) to 140°C for a short time results in the formation of traces of 1-methyltetrahydroimidazo[2,1-*b*]quinazolin-5-one:

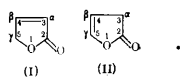
# The Chemistry of $\Delta^{\alpha\beta}$-Butenolides†

A.A.Avetisyan and M.T.Dangyan

Data on the chemistry of $\Delta^{\alpha\beta}$-butenolides are surveyed and described systematically and the available information in the literature about the methods of preparation of these compounds are discussed. The chemical reactions of $\Delta^{\alpha\beta}$-butenolides are examined and a brief account is given of the biological activity of unsaturated $\gamma$-lactones.
The bibliography includes 253 references.



CONTENTS

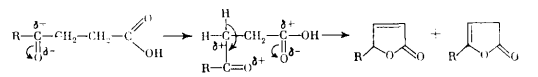
I. Introduction 643
II. Methods of synthesis of $\Delta^{\alpha\beta}$-butenolides 643
III. Chemical properties of $\Delta^{\alpha\beta}$-butenolides 648
IV. Biological activity of unsaturated $\gamma$-lactones 652

## I. INTRODUCTION

There has been a growth of interest in the simplest unsaturated $\gamma$-lactones after the discovery of the antibiotic properties of many natural products—protoanemonin, clavacin, penicilloic acid, vitamin C, and others. They all exhibit their antibiotic activity in combination with strong bactericidal properties [1,2]. Numerous investigations have shown that the unusual specific action of these antibiotics is determined mainly by the presence of the unsaturated $\gamma$-lactone ring and also by the nature and positions of the functional groups present. The unsaturated $\gamma$-lactone ring is also encountered in many other biologically active compounds [3-6]. Fairly extensive experimental data have now accumulated on the synthesis and reactions of unsaturated $\gamma$-lactones. These studies have demonstrated the possibility of the wide-scale employment of $\gamma$-lactones in various branches of the national economy and also in organic synthesis.

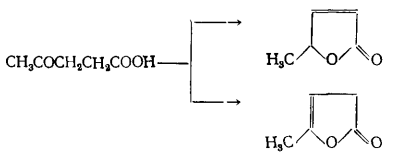
$\alpha\beta$-Unsaturated $\gamma$-lactones (I) and $\beta\gamma$-unsaturated $\gamma$-lactones (II) are distinguished on the basis of the position of the double bond and chemical properties:

(I) (II)



This review is a first attempt in the Soviet scientific literature at a survey and a systematic account of data on the chemistry of $\Delta^{\alpha\beta}$-butenolides published up to 1976.

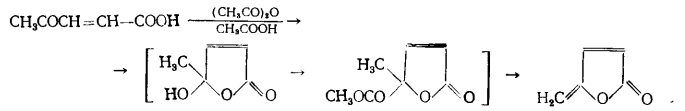
## II. METHODS OF SYNTHESIS OF $\Delta^{\alpha\beta}$-BUTENOLIDES



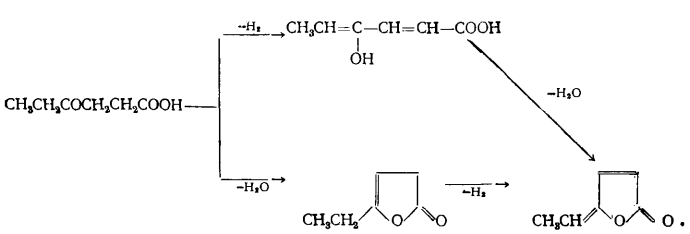
The available literature data on the methods of preparation of $\Delta^{\alpha\beta}$-butenolides can be in the main subdivided into several groups.

### 1. The Preparation of $\Delta^{\alpha\beta}$-Butenolides from Ketoacids and Their Derivatives

One of the commonest methods of the synthesis of $\Delta^{\alpha\beta}$-butenolides involves the intramolecular cyclisation of various keto- and diketo-acids and their derivatives. In order to achieve such synthesis, it is necessary that the oxo- and carboxy-groups in these compounds are in the $\gamma$-position; it is also essential that the ketoacid should be capable of existing in the enolic form:



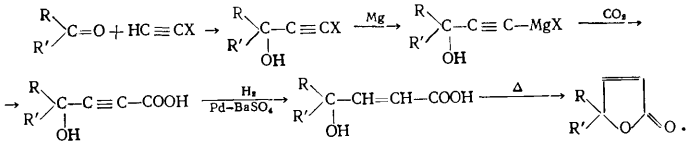
One of the first $\Delta\alpha\beta$-butenolides obtained was angelica lactone, synthesised as early as 1885 [7-12] from levulinic acid. On heating under atmospheric pressure, levulinic acid loses a water molecule and is converted into a mixture of two isomeric unsaturated $\Delta^{\alpha\beta}(\beta)$- and $\Delta^{\beta\gamma}(\alpha)$-angelica lactones:



$\beta$-Angelica lactone is also obtained on heating levulinic acid with keten [13] (or with added toluene-*p*-sulphonic acid [14]) and on distillation of acetyl-levulinic acid [15].

When $\beta$-acetylacrylic acid is heated with a mixture of acetic anhydride and acetic acid in the presence of a small amount of concentrated sulphuric or toluene-*p*-sulphonic acid, $\gamma$-methylene-$\Delta^{\alpha\beta}$-butenolide (protonemonine) is obtained [16]:

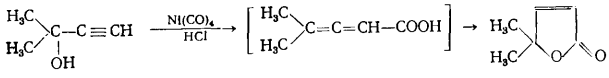
Substituted protoanemonines have been obtained from levulinic acid homologues in the presence of complex catalysts [17]. The elimination of water and dehydrogenation can be carried out consecutively:



†2(5*H*)-furanones (Ed. of Translation).

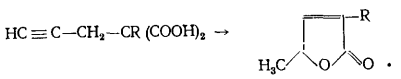
$\Delta^{\alpha\beta}$-Butenolides are obtained by the reaction of $\beta$-benzoyl-$\alpha$-phenylpropionic acid and its derivatives with acetyl chloride[18], acetic anhydride[19], and sulphuric acid[20]. This reaction is acoompanied by the formation of $\beta\gamma$-isomers[21,22] and bislactones[23-26]. The reaction of esters of these acids with aromatic aldehydes in the presence of bases leads to $\gamma$-hydroxy-$\Delta^{\alpha\beta}$-butenolides[27-29].

When benzylidinepyruvic acid reacts with aromatic amines, the products are $\gamma$-aryl-$\alpha$-arylamino-$\Delta^{\alpha\beta}$-butenolides[30-33] whose condensation with $o$-nitrobenzaldehyde leads to $\alpha$-hydroxy-$\gamma$-($o$-nitrophenyl)-$\Delta^{\alpha\beta}$-butenolide[34]. The reaction of acrolein with cyanoacetic acid yields $\alpha$-cyano-$\Delta^{\alpha\beta}$-butenolides[35].



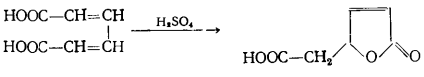
## 2. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from $\alpha\beta$-Unsaturated Carboxylic Acids and Their Derivatives

An important method for the synthesis of $\Delta^{\alpha\beta}$-butenolides is the intramolecular cyclisation of $\alpha\beta$-unsaturated carboxylic acids and their derivatives. When ethyl crotonate is heated with selenium dioxide, a $\Delta^{\alpha\beta}$-butenolide is obtained[36]. Acetylenecarboxylic acids are reduced to olefinic acids, which likewise can cyclise to the corresponding $\Delta^{\alpha\beta}$-butenolides on heating[37,38]:



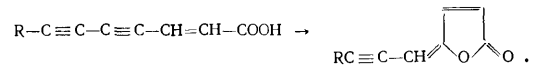
The intramolecular cyclisation of $\alpha\beta$-unsaturated carboxylic acids and their derivatives apparently proceeds via a mechanism which has been generally adopted for the formation of esters from acids and alcohols.

A variation of this reaction is the conversion of an acetylenic alcohol into $\Delta^{\alpha\beta}$-butenolide on heating with nickel carbonyl in a butanol–hydrochloric acid mixture[39]. It is suggested that the reaction proceeds via an allenecarboxylic acid:



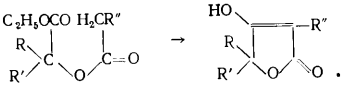
$\Delta^{\alpha\beta}$-Butenolide is also obtained when acetylene is heated with acetone and acetic anhydride in an autoclave at 100°C and under a pressure of 250 atm in the presence of dicobalt octacarbonyl[40,41].

In the presence of acid or alkaline catalysts, acetylenecarboxylic and acetylenedicarboxylic acids cyclise to $\Delta^{\alpha\beta}$-butenolides. The corresponding $\Delta^{\alpha\beta}$-butenolide and dilactones have been obtained by this reaction from various alkyl- and aryl-substituted malonic acids containing the propargyl or dipropargyl group[42-44]:

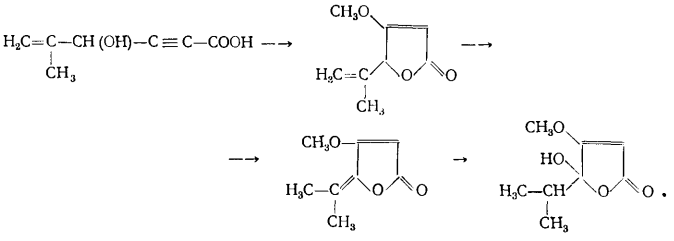


Carboxylic acids with two double bonds can be converted into lactones by treatment with sulphuric acid. Thus, the lactonisation of muconic acid results in the formation of $\gamma$-carboxymethyl-$\Delta^{\alpha\beta}$-butenolide[45,46]:

When monobasic or dibasic enynoic acids‡ are heated, they cyclise with formation of $\Delta^{\alpha\beta}$-butenolides of the type of protoanemonine derivatives[47-49].

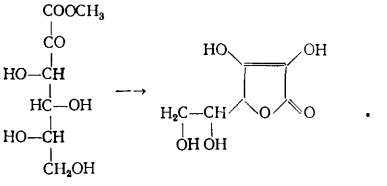


The cyclisation of endiynoic acids leads to $\Delta^{\alpha\beta}$-butenolides with an acetylenic group[54]:

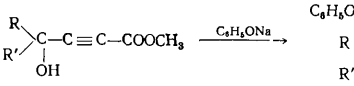


## 3. The Preparation of $\Delta^{\alpha\beta}$-Butenolides from Hydroxy- and Halogeno-Acids and Their Derivatives

The cyclodehydration of saturated and unsaturated hydroxyacids and their derivatives is widely used to synthesise $\Delta^{\alpha\beta}$-butenolides. Natural products such as vitamin C, dihydropenicilloic acid, etc. have been synthesised by this method.

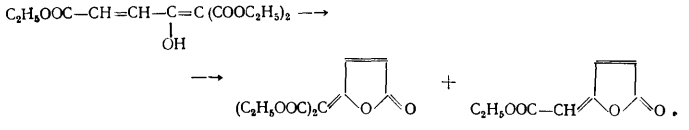


When $\alpha$-hydroxyacid diesters are heated in the presence of metallic sodium, tetronic acids are formed[55]:

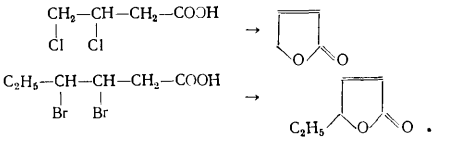


On heating, 3,4-dihydroxybutyric acid with phosphorus pentoxide, $\Delta^{\alpha\beta}$-butenolide is formed and can be obtained also from 3,4-dichlorobutyric acid when the latter is heated with potassium carbonate or a methanol solution of sodium hydroxide[56]. $\gamma$-Isopropenyl-$\beta$-methoxy-$\Delta^{\alpha\beta}$-butenolide has been synthesised by intramolecular cyclisation of 4-hydroxy-5-methylhex-5-en-2-ynoic acid in the presence of $BF_3$.HgO in methanol. The butenolide is converted by treatment with an aqueous alcoholic solution of alkali into $\gamma$-hydroxy-$\gamma$-isopropyl-$\beta$-methoxy-$\Delta^{\alpha\beta}$-butenolide (dihydropenicilloic acid)[57,58]:

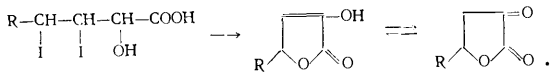
When methyl 2-oxogulonate is heated in methanol solution in the presence of sodium carbonate in an atmosphere of nitrogen, the product is vitamin C (L-ascorbic acid)[59]:



$\gamma\gamma$-Dialkyl-$\beta$-phenoxy-$\Delta^{\alpha\beta}$-butenolides have been obtained by the reaction of sodium phenoxide with the methyl esters of $\gamma$-hydroxyacetylenic acids[60]:

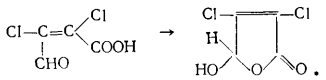


‡It is of interest that these acids cyclise to 2-pyrones under the influence of strongly basic catalysts[47,48,50-53].



Muconic acid derivatives have been used[61] as the starting materials for the synthesis of unsaturated $\Delta^{\alpha\beta}$-butenolides; thus pyrolysis of diethyl $\beta$-hydroxy-$\alpha$-ethoxycarbonylmuconate leads to a mixture of diunsaturated lactones—derivatives of the type of protoanemonine:

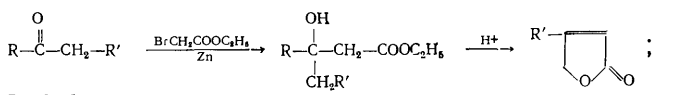
Halogenocarboxylic acids and their derivatives have also been used as the starting materials for the synthesis of unsaturated $\Delta^{\alpha\beta}$-butenolides. The corresponding $\Delta^{\alpha\beta}$-butenolides are obtained by the dehydrohalogenation of $\beta\gamma$-dihalogenobutyric[62,63] and $\beta\gamma$-dibromocaproic[64] acids in the presence of sodium carbonate, sodium bicarbonate, or triethylamine:



$\gamma$-Alkyl-$\alpha$-hydroxy-$\Delta^{\alpha\beta}$-butenolides, which are in equilibrium with the keto-forms, have been synthesised by the elimination of water from $\alpha$-hydroxy-$\beta\gamma$-diiodocarboxylic acids[65]:

$\beta$-Formyl-$\alpha\beta$-dihalogenoacrylic acids condensed with phenol, anisole, guaiacol, thymol, halogenobenzene, 1,2,3-trimethoxybenzene, and *o*-dimethoxybenzene in the presence of inorganic or Lewis acids to form $\gamma$-substituted $\Delta^{\alpha\beta}$-butenolides[66-69].

Halogenomuconate esters exist in the cyclic lactone form[70]:



When chloromuconic acid condenses with acetophenone, nitromethane, or nitroethane in the presence of sodium hydroxide, $\gamma$-substituted $\alpha\beta$-dichloro-$\Delta^{\alpha\beta}$-butenolides are obtained[71,72]; the condensation of the acid with benzene and chlorobenzene yields respectively $\alpha\beta$-dichloro-$\gamma$-phenyl-$\Delta^{\alpha\beta}$-butenolide and $\alpha\beta$-dichloro-$\gamma$-(*p*-chlorophenyl)-$\Delta^{\alpha\beta}$-butenolide[24,73] and the condensation with aromatic compounds (phenol and anisole) in the presence of polyphosphoric acid gives rise to $\alpha\beta$-dichloro-$\Delta^{\alpha\beta}$-butenolides[68,74].

Bromomuconic acid reacts with acetophenone to form $\alpha\beta$-dibromo-$\gamma$-phenacyl-$\Delta^{\alpha\beta}$-butenolide[75].

## 4. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides by the Reformatsky Reaction

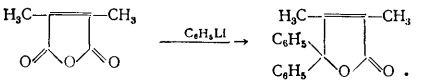
An important method for the synthesis of $\Delta^{\alpha\beta}$-butenolides and steroid lactones is the Reformatsky reaction. The starting materials in this case are $\alpha$-methoxy- or acetoxy-ketones. This method of synthesis of $\Delta^{\alpha\beta}$-butenolides has been used by many investigators[76-99]:

The acetoxyester is converted into the $\Delta^{\alpha\beta}$-butenolide by heating it in the presence of alkali metal hydrogen sulphates, anhydrous oxalic acid, or potassium phosphate[100]. The intramolecular Reformatsky reaction, i.e. the interaction of the above compounds with zinc or magnesium in inert solvents, constitutes a modification of this process[101].

## 5. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from the Corresponding $\Delta\beta\gamma$-Isomers

Under the influence of bases such as triethlyamine, piperidine, and benzylamine, $\Delta\beta\gamma$-butenolides are converted into the corresponding $\Delta^{\alpha\beta}$-isomers[8,102,103]. Acetic anhydride is sometimes used as the catalyst for this purpose[104,105].

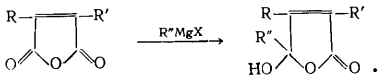
## 6. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from Substituted $\gamma$-Butyrolactones



When saturated $\gamma$-lactones containing substituents (OH, $OOCCH_3$, SH, $NH_2$) in the $\alpha$- or $\gamma$-positions are treated with acids or salts, the HX molecule is split off with formation of a mixture of $\Delta^{\alpha\beta}$- and $\Delta^{\beta\gamma}$-isomers. Treatment of the mixture with a base leads to the pure $\Delta^{\alpha\beta}$-isomer[106,107].

For example, $\alpha$-chloro-$\beta$-cyclohexylbutyrolactone is converted into $\beta$-cyclohexyl-$\Delta^{\alpha\beta}$-butenolide under the influence of potassium acetate[108,109]. $\beta$-Aroyl-$\beta$-bromoacrylic acids, which exist in the cyclic form, have been converted into the corresponding $\Delta^{\alpha\beta}$-butenolides[110-112]. A solution of $\gamma$-benzoyl-$\beta$-phenylacrylic acid contains approximately 70% of $\gamma$-hydroxy-$\alpha\beta$-diphenyl-$\Delta^{\alpha\beta}$-butenolide[109].

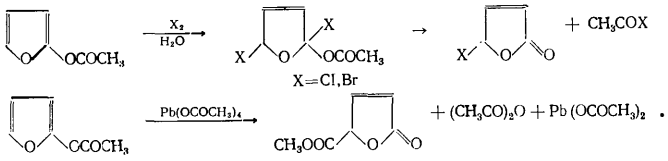
Pyrolysis of saturated $\gamma$-lactones containing substituents (H, $C_7H_{15}$ or $C_2H_5$, OAc) in the $\gamma$-position, in the presence of sulphuric acid at 200–330°C, gives rise to $\gamma$-alkyl-$\Delta^{\alpha\beta}$-butenolides[114]. $\gamma$-Substituted $\Delta^{\alpha\beta}$-butenolides are obtained by the oxidative decarboxylation of $\gamma$-substituted paraconic acid in the presence of $Na_2S_2O_8$, $AgNO_3$, and $CuSO_4$.[115]



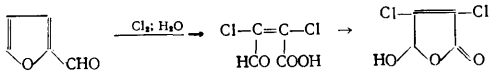
## 7. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from Substituted Maleic Acid Anhydrides

The next most important method of synthesis of $\Delta^{\alpha\beta}$-butenolides involves the interaction of a substituted maleic anhydride with organometallic compounds. Thus the reaction of dimethylmaleic anhydride with phenyllithium yields $\alpha\beta$-dimethyl-$\gamma\gamma$-diphenyl-$\Delta^{\alpha\beta}$-butenolide[116]:

$\gamma$-Alkyl-$\gamma$-hydroxy-$\Delta^{\alpha\beta}$-butenolides have been obtained by the reaction of mono- and di-alkylmaleic anhydrides with alkylmagnesium or arylalkylmagnesium halides[117].



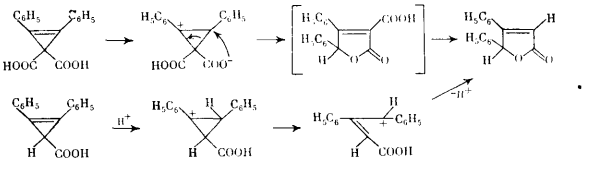
Dehydration of these butenolides leads to α-alkylidene-$\Delta^{\alpha\beta}$-butenolides [117]:



$\gamma\gamma$-Disubstituted $\alpha\beta$-dimethyl-$\Delta^{\alpha\beta}$-butenolides are obtained by the Friedel-Crafts reaction from dimethylmaleic anhydride and biphenyl in carbon disulphide [118].

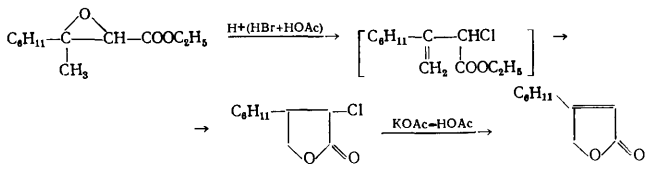
## 8. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from Furan and Furancarboxylic Acid Derivatives

The reaction of 2-acetoxyfuran with halogens (chlorine or bromine) in the presence of water or lead tetraacetate results in the synthesis of γ-halogeno- or γ-acetoxy-$\Delta^{\alpha\beta}$-butenolides [119]:



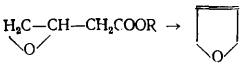
When bromine is allowed to react with pyromucic acid in the presence of water, a complex process takes place—decarboxylation, addition of bromine, and oxidation with formation of $\alpha\beta$-dibromo-γ-hydroxy-$\Delta^{\alpha\beta}$-butenolide [120]. $\alpha\beta$-Dichloro-γ-hydroxy-$\Delta^{\alpha\beta}$-butenolide is obtained when chlorine and furfural are added simultaneously to a concentrated solution of hydrochloric acid at 70°C [121]:

Acid hydrolysis of methyl 3,4-dihalogeno-2,5-dimethoxytetrahydrofurancarboxylates leads to $\alpha\beta$-dihalogeno-$\Delta^{\alpha\beta}$-butenolides [122].



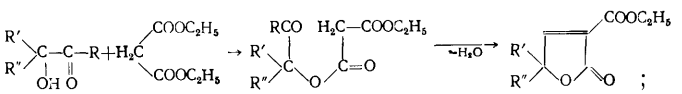
## 9. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from Cyclopropane Derivatives

The reaction of diphenylacetylene with diazomalonic ester in the presence of copper leads to 1,2-diphenylcyclopropane-3,3-dicarboxylic acid, the thermal decomposition of which results in the formation of $\beta\gamma$-diphenyl-$\Delta^{\alpha\beta}$-butenolide [123]. This butenolide is also obtained from acetic acid derivatives and from 1,2-diphenylcyclopropane-3-carboxylic acid in the presence of acid catalysts [124-126]:



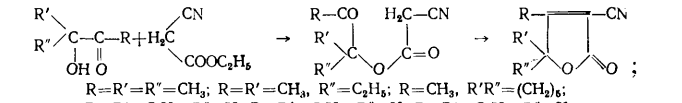
## 10. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from Epoxy-Compounds

$\Delta^{\alpha\beta}$-Butenolides are also obtained from epoxy-compounds. Thus ethyl 3-cyclohexyl-2,3-epoxybutyrate, which is readily formed by the Darzens reaction, is converted in the presence of catalysts into β-cyclohexyl-$\Delta^{\alpha\beta}$-butenolide [108,109]:



On treatment with sulphuric acid, esters of 3,4-epoxybutyric acid are converted into $\Delta^{\alpha\beta}$-butenolide [127]:

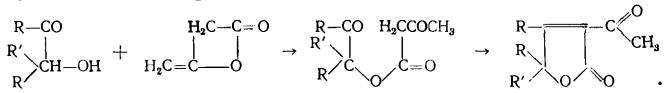
## 11. The Synthesis of $\Delta^{\alpha\beta}$-Butenolides from Hydroxyketo-Compounds



An important disadvantage of the above methods is the difficulty of introducing various functional groups into the unsaturated lactone ring. For this reason, the condensation of hydroxyketones with esters containing active methylene groups§ may be regarded as the most general method of synthesis of $\Delta^{\alpha\beta}$-butenolides with functional groups. The esters with active methylene groups employed are the acetoacetic, benzoylacetic, malonic, cyanoacetic, phenylacetic, and similar compounds, for example diketen.

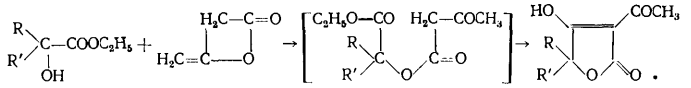
Thus acyloins and tertiary α-ketoalcohols interact with ethyl malonate in the presence of alkaline catalysts to form substituted α-ethoxycarbonyl-$\Delta^{\alpha\beta}$-butenolides [128-133]. Sodium ethoxide is an effective catalyst for this reaction [132,133]:

R=R′=R″=CH$_3$; R=R′=CH$_3$, R″=C$_2$H$_5$; R=CH$_3$, R′R″=(CH$_2$)$_5$; R=R′=C$_2$H$_5$, R″=H; R=R′=C$_3$H$_7$, R″=H; R=R′=C$_4$H$_9$, R″=H; R=R′=C$_5$H$_{11}$, R″=H .



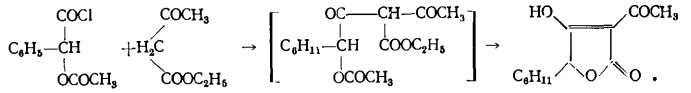
As is to be expected, cyanoacetic ester condenses with α-ketoalcohols in the presence of a basic catalyst more readily than malonic acid, the product being substituted α-cyano-$\Delta^{\alpha\beta}$-butenolides [133,134]:

R=R′=R″=CH$_3$; R=R′=CH$_3$, R″=C$_2$H$_5$; R=CH$_3$, R′R″=(CH$_2$)$_5$; R=R′=C$_2$H$_5$, R″=H; R=R′=C$_3$H$_7$, R″=H; R=R′=C$_4$H$_9$, R″=H; R=R′=C$_5$H$_{11}$, R″=H.

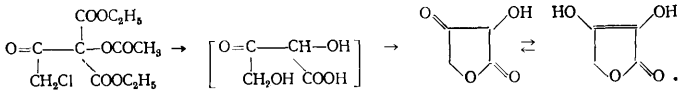


Under analogous conditions, benzoin reacts with cyanoacetic ester to form α-cyano-βγ-diphenyl-$\Delta^{\alpha\beta}$-butenolide [135].

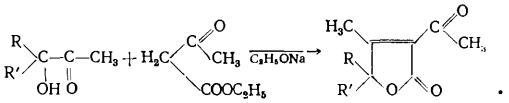
The esters of acyloins and acetoacetic acid can undergo intramolecular condensation with formation of $\Delta^{\alpha\beta}$-butenolides. For example, acyloins and tertiary α-ketoalcohols react with diketen in the presence of pyridine or triethylamine to form acetoacetic acid esters, which cyclise on heating to substituted $\Delta^{\alpha\beta}$-butenolides [136-138]:



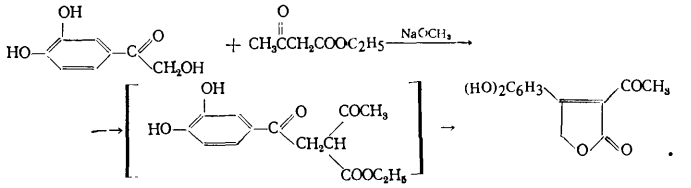
§Among the advantages of this method, one may note the ready availability of the initial compounds and the simple technology of the process.



Under analogous conditions $\alpha$-hydroxyacid esters also react with diketen to form the corresponding $\Delta^{\alpha\beta}$-butenolides—acetyltetronic acids [136,139]

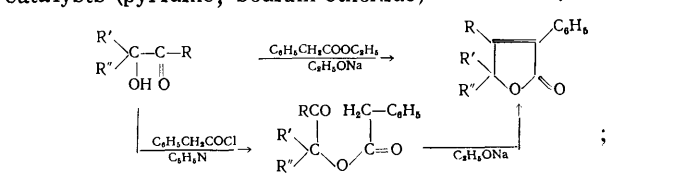


In order to synthesise tetronic acid derivatives, the chloride of acetoxy-mandelic acid was allowed to react with acetoacetic ester [140], which resulted in the formation of $\alpha$-acetyl-$\beta$-hydroxy-$\gamma$-phenyl-$\Delta^{\alpha\beta}$-butenolide:

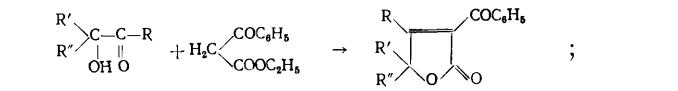


A number of acylated malonic and cyanoacetic acids have also been used for the same purpose [140]. Thus $\alpha$-hydroxytetronic acid has been obtained from diethyl acetoxychloroacetylmalonate in the presence of base [141]:

The condensation of tertiary $\alpha$-ketoalcohols with acetoacetic esters in the presence of sodium ethoxide proceeds with formation of the corresponding $\alpha$-acetyl-$\Delta^{\alpha\beta}$-butenolides [134]:



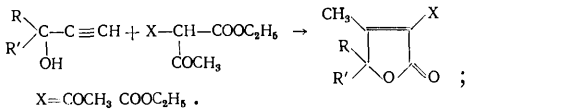
$\omega$-Hydroxyacetophenones containing hydroxy-groups in the benzene ring interact with acetoacetic ester in methanol solution to form $\Delta^{\alpha\beta}$-butenolides [142-144]:



2-Methyl-3,3-di-($p$-tolyl)propionic acid, which gives rise to a mixture of $\Delta^{\alpha\beta}$-$\Delta^{\beta\gamma}$-isomers on heating with acetic anhydride, was obtained similarly from acetophenone and $\beta$-benzoacrylic [$\beta$-benzoylacrylic?] acid [108]. [This paragraph is completely erroneous. 2-Methyl-3,3-di-($p$-tolyl)-propionic acid is not mentioned in Ref. 108 nor in Refs. 142 to 144 (Ed. of Translation)].

Substituted $\alpha$-phenyl-$\Delta^{\alpha\beta}$-butenolides have been synthesised by the condensation of $\alpha$-ketoalcohols with phenylacetic ester and phenylacetyl chloride as well as substituted phenylacetic acids in the presence of basic catalysts (pyridine, sodium ethoxide) [128,129,145,146]:

R=R′=R″=$CH_3$; R=R′=$CH_3$, R″=$C_2H_5$; R=$CH_3$, R′R″=$(CH_2)_5$; R=R′=$C_2H_5$, $C_3H_7$ or $C_4H_9$, R″=H.

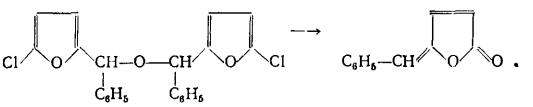


Secondary and tertiary $\alpha$-ketoalcohols are converted into the corresponding $\alpha$-benzoyl-$\Delta^{\alpha\beta}$-butenolides on condensation with benzoylacetic ester in the presence of sodium ethoxide [147,148]:

R=R′=R″=$CH_3$; R=R′=$CH_3$, R″=$C_2H_5$; R=$CH_3$R′R″=$(CH_2)_5$; R=R′=$C_2H_5$, $C_3H_7$,$C_4H_9$, R″=H.

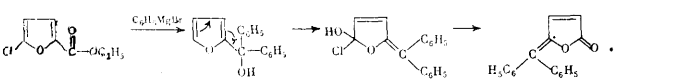
The ability of the above esters to form lactones in condensation reactions with $\alpha$-ketoalcohols diminishes in the sequence cyanoacetic > acetoacetic > malonic > benzoylacetic > phenylacetic. A probable reaction mechanism has been proposed [132,133,138].

Acetylenic carbinols have also been used as starting materials for the synthesis of $\Delta^{\alpha\beta}$-butenolides. Thus Lacey [138] obtained $\alpha$-acetyl- or $\alpha$-ethoxy-carbonyl-$\Delta^{\alpha\beta}$-butenolides by the reaction of ethynylmethanols with acetylacetoacetic or acetylmalonic esters at 135–200°C:



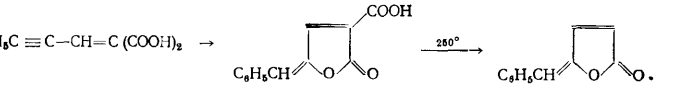
X=$COCH_3$ $COOC_2H_5$.

## 12. Oxidation with Peracids



When 2,5-dimethylphenol is oxidised with peracids, the product is $\alpha\alpha'$-dimethyl-*cis*,*cis*-muconic acid, which is converted into $\gamma$-ethoxycarbonyl-$\alpha$-methyl-$\Delta^{\alpha\beta}$-butenolide on heating in ethanol [149].

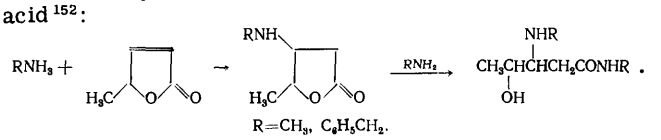
## 13. The Synthesis of $\gamma$-Arylidene- and $\gamma$-Alkylidene-$\Delta^{\alpha\beta}$-Butenolides



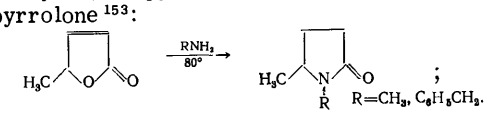
When bis-(5-chlorofuryl-2-methylphenyl) ether reacts with concentrated sulphuric acid, $\gamma$-benzylidene-$\Delta^{\alpha\beta}$-butenolide is formed [150]:

$\gamma$-Diphenylmethylene-$\Delta^{\alpha\beta}$-butenolide has been synthesised from ethyl 5-chlorofuran-2-carboxylate on treatment with phenylmagnesium bromide [150]:

When malonic acid reacts with phenylpropargylaldehyde, the product is phenylpropargylidenemalonic acid, which is converted into $\gamma$-benzylidene-$\alpha$-carboxy-$\Delta^{\alpha\beta}$-butenolide on heating to 190°C. [48] The decarboxylation of this product at 250°C leads to $\gamma$-benzylidene-$\Delta^{\alpha\beta}$-butenolide [48,151]:



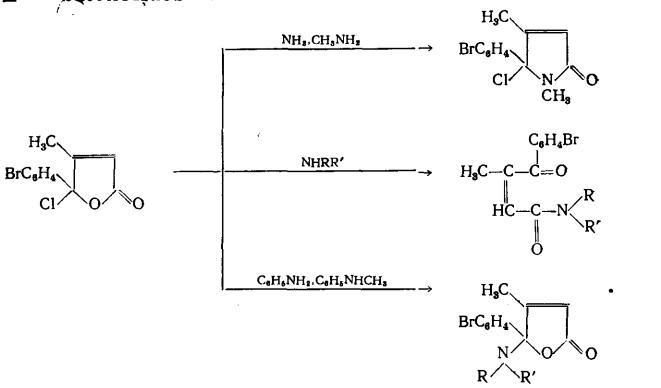
When mono- or di-alkylmaleic anhydrides are treated with a Grignard reagent at low temperatures, di- or trisubstituted $\gamma$-hydroxy-$\Delta^{\alpha\beta}$-butenolides are obtained [117]. Their dehydration with a mixture of acetic anhydride, acetic acid and sulphuric acid leads to $\gamma$-alkylidene or $\gamma$-arylidene-$\Delta^{\alpha\beta}$-butenolides [117].



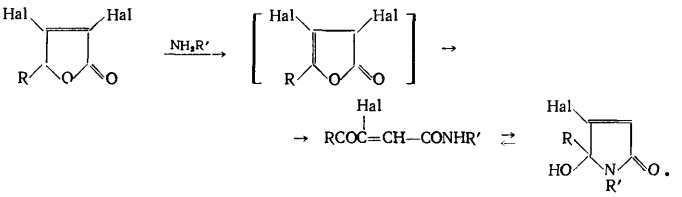
## III. CHEMICAL PROPERTIES OF $\Delta^{\alpha\beta}$-BUTENOLIDES

$\Delta^{\alpha\beta}$-Butenolides are very reactive. Owing to the presence of reactive centres such as the double bond and the lactone ring, they can react with nucleophiles and electrophiles and can undergo other reactions involving both the retention and the opening of the lactone ring.

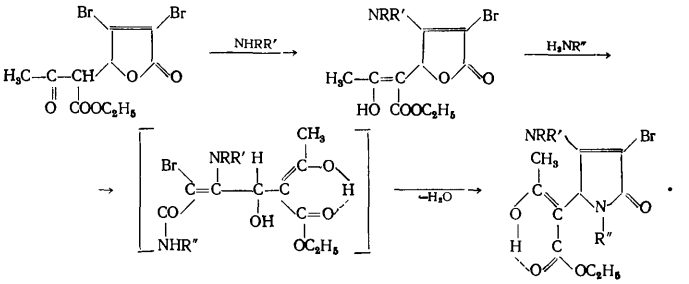
$\Delta^{\alpha\beta}$-Butenolides react with ammonia and amines in different ways. Jones and Young [152] showed that, when angelica lactone reacts with aqueous methylamine and benzylamine solutions at room temperature, the amines add to the unsaturated carbon–carbon bond in the lactone ring [152]. Since the distribution of electron density in the lactone ring is such that there is a deficiency of electron density at the second and fifth carbon atoms in the ring, presumably nucleophiles attack one of these carbon atoms with subsequent dissociation of the $C_{(1)}-C_{(2)}$ or $C_{(1)}-C_{(5)}$ bond and formation of the corresponding derivative. The product obtained, which is a derivative of butyrolactone, therefore reacts with a second amine molecule to form the methylamide of $\gamma$-hydroxy-$\beta$-methylaminovaleric acid and the benzylamide of $\beta$-benzylamino-$\gamma$-hydroxyvaleric acid [152]:



However, when angelica lactone is heated with an equimolar amount of methylamine or benzylamine to 80°C, 1,5-dimethyl-2(5*H*)-pyrrolone and 1-benzyl-5-methyl-2(5*H*)-pyrrolone [153]:

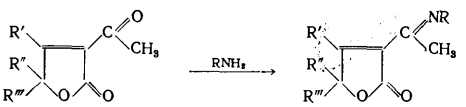


The reactions of halogenobutenolides with ammonia or amines can proceed in the following ways: opening of the butenolide ring with formation of the corresponding amide of a hydroxy- or an amino-acid [154–157], nucleophilic substitution of the halogen by an amino-residue [30,154–157], and addition of an amine to the C=C bond of the $\Delta^{\alpha\beta}$-butenolide ring [152]. The particular pathway followed in the reaction with a given nucleophile is apparently determined mainly by the thermodynamic stability of the addition products formed [158].

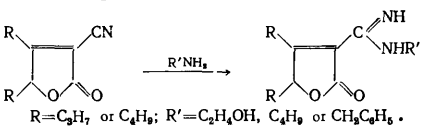


For example, when $\gamma$-(bromophenyl)-$\gamma$-chloro-$\beta$-methyl-$\Delta^{\alpha\beta}$-butenolide reacts with ammonia at room temperature in benzene, the product is a $\gamma$-hydroxylactam, the reaction with dimethylamine yields the alkylamide of *cis*-$\beta$-(*p*-bromobenzoyl)-$\beta$-methylacrylic acid, and the reaction with aniline or methylaniline results in the formation of $\gamma$-(*N*-arylamino)-$\gamma$-(bromophenyl)-$\beta$-methyl-$\Delta^{\alpha\beta}$-butenolides [30]:

It has been shown [156,157] that, when $\alpha\beta$-dihalogeno-$\Delta^{\alpha\beta}$-butenolides are treated with primary amines in methanol at temperatures between −5° and −10°C, the butenolide ring opens with formation of an amide, which readily cyclises under the reaction conditions and is in equilibrium with the corresponding lactam:

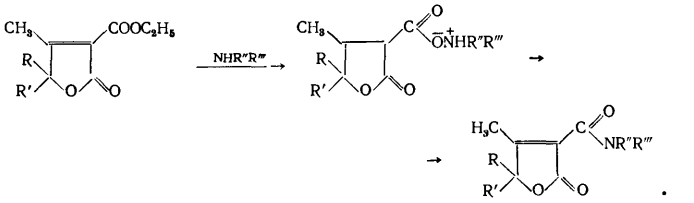


When $\alpha\beta$-dibromo-$\gamma$-($\alpha'$-ethoxycarbonylacetonyl)-$\Delta^{\alpha\beta}$-butenolide reacts with a twofold excess of a primary or secondary amine in methanol, the nucleophilic substitution of the halogen by the amino-residue takes place without involving the lactone ring; the products are $\beta$-amino-$\alpha$-bromo-$\Delta^{\alpha\beta}$-butenolides, which are converted into the corresponding $\Delta^{\alpha\beta}$-crotonolactams at room temperature in dioxan [159]:

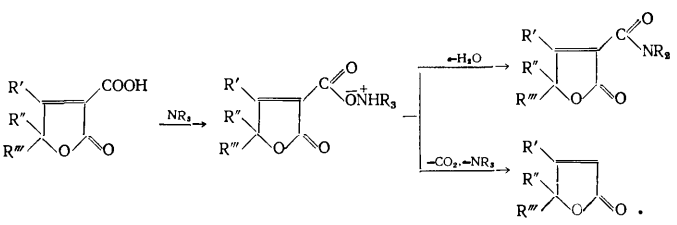


Bromine is substituted in the $\beta$-position, which can be explained by the fact that the electron density is a minimum at the corresponding carbon atom [160].

When substituted $\alpha$-acetyl-$\Delta^{\alpha\beta}$-butenolides react with primary amines, the nucleophilic attack by the amine is directed exclusively to the acetylcarbonyl group with formation of the corresponding amino-derivatives of $\alpha$-acetyl-$\Delta^{\alpha\beta}$-butenolides [161]:

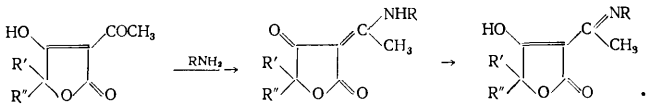


Primary amines add to the cyano-group of substituted $\alpha$-cyano-$\Delta^{\alpha\beta}$-butenolides with formation of the aminidines of the corresponding lactones [162]:

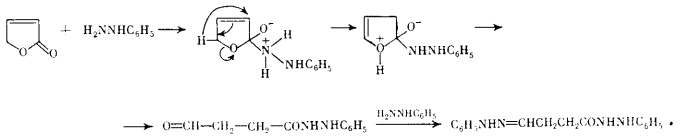


R=$C_3H_7$ or $C_4H_9$; R′=$C_2H_4OH$, $C_4H_9$ or $CH_2C_6H_5$.

The reaction of substituted $\alpha$-ethoxycarbonyl-$\Delta^{\alpha\beta}$-butenolides with primary and secondary amines proceeds via the nucleophilic attack by the amine exclusively on the ester group, with formation of the amides of salts of substituted $\gamma$-lactonoacids, i.e. the reactions proceed without the opening of the lactone ring [163–165]:

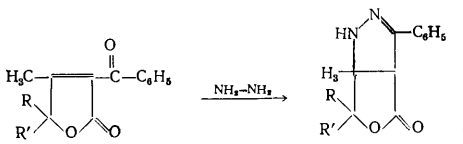


$\beta\gamma\gamma$-Trialkyl-$\alpha$-carboxy-$\Delta^{\alpha\beta}$-butenolides readily react with aqueous ammonia and aniline solutions and with primary and secondary amines to form the ammonium salts of $\alpha$-carboxy-$\Delta^{\alpha\beta}$-butenolides [164]:

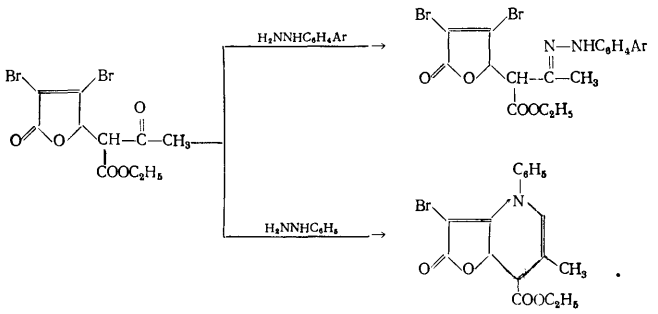


Depending on the nature of the amine, the salts decompose in two ways with formation of the amidolactones of $\alpha$-carboxy-$\Delta^{\alpha\beta}$-butenolides and $\beta\gamma\gamma$-trialkyl-$\Delta^{\alpha\beta}$-butenolides. In both cases the unsaturated lactone ring remains unchanged [164].

When $\alpha$-acetyltetronic acids are heated with ammonia and primary amines, imino-derivatives of tetronic acid are formed [139]:

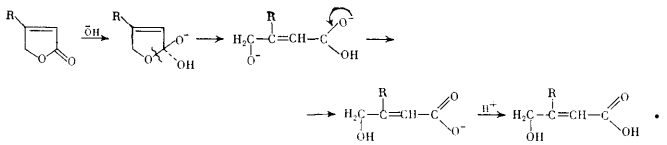


The reaction of $\Delta^{\alpha\beta}$-butenolides with phenylhydrazine entails the dissociation of the $C_{(1)}-C_{(2)}$ bond of the lactone ring with formation of the phenylhydrazide-phenylhydrazone of formylsuccinic acid [166]; the authors represent the reaction by the following scheme:



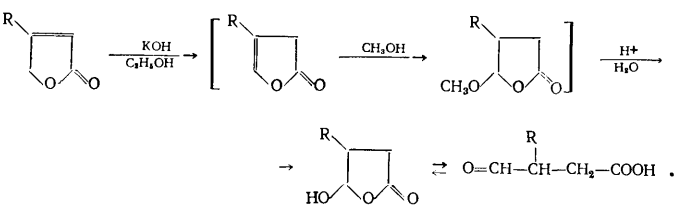
The reaction of $\alpha$- and $\beta$-acetyl-$\Delta^{\alpha\beta}$-butenolides with hydrazine, phenylhydrazine, and hydroxylamine at room temperature involves the oxo-group without the opening of the lactone ring and without addition to the double bond [161,167].

The reaction of hydrazine with substituted $\alpha$-benzoyl-$\Delta^{\alpha\beta}$-butenolides yields pyrazolines containing the $\gamma$-lactone ring [168]:

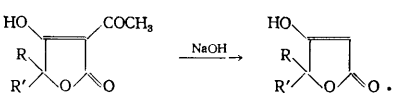


Similar pyrazolines were obtained also by the reaction of $\Delta^{\alpha\beta}$-butenolides with aliphatic diazo-compounds [169].

Kalnina and Gudriniece [159] showed that the reaction of $\alpha\beta$-dibromo-$\gamma$-($\alpha'$-ethoxycarbonylacetonyl)-$\Delta^{\alpha\beta}$-butenolide with $p$-nitro- and 2,4-dinitro-phenyl-hydrazines at room temperature yields the corresponding arylhydrazones, while the reaction of $\alpha\beta$-dibromo-$\Delta^{\alpha\beta}$-butenolide with phenylhydrazine involves also the elimination of hydrogen bromide and the closure of the tetrahydropyridazine ring [159]:

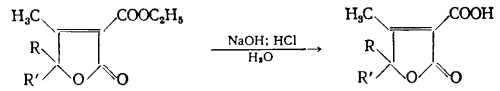


Thus the study of the reactions with ammonia and nitrogen-containing bases showed that, in contrast to the saturated analogues, the lactone ring in unsaturated substituted butenolides is unreactive towards nucleophiles. Comparative studies of the reactivities of the functional groups and the double bond clearly demonstrated the much weaker electrophilic properties of the double bond in these reactions.

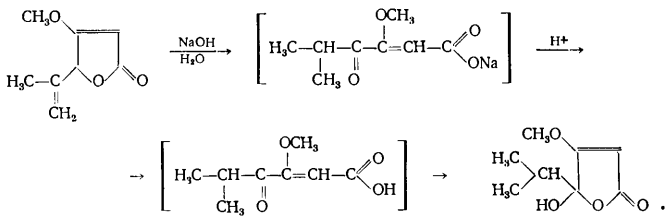


$\Delta^{\alpha\beta}$-Butenolides are hydrolysed with and without the opening of the lactone ring. The ease of ring opening in hydrolysis depends on the nature and positions of the substituents. Thus when $\beta$-substituted $\Delta^{\alpha\beta}$-butenolides were acted upon by alkali, two different reactions were noted [86]. In an aqueous medium, the lactone hydrolyses, forming the salt of the corresponding acid [86]:

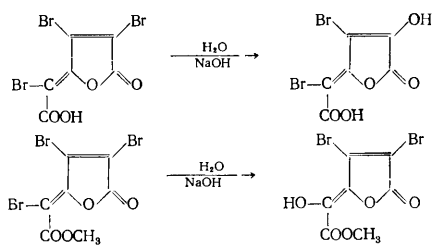
In alcoholic solution, the double bond migrates irreversibly to the $\beta\gamma$-position and the resulting vinyl ether combines with the elements of the alcohol to form an acetal. After acidification, the acetal hydrolyses to the hydroxylactone, which exists in equilibrium with the non-cyclic formyl-substituted acid [86]:



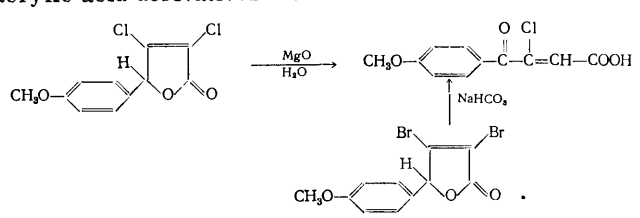
On treatment with aqueous solutions of alkali, the unsaturated lactone ring in $\alpha$-acetyl-$\gamma$-methyl- and $\alpha$-acetyl-$\gamma\gamma$-diphenyltetronic acids remain unchanged, the products being $\gamma$-alkyltetronic acids [139]:



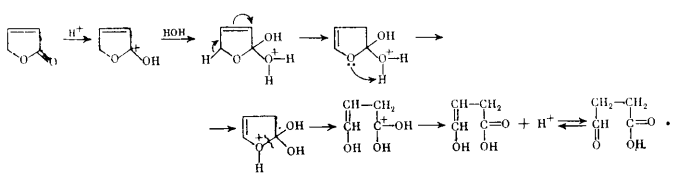
Alkaline and acid hydrolysis of substituted $\alpha$-ethoxycarbonyl-$\Delta^{\alpha\beta}$-butenolides involves only the ethoxycarbonyl



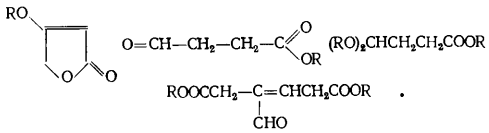
group with retention of the lactone ring and the formation of $\alpha$-carboxy-$\Delta^{\alpha\beta}$-butenolides [163,164]:



Killian et al.[170] showed that, when penicilloic acid reacts with a cold dilute solution of sodium hydroxide, dihydropenicilloic acid is formed. It is suggested that treatment with alkali involves a shift of the double bond with subsequent opening and reclosure of the lactone ring:

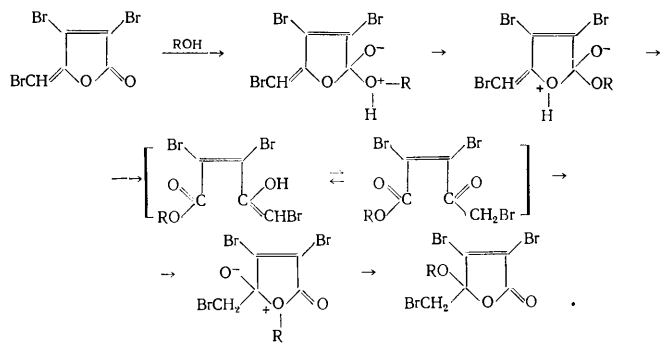


The alkaline hydrolysis of halogeno-$\Delta^{\alpha\beta}$-butenolides involves only the halogen with retention of the lactone ring. Thus the alkaline hydrolysis of the $\gamma$-lactone and the methyl ester of the $\gamma$-lactone of $\alpha\beta\delta$-tribromomuconic acid yields respectively the $\gamma$-lactone of $\beta\gamma$-dibromo-$\alpha$-hydroxymuconic acid[171] and the $\gamma$-lactone of the methyl ester of $\alpha\beta$-dibromo-$\delta$-hydroxymuconic acids[172]:



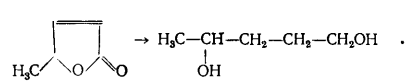
Hydrolysis of halogeno-$\Delta^{\alpha\beta}$-butenolides also proceeds on treatment with magnesium oxide in aqueous dioxan or in sodium bicarbonate solution with formation of acrylic acid derivatives[173]:

Acid hydrolysis of $\gamma$-lactones, which proceeds with opening of the lactone ring, has been described only for an unsaturated $\Delta^{\alpha\beta}$-butenolide[166]. The opening of the $\Delta^{\alpha\beta}$-butenolide ring in an acid medium is accompanied by the appearance of the formyl group and leads to the formation of 4-hydroxybut-3-enoic acid, which is converted into the tautomeric formylsuccinic acid[166]:

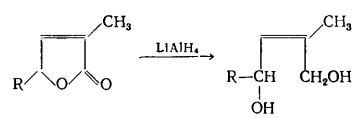


Alcoholysis of $\Delta^{\alpha\beta}$-butenolides takes place in the presence of acid catalysts (in the absence of catalysts, the reaction proceeds only slowly and requires prolonged heating) and leads to the formation of hydroxyacids. Thus heating of a $\Delta^{\alpha\beta}$-butenolide with alcohols leads to a mixture of products[12,166,174-176], which were isolated by fractional distillation and identified by the formation of various derivatives and by infrared and Raman spectroscopy:

$\Delta^{\alpha\beta}$-Butenolides react with alcohols in the presence of hydrogen chloride[43] or thionyl chloride[174] with formation of hydroxyacid esters.



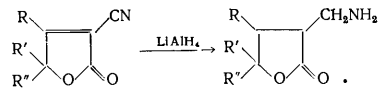
The reaction of $\alpha\beta$-dibromo-$\gamma$-bromomethylene-$\Delta^{\alpha\beta}$-butenolide with alcohols on boiling leads to the formation of $\gamma$-alkoxy-$\alpha\beta$-dibromo-$\gamma$-bromomethyl-$\Delta^{\alpha\beta}$-butenolides[177]. The initial products are apparently esters, whose conversion into a cyclic form involves the stabilisation of oxonium derivatives of $\Delta^{\alpha\beta}$-butenolides:



Systematic study of the catalytic hydrogenation of $\Delta^{\alpha\beta}$-butenolides showed that they readily react with hydrogen at the double bond, being converted into the corresponding butyrolactone derivatives[139,162,165,178,179]. Palladium black, Raney nickel, and palladium calcium on carbonate are used as catalysts.

The catalytic hydrogenation of $\alpha$-ethoxycarbonyl, $\alpha$-carboxy-, $\alpha$-carbamoyl, $\alpha$-acetyl, and $\alpha$-cyano-$\Delta^{\alpha\beta}$-butenolides over $Pd/CaCO_3$ proceeds selectively, involving the unsaturated bond of the lactone ring, and leads to the synthesis of the corresponding butyrolactone derivatives[139,162,165].

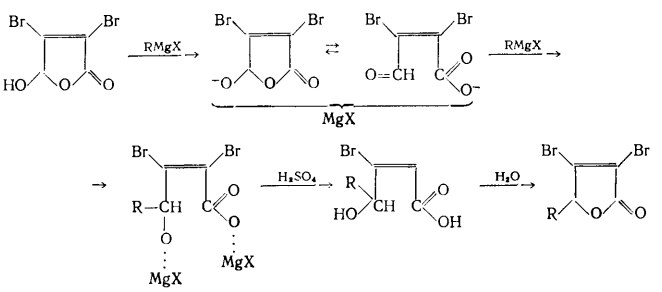
The effect of complex metal hydrides on $\Delta^{\alpha\beta}$-butenolides has been investigated[180-182]. $\Delta^{\alpha\beta}$-Butenolides are reduced by lithium tetrahydroaluminate to the corresponding diols. Thus pentane-1,4-diol is obtained when $\beta$-angelica lactone is treated with lithium tetrahydroaluminate[183]:



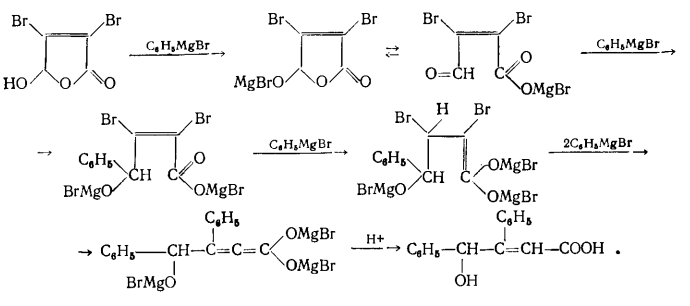
The reduction of $\alpha$-methyl-$\gamma$-phenyl-$\Delta^{\alpha\beta}$-butenolide and $\alpha$-methyl-$\gamma$-(2-naphthyl)-$\Delta^{\alpha\beta}$-butenolide leads to the corresponding diols[181]:

The opening of the lactone ring is observed also when $\Delta^{\alpha\beta}$-butenolides react with dimethyl- and diethyl-aluminium chlorides[184]. Ketoalcohols and the corresponding unsaturated and saturated diols are obtained for different

proportions of the lactone and lithium tetrahydroaluminate taken for the reaction[181-183].

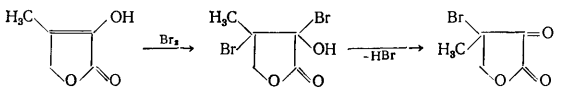


The reduction of substituted α-cyano-Δ$^{\alpha\beta}$-butenolides with lithium tetrahydroaluminate involves the cyano-group with simultaneous reduction of the unsaturated bond in the lactone and leads to α-aminomethylbutyrolactones[182]:

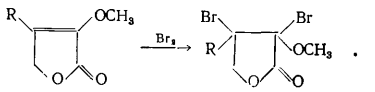


α-Hydroxymethyl-, α-(1-hydroxyethyl)-, and α-(1-hydroxybenzyl)-Δ$^{\alpha\beta}$-butenolides have been obtained under analogous conditions from α-ethoxycarbonyl, α-acetyl-, and α-benzoyl-Δ$^{\alpha\beta}$-butenolides[182].

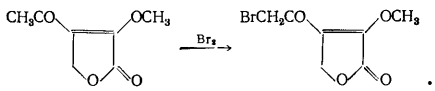
Since Δ$^{\alpha\beta}$-butenolides can be regarded as dihydrofuranones, one may expect that they can be readily converted into furan derivatives. Thus α-acetyl-Δ$^{\alpha\beta}$-butenolides undergo a very interesting rearrangement. When α-acetyl-Δ$^{\alpha\beta}$-butenolides [i.e. 3-acetyl-2(5*H*)-furanones] are heated with a mixture of acetic and hydrochloric acids, furan-3-carboxylic acids are obtained[136,138,139].



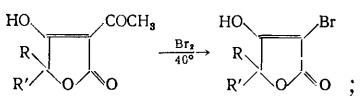
The reaction of Δ$^{\alpha\beta}$-butenolides aith organometallic compounds has been investigated. Δ$^{\alpha\beta}$-Butenolides behave in different ways in reactions with organomagnesium compounds. Thus, when bromomuconic acid is treated with alkylmagnesium halides in ethereal solution, γ-alkyl-αβ-dibromo-Δ$^{\alpha\beta}$-butenolides are obtained[75,154]:



Bromomuconic acid reacts with phenylmagnesium bromide with much greater difficulty[75,154], undergoing a series of transformations: the reaction leads to a magnesium halide alkoxide:

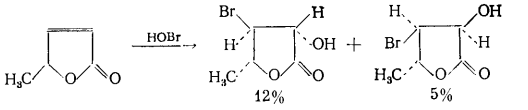


When the final organomagnesium compound is treated with dilute sulphuric acid, cinammic acid derivatives are obtained. The ability of the double bond in Δ$^{\alpha\beta}$-butenolides to undergo electrophilic reactions has also been investigated in relation to halogenation reactions. The latter proceed with retention of the lactone ring. It has been shown[185] that α-hydroxy-β-methyl-Δ$^{\alpha\beta}$-butenolide reacts with an equimolar amount of bromine, forming αβ-dibromo-α-hydroxy-β-methyl-γ-lactone, which splits off one molecule of hydrogen bromide and is converted into β-bromo-β-methyl-α-oxo-γ-lactone:



Bromination of β-alkyl-α-methoxy-Δ$^{\alpha\beta}$-butenolides leads to the formation of β-alkyl-αβ-dibromo-α-methoxybutyrolactones[186]:

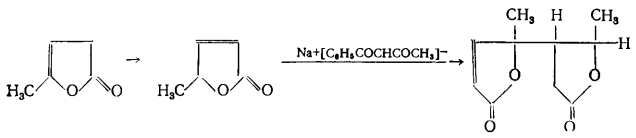
In the presence of the acetyl group as a substituent, the bromination involves the latter with formation of β-bromoacetyl-α-methoxy-Δ$^{\alpha\beta}$-butenolide:



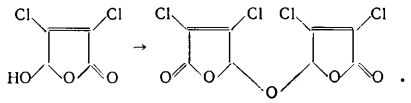
When α-acetyl-γγ-dimethyl- and α-acetyl-γγ-spirocyclohexane-tetronic acids are acted upon by bromine, the acetyl group is split off and the corresponding α-bromo-γγ-dimethyl- and α-bromo-γ-spirocyclohexane-tetronic acids are obtained[156]:

When α-acetyl-Δ$^{\alpha\beta}$-butenolides react with an equimolar amount of phosphorus pentachloride, α-(α-chlorovinyl)-Δ$^{\alpha\beta}$-butenolides are formed, while an excess of phosphorus pentachloride leads to the formation of α-(αβ-dichlorovinyl)-Δ$^{\alpha\beta}$-butenolides[187].

The reaction of β-angelica lactone with hypobromous acid results in the formation (in very low yields) of crystalline diastereoisomers of β-bromo-α-hydroxy-γ-valerolactone[188]:

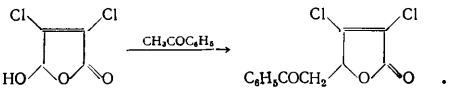


When hydrogen chloride or bromide combines with a Δ$^{\alpha\beta}$-butenolide, the product is β-chloro- or β-bromo-γ-butyrolactone[189]. In the latter case, 3,4-dibromobutyric acid is also formed[189].



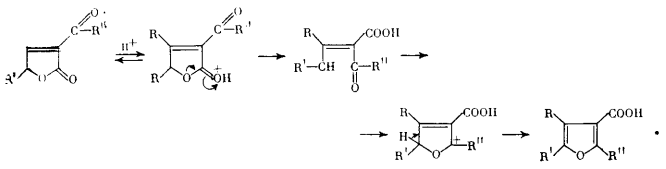
Δ$^{\alpha\beta}$-Butenolides react with diazomethane to form methylated products[34,151,167,190,191]. Thus the reaction of γ-benzylidene-α-methoxycarbonyl-Δ$^{\alpha\beta}$-butenolide with diazomethane yields the corresponding β-methylderivative. *C*-Methylation therefore proceeds more rapidly than the formation of the cyclopropane derivative. γ-Benzylidene-α-cyano-β-methyl-Δ$^{\alpha\beta}$-butenolide has been obtained similarly[151].

β-Angelica-lactone or a mixture of the α- and β-isomers dimerises at 20–200°C in the presence of tertiary amines, alkali metals, or alkali metal alkoxides and hydroxides[192-194]. It has been established that β-angelica lactones are more reactive than their α-isomers. The isomerisation of β-angleica lactones also proceeds in the presence of the sodium salt of benzylacetone or anhydrous potassium

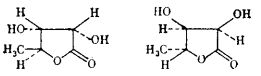


carbonate[195,196]; the authors suggest that the process proceeds as follows:

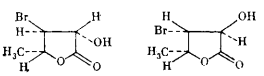
Dimerisation is also observed when $\alpha\beta$-dichloro-$\gamma$-hydroxyangelica lactone is dehydrated by benzenesulphonic acid[70]:



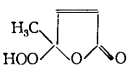
Dieckman and Platz[197] achieved for the first time the condensation of chloromuconic acid and acetophenone in the presence of an aqueous alcoholic solution of alkali, which gave a low yield of $\alpha\beta$-dichloro-$\gamma$-phenacyl-$\Delta^{\alpha\beta}$-butenolide:



Later it was shown[75] that, when the condensation is carried out in an aqueous alkaline solution, the yield of $\gamma$-phenacyl-$\Delta^{\alpha\beta}$-butenolide increases appreciably[75].



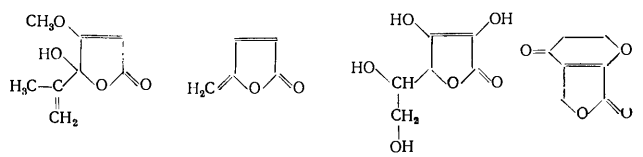
$\Delta^{\alpha\beta}$-Butenolides are readily oxidised by potassium permanganate to dihydroxylactones, which may be hydrolysed to the corresponding trihydroxyacids[103,198]. Thus $\alpha\gamma$-dimethyl-$\Delta^{\alpha\beta}$-butenolide is oxidised to $\alpha\beta$-dihydroxy-$\alpha\gamma$-diphenyl-$\gamma$-butyrolactone[199]. However, this reaction pathway is not general since, $\beta\gamma$-diphenyl-$\Delta^{\alpha\beta}$-butenolides, for example, does not form hydroxy-derivatives at all[103]:



In the presence of osmium tetroxide in an aqueous sodium chloride solution, $\beta$-angelica lactone gives rise to a mixture of hydroxylactones[200]:

Stereoisomeric $\beta$-bromo-$\alpha$-hydroxy-$\gamma$-valerolactones are formed when $\beta$-angelica lactone is treated with hypobromous acid[188]:

$\beta$-Angelica lactone also undergoes autoxidation with formation of a hydroperoxy-compound[201]:



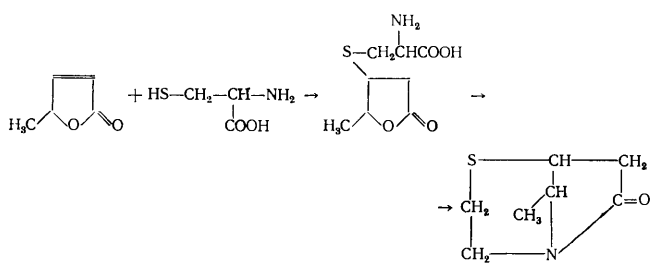
In the presence of silica or pumice at 450–650°C, it is pyrolysed with formation of methyl vinyl ketone[202].

In contrast to their saturated analogues ($\gamma$-butyrolactones)[203,204], $\Delta^{\alpha\beta}$-butenolides show little reativity in polymerisation reactions[205-207], but readily copolymerise with various vinyl monomers. Thus the $\Delta^{\alpha\beta}$-butenolide–styrene copolymer has been obtained in the presence of radical initiators[205]. The copolymerisation reactions of $\beta\gamma\gamma$-trialkyl-$\alpha$-ethoxycarbonyl-$\Delta^{\alpha\beta}$-butenolides with acrylonitrile, *N*-vinylcaprolactam, *N*-vinylpyrrolidinone, methyl acrylate, and vinyl acetate have been investigated[208,209]. The copolymers of $\alpha$-acetyl- and $\alpha$-cyano-$\beta\gamma\gamma$-trimethyl-$\Delta^{\alpha\beta}$-butenolides with styrene, acrylonitrile, methyl methacrylate, and *N*-vinylcaprolactam have been obtained[208,209]. The relative activity constants have been determined for certain pairs of monomers[208,209].

Dichloroprotoanemonine also readily copolymerises with vinyl monomers via a radical mechanism[210]. These reactions proceed with retention of the lactone ring and the formation of reactive copolymers.

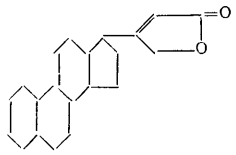
## IV. BIOLOGICAL ACTIVITY OF UNSATURATED $\gamma$-LACTONES

The unsaturated lactone ring is present in many natural products[3-6,57,211,212] and physiologically active substances[211-218]. For example, it is a constituent of penicilloic acid, protoanemonine, vitamin C, clavacin, etc:



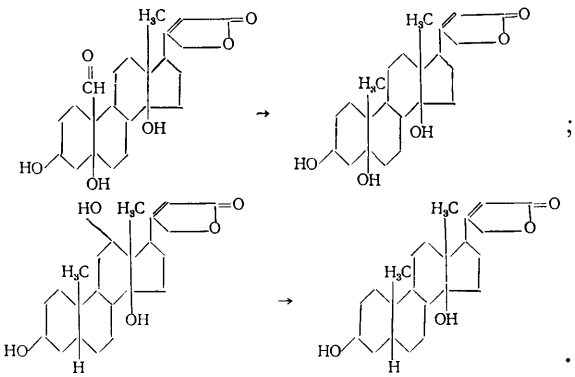
It has been established that the vitamin activity of L-ascorbic acid is due to the presence of the $\Delta^{\alpha\beta}$-butenolide system[211].

Both $\alpha$- and $\beta$-angelica lactones exhibit bactericidal properties[14]. Hydrolysis of the lactone as well as hydrogenation of the double bond entails the loss of activity by these compounds.



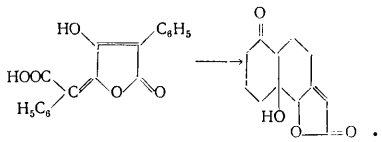
The antibiotic activity of unsaturated lactones has been explained by their ability to react readily with cystine and also with certain enzymes containing mercapto-groups which are important for the normal activity of microorganisms[219-221]. It has been suggested that the bactericidal activity of unsaturated lactones is associated with the ability of the lactone double bond to combine with the SH groups present in bacterial proteins, inhibiting thereby the processes involved in the growth of bacteria[220,221]. A special study has been made of the reaction of cysteine with certain unsaturated lactones, particularly with angelica lactone[220,221].

The reaction proceeds via the mechanism:



Protoanemonine is an effective antibacterial substance[221].

The class of natural products containing the unsaturated $\gamma$-lactone ring, namely natural steroids having the general structure [222-226]



is of interest. Compounds of this type (cardenolides) promote the normal activity of the cardiac muscle in man and animals. Cardenolides are steroids containing a $\Delta^{\alpha\beta}$-butenolide ring in the side chain [223,227-250]. They include for example, strophanthidin, periplogenin, digoxigenin, digitoxigenin, etc:

Cardiac glucosides, incorporating the $\Delta^{\alpha\beta}$-butenolide ring, are present in the cardenolide, the aglycone, or the sugar residue [227].

Vulphinic acid [$\beta$-hydroxy-$\alpha$-phenyl-$\gamma$-(phenylcarboxymethylene)-$\Delta^{\alpha\beta}$-butenolide] and $\psi$-santonin, which exhibits a high physiological activity, also contain the $\Delta^{\alpha\beta}$-butenolide structure [21,251-253]:

# Fundamental Hydrodynamic Characteristics of Polymers with Star and Comb Macromolecular Structures

I.I.Tverdokhlebova

The review considers the majority of studies published up to 1976 and dealing with the hydrodynamic properties of polymers having star and comb macromolecular structures. Methods for the estimation of the degree of branching are presented and it is shown how the dependence of the intrinsic viscosity on molecular weight changes on passing from randomly branched macromolecules to star and comb macromolecules. The influence of the polydispersity of the branches on the size of the macromolecules and their rigidity parameters is examined.
The bibliography includes 110 references.

CONTENTS

I. Introduction 658
II. Star macromolecules 658
III. Comb macromolecules 659
IV. Characteristics of the behaviour in solution of star and comb macromolecules 661
V. The influence of polydispersity on the branching parameters 665
VI. Conclusion 667

NOTATION

$\eta_0$ = solvent viscosity;
$[\eta]$ = intrinsic viscosity of the polymer solution;
$[\eta]\theta, [\eta]l, [\eta]_g$ = intrinsic viscosities in a $\theta$-solvent and of linear and branched macromolecules respectively;
$M$ = molecular weight (M.W.); $\overline{M}_n$, $\overline{M}_w$, and $\overline{M}_z$ are the number-average, weight-average, and $z$-average molecular weights;
$A$ = Kuhn segment; $Al$, $A_g$, $A_s$, and $A_b$ are the corresponding segments for linear and branched macromolecules and in the main and side chains of a branched macromolecule ("backbone" and "branches");
$S$ = number of monomeric units in the Kuhn segment; $S_s$ is the corresponding number for the main chain of a branched macromolecule;
$a$ = persistent length (correlation length);
$L$ = contour length of the macromolecule (the length of the macromolecule straightened without distortion of the valence angles); $L_s$ and $L_b$ are the corresponding values for the main and side chains;
$l$ = distance between two neighbouring branches;
$\lambda$ = projection of the monomeric unit in the direction of the main chain;
$[\overline{R}^2]^{1/2}$ = mean square radius of inertia; $[\overline{R}^2]_l^{1/2}$ and $[\overline{R}^2]_g^{1/2}$ are the corresponding radii for the linear and branched macromolecule;
$[\overline{h}^2]^{1/2}$ = mean square distance between the ends of the macromolecules;
$g$ = factor characterising the degree of branching of the macromolecule;
$\epsilon$ = swelling parameter of the polymeric coil;
$N$ = number of Kuhn segments in the macromolecule; $N_s$ and $N_b$ are the corresponding numbers for the main and side chains;
$f$ = number of branches in the branched macromolecule;
$m$ = average number of branching centres (points) per macromolecule;
$\Phi$ = Flory constant;
$h$ = ratio of the hydrodynamic radii of the branched and linear macromolecules with the same degrees of polymerisation;
$P$ = degree of polymerisation;
$F$ = translational friction constant;
$\alpha$ = swelling coefficient;
$\chi$ = parameter characterising the excess energy of the interaction of macromolecules in solution per solvent molecule;
$z$ = parameter characterising the number of collisions of the chain units within the limits of the coil per unit volume;
$\gamma$ = effective excluded volume of the segment;
$\mu$ = chemical potential of the system;
$C_m$ = coefficient of polymer–solvent interaction:

$$C_m = \left(\frac{3^3}{2^{5/2}\pi^{3/2}}\right)\left(\frac{\bar{v}^2}{V_1 \cdot N_A}\right)\left(\frac{M}{\overline{h}_\theta^2}\right)^{3/2},$$

Here the symbols have the following significance:
$V_1$ = molar volume of the solvent; $N_A$ = Avogadro number;
$v$ = specific partial volume of the polymer;
$\psi_1$ = entropy parameter of the system;
$T$ = temperature of the solution;
$A_2$ = second virial coefficient in the expansion of the osmotic pressure in terms of concentration;
$a, b, K_\eta, K_s$ = parameters of the equation relating $[\eta]$ to $M$;
$\varphi$ = variable.

## I. INTRODUCTION

The extensive development of the theory and practical applications of anionic polymerisation made it possible to obtain polymers with a strictly specified macromolecular structure. Thus virtually monodisperse polystyrenes have now been synthesised and investigated in detail[1-5]. The anionic polymerisation of organocyclosiloxanes in the presence of tri- and tetra-functional sodium initiators led to the synthesis of star polydimethylsiloxanes with a narrow molecular weight distribution (MWD).[6-9] The use of a trifunctional activator for the synthesis of branched polyamides[10] and the synthesis of a star dextran[11] and a star polyethylene[12] have been described.

The synthesis of polymers with a comb macromolecular structure has been developed on an even larger scale during the last decade. Numerous studies were published between 1965 and 1975, in which the properties of comb polymers and the difference of their behaviour in solution from that of polymers with a linear macromolecular structure were discussed.

The behaviour of polymers in solution is determined by many factors, the main ones being the chemical structure and the geometry of the macromolecules, the nature of the solvent, the molecular weight (M.W.) of the polymer, and the temperature of the solution. Thus the introduction of only a few long branches into the macromolecule of a linear polymer leads to an appreciable decrease in the size of the molecular coil in solution and hence to a decrease of $[\eta]$ relative to the linear polymer with the same chemical composition[13]. The most reliable data on the degree of branching of macromolecules can therefore be obtained by studying the properties of dilute solutions of polymers and the dependence of these properties on the size and number of branches in the macromolecule[4,13-20].

However, a quantitative interpretation of the experimental results is in most cases extremely difficult. A common disadvantage of the existing methods is the necessity to compare the results with the corresponding results for linear polymers having the same chemical composition and molecular weight[13].

If a branched macromolecule does not obey Gaussian statistics, it is necessary to compare the dimensions of molecules having not only the same molecular weight but also the same thermodynamic rigidity, i.e. with $A_g = A_l$. One must then take into account also the thermodynamic rigidity of the main ($A_s$) and side ($A_b$) chains of the branched macromolecule[21].

In certain cases, it is convenient to compare the experimental characteristics of the branched macromolecules with the analogous characteristics of the linear molecules whose molecular weight is equal to that of the main chain of the branched macromolecule, i.e. of the "backbone".[21]

The problem of determining the influence of the degree of branching on the parameters of the macromolecular coil is complicated by the existence of a wide variety of types of branching. It is usual to distinguish three types of branching: star, comb, and cascade branching[22-26]. In the comb and cascade branching, the molecule contains not one but several branching nodes, in contrast to star branching. Regular (equal lengths of the branches) and random (different lengths of the branches) structures are also characteristic of these three types of branching. One of the types of regular star branching has been examined by Tsvetkov[27]. In addition, it is possible to distinguish long-chain and short-chain branching. In certain cases, short-chain branching has only an insignificant influence on the properties of macromolecules in solution[24-26].

All the comb polymers known at present can be divided into two types: comb homopolymers and graft comb heteropolymers (copolymers). Comb homopolymers include polymers whose macromolecules have long straight-chain aliphatic side branches in each monomeric unit, for example, poly-$\alpha$-olefins, poly(alkyl acrylates), polyvinyl ethers, polyvinyl esters, etc.[28-39]. The structures of graft comb copolymers depend on the molecular parameters of the homopolymers incorporated in them[40-48].

Fairly numerous experimental studies of the properties in solution of polymers with the comb macromolecular structure have now been published[18,19,25,28-51]. However, the hydrodynamics of solutions of star polymers have been investigated only in relation to polystyrene[1-5,52] and polyorganosiloxanes[6-9].

Macromolecules with cascade random branching are the type most frequently synthesised. At high degrees of conversion, such macromolecules can be transformed into microgels and gels.

A comparative examination of the hydrodynamics of solutions of polymers with the comb and star macromolecular structures on the basis of the available theoretical[3,22,23,25,50-52,54,55] and experimental[2,18,19,21,25,53,56-60] data is of undoubted interest. For all types of branching, the dimensions of macromolecules are characterised solely by their average radius of inertia $[\bar{R}^2]_g^{1/2}$, since the concept of the distance between the ends of the polymer chain $[\bar{h}^2]^{1/2}$, defining the size of linear macromolecules, loses its significance in the present instance[22,24,57]. Usually $[\bar{R}^2]_g^{1/2} < [\bar{R}^2]_l^{1/2}$, so that the intrinsic viscosity $[\eta]_g < [\eta]_l$.

The degree of branching of macromolecules has come to be characterised by the factor $g$[22,25,50,55]:

$$g^{\epsilon} \simeq [\bar{R}_0^2]_g/[\bar{R}_0^2]_l \text{ and } g^{\circ} = [\eta_\theta]_g/[\eta_\theta]_l, \qquad (1)$$

where $\epsilon$ may assume values of 1/2, 1, and 3/2. The factor $g$ is determined by the number of segments in the backbone of the macromolecule and in the branches[61,62]:

$$g = \frac{N - \sum_b N_b}{N} = \frac{N_s}{N}.$$

However, the factor $g$ depends also on the number, rigidity, and polydispersity of the side branches, and on the length, rigidity, and polydispersity of the main chain[61].

Depending on the type of branching, short side branches, which usually do not have a significant influence on the macromolecular size, can affect the values of $[\bar{R}_\theta]_g^2$ in a $\theta$-solvent[50,51-54,56-60]. On the other hand, in effective solvents the presence of short branches can appreciably increase the size of the macromolecule[56-58].

## II. STAR MACROMOLECULES

Three-, tetra-, and poly-functional star macromolecules with single and multiple branching centres are known. Star macromolecules may be homogeneous, with the centre of the star and the branches consisting of atoms of the same kind (Fig. 1*a*), and heterogeneous (Fig. 1*b*). The branches of the star may be of the same or different length, short and long, mono- and poly-disperse.

In 1949, Zimm and Stockmayer[50] suggested that the degree of branching of homogeneous star polymers whose molecules have different branching functionalities (tri- and tetra-functional branching) be characterised by a quantity

$g$ proportional to the ratio of the mean square radii of inertia of the branched and linear macromolecules and to the ratio of the intrinsic viscosities:

$$g^{3/2} \simeq ([\bar{R}^2_\theta]_g/[\bar{R}^2_\theta]_l)^{3/2}; \quad g^{3/2} = [\eta_\theta]_g/[\eta_\theta]_l. \qquad (2)$$

The use of this relation is based on the hypothesis that the Flory equation for linear polymers [63]

$$[\eta_\theta]_l = \Phi_\theta [\bar{R}^2_\theta]^{3/2}_l/M$$

is valid also for branched specimens.

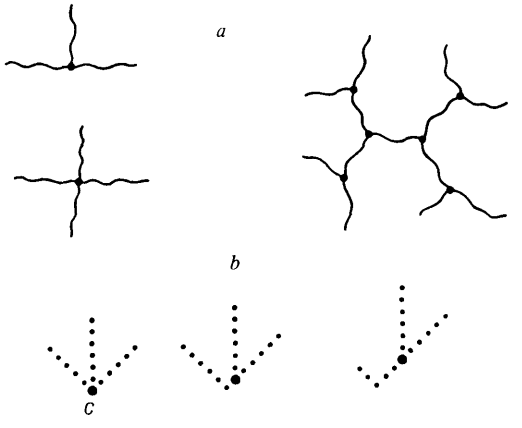

Figure 1. Graphical representation of the possible structures of a star macromolecule: *a*) homogeneous branching [27]; *b*) heterogeneous branching [98]; *c*) centre of the star.

However, Stockmayer and Fixmann [54] and Zimm and Kilb [27,55] showed that the effective hydrodynamic radius of the polymeric molecule is less sensitive to branching than the radius of inertia $[\bar{R}^2_\theta]^{1/2}$. In this case, the Flory equation for star macromolecules can be formulated as follows:

$$[\eta_\theta]_g = \Phi_\theta \frac{[\bar{R}^2_\theta]^{3/2}_g}{M} h^3. \qquad (3)$$

In 1953 Stockmayer and Fixmann [24,54] showed that the coefficient of friction of a branched macromolecule is related to the radius of inertia and the hydrodynamic radius:

$$F_{\theta g}/\eta_0 = \frac{\Phi^{1/3}_\theta}{2.5 \times 10^6} [\bar{R}^2_\theta]^{1/2} h, \qquad (4)$$

where $F_{\theta g}$ is the translational friction constant and

$$h^3 = [\eta_\theta]_g/[\eta_\theta]_l = f^{3/2}/[2 - f + \sqrt{2}\,(f-1)]. \qquad (5)$$

In this case $g^{1/2} < h^3 < g^{3/2}$.

Stockmayer and Fixmann [24,54] suggested that this relation remains valid for any branching model and can be used to find the functionality and the number of branching nodes, provided that the ratio $[\eta\theta]_g/[\eta\theta]_l$ is known.

However, Zimm and Kilb showed subsequently [55,61] that neither Eqn. (2) nor Eqns. (4) and (5) can be used with adequate reliability for the description of the behaviour of any star macromolecule in solution.

Zimm and Kilb [55,61] based their calculations on the model of a star molecule with $f$ branches and $N$ subchains, the centres of hydrodynamic interactions being located at the ends of the subchains. Zimm and Kilb examined two models of macromolecules with star branching: comprising one branching centre with four branches of equal length and one branching centre with two long and eight short branches. It was shown that the influence of branching on the hydrodynamic properties of macromolecules is somewhat smaller than on the size of the coil [22,26,55,62-64]. The increase of the hydrodynamic interaction factor only partly compensates the influence of the "contraction"† of the coils owing to branching on the hydrodynamic properties. The value of $\Phi$ for branched polymers exceeds by a factor of 6–27 that for linear polymers [2,65,66]. For this reason, Eqn. (4) is not rigorously justified, since the coefficient of friction and the viscosity, on which it is based, depend in different ways on the details of the structure of the macromolecule [23].

All this was taken into account in the studies of Zimm and Kilb [55,64], who showed that

$$[\eta_\theta]_g/[\eta_\theta]_l = g^{1/2},$$

for star macromolecules and

$$[\eta_\theta]_l/[\eta_\theta]_g \simeq \sqrt{3}.$$

Zimm and Kilb suggest that these equations can be applied with adequate approximation to any types of branched macromolecules [55,61]. However, it has been stated [61] that the Stockmayer–Fixmann and Zimm–Kilb calculations have been carried out for star macromolecules and that the *a priori* extension of the results to comb macromolecules is not always correct. Thus Kurata and Fukatsu [67] showed that, for statistically branched polymers, the ratio $P_g/P_l$, where $P \simeq \Phi^{1/2}/2.5 \times 10^6$, increases monotonically with increase of branching density, tending asymptotically to 1.34. For graft comb polymers, the ratio $P_g/P_l$ initially increases with increasing branching density, passes through a maximum, and then falls, tending to unity regardless of the functionality of the branching. These results show that, in translational motion of macromolecules, the effective hydrodynamic dimensions depend not only on the density but also on the type of branching. Stockmayer and Fixmann [54,61] suggest that the effective hydrodynamic dimensions are the same in translational and rotational motion.

## III. COMB MACROMOLECULES

### 1. Comb Homopolymers

Homopolymers with a comb macromolecular structure should be formally assigned to the class of linear polymers, since the length of the side branches is much smaller than the length of the main chain [32,68]. However, many specific properties make it necessary to treat comb polymers as a special type of branched polymer. Thus mainly orientation short-range order obtains in linear polymers and is to an overwhelming extent one-dimensional with a symmetry axis parallel to the molecular axis. In

† It is understood that the term "contraction" does not imply that the macromolecule actually contracts. The effective volume of the branched macromolecule is simply smaller than that of its linear analogue having the same molecular weight.

comb homopolymers, there is a possibility of two-dimensional order due to the intramolecular interaction of the long side branches and the intermolecular interaction between the main chains. Comb macromolecules tend to become ordered as a result of the association of the side chains, which is the reason for the ease of formation of ribbon structures[32,68]. Even in amorphous polymers with short side branches, order is observed, entailing the appearance of layer structures. The interaction of methylene chains in homopolymeric comb macromolecules has a decisive influence on the type of crystallisation, but the degree of ideality of the packing depends in many ways on the nature of the main chain[32,68]. An increase of the length of the side groups in comb homopolymers leads to an increase of the equilibrium rigidity of both the main chain of the macromolecule and of its side groups. This was demonstrated in a study of the behaviour of poly(methyl acrylate), poly(butyl acrylate), poly(octyl acrylate), and poly(octadecyl acrylate) in solution[37]. With increase of length of the side branches, the number of coiled conformations and the conformational stability of the macromolecules in solution increase[35].

It has been found for poly(cetyl methacrylate) that the length of the Kuhn segment is $A = 43$ Å.[34] This value exceeds by a factor of two the segmental dimensions of the majority of flexible chain molecules without complex side groups. It has been concluded[34] that the side chains of poly(cetyl methacrylate) molecules possess a high equilibrium rigidity and that there is an intramolecular orientation order in this polymer, exceeding the orientation order of Gaussian chains.

On the basis of the results of X-ray diffraction analysis of poly(hexadecyl acrylate) and poly(hexadecyl methacrylate), Shibaev and coworkers[33] showed that the side branches of poly(alkyl acrylates) and poly(alkyl methacrylates) in which the length of the side chains corresponds to ten and more carbon atoms form two-layer and one-layer types of hexagonal packing. The critical length of the side chain, equivalent to 9–10 carbon atoms, corresponds to the transition from the helical conformation of the macromolecules to layer structures with hexagonal packing of the side branches[32,68].

With increase of the length of the side chains in comb homopolymers [poly(phenyl methacrylate) and poly(chlorophenyl methacrylate)], the segmental anisotropy of the molecules becomes more pronounced, which can also be attributed to the influence of the interaction of the side groups, which becomes more intense with increase of their size[28].

## 2. Comb Heteropolymers (Copolymers)

In a study of the graft copolymers of poly(methyl methacrylate) and poly(butyl methacrylate) with polystyrene, which are distinguished by a high frequency of grafts and long main and side chains, it was shown[43] that, in all cases the hydrodynamic dimensions of the macromolecules of the graft comb copolymers in the same solvent are much smaller than those of the macromolecules of its constituent homopolymers having the same molecular weight (Fig. 2). However, the persistent chain length $a$, for example in the graft copolymer, is 50 Å, and the ratio $P = a/d = 1.8$, i.e. the macromolecules are rigid [$d$ is the diameter (thickness) of the macromolecule].

Studies by Birshtein and coworkers[69] have shown that comb homo- and hetero-polymers should be regarded as pseudorigid (see Table). The persistent length $a = [\overline{h^2_\theta}]/2L$ characterises the degree of coiling or the equilibrium flexibility of the polymer chain. In the absence of bulk-phase interactions (at the $\theta$-point), the statistical properties of polymer chains are determined mainly by the flexibility parameters $a$ (or the length of the Kuhn segment $A = 2a$) and the relative dimensions $L/a$. However, many important properties of polymer chains are influenced by the interactions not only along but also across the chain. These include the degree of foldability, the arrangement of polymers in the amorphous and crystalline states, the extent and nature of the bulk-phase interactions between the macromolecules in solution, etc. The above characteristics depend not only on the length of the rigid section but also on its thickness or, more precisely, on the relative quantity $a/d$ characterising the degree of extention of an individual persistent section of the chain ($a/d$ is the parameter of the local asymmetry of the macromolecule[69]).

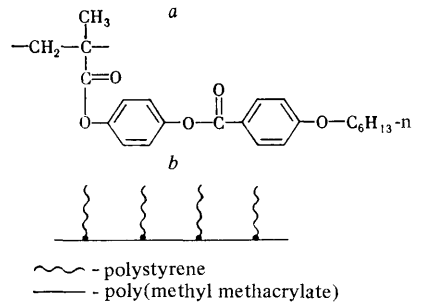

Figure 2. Comb macromolecules: *a*) comb homopolymers[29]; *b*) graft comb copolymers.

The main characteristic of pseudorigid polymers is large transverse dimensions of the chain. In the absence of a thick shell, the backbone of such pseudorigid comb macromolecules is appreciably flexible. However, when the chain is thick, the flexibility cannot be realised: the persistent length, i.e. the length of the section along which the chain bends, evidently cannot be smaller than its thickness. Therefore, for "thick" comb polymers of this kind, one must assume that $d \simeq a$, so that $a/d \simeq 1$. Thus pseudorigid macromolecules are characterised by a high value of $a$ for a small local asymmetry[69]. In essence, pseudorigid molecules constitute to some extent an analogue of flexible molecules magnified severalfold: the scale factor $a$ varies, but, for fixed relative dimensions $L/a$ and $a/d$, the physical picture remains unaltered[69].

However, polymers with long side groups can be justifiably regarded as similar to the usual flexible but short chains only when the frequency of the distribution of side groups is fairly high. Otherwise, the differences between the chemical natures of the side groups and the chain backbone will have an effect. The microstructure of the section through a macromolecule with long side groups is determined primarily by the properties of the side chains, in particular by their intrinsic local asymmetry[69].

Furthermore, in contrast to linear macromolecules, the long-range interactions in graft comb copolymers (as in uniformly branched macromolecules[21]) are intense, which leads to very considerable (but virtually isotropic) swelling of the macromolecules in effective solvents[48].

Types of polymers with different local asymmetry[69].

| Class of polymer | Polymer | $d$, Å | $a$, Å | $a/d$ |
|---|---|---|---|---|
| Flexible | Polystyrene | 10 | 9 | ~1.0 |
| | Polyethylene | 4 | 6 | 1.5 |
| Rigid | Trinitrocellulose | 8.3 | 100 | ~10 |
| | Polyphenylsilsesquioxane | 7 | 70 | 10 |
| | Poly(butyl isocyanate) | 8 | 500 | ~60 |
| Pseudorigid | Poly(n-alkyl acrylates) | 40 | 40 | 1 |
| | Poly(methyl methacrylate)–polystyrene grafted copolymers | 40 | 40 | 1 |

If the main chains of graft comb copolymers are capable of crystallisation and the side chains consist of irregular macromolecules (or conversely), then X-ray diffraction data suggest that order should persist in such a polymer even in the presence of a high content of the amorphous component[46].

It has been shown[53,56–60,70] that the theory of the worm-like chain is applicable to the description of the behaviour in solution of heteropolymeric comb macromolecules with short branches ($L_b \ll L_s$ and $l_b > L$). The rigidity of the main chain of such comb macromolecules proved to be much greater than that of the macromolecules of the corresponding homopolymers, since in graft macromolecules of this kind the conformation of the side chain is similar to that of a slightly bent rod. A unique combination of the considerable rigidity of the coil with its virtual impenetrability by the solvent has been observed, which is due to the large hydrodynamic (effective) diameter of such a worm-like chain.

## IV. CHARACTERISTICS OF THE BEHAVIOUR IN SOLUTION OF STAR AND COMB MACROMOLECULES

### 1. Non-Gaussian Chains

Linear macromolecules in thermodynamically ideal solutions can be regarded as impenetrable coils with a Gaussian distribution of the segments relative to the centre of gravity. Branching leads to compacting of the segments and their more uniform distribution in the bulk of the macromolecule. Conformational statistics of a branched molecule can therefore be non-Gaussian even in an ideal solvent[61,71,72].

The dimensions of star and comb macromolecules depend both on the lengths of the branch and the backbone ($L_V$ and $L_S$) and on the number of branches[73,74]. The comb macromolecule is characterised by the number of segments $N_b$ belonging to a single branch and the number of segments $N_S$ constituting the backbone of the macromolecule. For small values of $N_b$, the star molecule ceases to be a Gaussian coil and the same happens in the case of the comb macromolecule for small values of $N_b$ and $N_S$.

Calculation of the branching factor $g$ for star and comb macromolecules showed that, when $N_S$ and $N_b \geq 100$, then the macromolecule is a Gaussian coil in a $\theta$-solvent. Knowing the values of $g$ for such macromolecules, it is possible to calculate the number of branches using tabulated data[55,56,67,73,75]. When $N_b < 100$, the branches of the star macromolecule become non-Gaussian. The factor $g$ then diminishes with decrease of the number of segments in the branch. For example, when $f = 8$ and $N_b = 0.1$, 10, and 100, then $g = 0.075$, 0.325, and 0.340 respectively.

A similar dependence has been observed for comb macromolecules: for $f = 100$ and the ratio $N_b/N_S = 0.1$, we have $g = 0.038$ for $N_S = 1$ and $g = 0.114$ for $N_S = 100$. Thus the greater the rigidity of the backbone, the smaller the factor $g$.[73]

The radius of inertia of unperturbed star macromolecules is characterised by the relation[3]

$$[\bar{R}_\theta^2]_q = \frac{N_b A^2}{6}\left(\frac{3f-2}{f}\right), \tag{6}$$

the corresponding relation for comb macromolecules being

$$[\bar{R}_\theta^2]_g = \frac{A^2}{6}\left[N_s + 3N_b\frac{r}{1+r}\right], \tag{7}$$

where $r = N_b/l$.

On the other hand, if the branched macromolecule does not obey Gaussian statistics, the factor $g$ must be estimated by comparing the dimensions of macromolecules having not only the same molecular weights but also the same thermodynamic rigidities, i.e. $A_g = A_l$. One must bear in mind that the thermodynamic rigidities of the main and side chains of a branched macromolecule are the same[21].

On the other hand, when $A_g \neq A_l$, the experimental factor $g_e$ is related to the calculated factor $g_t$ in the following way:

$$g_e = g_t\frac{A_g\left[1-\frac{3A_g}{2L}+\frac{3A_g^2}{2L^2}-\frac{3A_g^3}{4L^3}\left(1-e^{-\frac{2L}{A_g}}\right)\right]}{A_l\left[1-\frac{3A_l}{2L}+\frac{3A_l^2}{2L^2}-\frac{3A_l^3}{4L^3}\left(1-e^{-\frac{2L}{A_g}}\right)\right]}. \tag{8}$$

For a Gaussian chain, Eqn. (8) is converted into the relation $g_e = g_t A_b/A_l$.

For a non-Gaussian star macromolecule, in which the chains are randomly oriented, the branching factor $g_t$ is related to the number of branches $f$ and the number of segments $N_b$ in one branch[21]:

$$g_t = \frac{1}{Bf}\left\{6f\left[\frac{1}{6}-\frac{1}{4N_b}+\frac{1}{4N_b^2}-\frac{(1-e^{-2N_b})}{8N_b^3}-3f(f-1)\right]\times\right.$$
$$\left.\times\left[1-\frac{1}{2N_b}+\frac{(1-e^{-2N_b})^2}{8N_b^2}\right]\right\}, \tag{9}$$

where

$$B = 1-\frac{3}{2N_b f}+\frac{3}{2N_b^2 f^2}-\frac{3}{4N_b^3 f^3}(1-e^{-2fN_b}).$$

When $N_b > 100$, the relation is converted into the familiar relation for Gaussian branched macromolecules:

$$g_t = \frac{3f-2}{f^2}. \tag{10}$$

For regularly branched non-Gaussian comb macromolecules, in which the main and side chains have the same thermodynamic rigidities, the branching factor $g_t$ is related to $\gamma = L_b/L_S$ and $f$ in a very complex manner[21].

For Gaussian chains ($N_S > 100$, $\gamma N_S > 100$), $g_t$ becomes

$$g_t = \left\{1 + \frac{\gamma f}{f+1}[(2f+1+3\gamma(f+1)] + \gamma^2 f(f-1)(1+3\gamma) + f\gamma^3\right\}(1+\gamma f)^{-3}. \quad (11)$$

If the main chain is Gaussian and the side chains are rigid rods, the[21] $g_t$ becomes[12]

$$g_t = \frac{1}{(1+\gamma f)^3}\left\{1 + \frac{\gamma f}{f+1}[2f+1+\gamma(f+1)\ (2\gamma N_s+1)] + \right. \quad (12)$$
$$\left. + \gamma^2 f(f-1)(1+\gamma^2 N_s+\gamma) + \frac{f\gamma^3}{2}(\gamma N_s - 1)\right\}.$$

These equations are applicable to the estimation of the rigidities of comb homopolymers and graft comb copolymers. The factor $g$ can be used to estimate quantitatively the degree of branching of the polymer. On comparing these results with those of Thurmond and Zimm[76], Kilb[64] and subsequently Kotlyar[77,78] and other workers[13,22] showed that the ratio of the intrinsic viscosities is a sufficiently reliable measure of the degree of branching:

$$g^{1/2} = [\eta_\theta]_g/[\eta_\theta]_l \cong [\eta]_g/[\eta]_l \cong g^n, \quad (13)$$

where $g^i$ is the degree of branching of an impenetrable macromolecule. This ratio varies with the solvent used. However, the estimate of $[\eta\theta]$g must be treated critically and the use of very effective solvents must be avoided[25,79,80], since

$$[\eta]_g/[\eta]_l > [\eta_\theta]_g/[\eta_\theta]_l,$$

the discrepancy being greater the more effective solvent and the higher the molecular weight of the polymer.

The knowledge of the factor $g_e$ makes it possible to determine with an adequate approximation the parameter $f$—the functionality of each point, provided that the number of branching points $m$ is known. For star polymers with one, two, and three branching points, we have[22]

$$g_\theta^2 = \begin{cases}(3f-2)/f^2 & \text{when } m=1\\ (18f^2-28f+11)/(2f-1)^2 & \text{when } m=2\\ (51f^2-90f+40)/(3f-2)^3 & \text{when } m=3\end{cases}. \quad (14)$$

Knowing $f$, it is possible to determine in turn the number of branching points $m$[55,67]:

$$g^i = \begin{cases}\left[\left(1+\frac{m}{7}\right)^{1/2}+\frac{4m}{9\pi}\right]^{-1/4} & \text{when } f=3\\ \left[\left(1+\frac{m}{6}\right)^{1/2}+\frac{4m}{9\pi}\right]^{-1/4} & \text{when } f=4.\end{cases} \quad (15)$$

All the above values have been tabulated[55,67,75]. When the lengths of the branches in the macromolecule are not the same and there is a possibility of both long and short chains, Eqn. (15) becomes[81,82]

$$g_\theta^i = \frac{1}{m+1}[1+m(1-2f+2f^2-2f^3)+m^2(-f+4f^2-4f^3)]. \quad (16)$$

## 2. The Degree of Branching and Swelling of Macromolecules

Another distinctive feature of branched macromolecules, particularly star and comb macromolecules, is as follows: under non-ideal conditions, the swelling of the macromolecular coil influences its size in opposition to the change in size caused by branching. The influence of the degree of branching is opposed to the influence of bulk-phase effects in effective solvents, where the segments are "diluted" in the bulk of the macromolecule[22,26,61,63].

Ptitsyn and Kron[22] showed that the bulk-phase effects influence the dimensions of the branched chains (the volume of the coil) much more than the dimensions of the corresponding linear chains, i.e. the nature of the excluded volume is determined by the probability of intramolecular contacts between the units in the coil. Furthermore, they showed[4,22] that the coefficient of volume expansion of a star molecule is a complex function:

$$\alpha_g^2 = \bar{R}_g^2/\bar{R}_{\theta g}^2 = 1 + \frac{134}{105}\chi z;\ z = \left(\frac{3}{2\pi}\right)^{3/2}\frac{N^{1/2}v}{6}. \quad (17)$$

For $\alpha_g$ close to unity, we have

$$\alpha_g^2 = 1 + \frac{134}{105}\frac{z}{g_\theta^3} + \ldots,$$

so that $\chi = 1/g_\theta^3$. For linear chains, $\chi = 1$. Ptitsyn and Kron[22] showed that Eqn. (17) is applicable only in the vicinity of the $\theta$-point, where the bulk-phase effects are small. For large values of $\alpha_g$, the equation for the swelling of branched macromolecules is analogous to Flory's equation for the swelling of a linear coil:

$$\alpha^5 - \alpha^3 = \frac{134}{105}\chi z. \quad (18)$$

Then we have $\bar{R}_g^2 \sim g_\theta^{4/5}$ when $\alpha \gg 1$, while $\bar{R}_{\theta g}^2 \sim g_\theta^2$, i.e. the bulk-phase effects partly compensate the decrease in the size of the macromolecule due to branching (the star shape).

When $\alpha \gg 1$, we have $\alpha_g = \alpha_l \chi^{1/3}$, whence

$$g \equiv [\bar{R}_g^2/\bar{R}_l^2]^{1/2} = g_\theta \frac{\alpha_g}{\alpha_l} \simeq g_\theta \chi^{1/2}. \quad (19)$$

Since $\chi \simeq \mu/g_\theta^3$, it follows that $g = \mu^{1/3}$. The parameter $\mu$ depends on the type of branching model and increases with increase of $m$. For high degrees of branching, $g \simeq \mu^{1/3}$, i.e. the ratio of the sizes of the branched and linear macromolecules with the same molecular weights tends to a constant value in an effective solvent as $f$ increases, while in a $\theta$-solvent it tends to zero[22].

The factor $g_\theta$ can decrease rapidly with increase of the molecular weight[22], which leads to a weaker dependence of $\bar{R}_{\theta g}^2$ on $M$ for branched chains than for linear chains. Consequently the sizes of macromolecules in effective solvents, characterised by $[\bar{R}_g^2]^{1/2}$, are relatively insensitive to the degree of branching and cannot be used together with the ratio $\bar{R}_{\theta g}^2/M$ for the quantitative estimation of the degree of branching.

## 3. The $\theta$-Temperatures

The third distinctive feature of star and comb polymers was noted in studies by Benoit and coworkers[3,4]. Whereas the equation for the swelling of a linear polymer in effective solvents is

$$\alpha^5 - \alpha^3 = 2C_{ml}\psi_1(1-\theta/T)M^{1/2}, \quad (20)$$

where the coefficient $C_m$ for a given polymer and solvent is independent of the molecular weight of the polymer, for branched polymers Eqn. (20) assumes the following form:

$$\alpha^5 - \alpha^3 = 2C_{ml}\psi_1(1-\theta/T)M^{1/2}g^{3/2} + \left(\frac{2}{3}\right)\frac{C_{ml}}{\alpha^3}g^{-3}. \quad (21)$$

In this case $g = [\bar{R}_\theta^2]_g/[\bar{R}_\theta^2]_l$. The swelling coefficient $\alpha$ increases slowly with increasing molecular weight and depends on the properties of the solvent, the dependence

being more pronounced the higher the value of $\psi_1(1 - \theta/T)$, i.e. the more effective the solvent. When $T = \theta$, $\alpha = 1$.

Eqn. (21) shows that the swelling coefficient $\alpha$ for branched polymers (particularly for comb and star polymers) is not unity when $T = \theta$.[3,4] If the temperature at which $\alpha = 1$ is designated by $\theta_\alpha$. Eqn. (21) can be formulated thus:

$$\frac{\theta}{\theta_\alpha} - 1 = \frac{C_{ml} g^{-1/2}}{3 C_{ml} \psi_1 M^{1/2}}. \qquad (22)$$

According to this expression, the decrease in the molecular weight of the polymer or the increase in the reduced ratio results in a deviation of $\theta_\alpha$ from Flory's $\theta$-point. $\theta_\alpha$ is always greater than $\theta$ and becomes equal to $\theta$ only when $M \to \infty$.

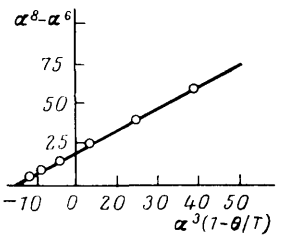

Figure 3. Determination of the $\theta$-temperature by extrapolating a plot of $\alpha^8 - \alpha^6$ against $1 - \theta/T$ for star and comb polymers[3].

If the expansion (swelling) factor of the macromolecule $\alpha$ is designated by $\alpha_\theta$ at Flory's temperature, Eqn. (21) can be written as follows:

$$\alpha_\theta^8 - \alpha_\theta^6 = \frac{2}{3} C_{ml} \cdot g^{-3}, \qquad (23)$$

i.e. $\alpha_\theta$ is independent of $M$, depending only on $g$.

On the basis of the foregoing, one should consider two temperatures: one at which $A_2 = 0$, i.e. $\theta_{A_2}$ and the other, Flory's $\theta$-temperature, at which $A_2$ is not zero, i.e. is equal to $A_{2\theta}$. Incidentally $\theta_{A_2}$ does not differ very significantly from the $\theta$-temperature‡. Thus one may speak of the existence of two characteristic temperatures for star and comb polymers, namely the $\theta_\alpha$ temperature at which $\alpha = 1$ and $\theta_{A_2}$, the temperature at which $A_2 = 0$. Both temperatures differ from Flory's classical§ $\theta$-temperature, and the relation[3,4]

$$\theta_\alpha < \theta_{A_2} < \theta$$

holds most frequently.

However, Vrii[83] and Casassa[84] claim that the relation $\theta_\alpha < \theta < \theta_{A_2}$ is valid.

In order to find $\theta_\alpha$ (and hence $\bar{R}^2_{\theta g}$), the sizes of the branched macromolecules are determined in any solvent at different temperatures and plots of the type shown in Figs. 3 and 4 are constructed[3,4].

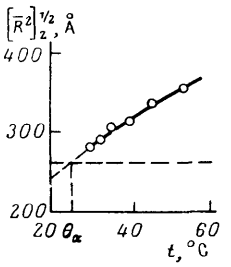

Figure 4. Determination of the $\theta$-temperatures for star and comb polymers from the variation of $[\bar{R}^2]_z^{1/2}$ with increasing temperature of the solution[3].

The swelling factors $\alpha_R$ for star and comb polymers are equal[4,83,85]:

$$\alpha_{Rg}^2 = \bar{R}^2_{\theta g} / \bar{R}^2_{\theta r}.$$

The viscometric coefficient of expansion for polymers with randomly branched macromolecules and star macromolecules $\alpha_\eta$ is given correspondingly by the expressions

$$\alpha_{\eta g^*} = [\eta]_{g^*} / [\eta_\theta]_{g^*}; \quad \alpha_{\eta g} = [\eta]_g / [\eta_\theta]_g.$$

The relation between $\alpha_{\eta g^*}$ and $\alpha_{\eta g}$ can be formulated as follows:

$$\alpha^3_{\eta g^*} - 1 = \frac{3}{2}(\alpha^3_{\eta g} - 1). \qquad (24)$$

The relations between $\alpha^3_{\eta g} - 1$ and $(1 - \theta/T)M^{1/2}$ and between $\alpha_{\eta g^*}$ and $\alpha_{\eta g}$ are linear for branched polymers with different functionalities (Figs. 5 and 6). Fig. 6 shows that $\alpha_{\eta g}$ for star macromolecules is always greater than for randomly branched macromolecules[5].

‡ In order to avoid terminological and semantic confusion, we may note that, according to Flory, the only sign of the $\theta$-state, i.e. of the pseudoideality of the solution, is not the equality of the swelling parameter $\alpha$ to unity, but the equality of the second virial coefficient to zero. This should be remembered in considering $\theta$-points with different subscripts.

§ When $\alpha = 1$ and $A_2 = 0$ simultaneously.

4. Dependence of $[\eta]$ on $M$

The degree of branching of macromolecules is reflected in the nature of the dependence of $[\eta]$ on $M$.[24,55,63,75,76,86-89] The plot of $\lg[\eta]$ against $\lg M$ for cascade polymers may become curved in the presence of macromolecules with different degrees of branching and the greater the increase of the degree of branching with increasing molecular weight of the polymer the smaller the value of $a$ and the larger the value of $K$ in the Mark-Kuhn-Houwink equation [Eqn. (25)]:

$$[\eta]=K_\eta M^{a-\varphi};\ S_0=K_s M^{1-b}\equiv K_s M^{1-\left(\frac{a-\varphi+1}{3}\right)}=K_s M^{1-\left(b-\frac{\varphi}{3}\right)}. \quad (25)$$

The relation $b = (a + 1)/3$ holds for branched polymers.

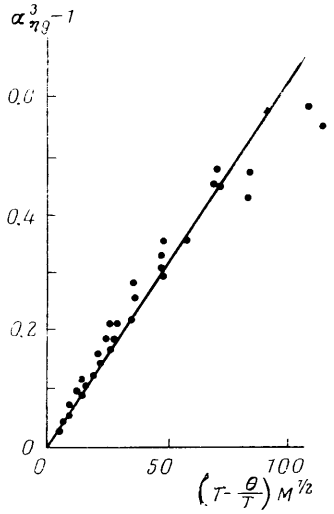

Figure 5. Increase of the swelling coefficient of star polystyrene with $(1 - \theta/T)M^{1/2}$.

Zimm and Stockmayer[50] showed that $a$ can vary as follows with the degree of branching:

$$a_g=a_l+(2-a_l)\frac{d\ln g}{d\ln P}. \quad (26)$$

Since $d \ln g/d \ln P < 0$, we have $a_g < a_l$.

According to Zimm and Kilb[55,75], for a high degree of branching in effective solvents, Eqn. (25) becomes

$$[\eta]=K_\eta M^{a-0.25}, \quad (27a)$$

while in a $\theta$-solvent we have

$$[\eta]_{\theta g}=K_\theta \cdot M^{0.25}. \quad (27b)$$

Thus the parameter $a$ in Eqn. (25) is always smaller for branched polymers than for linear polymers (star polymers are an exception). In a $\theta$-solvent, the parameter becomes equal to 0.25, in contrast to 0.5 for linear polymers.

The dependence of the parameter $g^i = [\eta_\theta]_g/[\eta_\theta]_l$ on $M$ is determined by the dependence of the number of branching units $m$ on $M$. For single-centre star macromolecules, the factor $m$ is independent of $M$.

As early as 1948, Flory showed that the parameter $a$ in Eqn. (25) for star molecules with $f = 1$, **2**, or 3 is the same as the value of $a$ for linear macromolecules. Flory observed the variation of $a$ only with increase of $f$ (for $f$ = 8), which can probably be explained by the breakdown of the star properties.

It has been shown[52] for star polystyrene that the parameters $a$ and the swelling factors $\alpha^3_\eta$ for linear and star polystyrenes are identical. The parameter $a$ remains constant even in solvents which are not $\theta$-solvents.

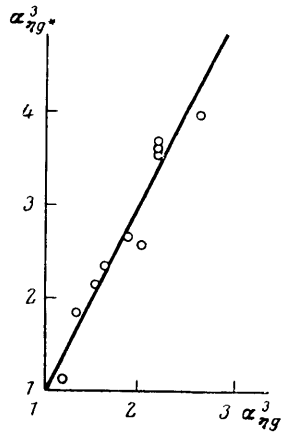

Figure 6. Relative change in the viscometric swelling coefficient of star ($\alpha^3_{\eta g}$) and randomly branched ($\alpha^3_{\eta g*}$) polystyrene[5].

For polymers with the comb structure of macromolecules, the dependence of $[\eta]$ on $M$ is different[90-93]. As noted above, a characteristic feature of a comb macromolecule is the great rigidity of its main chain accompanied by an appreciable density in the distribution of segments in the part of the volume adjoining the main chain (owing to the branches)[53,56-60]. As noted by Tsvetkov and coworkers[70,90,94] the best model for the description of the hydrodynamic properties of such a molecule is a wormlike chain, the main parameters of which are the contour length $L$, the hydrodynamic diameter $d$, and the persistent length $a$ (formally equal to half the statistical Kuhn segment $A$).

The use of the worm-like chain model, the viscosity data, and data for translational and rotational friction can yield reliable data on the conformational characteristics of the macromolecules of comb heteropolymers[93]. As for rigid-chain polymers, the sizes of the macromolecules of comb polymers vary little with the solvent, which makes it possible to neglect the influence of bulk-phase effects on their conformational properties[93].

A characteristic feature of many comb copolymers is their relatively low intrinsic viscosity compared with that of the linear homopolymer having the same structure as the main chain of the comb copolymer and the same molecular weight. This led some investigators to the idea of a globular structure of the molecules of comb copolymers. However, in reality the hydrodynamic properties of comb copolymers are fully consistent with those of a linear worm-like chain[93].

The value $a = 0.5$ in Eqn. (25) is not limiting for comb copolymers. We have[93]

$$M/[\eta] = \frac{1}{0.43\,N_A}(M/LA)^{3/2}M^{1/2} = \left(\frac{2.3\lg A}{d} - 1.6\right)\cdot\frac{M^2}{L^2}\cdot\frac{1}{A}. \quad (28)$$

For a fairly large diameter of the macromolecule ($d > 0.2$ Å), the dependence of $M/[\eta]$ on $\sqrt{M}$ can be represented by a straight line, which makes a negative intercept on the ordinate axis. With increase of $M$, the intrinsic viscosity $[\eta]$ evidently increases more slowly than does $M^{0.5}$, i.e. we have $a < 0.5$ depending on $[\eta] = KM^a$. This case has been examined (for $S = 33$).[93,94]

If the structure of the chain of a comb copolymer corresponds to the condition $A/d \simeq 1$, it follows from Eqn. (28) and the expression[93]

$$S_s = A/\lambda = \frac{M_0}{\lambda^2(1-x_1)}\cdot(0.43\,N_A\,d\,y/d\,z)^{-3/2} \quad (29)$$

(where $x_0$ is the mole fraction of component $B$ forming the branches of the comb macromolecule) that

$$S_s = [M_0[\eta]/0.43\,N_A P^{1/2}(1-x_0)]^{-3/2}\lambda^{-2}. \quad (30)$$

Eqn. (30) shows that the rigidity of the main chain of the comb macromolecule may be determined directly from the intrinsic viscosity[93].

It must be emphasised again that the cause of the great rigidity and order of the macromolecules of comb copolymers investigated[53,56-60,90,94] should be sought in the interaction of the branches. These interactions lead to the formation of intramolecular structures with a high degree of orientation order. Such structures may be a consequence of the strong dispersion interaction of the polystyrene chains constituting the branches of graft comb macromolecules. Relations of this kind have been traced for the homologous series of graft comb copolymers of poly(methyl methacrylate) with styrene, the contour length of the main chain of which $L$ varies from 9000 to 3700 Å.[90,93]

A rare instance (see Table) of comb copolymers [grafted copolymers of poly(methyl methacrylate) with styrene] whose contour length $L$ is comparable to their persistent length has been examined[90]. Low values of the exponential coefficients $a$ and $b$ ($a < 0.5$) have been noted for such copolymers: $[\eta] = 0.11\times10^{-4}M^{0.43}$ and $S_0 = 1.2\times10^{-15}M^{0.54}$. In this case, the contour length of the macromolecule $L$ is modelled by a persistent chain with a contour length $L$ equal to the length of the main chain of poly(methyl methacrylate):

$$L = \frac{M(1-x_1)\lambda}{M_0}, \quad (31)$$

where $M_0$ is the molecular weight of the monomer unit of the main chain.

In conclusion of the discussion of comb macromolecules, we emphasise yet again that the different "anomalies" in their properties compared with their linear analogues or homologues can be due to three different causes, linked directly with the configuration (structure) of the macromolecules.

1. In comb homopolymers, more than 80% of the molecular weight is as a rule contained in the branches. Depending on the structure of these branches, gel formation may begin already at low concentrations, regardless of the degree of stereoregularity, owing to the crystallisation of sections of the branches or, according to Tsvetkov[29], a long-range order, similar to that in liquid crystals, may arise within the chains. The first version is characteristic of poly(alkyl acrylates) or poly(alkyl methacrylates) and the second is characteristic of polymers whose side groups are capable of forming thermotropic or lyotropic liquid crystals in the "free state".

These anomalies in the two versions persist for a fairly long time also on diluting the "long-chain" units by short-chain units (for example, methyl methacrylate or acrylate units), i.e. on passing from a comb homopolymer to a statistical comb copolymer with infrequent long side chains. However, after the attainment of a "critical" dilution, the effects of intrachain and interchain ordering, leading to "anomalies", vanish.

2. In comb heteropolymers, i.e. in graft copolymers, the anomalies arise from segregation effects due to the different natures of the backbone chain and the branches¶. The hydrodynamic (but not thermodynamic!) behaviour of such macromolecules is simulated by a "thick" impenetrable worm-like chain.

3. In "classical" branched comb homopolymers, there are no longer any selective effects; however, the increased density in the distribution of segments—a direct consequence of branching—leads to a decrease ("slight contraction") of the hydrodynamic volume of the macromolecules and hence to a change in the "normal" parameters in Eqns. (25) for the intrinsic viscosity and the translational friction constant.

## V. THE INFLUENCE OF POLYDISPERSITY ON THE BRANCHING PARAMETERS

The branching parameters of macromolecules are influenced significantly not only by the type of branching and the length and frequency of the branches, but also by parameters such as the molecular weights, the polydispersities of the main and side chains, and the distribution of branches with respect to molecular weight. This is manifested particularly clearly in the study of long-chain branching[1,95-101].

The number-average molecular weight of a branched macromolecule with $f$ branches varies as follows with the number of branches relative to the molecular weight of a linear polymer having the same chemical composition[1,95,96]:

$$\overline{M}_{nf}/\overline{M}_{nl} = f. \quad (32)$$

The variation of $f$ is associated solely with the number of branches regardless of their length. A higher-order molecular weight ($\overline{M}_w$, $\overline{M}_z$, etc.) is influenced also by the size of the chains. Comparison of different average molecular weights ($\overline{M}_n$, $\overline{M}_w$, $\overline{M}_z$) of branched and linear specimens therefore yields information not only about the number but also about the size of the branches. For example, the large change in $\overline{M}_n$ associated with a slight change in $\overline{M}_w$ indicates a large number of short branches.

¶See "Entsiklopediya Polimerov" (The Encyclopaedia of Polymers), Vol. II, "Makromolekula" (The Macromolecule).

Conversely, a small number of long branches (comparable in length to the main chain) leads to an appreciable decrease of $\bar{M}_w$ with a relatively slight change in $\bar{M}_n$.[95]

The knowledge of the average molecular weights of branched and linear polymers makes it possible to calculate other branching parameters. This was done by Budtov and coworkers[95,102] for the comb esters of poly(vinyl alcohol) with long-chain branching and by Burchard[103,104] for star polymers. Such branching parameters include the distribution of the branching centres among molecules with different molecular weights, the polydispersities of the branches and backbones with respect to length, and the average molecular weights of the centre of the star and its branches in the case where the centre has a chemical structure different from that of the branches (Fig. 1*b*).[103] Burchard showed that in the latter case the masses of the centre and of the star are given by the following expressions respectively:

$$m_c = \frac{(1-\beta)\bar{M}_{wc}}{\alpha f\bar{M}_{wg} + (1-\beta)\bar{M}_{wc}}\ ;\ m_g = \frac{\alpha f\bar{M}_{wg}}{\alpha f\bar{M}_{wg} + (1-\beta)\bar{M}_{wc}}\ . \qquad (33)$$

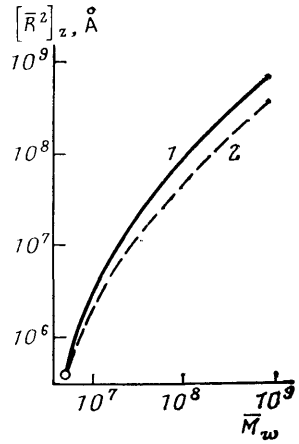

Figure 7. Variation of the mean square radius of inertia with increase of the molecular weight of a polyfunctional star macromolecule[97]: 1) polymer with the "most probable" distribution of branches; 2) monodisperse branches.

For a homodisperse centre, $\bar{M}_{nc} = \bar{M}_{wc}$; in the case of branches with the "most probable" distribution $\bar{M}_{ng} = \bar{M}_{wg}(1-\beta)$ ($\bar{M}_{ng}$, $\bar{M}_{nc}$, and $\bar{M}_{ns}$ are the number average molecular weights of the centre and branches of a star macromolecule respectively, $\bar{M}_{wg}$ is the weight-average molecular weight of the star macromolecule, and $\beta$ is the probability of the interaction of the branches with one another). Evidently this equation is valid also for comb polymers.

The relations examined above were derived for a star macromolecule with polydisperse branches[103]. The mean square radii of inertia of star macromolecules with polydisperse and monodisperse branches are significantly different. This difference increases particularly markedly with increased molecular weight of the star polymer (Fig. 7). For the same functionality of branching, the factor $g$ of star polymers depends on the polydispersity of the branches.

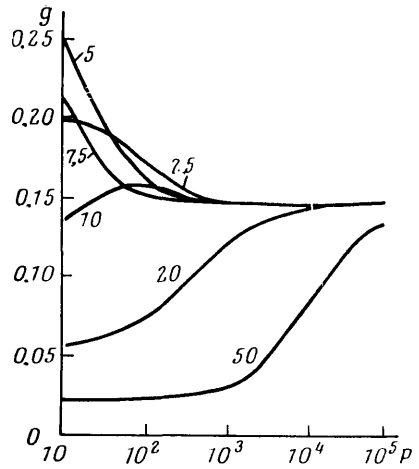

Figure 8. Variation of the factor $g$ with increase of the degree of polymerisation for star macromolecules having a large centre[97]. The numerals against the curves represent the ratio $l_c/l_s$.

Fig. 8 shows that, for the "most probable" distribution with respect to the lengths of the branches ($\alpha = 1$), the value of $g$ for a homodisperse star polymer is smaller than for a polydisperse star polymer. For the same degree of polymerisation of a star polymer $P$, the rigidity factor $g$ of a star with a large centre depends significantly on the effective length of the bond $l_c$ between two centres and the length of the bond $l_s$ between two branches, as can be seen in Fig. 8. The average hydrodynamic radii of inertia of such polymers with polydisperse branches $[\bar{R}^2]_z^{1/2}$ vary in accordance with the following law[103]:

$$[\bar{R}^2]_{zi} = \frac{l_s^2}{4}\frac{\bar{M}_{wg}}{\bar{M}_s} = \frac{l_s^2}{4(1-\beta)}[2+(f-1)\alpha], \qquad (34)$$

where $\beta$ is the probability of the interaction of the branches with one another.

For a polymer with monodisperse branches, we have

$$[\bar{R}^2]_{zi}^{1/2} = \frac{l_s^2}{6}\frac{\bar{M}_{wg}}{\bar{M}_s} = \frac{l_s^2}{6}N[1-(f-1)\alpha]. \qquad (35)$$

Thus the parameter $g$ cannot be used by itself without a far-reaching study of other branching parameters, the molecular weight, and the molecular weight distribution of the polymer, its branches, and the centre of the macromolecule, with both star and comb structures[91,92].

Budtov and Godunova[102] proposed a method for the estimation of the polydispersities of the branches and backbones from the lengths for comb polymers and a method for estimating the distribution of branching nodes.

The following relations are valid for the number-average and weight-average molecular weights of comb polymers $\bar{M}_{ng}$ and $\bar{M}_{wg}$:

$$\bar{M}_{ng} = \bar{M}_{ns} + f_n\bar{M}_{nb} \qquad (36)$$

$$\bar{M}_{ng}\ \bar{M}_{wl} = \bar{M}_{ws}\ \bar{M}_{ns} + f_n\bar{M}_{bs}\bar{M}_{wb}, \qquad (37)$$

$$\bar{M}_{ng}\bar{M}_{wg} = \bar{M}_{ws}\bar{M}_{ns} + 2\bar{M}_{ns}B_{ws} + f_n\bar{M}_{bs}B_w,$$

where $\bar{M}_{ns}$, $\bar{M}_{ws}$, $\bar{M}_{nb}$, and $\bar{M}_{wb}$ are the number-average and weight-average molecular weights of the backbones and branches and $f_n$ is the number-average number of branches per molecule,

$$B_w = \frac{\sum_i B_i^2}{\sum_i B_i}; \quad B_{ws} = \frac{\sum_i \bar{M}_{si} B_i}{\sum_i \bar{M}_{si}}, \tag{38}$$

(here $B_i = \Sigma_k f_{ik} \bar{M}_{bk}$ is the mass of all the branches of the $i$th molecule, and $f_{ik}$ is the number of branches in the $i$th molecule with the molecular weight equal to $\bar{M}_{bk}$).

The branched structure is characterised by the polydispersity of the backbones and branches:

$$\alpha_s = \frac{\bar{M}_{ws}}{\bar{M}_{ns}}; \quad \alpha_b = \frac{\bar{M}_{wb}}{\bar{M}_{nb}}. \tag{39}$$

If

$$\bar{M}_{ns} \leq \bar{M}_{ng},$$

then

$$\bar{M}_{ns} = \frac{\bar{M}_{ng}}{\alpha_b/\alpha_s + f_n}\left[\frac{\alpha_b}{\alpha_s} + f_n\sqrt{\frac{\bar{M}_{wl}}{\alpha_s \bar{M}_{ng}} - \frac{\alpha_b}{\alpha_s f_n}\left(1 - \frac{\bar{M}_{wl}}{\alpha_s \bar{M}_{ng}}\right)}\right], \tag{40a}$$

$$\bar{M}_{nb} = \frac{\bar{M}_{ng}}{\alpha_b/\alpha_s + f_n}\left[1 - \sqrt{\frac{\bar{M}_{wl}}{\alpha_s \bar{M}_{ng}} \frac{\alpha_b}{\alpha_s f_n}\left(1 - \frac{\bar{M}_{wl}}{\alpha_s \bar{M}_{ng}}\right)}\right]. \tag{40b}$$

In all cases, $f_n = \bar{M}_{ng}/\bar{M}_{nl} - 1$. The limits of the variation of $\alpha_s$ and $\alpha_b$ may be as follows:

$$\alpha_s \geqslant \frac{\bar{M}_{wl}}{\bar{M}_{ng}}; \quad \alpha_b \leqslant f_n \cdot \frac{\bar{M}_{wl}/\bar{M}_{ng}}{1 - \bar{M}_{wl}/\alpha_s \bar{M}_{ng}}. \tag{41}$$

The lower limit of the polydispersity of the branches $\alpha_b \geqslant 1$ and the upper limit of the polydispersity of the backbone is defined by the condition

$$\alpha_s \leqslant \frac{\bar{M}_{wl}/\bar{M}_{ng}}{1 - f_n \bar{M}_{wl}/\bar{M}_{ng}}. \tag{42}$$

At the same time, the polydispersities of the backbones and branches, $\alpha_s$ and $\alpha_b$, should be smaller than the polydispersities of linear and branched specimens:

$$\bar{M}_{wl}/\bar{M}_{ng} \leqslant \alpha_s; \quad 1 \leqslant \alpha_b \leqslant \bar{M}_{wl}/\bar{M}_{nl}. \tag{43}$$

The relations obtained are fairly general and make it possible to estimate reliably branching parameters such as $\bar{M}_{ns}$, $\bar{M}_{nb}$, $\alpha_s$, and $\alpha_b$.

If it is assumed that the mass of all the branches is smaller than that of the backbone, we obtained from Eqn. (38)[102]

$$B_{ws} \simeq \frac{\bar{M}_{ng} \cdot \bar{M}_{wg} - \bar{M}_{ws} \cdot \bar{M}_{ns}}{2\bar{M}_{ns}}, \tag{44}$$

which leads to yet another branching parameter:

$$f_{ws} = B_{ws}/\bar{M}_{wb}. \tag{45}$$

Substitution in Eqn. (45) of various model distribution functions and of the equations for the dependence of $f_i$ and $M_{B_i}$ on $B_{S_i}$ leads to the conclusion that $f_{ws} \geqslant f_w$ ($f_w$ is the number-average number of branches per molecule).

Comparison of $f_n$ and $f_{ws}$ permits a qualitative conclusion concerning the distribution of branching nodes among molecules having different molecular weights.

For a faster quantitative determination of the dependence of the branching parameters of star and comb polymers on their hydrodynamic properties and for the determination of molecular weights in the presence of long-chain branching, nomograms [97,103-106] and matrix methods [107] have been proposed in a number of studies.

The experimental studies carried out by Frenkel and coworkers [99-101] in order to test the influence of the polydispersity of the initial homopolymers on the final polydispersity of the graft comb copolymers showed that, for example, the molecular weight distribution (MWD) in a graft copolymer of cellulose with polyacrylonitrile and poly(methyl methacrylate) and the distribution of the molecular weights of polyacrylonitrile and poly(methyl methacrylate) as well as the cellulose chains is narrower than in homopolymerisation. The Schultz inhomogeneity parameter $U = \bar{M}_w/\bar{M}_n - 1$ varies from 0.25 to 0.57 under these conditions [101].

The study of the graft polymerisation of methyl methacrylate on wool [100] showed that the molecular weight distribution of the graft poly(methyl methacrylate) chains is unimodal and narrower than in free homopolymerisation.

Such narrowing of the molecular weight distribution of the chains compared with the free polymerisation of the monomer constituting the branches is due (other conditions being equal) to the same segregation effects which give rise to the anomalies in the hydrodynamic and thermodynamic behaviour of graft comb copolymers. Segregation occurs for high positive values of the thermodynamic parameter $\chi_{AB}$, which can be treated, by analogy with the Flory–Huggins parameter $\chi_1$, as the change in the free energy of the polymer A, playing the role of the "solvent", when a bound (in the chain of a second polymer) unit or segment of type B is introduced into it (or conversely). The theory of $\chi_{AB}$ is fairly complex and we cannot consider it here. However, it follows from it that the free energy of a macromolecule increases continuously as branches of another polymer grow on it. For this reason, a moment is inevitably reached when further growth of the branches become energetically unfavourable. This leads to a sharp increase of the chain termination rate constant or a decrease of the chain propagation rate constant or both simultaneously. Since the width of the molecular weight distribution is determined unambiguously by the ratio of the rate of termination $r_t$ to the rate of propagation $r_p$, the normal distribution of the molecular weights of the branches must be

$$q_n(P) = \alpha(P)\, e^{-\int_i^P \alpha(P)\, dP}, \tag{46}$$

where $\alpha = r_t/r_p$ and $P$ is the degree of polymerisation at any instant. Eqn. (46) shows immediately that, when $d\alpha/dP > 0$ (this happens precisely because of segregation and to a greater extent the higher the value of $\chi_{AB}$), the statistical width of the molecular weight distribution, estimated from the ratio $\bar{P}_w/\bar{P}_n$, should diminish.

Graft polymerisation is frequently accompanied by the partial degradation of the chains on which grafting takes place; the equalisation of the molecular weight distribution can now proceed with respect to two parameters $M_A$ and $M_B$. Some evidence for such equalisation has been obtained recently in the analysis of the grafting of acrylamide on cellulose [109].

## VI. CONCLUSION

If we disregard three-dimensional polymerisation or polycondensation, the problem of the branching of macromolecules arose initially as a side effect in linear polymerisation at the expense of higher degrees of conversion when polymerisation is carried out under technological conditions.

The marked influence of branching on the set of physical characteristics and the practical properties of articles made of polymers required the development of analytical methods for the determination of the degree of branching, mainly in order to monitor the polymerisation process itself. However, the difficulty of direct linear analysis required the development of model concepts. Star and comb polymers cannot arise as a result of a random process. However, it is more convenient to carry out experiments with such polymers in order to test theoretical relations. Special syntheses of polymers of this kind were therefore undertaken and it was found that, in contrast to statistically branched polymers, they may possess "intrinsic useful properties", which is a situation characteristic of the development of the chemistry and physics of polymers at the present stage where research techniques are converted into applied methods and model compounds are converted into real materials (in a broad sense of the last term).

This applies particularly to two of the three types of comb polymers examined--capable of forming ordered (and regular) structures via their branches and of forming microheterogeneous "alloys" as a result of segregation (graft copolymers). Segregation has now found wide-scale applications in the industrial manufacture of impact-resistant polystyrene plastics.

The applications of star polymers are associated, in principle, with imparting catalytic functions to the latter.

The purely analytical aspect still retains its importance--in all cases where branching develops via a cascade mechanism it becomes uncontrollable and can lower significantly the useful characteristics of the polymer. Since, as in the case of the molecular weight distribution or the inhomogeneity of the composition of the copolymers, the quantitative branching characteristics reflect fine details of the kinetics and mechanism of the polymerisation or polycondensation, the study of these characteristics is not only of interest from the standpoint of "control" but is also of independent interest. (A completely up to date example is provided by the analysis of the side reactions in the formation of ladder polysiloxanes [110].)

# Polarography of Coumarins (Chromen-2-ones)

Yu.E.Orlov

The mechanism of the reduction of natural and synthetic coumarins at a dropping mercury electrode is examined. The dependence of the half-wave potential on chemical structure is demonstrated by means of correlation equations and quantum-chemical characteristics. The polarographic properties are interpreted in terms of other physicochemical characteristics (optical, adsorption, polarisation, kinetics of important chemical reactions, microwave-spectroscopic, etc.). Polarography can be applied in various fields of the chemistry of coumarins (in the study of adsorption, complex formation, inhibition of chain oxidations, and the mechanism of organic reactions). A list of 200 references is included.

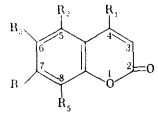
## I. INTRODUCTION

Coumarins are typical heterocyclic compounds, present as structural units in the molecules of tanning agents, antibiotics, phytocides, and a large group of polyphenolic compounds[1-3]. Considerable interest in this group of natural compounds arose from the specificity[1,2] and the breadth of their biological action[3,4]. They have since found wide application in analytical chemistry as luminescent and other indicators[5], optical brightening agents in the textile industry[6], sensitisers in copying techniques[7], aroma-producing substances in foodstuffs, printing, and perfumery industries[1], organic reagents in laser technology[8], toxic chemicals in agriculture[9], and pharmaceutical preparations[1,10] in medicine. In view of the specificity of their physicochemical properties further application of coumarins is envisaged in the production of organic semiconductors, scintillation materials, quantum generators, vitamins, and various organic reagents.

Further investigation of the physicochemical properties of these compounds is of great interest for expanding their fields of application, studying the peculiarities of their electronic structure, elucidating their biological role and aspects of their biosynthesis, and revealing effective new methods of preparation. Polarography has gained a lasting position among other physicochemical methods of examining organic compounds and enables a vast range of theoretical and practical problems to be solved. Results obtained by the polarographic investigation of coumarins can be transferred to other heterocyclic compounds and classes of organic substances.

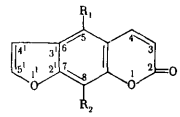
A considerable number of papers have now appeared on the polarography of coumarins, but there is no critical review of existing achievements in this field with an indication of future lines of research. The present Review discusses not only the polarography of coumarins but also aspects of that of other classes of organic compounds (carbohydrates, cardiac glycosides, chromones, and flavonoid compounds, cinnamic and hydroxycinnamic acids) to the extent necessary for the interpretation of polarographic data and other physicochemical investigations on coumarins.



## II. MECHANISM OF ELECTRODE REACTIONS

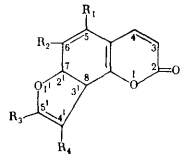
A necessary condition for a heterocyclic compound to be electrochemically active is that the ring should be conjugated and the compound polarisable. The most objective criteria of the presence of conjugation are provided by spectral data characterising the distribution of $\pi$-electron density in the molecule and by the dipole moments. Thus several workers have shown[1,11-13] that hydrogenation of the $C_{(3)}=C_{(4)}$ double bond in the 2-pyrone ring of coumarin entails disappearance of fluorescence, characteristic absorption bands, and reducibility at a dropping mercury electrode[14], because of the disruption of conjugation in the pyrone ring. The dipole moment together with the conjugation characteristic indicates also the degree of polarisability of the molecule[15,16]. Dipole moments lying in the range 4.0–8.0 D have been determined experimentally and calculated by an additive vector scheme for several compounds of the coumarin series[16-19]. The dipole moment of coumarin itself has been measured[16] as 4.5 D.

Voitkevich showed[20] that increase in the dipole moment of aliphatic and aromatic compounds is accompanied by increase in their depolarising power at a dropping mercury electrode. However, there may be departures from this general rule, since electrochemical reduction and oxidation depend on many factors and are complicated by adsorption, protonation, dimerisation, solvation, etc. In several cases the dipole moments of the electrochemically active group are more significant than that of the whole molecule. Furthermore, the electrochemical activity of a molecule can be assessed more accurately from the dipole moment not under static conditions, as is usually done, but in an excited state[21].



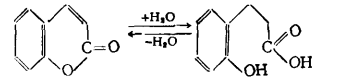
Several workers have shown that both coumarin itself and its derivatives are reduced at a dropping mercury electrode[14,22-60] when various salts—lithium, ammonium, and potassium chlorides, tetraethylammonium iodide and its base, and also Britton–Robinson buffer solutions—are used as supporting electrolyte. Various media have been employed—alcoholic (methanol, ethanol, and propan-1(and 2)-ols), aqueous alcohols, dimethylformamide, and acetone.

The subjects of investigation were natural coumarins of the coumarin (I)



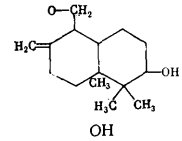
(I)

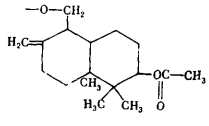
psoralen (II)

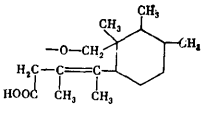


(II)

and angelicin (III)







(III)

series, whose principal polarographic characteristics are given in Tables 1–3. These show that coumarin derivatives are reduced at a dropping mercury electrode in two stages, producing in aqueous methanol two waves with tetraethylammonium iodide, and one wave with lithium chloride, as supporting electrolyte. A single wave is obtained also in Britton–Robinson buffer solutions. However, two reduction waves are formed in tetraethylammonium hydroxide used as base in the buffer mixture. The first wave at pH > 10 decreases in height with time, owing to cleavage of the lactone ring[1,33–36,56,62–70]:

The influence of the nature of the base, the substituent, and the solvent on the kinetics of this process has been investigated[56]. Fission of the lactone ring can be affected by daylight and by ultraviolet radiation[1,36].

*** With tetraethylammonium iodide as supporting electrolyte in 75% methanol.

Investigation of the kinetics and the mechanism of cleavage of the lactone ring not only is of theoretical interest in connection with the chemistry of lactones, on whose physicochemical and kinetic characteristics very few data are available, but also is one of the most important aspects of the chemistry of coumarins, since a considerable number of their fundamental chemical reactions (hydrogenation, azo-coupling, methylation, oxidation,

halogenation, mercuration, and arsenation) are based on preliminary cleavage of the lactone ring in alkaline medium and are widely used for the identification[1-3,68,71-72], quantitative analysis[71-73], preparative isolation[1,73], and synthesis[68,73] of these compounds. Experimental results confirm that the lactone ring opens in alkaline medium. The initial wave of coumarin is obtained when the solutions are acidified to neutral pH[14,36]. Reaction velocities at high rates of cleavage of the lactone ring are determined by oscillographic polarography[35].

The morphology of the waves from coumarin derivatives and their relative heights exhibit several special features. Waves due to hydroxycoumarins are diffuse, showing a considerable tendency to coalesce owing to the small differences in half-wave potentials caused by the formation of intermolecular hydrogen bonds. The hydroxycoumarins—fraxinol and aesculetin—on polarographic reduction give an intense lemon-yellow coloration, the optical density of the solutions remaining constant for a long time[14]. Spectral investigations have shown that the formation of coloured products is due to conversion of the coumarin into a quinonoid system. Only one wave is recorded with farnesiferol, clearly owing to the impossibility of obtaining the second stage of reduction in tetraethylammonium iodide as supporting electrolyte. With the acylangelicins—peucenidin and libanotin—the second wave is threefold the height of the first wave, as a consequence of further reduction at the second stage of residues of organic acids present in side-chains. These features together with the considerable differences among half-wave potentials for several coumarins—coumarin itself, aesculetin, umbelliprenin, farnesiferol, psoralen, xanthotoxol—may form a basis for the identification and qualitative analysis of coumarins.

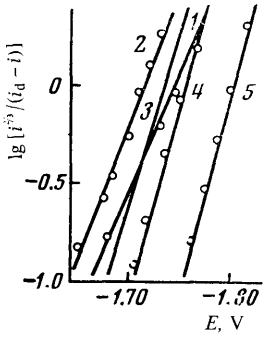

Figure 1. Dependence of $\lg[i^{2/3}/(i_d - i)]$ on $E$ for the first wave of coumarin in 3% tetraethylammonium iodide in methanolic (vol.%) solutions: 1) 12.5; 2) 25.0; 3) 37.5; 4) 62.5; 5) 87.5.

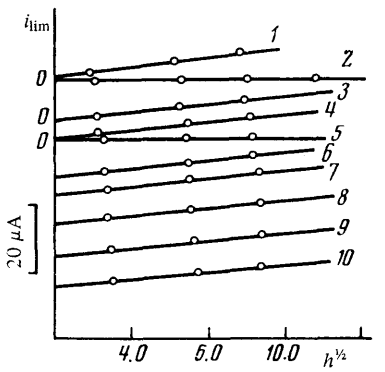
The linear concentration dependence of the limiting current[14,27-30,35-39,41-60] and also the temperature coefficients (1.2–2.0% $deg^{-1}$) indicate a limiting diffusion current of coumarin derivatives when they are reduced at a dropping mercury electrode. These relationships have been verified with various supporting electrolytes (lithium chloride, tetraethylammonium iodide, Britton–Robinson buffer) in aqueous, alcoholic (methyl, ethyl, propyl, and isopropyl), and aqueous–alcoholic solutions, in dimethylformamide alone and mixed with water and with alcohols, and in acetone. With the quaternary ammonium iodide a linear concentration dependence of the limiting current has been established[14] for both reduction stages in the concentration range 0.1–0.001 mass %, which formed the basis for the development of methods for the quantitative analysis of coumarins in various materials[35,41-57,60]. The observed limiting currents are consistent with the Ilkovič equation[74].

Čapka[27] used the diffusion coefficients of acetophenone and benzophenone in comparing the limiting currents, and reached the erroneous conclusion that coumarins undergo two-electron reduction at the potential of the first wave.

Polarographic coulometry[75], with graphical analysis of the voltage–current curves by means of the Heyrovský[76] and Mairanovskii[77] equations, has shown that the first stage in the reduction of coumarins in various supporting electrolytes takes place reversibly, with addition of a single electron followed by slow dimerisation (Fig. 1). Cyclic polarograms obtained at a suspended drop also show reversibility of the electrode process. The half-wave potential becomes more negative with increase in the alcohol concentration. Fig. 1 shows that this involves little change in the reversibility.



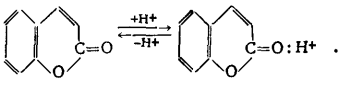


Figure 2. Dependence of limiting current of first wave of coumarin on $h^{1/2}$ in solutions of ionic strength 0.39 at different pH-values: 1) 3.29; 2) 3.79; 3) 4.10; 4) 4.50; 5) 5.02; 6) 7.10; 7) 8.36; 8) 8.91; 9) 10.36; 10) 11.2.

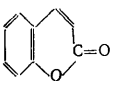
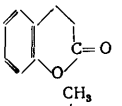
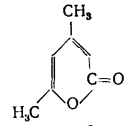
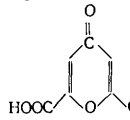
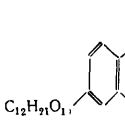
The half-wave potential at the first reduction stage remains unchanged over the pH range 6–9. In the second stage, recorded only in Britton–Robinson buffer solutions containing tetraethylammonium hydroxide as base, the half-wave potential depends on the pH, which can be explained by polarography of cinnamic and hydroxycinnamic[78-80] acids, in whose reduction the dissociation of their phenolic and carboxylic groups plays a considerable part[81]. Therefore the first and second half-wave potentials of hydroxycoumarins change with increase in pH. The second stage in the cathodic reduction of still undecomposed coumarin in the presence of tetraethylammonium hydroxide is accompanied by reduction of hydroxycinnamic acids formed by cleavage of the lactone ring in the coumarins. The second wave is therefore complicated in character. The half-wave potential of hydroxycinnamic acids, like that

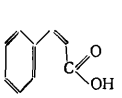


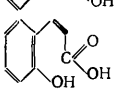


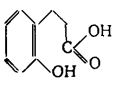


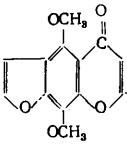












of cinnamic acids[76,82-88], is markedly dependent on pH, and hence that of the second wave of coumarins also depends on pH under the above conditions.

The occurrence of kinetic currents at acid pH values (Fig. 2, curves *2* and *5*), the variation of the half-wave potential over the pH range 4.1–6.0, the electronic structure, quantum-chemical calculations[89], the basicity constants[90], and also the mechanism of formation of oxonium salts[91-93] prove that coumarin molecules undergo protonation:

Thus coumarins exhibit a diffusion current at pH 4.10–10.36; a coumarin wave cannot be recorded at pH < 3.29, owing to superposition of the discharge of hydrogen ions on the reduction of coumarin. Investigations of the dependence of $I_d$ on $h^{1/2}$ at various pH[14] indicate a kinetic current over the pH range 3.29–4.10, whose magnitude is determined by the rate of protonation of coumarin. In alkaline medium (pH > 10.3) the strength of the current is limited by the rate of cleavage of the lactone ring. The second reduction wave of coumarins and the wave of cinnamic acids are not recorded at all in supporting electrolytes that are more easily reduced than are tetra-alkylammonium salts, whence Knobloch[28,29] wrongly concluded that cinnamic acids are polarographically inactive.

**Table 4.** Half-wave potentials of model compounds polarographed in 75% methanol*.

| Compound | Structural formula | $-E_{1/2}$, V(s.c.e.), in | | | | | |
|---|---|---|---|---|---|---|---|
| | | 3% $(C_2H_5)_4NI$ | | 3% LiCl | | Britton-Robinson buffer | |
| | | I | II | I | II | I | II |
| Coumarin |  | 1.40 | 1.97 | 1.32 | — | 1.67 (pH 7.10) | — |
| 3,4-Dihydrocoumarin |  | — | — | — | — | — | — |
| 4,6-Dimethyl-2-pyrone |  | 1.72 | 1.94 | 1.90 | 2.20 | — | — |

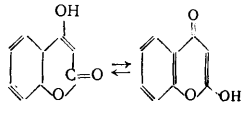
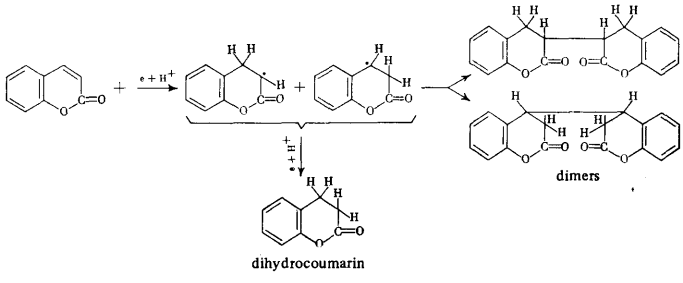
| Kellin** |  | 1.56 | 2.10 | 1.57 | 1.80 | — | — |



*Dihydrocoumarin was prepared by hydrogenating coumarin in alkaline medium with molecular hydrogen in the presence of a palladium catalyst[94,95]; 4,6-dimethyl-2-pyrone was synthesised from acetoacetic ester[68]; and chelidonic acid was obtained by N. F. Komissarenko from Far Eastern lily of the valley (*Convallaria keiskei Mig.*) in the Phytochemistry Laboratory of the Kharkov Chemical and Pharmaceutical Scientific Research Institute.

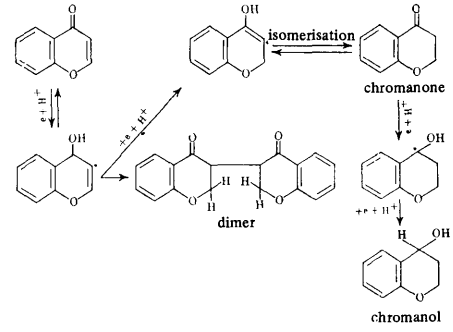
**With 3% tetraethylammonium iodide as supporting electrolyte kellin has a third wave with $E_{1/2}$ = −2.35 V.

Various model compounds have been examined[14] in order to interpret the mechanism of polarographic reduction of coumarins at a dropping mercury electrode. The results (Table 4) show that polarographic activity is due to the presence of the conjugated chain CH : CH.CO.O in the 2-pyrone structure. This chain disappears on hydrogenation of the $C_{(3)} : C_{(4)}$ double bond, in contrast to chromones, which have an O : C.CH : C.O chain in the 4-pyrone structure. Coumarins containing substituents having double bonds that are either isolated from or only slightly conjugated with the 2-pyrone ring (farnesan in umbelliprenin, isopentenyl in imperatorin and osthole, ester groups in athamantin) do not show the enhanced electrochemical activity of these groups observed in peucenidin and libanotin.



Chromatographic, mass-spectral and spectral (ultraviolet and infrared), and combined chromatographic and mass-spectrometric examination of the products of electrolysis at a dropping mercury electrode and at a controlled potential on a macroelectrode[14], as well as preparative electrolysis[36,39], show that the electrode reaction results in formation of dihydrocoumarin and dimers of coumarin. Other compounds have also been detected in preparative electrolysis, which may be products of hydrogenation by hydrogen[96,97] formed during electrolysis and of subsequent reaction of the products with radicals and with the electrode material[98].

In contrast to chromones and chalcones, coumarins exhibit intense infrared absorption bands due to the carbonyl group[1,11,13] and diminished reactivity towards cationic reactants[68], so that it may be concluded that this group is more weakly protonated in coumarin derivatives than in chalcones[22,23,99-102], flavonoid compounds[22,23,103-111], and chromones[22,23,104-112], whose half-wave potentials depend on the pH and which produce a catalytic current[28,29,77]. Such a current has been observed[43,49] with kellin, a pharmaceutical preparation. Chromones are genetically so close to coumarins in chemical structure that conversion of 4-hydroxycoumarins into 2-hydroxychromone is observed[29]:



Reducibility at a dropping mercury electrode is observed also with other classes of compounds containing a 2-pyrone ring (cardiac glycosides)[113-117].

The results of the investigations enable schemes to be postulated for reduction at a dropping mercury electrode—for coumarins

and for chromones

The same mechanism of reduction has been suggested by Stradyn'[23] and by Perrin[22] in fundamental reviews on the polarography of heterocyclic organic compounds.

Carbohydrates present in side-chains in coumarins, cardiac glycosides, flavonoid compounds, and chromones are not reduced at a dropping mercury electrode, since their reduction requires the presence of a carbonyl form, which cannot be produced in solution owing to the absence of ring–chain tautomerism in the glycosidic state[24,76]. In the case of furochromones[111,112] (kelloglycoside) the introduction of the carbohydrate residue converts a single-wave into a two-wave polarogram. The polarograms of kellin and the glycoside in various supporting electrolytes are quite complicated, containing diffusion and catalytic waves. In acid medium the electrode process is complicated by formation of protonated complex compounds (oxonium salts), and in alkaline medium by cleavage of the 4-pyrone ring, so that kinetic currents may also be observed.

The reduction of coumarin derivatives at a dropping mercury electrode is accompanied by adsorption phenomena[14,32,118-120] depending on the structure of the electrical double layer[17,32,120].

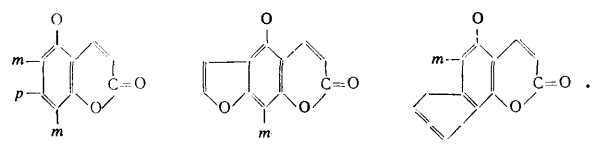
## III. CHEMICAL STRUCTURE AND HALF-WAVE POTENTIAL

One of the most important tasks of the polarography of organic compounds is to find relations between chemical structure and half-wave potential, since knowledge of this correlation will enable the electrochemical activity of organic compounds to be assessed, to a certain extent the mechanism of electrochemical processes, their kinetics, the structure of the products of electrolysis, and also several important physicochemical constants (ionisation potential, electron affinity, redox potential of biochemically important systems), defined directly or indirectly in terms of the half-wave potential, which have played some part in assessing the results of quantum-chemical calculations on the molecules of benzenoid aromatic compounds[121-123]. Such relations can be gauged in several ways—(i) by qualitative and semi-quantitative comparison of half-wave potentials with the electronic structure of functional groups, with conjugation, steric, and inductive effects[24,25,64,76,124], (ii) by means of correlation equations[125-129], (iii) by quantum-chemical methods[121-123,130-131], and (iv) from the relation between the half-wave potential and other physicochemical constants (refraction, dipole moments, ultraviolet and infrared spectra, mass spectra, and microwave spectroscopy—nuclear magnetic and electron spin resonance) containing considerable information on the chemical structure of the molecules[25,74,121,132]—on which

several reviews have been published[25,121,132-136], besides individual chapters in special monographs[74,130,131], devoted to a detailed examination of the relation between half-wave potentials and chemical structure.

In order to trace a correlation with the structure of coumarins and to reach conclusions on the influence of substituents on the half-wave potential, the Reviewer has selected series both of naturally occurring compounds and of products of chemical reactions[40]. Such comparison cannot be based on published values, since half-wave potentials have been obtained by different workers under different conditions (different supporting electrolytes, solvents, and apparatus). The individual values may be contradictory even under the same conditions, and several compounds when tested did not exhibit any polarographic activity (derivatives of 4-hydroxycoumarins)[37,38].

Table 1 gives the chemical structure and the half-wave potentials of derivatives of coumarin, psoralen, and angelicin. Only the values for the first wave, corresponding to a reversible process, were used for the comparison. Table 1 shows that alkylated coumarins, containing donor substituents, are reduced with greater difficulty than are the corresponding unsubstituted compounds. The 2-pyrone ring in the coumarin system is reduced more readily than is 2-pyrone itself, because of conjugation with the aromatic benzene system.



The fusion of a furan ring with the coumarin system in psoralen and angelicin derivatives hinders reduction of the furocoumarins owing to the donor influence of the furan heteroatom. Introduction of ester substituents lowers the half-wave potential of the corresponding hydroxy-compounds (umbelliferone, fraxinyl, xanthotoxyl, and peucenidinyl acetates, libanotin, and athamantin). Coumarin ethers exhibit the considerable electron-donating activity of the radicals, reflected in more negative half-wave potentials. The lengthening of the unconjugated chain in geranyl- and 7-farnesyl-oxycoumarins produces no change in the half-wave potential of 7-isopentenyloxycoumarin. This proves the absence of steric hindrance by groups to reduction of the $C_{(3)}:C_{(4)}$ double bond in benzo-2-pyrone.

Among simple coumarins the highest reduction potential is shown by farnesiferol A, probably because of the specific conformation of the farnesyl group, causing steric hindrance to reduction of the $C_{(3)}:C_{(4)}$ double bond at a dropping mercury electrode[124,137,138]. The half-wave potentials of 5-mono- and 5,8-di-substituted psoralen derivatives lie in the narrow range from −1.41 to −1.45 V, with the exception of xanthotoxol and alloimperatorin, in which the 8-hydroxyl produces a displacement of electron density owing to conjugation with the carbonyl of the 2-pyrone through the heteroatomic oxygen. Angelicin derivatives substituted at position 5 or in the furan ring have values between −1.43 and −1.48 V; the 6-substituted derivatives have more negative half-wave potentials.

Correlation equations have been used to find a quantitative relation with chemical structure, and half-wave potentials have been compared with the energy of the lowest vacant level. Naturally occurring coumarins contain substituents mainly in the benzene ring, at a considerable distance from the reactive centre—the $C_{(3)}:C_{(4)}$ double bond—that undergoes electrochemical hydrogenation. It is therefore advisable to use the Hammett equation, representing the inductive and mesomeric influence of substituents[22,125-129,139,140], whose application has been described in detail by Zuman[127,128]. According to its physical meaning the Hammett equation is applicable mainly to benzenoid compounds, but several workers have shown that it can be used for heterocyclic compounds[22,23,126,141]. Its application requires accurate knowledge of the position of a substituent with respect to the reaction centre, a problem that is made more difficult by the location of substituents and centre in different rings.

In one paper Zuman[58] stated that the Hammett equation must be used for coumarin derivatives substituted in the benzene ring, but the Taft equation[125,126,139] for those substituted in the pyrone ring; yet no information is available on how to control the position of a substituent. Several workers have shown that the orienting effects of substituents depend on the electron density on the carbon atoms[130,142,143].

Published molecular diagrams of coumarin, psoralen, and angelicin[12,89,131] and those calculated by the Reviewer using the LCAO-MO method to the Hückel approximation suggest that the orientation of substituents can be represented by

The test compounds cannot be regarded as belonging to a single reaction series, for they are based on different structures—coumarin, angelicin, and psoralen—although all the compounds are reduced at a dropping mercury electrode by the same mechanism. Furthermore, the influence of a substituent in a given ring changes with its orientation relative to the heteroatoms. In view of these considerations, some of the natural coumarins having tabulated values of $\sigma$ were divided, on treatment of their half-wave potentials, into the reaction series

(*a*) coumarin, 6-methylcoumarin, umbelliferone, 4-methylumbelliferone, herniarin, coumarin-7-yl acetate

(*b*) aesculin, aesculetin, fraxinol, fraxinyl acetate

(*c*) psoralen, xanthotoxol, xanthotoxin, xanthotoxyl acetate.

For other compounds either tabulated values of $\sigma$ are not available or the Hammett equation is inapplicable.

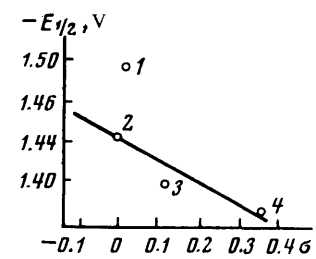


**Figure 3.** Correlation of half-wave potentials of reaction series (*a*) with Hammett $\sigma$ constants for: 1) *p*-OH; 2) *p*-$OCH_3$; 3) *m*-$CH_3$; 4) H; 5) *p*-$OCOCH_3$.

The results plotted in Figs. 3 and 4 show that reaction series (*a*) and (*c*) satisfy the Hammett equation. Departures from the correlation can be explained by absence of additivity, between the electrochemical activity of the coumarins at the dropping mercury electrode and the $\sigma$ values, resulting from intra- and inter-molecular hydrogen bonding, adsorption, dimerisation, and solvation effects.

The Reviewer has assessed the rigour with which the Jaffé correlation[125,126,144] is satisfied only on reaction series (*a*), for which the principal correlation parameters have the values $\eta = 0.974$, $\rho = 0.13$, and $S = 0.058$. The positive value of $\rho$ indicates that the reaction is electrophilic in character: i.e. the introduction of electron-donating substituents retards hydrogenation of the double bond, whereas electron-accepting substituents accelerate it (respectively more and less negative half-wave potentials). The small $\rho$ for series (*a*) indicates the low polarity of the transition state. Values of $\sigma$ have been taken from the paper by McDaniel and Brown[145].

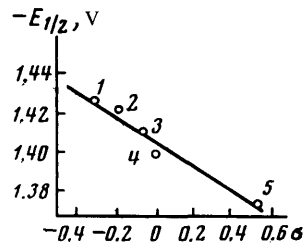

Figure 4. Correlation of half-wave potentials of reaction series (*c*) with Hammett $\sigma$ constants for: 1) *m*-OH; 2) H; 3) *m*-$OCH_3$; 4) *m*-$OCOCH_3$.

Coumarin has 11 molecular orbitals, of which 6 are bonding and 5 antibonding. All 12 $\pi$-electrons can be distributed among bonding molecular orbitals to form a closed system. The energies of delocalisation and of aromatisation for coumarin are respectively $3.36\beta$ and $0.575\beta$†. Of the 14 molecular orbitals in the psoralen molecule 8 are bonding and 6 are antibonding; the 16 mobile $\pi$-electrons of psoralen also occupy all the bonding orbitals and form a closer electron system. Thus the compounds studied form closed electron shells with 8, 12, and 16 $\pi$-electrons. The Hückel rule is inapplicable to them, since the 2-pyrone ring is not a regular polygon owing to the presence of the carbonyl group, and the $4n + 2$ $\pi$-electrons rule is not satisfied.

The polarographic activity of organic compounds involves the donation of electrons from the highest occupied level and the acceptance of electrons by the lowest vacant level, so that the half-wave potential is a linear function of the energy of these levels, and can be measured by the electron affinity or the ionisation potential[130-132,146]. This provides a ready explanation of the satisfactory correlation of this potential with various physical and chemical[74,131,147-152] properties of organic compounds.

A theoretical basis for the possibility of correlating half-wave potentials with the energy of the lowest vacant orbital was first provided by Maccoll[153]. This dependence for the coumarin, psoralen, and angelicin series (Fig. 5) shows that half-wave potentials may be predicted for furocoumarins. Departures from this dependence exhibited by acetylated derivatives and diols (aesculetin) in the coumarin series can be explained by insufficient allowance in quantum-chemical calculations for exchange interaction between adjacent groups and interaction of groups with the solvent or by distortion of the potentials by adsorption, solvation, protonation, and dimerisation of intermediate products.

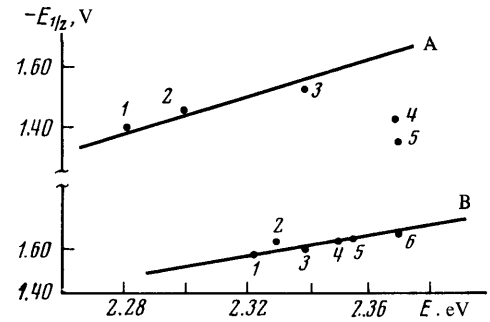

Figure 5. Correlation of energies of lowest vacant orbitals $E$ and the polarographic half-wave potentials for the coumarin series (*A*): 1) coumarin; 2) umbelliferone; 3) fraxinol; 4) fraxinyl acetate; 5) umbelliferone acetate; and for the psoralen and the angelicin series (*B*): 1) psoralen; 2) angelicin; 3) xanthotoxin; 4) sphondin; 5) begapten; 6) isopimpinellin.

## IV. PHYSICOCHEMICAL PROPERTIES AND HALF-WAVE POTENTIAL

It is of great theoretical and practical interest to find the interrelationship between the polarographic characteristics and the physicochemical properties of organic molecules, for the reasons outlined below.

1. It will become possible to assess the relation between the half-wave potential and chemical structure—more precisely to understand how this potential reflects features in the electronic structure of molecules (inductive and mesomeric effects), conformational characteristics (steric effects), the distribution of electron density, the polarisability and polarity of molecules, electrochemical activity, reactivity, and in several cases also the biological action of the substance.

2. Comparison of half-wave potentials with redox potentials will give information on the reversibility of an electrode process, and sometimes polarography may become an independent method for determining redox potentials, since it is more sensitive than the potentiometric method and can be applied over a wider composition range of the medium (quinones, vitamins).

3. Comparison of half-wave potentials with spectral characteristics will permit estimation of the degree of homolysation of molecules[154-156] and the parameters in the equation relating these potentials with the energy of the orbitals, with some indication of the mechanism of electron transfer in the electrochemical step.

4. Comparison of half-wave potentials with dipole moments and refractions enables the electrochemical activity of individual functional groups or structural units of the molecule to be estimated, and also the direction of the polarisation vector to be assessed.

†Here $\beta$ represents the resonance integral used in quantum-chemical calculations[130].

5. The relation between the diffusion-current constant (from the Ilkovič equation) and the molecular mass enables the latter to be evaluated, and also to some extent the degree of sphericity of the molecule (which occurs in the main condition for the Stokes–Einstein equation to be satisfied).

6. Comparison of half-wave potentials for the oxidation of organic compounds with mass-spectral characteristics (ionisation potential, peak appearance potential) will enable the ionisation potential to be evaluated.

7. Comparison of the half-wave reduction potentials with the energy of the longer-wavelength band of the donor (charge-transfer complex) will enable the electron affinity to be evaluated.

8. Comparison of half-wave potentials for polarographic oxidation and reduction will enable the alternance and non-alternance of hydrocarbons to be assessed.

Undoubtedly we could still find quite a few important aspects of the theoretical and practical applicability of the correlation of polarographic characteristics with other physicochemical characteristics of the molecules.

The Reviewer has compared half-wave potentials for the polarographic reduction of coumarins with (i) the energy of the longer-wavelength ultraviolet absorption band, (ii) the dipole moments, (iii) mass-spectral characteristics, (iv) the chemical shift in the nuclear magnetic resonance spectra, and (v) the electron affinity, besides comparing the diffusion-current constants in the first wave of coumarins in 5% tetraethylammonium iodide solution as supporting electrolyte with the molecular mass.

## 1. Half-wave Potential and Ultraviolet Spectra of Coumarins

Comparison of half-wave potentials with ultraviolet absorption band energies is based on the identity of primary physicochemical steps in an electrochemical reaction and in photoexcitation. Watson and Matsen[157]‡ used Maccoll's relation[153] to show that for many compounds the dependence of the half-wave potential on the energy of transition of an electron from the highest occupied to the lowest vacant orbital can be established directly:

$$-E_{1/2}={}^1/_2\, h\nu+\text{const.},$$

where $\nu$ is the frequency of the longer-wavelength absorption band.

A defect in most papers in this field is non-observance of the dimensions of the units in which $E_{1/2}$ and $\lambda_m(\nu)$ are expressed. The former is measured in *volts*, and the latter in *nanometres*. If both parameters are expressed in *electron-volts*, the values of $E_{1/2}$ will partly take into account also the mechanism of reduction at the dropping mercury electrode, since $E_{1/2}$ will have to be multiplied by the number of electrons involved in the electrochemical step.

Grabovskii[157] showed that the relations between the reduction potential and the energy of the electron transition may assume different forms depending on the nature of the substituent and the electron transition. There may be other approaches to a physical explanation of the correlation between half-wave potential and ultraviolet spectral data.

Several substances undergoing an electrochemical reaction at a dropping mercury electrode form charge-transfer complexes with components of the supporting electrolyte and act as acceptors, so that the relation[158]

$$h\nu=I_D-E_A+C$$

holds for them, where $h\nu$ (in eV) is the energy of charge transfer, $I_D$ (eV) the ionisation potential of the donor, $E_A$ (eV) the electron affinity of the acceptor, and $C$ a constant. As several workers have shown, a linear dependence exists between $h\nu$ and $E_A$, as between $h\nu$ and $I_D$, and since the reduction half-wave potential of an organic molecule most often corresponds to $E_A$,[159] this potential should vary linearly with the energy of the longer-wavelength absorption band. On the other hand, the frequency of variation in the variable dipole moment $P$ is described by the formula[160]

$$P=P_0\cos(2\pi\nu t),$$

(in which $P_0$ is the constant dipole moment of the molecule, $\nu$ the frequency of vibration of the molecule, and $t$ the time), which shows that the frequency depends on the dipole moment. In several cases the half-wave potential is a linear function of the dipole moment[20,74], so that a linear relation should exist between this potential and the energy of the corresponding absorption band.

The spectrum of coumarins contains 4–6 strong absorption bands (molar extinction coefficients 3000–30 000). The bands are due to $\pi-\pi^*$ transitions[11,12], but $n-\pi^*$ transitions may also occur (masked by $\pi-\pi^*$ transitions). The polarographic reduction of naturally occurring coumarins at a dropping mercury electrode is due, by analogy with other organic compounds, to the presence of a system of delocalised $\pi$ electrons in the 2-pyrone ring, and is accomplished by passage of electrons from the electrode to the lowest vacant level in the molecule.

The long-wavelength bands corresponding to $\pi-\pi^*$ transitions characterise the energetic state of the functional part of the molecule (containing the conjugated $\pi$-electron system), which is also electrochemically active, so that it is the energy of such a band that must be compared with the half-wave potential. The ultraviolet band energies of coumarins were obtained (in electron-volts) from the corresponding $\lambda_m$ values by means of the classical Bohr frequency rule $h\nu = hc/\lambda = \epsilon_2 - \epsilon_1$.[160] Relative energies of polarographic reduction of the molecules of coumarins $\epsilon$ can be determined as the product of the polarographic half-wave potential $E_{1/2}$ and the number of electrons $n$ taking part in the electrochemical step. The half-wave potentials of the first, reversible wave are usually taken in finding the correlation of spectral and polarographic characteristics, as in the present case.

A linear dependence of the half-wave potential of the first wave on the longer-wavelength ultraviolet absorption maximum has indeed been established for the series—coumarin, psoralen, and angelicin—with the potential falling as the band energy increases[41]. However, since the correlation is based on the energy of the whole band corresponding to $\pi-\pi^*$ transitions predominantly of the $C_{(3)}:C_{(4)}$ double bond, not of part of it, the whole energy of polarographic reduction of the double bond must obviously be taken, i.e. the half-wave potential of the second wave, corresponding to the sum of the electron affinities of the coumarin molecule and of its radical. It is probable that, as in polarography, the transfer of electrons in a spectroscopic experiment takes place in stages (transfer of the first electron followed by that of the second, and so on).

‡This reference appears to be in error (Ed. of Translation).

The polarographic and spectral characteristics found by the Reviewer for naturally occurring coumarins show (Table 5) a deviation of 0.4–0.5 eV from a linear relation only with five compounds (angelicin, acetylumbelliferone, imperatorin, 4-methylumbelliferone, and xanthotoxin): with all the remaining compounds a precise correlation between optical and electrochemical characteristics is observed, which enables half-wave potentials in the coumarin series to be calculated from the energy of the longer-wavelength absorption band.

**Table 5.** Electrochemical and optical characteristics of naturally occurring coumarins.

| Compound | $-E_{1/2}$, V | $\epsilon$, eV | $\lambda_m$, nm | $h\nu$, eV |

## 2. Mass-spectral Characteristics and Half-wave Potentials

Electron bombardment of coumarin produces molecular ions[161–163], whose measured appearance potential was corrected for the contact potential of the nickel–molybdenum system (the ion source)[164]. This can be accepted as the ionisation potential, which in the Reviewer's experiments was around 4.0 eV. The correlation of spectral, mass-spectral, and polarographic data enables spectral characteristics to be used to find ionisation potentials, and the equality of the latter to the half-wave potentials as a criterion of the degree of homolysation of the molecule[154, 155] and the consequent possibility of formation of a charge-transfer complex, since the half-wave potentials can be used to find electron affinities[159].

## 3. Electron Affinity and Half-wave Potential

Since half-wave potentials are often used to estimate electron affinities, it was of interest to compare these quantities. Experimental determination of electron affinity is usually based on the examination of charge-transfer complexes, the theory of which was developed by Mulliken[165], or on polarography[159,166]. The Reviewer has calculated electron affinity $A$ by Scott and Becker's method[167] based on the equation

$$A = -\alpha^2 - \left(m_{\overline{N}} - \frac{\eta+1}{\eta} N\right)\beta^0,$$

obtained from approximate quantum-chemical calculations, in which $\alpha^2 = -9.878$ eV, $\beta^0 = 2.110$ eV, $m_{\overline{N}}{}^{12}$ is the Hückel coefficient of the highest occupied orbital or of the anion, $\eta$ is the number of $\pi$ electrons in the neutral molecule, and $N$ is a constant.

**Table 6.**

| Compound | $\eta$ | $m_{\overline{N}}$ (Ref.12) | $-A$, eV | $-E_{1/2}$, V |
|---|---|---|---|---|
| Coumarin | 12 | 1.2391 | 3.70 | 1.40 |
| Herniarin | 12 | 1.1903 | 3.80 | 1.44 |
| 4-Methylumbelliferone | 12 | 1.2000 | 3.93 | 1.61 |
| Psoralen | 16 | 1.1200 | 3.65 | 1.44 |

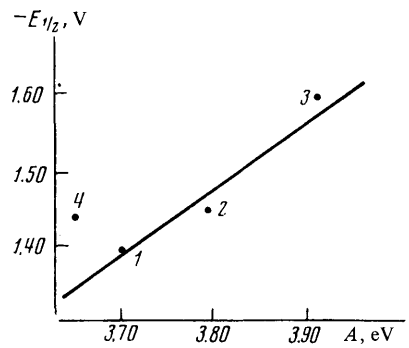

Figure 6. Relation between half-wave potential and electron affinity of coumarins: 1) coumarin; 2) herniarin; 3) 4-methylumbelliferone; 4) psoralen.

The calculated results are given in Table 6. The graphical relation between the two quantities shows (Fig. 6) that the polarographic half-wave potential varies linearly with the electron affinity of the coumarins.

## 4. Dipole Moments and Half-wave Potentials

Data on the dipole moments of coumarins are extremely limited, but the Reviewer's attempts to calculate them by quantum-chemical methods[15,168,169] gave overestimates.

For most substances the wave is considered[20] to move to less negative potentials with increase in the dipole moment. The present case constitutes an exception to the general rule (Fig. 7), which merits special examination.

## 5. Nuclear Magnetic Resonance and Half-wave Potential

The fine structure of an organic molecule is characterised by the chemical shift and the spin distribution constant, which is why n.m.r. spectroscopy[170,171] finds such great use for confirming the conformations of molecules, the distribution of electron density on the atoms, found by other physicochemical methods (spectroscopy, dipole moments) and by quantum-chemical methods. Comparison of polarographic and n.m.r. results is of the greatest

interest, since it enables the electrochemically active units of the molecule, i.e. the sites of lowest electron density, to be determined.

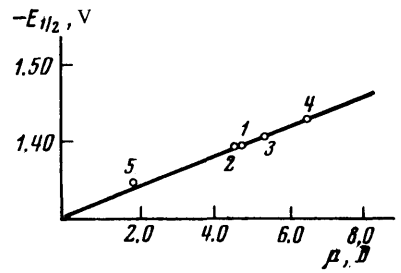

**Figure 7.** Relation between half-wave potentials and dipole moments (determined according to Debye) for coumarins: 1) coumarin; 2) coumarin-6-sulphonic acid; 3) 6-methylcoumarin; 4) 6-aminocoumarin; 5) 6-nitrocoumarin.

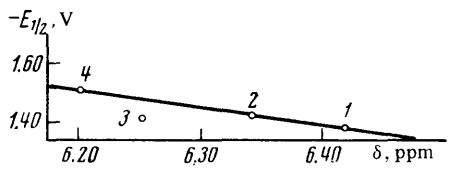

**Figure 8.** Relation between half-wave potential and chemical shift for coumarins: 1) coumarin; 2) fraxinyl acetate; 3) herniarin; 4) 7-hydroxyisopentenyloxycoumarin.

Nuclear magnetic resonance data for coumarins[12,172-174] show that the $C_{(3)}:C_{(4)}$ double bond is the site of lowest electron density, and the 2-pyrone carbonyl group the site of maximum electron density, in agreement with quantum-chemical calculations[12,131] and the vector diagram of the dipole moment of the coumarin molecule. This is confirmed by the comparison of half-wave potentials and chemical shifts plotted in Fig. 8.

### 6. Diffusion-current Constants and Molecular Mass

Increase in molecular mass entails a decrease in the diffusion-current constant (Fig. 9). This provided a method for estimating the molecular masses of coumarins, and also for estimating the constant from the latter, which is very important in calculating the number of electrons and interpreting the mechanism of electrode reactions.

## V. METHODS OF POLAROGRAPHIC ANALYSIS

The polarographic method of analysis is widely used for coumarins[30,31,35,41-46,48,51,54,57,175] and the related chromones[43,175]. The techniques employed are based on displaying the depolarising ability of these compounds at a dropping mercury electrode in the cathodic potential range. Novel physicochemical properties of coumarins detected in this way are of the greatest interest.

Investigation of the mechanism of the chain autoxidation of sulphites revealed that naturally occurring coumarins have a considerable inhibiting effect[46]. A linear dependence exists between the duration of inhibition and the concentration of the coumarins (within the range $10^{-4}$–$10^{-6}$M), which can be used in quantitative analysis. Different coumarins have different ranges of linearity. The inhibiting effect is detected from the change in the rate of fall of the maximum oxygen content in the presence of a sulphite by polarography with 0.01% potassium chloride solution as supporting electrolyte. The sensitivity of this method of analysis ($10^{-7}$ M) is hundredfold that of methods based on the electrochemical reduction of coumarins ($10^{-5}$ M). It will give good results in the analysis of polarographically inactive coumarins (dihydrocoumarin, 4-hydroxycoumarin derivatives) and of coumarins that have poorly developed polarographic waves (hydroxycoumarins).

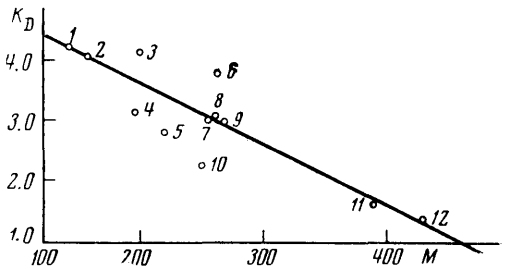

**Figure 9.** Dependence of $K_D$ on molecular mass for the coumarins: 1) coumarin; 2) 6-methylcoumarin; 3) xanthotoxin; 4) psoralen; 5) isobergapten; 6) 7-isopentenyloxycoumarin; 7) fraxinol; 8) imperatorin; 9) fraxinyl acetate; 10) pimpinellin; 11) farnesiferol; 12) athamantin.

A very urgent problem in the chemistry of coumarins is the determination of molecular mass. Hitherto it has been found via the diffusion coefficient by the use of diffusion currents, which is time-consuming and not always accurate. The molecular mass can be determined experimentally by polarography using a standard compound. This gives a formula, based on the Ilkovič and Stokes–Einstein equations[156], from which diffusion coefficients are absent[47,176]:

$$M_x = \left( \frac{10^{16} I_{st}^4 \cdot M_{st} \cdot c_x^4}{I_x^4 \cdot c_{st}^4} \right)^{1/4},$$

where $M_X$ is the molecular mass of the test coumarin, $I_{st}$ and $I_X$ (in μA) are the limiting currents of standard and test coumarin solutions, $M_{st}$ is the molecular mass of the standard coumarin derivative, $c_{st}$ (mM) is the concentration of the standard coumarin solution, and $c_X$ (%) that of the test solution. The relative error of the determination is ±2.5%. The method developed by the Reviewer is far simpler than the mass-spectral method with respect to equipment and more reliable than Rast's method. The methods of analysis of coumarins are applicable also to other classes of organic compounds, and have entered the USSR State Pharmacopoeia[102].

The use of chromatographic methods—paper, thin-layer, and gel—for the preliminary separation of mixtures of coumarins and chromones extends the possibilities of polarography in the investigation and the analysis of these compounds[98,177-180].

## VI. APPLICATION OF POLAROGRAPHY TO THE CHEMISTRY AND BIOLOGY OF COUMARINS

### 1. Kinetics of Cleavage of the Lactone Ring

As already mentioned, the kinetics of cleavage of the lactone ring is not only of practical interest, from the point of view of finding optimum conditions for the analysis, synthesis, and isolation of coumarins, but also of theoretical interest, since by analogy with benzoic esters the determination of rate constants should permit establishment of a scale of the values of $\sigma$ required for the correlation of chemical structure with the physicochemical properties of coumarins.

The polarographic method is absolute in recording the lactone form of coumarin in solution, since the cleaved form—hydroxycinnamic acid—is not established in several supporting electrolytes. Other methods (spectrophotometric, conductometric, potentiometric) enable relative measurements to be made[64-66]. An oscillographic technique enables measurements to be made at high rates of fission of the lactone ring.

Table 7. Rate constants ($M^{-1}$ $s^{-1}$) of cleavage of the lactone ring of coumarin in various media.

| Solvent compound | concn., vol.% | LiOH | NaOH | KOH | $(C_2H_5)_4$ NOH |
|---|---|---|---|---|---|
| Water | 100.0 | 0.338 | 0.347 | 0.388 | 0.130 |
| Methanol | 25.0 | — | 0.227 | — | — |
| Methanol | 30.8 | — | 0.101 | — | — |
| Methanol | 50.0 | 0.073 | 0.069 | 0.082 | — |
| Methanol | 70.0 | — | 0.020 | — | — |
| Ethanol | 19.0 | — | 0.146 | — | — |
| Ethanol | 30.8 | — | 0.131 | — | — |
| Ethanol | 50.0 | 0.132 | 0.124 | 0.129 | — |
| Ethanol | 70.0 | — | 0.056 | — | — |
| Propan-1-ol | 19.0 | — | 0.162 | — | — |
| Propan-1-ol | 30.8 | — | 0.075 | — | — |
| Propan-1-ol | 50.0 | 0.032 | 0.0638 | 0.054 | 0.059 |
| Propan-1-ol | 70.0 | — | 0.062 | — | — |
| Propan-1-ol | 96.0 | — | 0.645 | — | — |
| Propan-2-ol | 19.0 | — | 0.266 | — | — |
| Propan-2-ol | 30.8 | — | 0.124 | — | — |
| Propan-2-ol | 50.0 | 0.106 | 0.124 | 0.108 | 0.131 |
| Propan-2-ol | 70.0 | — | 0.116 | — | — |
| Dimethylformamide | 50.0 | 0.035 | 0.036 | 0.047 | — |

Application of polarography[56] and colorimetry[72,182] to isomolar series[181] shows that coumarin reacts in equimolecular proportions with a base. The reaction is of the second order[67,183]. The investigations have been made in aqueous-alcoholic solutions in the presence of various bases—ammonium, lithium, sodium, potassium, and tetraethylammonium hydroxides—and reaction rate constants have been determined for various concentrations of the alcohol (Table 7). The reaction does not take place in purely alcoholic solvents (methanol, ethanol, propan-1(or 2)-ol). The rate constant increases with decrease in the mole fraction of the organic solvent and in the inductive effect of the substituent but with increase in the strength of the base. The more negative the half-wave potential of coumarin, the more difficult is cleavage of the lactone ring. All the researches show that this process depends on many factors and involves water molecules.

### 2. Complex Formation in the Coumarin Series

Polarography is widely used to investigate complex formation[75,76,184]. The first polarographic study of the formation by aesculetin of complexes with copper, gold, tin, and rhodium salts has been made by the Reviewer. Copper salts give stable complexes, but the process is protracted, taking place in several stages with formation of a mixture of complexes differing in chemical structure, as chromatography[1,185,186] and spectroscopy[187,188] have shown. Earlier spectral results[187] are dubious in view of the close similarity in physicochemical properties of the components of the aggregate complex.

The presence of a complex is established polarographically from the difference between the half-wave potentials of metal and coumarin. The stoichiometric ratio of copper and aesculetin in the complex has been determined[162]. The other complexes—with rhodium, gold, and tin—have only been identified polarographically during their formation.

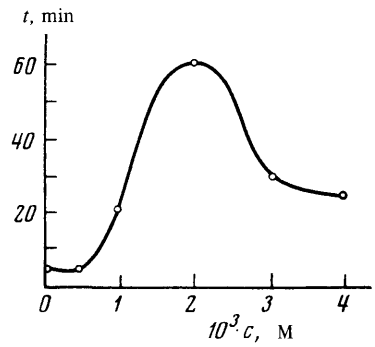

Figure 10. Dependence of the duration $t$ of inhibition by coumarin of the chain autoxidation of sodium sulphite on its concentration $c$.

### 3. Inhibition of Chain Reactions
